We dedicate the ACL 2011 proceedings to the memory of Fred Jelinek (1932-2010), who received ACL's Lifetime Achievement Award in 2009. His award acceptance speech can be found in Computational Linguistics 35(4), and an obituary by Mark Liberman appeared in Computational Linguistics 36(4). Several other newspaper and professional society obituaries have described his extraordinary personal life and career.

Fred's influence on computational linguistics is almost impossible to overstate. In the 1970s and 1980s, he and his colleagues at IBM developed the statistical paradigm that dominates our field today, including a great many specific techniques for modeling, parameter estimation, and search that continue to enjoy wide use. Even more fundamentally, as Mark Liberman recounts in his obituary, Fred led the field away from a mode where lone inventors defended their designs by appealing to aesthetics and anecdotes, to a more communal and transparent process of evaluating methods objectively through controlled comparisons on training and test sets.

Under Fred's visionary leadership, the IBM group revolutionized speech recognition by adopting a statistical, data-driven perspective that was deeply at odds with the rationalist ethos of the time. The group began with Fred's information-theoretic reconceptualization of the task as recovering a source signal (text) after it had passed through a noisy channel. They then worked out the many components needed for a full speech recognizer, along with the training algorithms for each component and global decoding algorithms. Steve Young, in an obituary in the IEEE SLTC Newsletter, describes Fred as not a pioneer but the pioneer of speech recognition.

In the 1980s, the IBM speech group's work on language modeling drew them toward deeper analysis of text. Fred and his colleagues introduced NLP methods such as word clustering, HMM part-of-speech tagging, history-based parsing, and prefix probability computation in PCFGs. They famously turned their noisy-channel lens on machine translation, founding the field of statistical MT with a series of ingenious and highly influential models.

After Fred moved to Johns Hopkins University in 1993, he worked tirelessly to improve language modeling by incorporating syntactic and other long-range dependencies as well as semantic classes. He also presided for 16 years over the Johns Hopkins Summer Workshops, whose 51 teams from 1995-2010 attacked a wide range of topics in human language technology, many making groundbreaking advances in the field.

There is a popular conception that Fred was somehow hostile to linguistics. Certainly he liked to entertain others by repeating his 1988 quip that "Any time a linguist leaves the group, the recognition rate goes up." Yet he had tried to leave information theory for linguistics as early as 1962, influenced by Noam Chomsky's lectures and his wife Milena's earlier studies with Roman Jakobson. He always strove for clean formal models just as linguists do. He was deeply welcoming toward any attempt to improve models through better linguistics, as long as they had a large number of parameters. Indeed, it was one of the major frustrations of his career that it was so difficult to beat n-gram language models, when humans were evidently using additional linguistic and world knowledge to obtain much better predictive performance. As he said in an award acceptance speech in 2004, "My colleagues and I always hoped that linguistics will eventually allow us to strike gold."

Fred was skeptical only about the relevance of armchair linguistics to engineering, believing that there was far more variation in the data than could be described compactly by humans. For this reason, while he was quite interested in recovering or exploiting latent linguistic structure, he trusted human-annotated linguistic data to be a better description of that structure than human-conceived linguistic rules. Statistical models could be aided even by imperfect or incomplete annotations, such as unaligned orthographic transcriptions, bilingual corpora, or syntactic analyses furnished by ordinary speakers. Fred pushed successfully for the development of such resources, notably the IBM/Lancaster Treebank and its successor, the Penn Treebank.

Fred influenced many of us personally. He was warm-hearted, witty, cultured, thoughtful about the scientific process, a generous mentor, and always frank, honest, and unpretentious. The changes that he brought to our field are largely responsible for its recent empirical progress and commercial success. They have also helped make it attractive to many bright, technically sophisticated young researchers. This proceedings volume, which is dedicated to his memory, testifies to the overwhelming success of his leadership and vision.

By Jason Eisner, on behalf of ACL 2011 Organizing Committee

Preface: General Chair

Welcome to the 49th Annual Meeting of the Association for Computational Linguistics in Portland, Oregon. ACL is perhaps the longest-running conference series in computer science. Amazingly, it is still growing. We expect this year's ACL to attract an even larger number of participants than usual, since 2011 happens to be an off-year for COLING, EACL and NAACL.

The yearly success of ACL results from the dedication and hard work of many people. This year is no exception. I would like to thank all of them for volunteering their time and energy in service to our community.

I thank the Program Co-Chairs Rada Mihalcea and Yuji Matsumoto for putting together a wonderful main conference program, including 164 long papers, 128 short papers and much anticipated keynote speeches by David Ferrucci and Lera Boroditsky. Tutorial Co-Chairs, Patrick Pantel and Andy Way solicited proposals and selected six fascinating tutorials in a wide range of topics. The Workshop Co-Chairs, Hal Daume III and John Carroll, organized a joint selection process with EMNLP 2011. The program consists of 3 two-day workshops and 13 one-day workshops, a new record number for ACL. Sadao Kurohashi, Chair of System Demonstrations, assembled a committee and oversaw the review of 46 demo submissions.

The Student Session is organized by Co-Chairs, Sasa Petrovic, Emily Pitler, Ethan Selfridge and Faculty Advisors: Miles Osborne, Thamar Solorio. They introduced a new, poster-only format to be held in conjunction with the main ACL poster session. They also obtained NSF funding to provide travel support for all student session authors.

Special thank goes to Publication Chair, Guodong Zhou and his assistant Hong Yu. They produced the entire proceedings of the conference.

We are indebted to Brain Roark and the local arrangement committee for undertaking a phenomenal amount detailed work over the course of two years to host this conference, such as allocating appropriate space to meet all the needs of the scientific program, compiling and printing of the conference handbook, arranging a live tango band for the banquet and dance, to name just a few. The local arrangement committee consists of: Nate Bodenstab (webmeister), Peter Heeman (exhibitions), Christian Monson (student volunteers), Zak Shafran and Meg Mitchell (social), Richard Sproat (local sponsorship), Mahsa Yarmohammadi and Masoud Rouhizadeh (student housing coordinators) and Aaron Dunlop (local publications coordinator).

I want to express my gratitude to Ido Dagan, Chair of the ACL Conference Coordination Committee, Dragomir Radev, ACL Secretary, and Priscilla Rasmussen, ACL Business Manager, for their advice and guidance throughout the process.

ACL 2011 has two Platinum Sponsors (Google and Baidu), one Gold Sponsor (Microsoft), two Silver sponsors (Pacific Northwest National Lab and Yahoo!), and seven Bronze Sponsors and six Supporters. We are grateful for the financial support from these organizations. I would like to thank and applaud the tremendous effort by the ACL sponsorship committee: Srinivas Bangalore (AT&T), Massimiliano Ciaramita (Google), Kevin Duh (NTT), Michael Gamon (Microsoft), Stephen Pulman (Oxford), Priscilla Rasmussen (ACL), and Haifeng Wang (Baidu).

Finally, I would like to thank all the area chairs, workshop organizers, tutorial presenters, authors, reviewers and conference attendees for their participation and contribution. I hope everyone will have a great time sharing ideas and inspiring one another at this conference.

ACL 2011 General Chair
Dekang Lin, Google, Inc.

Preface: Program Committee Co-Chairs

Welcome to the program of the 2011 Conference of the Association for Computational Linguistics! ACL continues to grow, and this year the number of paper submissions broke once again the record set by previous years. We received a total of 1,146 papers, out of which 634 were submitted as long papers and 512 were submitted as short papers. 25.7

To achieve the goal of a broad technical program, we followed the initiative from last year and solicited papers under four main different categories: *theoretical computational linguistics*, *empirical/data-driven approaches*, *resources/evaluation*, and *applications/tools*. We also continued to accept other types of papers (e.g., surveys or challenge papers), although unlike the previous year, no separate category was created for these papers. The papers falling under one of the four categories were reviewed using specialized reviewed forms; we also had a general review form that was used to review the papers that did not fall under one of the four main categories.

A new initiative this year was to also accept papers accompanied by supplemental materials (software and/or datasets). In addition to the regular review of the research quality of the paper, the accompanied resources were also reviewed for their quality, and the acceptance or rejection decisions were made based on the quality of both the paper and the supplemental materials. Among all the submissions, a total of 84 papers were accompanied by a software package and 117 papers were accompanied by a dataset. Among all the accepted papers, 30 papers are accompanied by software and 35 papers are accompanied by a dataset. These materials will be hosted on the ACL web site under http://www.aclweb.org/supplementals.

We are delighted to have two distinguished invited speakers: Dr. David Ferrucci (Principal Investigator, IBM Research), who will talk about his team's work on building *Watson* – a deep question answering system that achieved champion-level performance at Jeopardy!, and Lera Boroditsky (Assistant Professor, Stanford University), who will give a presentation on her research on how the languages we speak shape the way we think. In addition, the recipient of the ACL Lifetime Achievement Award will present a plenary lecture during the final day of the conference.

As in previous years, there will be three awards, one for the best long paper, one for the best long paper by a student, and one for the best short paper. The candidates for the best paper awards were nominated by the area chairs, who took into consideration the feedback they received from the reviewers on whether a paper might merit a best paper prize. From among the nominations we received, we selected the top five candidates for the long and short papers, and the final awards were then selected by the area chairs together with the program co-chairs. The recipients of the best paper awards will present their papers in a plenary session during the second day of the conference.

There are many individuals to thank for their contributions to the conference program. First and foremost, we would like to thank the authors who submitted their work to ACL. The growing number of submissions reflects how broad and active our field is. We are deeply indebted to the area chairs and the reviewers for their hard work. They enabled us to select an exciting program and to provide valuable feedback to the authors. We thank the general conference chair Dekang Lin and the local arrangements committee headed by Brian Roark for their help and advice, as well as last year's program committee co-chairs, Stephen Clark and Sandra Carberry, for sharing their experiences. Additional thanks go to

the publications chair, Guodong Zhang, who put this volume together, and Yu Hong, who helped him with this task.

We are most grateful to Priscilla Rasmussen, who helped us with various logistic and organizational aspects of the conference. Rich Gerber and the START team responded to our questions quickly, and helped us manage the large number of submissions smoothly.

Enjoy the conference!

ACL 2011 Program Co-Chairs
Yuji Matsumoto, Nara Institute of Science and Technology
Rada Mihalcea, University of North Texas

Table of Contents

Conference Program

Monday, June 20, 2011

(8:45-9:00) Opening Session

(9:00-10:00) Invited Talk 1:IBM Watson Deep QA System (tentative title) by David Ferrucci

(10:00-10:30) Coffee Break

Session 1-A: (10:30-12:10) MT: Methods

A Word-Class Approach to Labeling PSCFG Rules for Machine Translation
Andreas Zollmann and Stephan Vogel

Deciphering Foreign Language
Sujith Ravi and Kevin Knight

Effective Use of Function Words for Rule Generalization in Forest-Based Translation
Xianchao Wu, Takuya Matsuzaki and Jun'ichi Tsujii

Combining Morpheme-based Machine Translation with Post-processing Morpheme Prediction
Ann Clifton and Anoop Sarkar

Session 1-B: (10:30-12:10) Machine Learning Methods 1

Evaluating the Impact of Coder Errors on Active Learning
Ines Rehbein and Josef Ruppenhofer

A Fast and Accurate Method for Approximate String Search
Ziqi Wang, Gu Xu, Hang Li and Ming Zhang

Domain Adaptation by Constraining Inter-Domain Variability of Latent Feature Representation
Ivan Titov

Exact Decoding of Syntactic Translation Models through Lagrangian Relaxation
Alexander M. Rush and Michael Collins

Monday, June 20, 2011 (continued)

Session 1-C: (10:30-12:10) Information Retrieval

Jigs and Lures: Associating Web Queries with Structured Entities
Patrick Pantel and Ariel Fuxman

Semi-Supervised SimHash for Efficient Document Similarity Search
Qixia Jiang and Maosong Sun

Joint Annotation of Search Queries
Michael Bendersky, W. Bruce Croft and David A. Smith

Query Weighting for Ranking Model Adaptation
Peng Cai, Wei Gao, Aoying Zhou and Kam-Fai Wong

Session 1-D: (10:30-12:10) Sentiment Analysis/Opinion Mining 1

Automatically Extracting Polarity-Bearing Topics for Cross-Domain Sentiment Classification
Yulan He, Chenghua Lin and Harith Alani

Using Multiple Sources to Construct a Sentiment Sensitive Thesaurus for Cross-Domain Sentiment Classification
Danushka Bollegala, David Weir and John Carroll

Learning Word Vectors for Sentiment Analysis
Andrew L. Maas, Raymond E. Daly, Peter T. Pham, Dan Huang, Andrew Y. Ng and Christopher Potts

Target-dependent Twitter Sentiment Classification
Long Jiang, Mo Yu, Ming Zhou, Xiaohua Liu and Tiejun Zhao

Monday, June 20, 2011 (continued)

Session 1-E: (10:30-12:10) Language Resource

A Comprehensive Dictionary of Multiword Expressions
Kosho Shudo, Akira Kurahone and Toshifumi Tanabe

Multi-Modal Annotation of Quest Games in Second Life
Sharon Gower Small, Jennifer Strommer-Galley and Tomek Strzalkowski

A New Dataset and Method for Automatically Grading ESOL Texts
Helen Yannakoudakis, Ted Briscoe and Ben Medlock

Collecting Highly Parallel Data for Paraphrase Evaluation
David Chen and William Dolan

(12:10 - 2:00) Lunch

Session 2-A: (2:00-3:40) MT: Models & Evaluation

A Large Scale Distributed Syntactic, Semantic and Lexical Language Model for Machine Translation
Ming Tan, Wenli Zhou, Lei Zheng and Shaojun Wang

Goodness: A Method for Measuring Machine Translation Confidence
Nguyen Bach, Fei Huang and Yaser Al-Onaizan

MEANT: An inexpensive, high-accuracy, semi-automatic metric for evaluating translation utility based on semantic roles
Chi-kiu Lo and Dekai Wu

An exponential translation model for target language morphology
Michael Subotin

Session 2-B: (2:00-3:40) Machine Learning Methods 2

Bayesian Inference for Zodiac and Other Homophonic Ciphers
Sujith Ravi and Kevin Knight

Interactive Topic Modeling
Yuening Hu, Jordan Boyd-Graber and Brianna Satinoff

Faster and Smaller N-Gram Language Models
Adam Pauls and Dan Klein

Learning to Win by Reading Manuals in a Monte-Carlo Framework
S.R.K Branavan, David Silver and Regina Barzilay

Session 2-C: (2:00-3:40) Linguistic Creativity

Creative Language Retrieval: A Robust Hybrid of Information Retrieval and Linguistic Creativity
Tony Veale

Local Histograms of Character N-grams for Authorship Attribution
Hugo Jair Escalante, Thamar Solorio and Manuel Montes-y-Gomez

Word Maturity: Computational Modeling of Word Knowledge
Kirill Kireyev and Thomas K Landauer

Finding Deceptive Opinion Spam by Any Stretch of the Imagination
Myle Ott, Yejin Choi, Claire Cardie and Jeffrey T. Hancock

Monday, June 20, 2011 (continued)

Session 2-D: (2:00-3:40) Sentiment Analysis/Opinion Mining 2

Joint Bilingual Sentiment Classification with Unlabeled Parallel Corpora
Bin Lu, Chenhao Tan, Claire Cardie and Benjamin K. Tsou

A Pilot Study of Opinion Summarization in Conversations
Dong Wang and Yang Liu

Contrasting Opposing Views of News Articles on Contentious Issues
Souneil Park, Kyung Soon Lee and Junehwa Song

Content Models with Attitude
Christina Sauper, Aria Haghighi and Regina Barzilay

Session 2-E: (2:00-3:40) NLP for Web 2.0

Recognizing Named Entities in Tweets
Xiaohua LIU, Shaodian ZHANG, Furu WEI and Ming ZHOU

Lexical Normalisation of Short Text Messages: Makn Sens a #twitter
Bo Han and Timothy Baldwin

Topical Keyphrase Extraction from Twitter
Xin Zhao, Jing Jiang, Jing He, Yang Song, Palakorn Achanauparp, Ee-Peng Lim and Xiaoming Li

Event Discovery in Social Media Feeds
Edward Benson, Aria Haghighi and Regina Barzilay

Monday, June 20, 2011 (continued)

(3:40-4:10) Coffee Break

Session 3-A: (4:10-5:50) Transliteration/Alignment

How do you pronounce your name? Improving G2P with transliterations
Aditya Bhargava and Grzegorz Kondrak

Unsupervised Word Alignment with Arbitrary Features
Chris Dyer, Jonathan H. Clark, Alon Lavie and Noah A. Smith

Model-Based Aligner Combination Using Dual Decomposition
John DeNero and Klaus Macherey

An Algorithm for Unsupervised Transliteration Mining with an Application to Word Alignment
Hassan Sajjad, Alexander Fraser and Helmut Schmid

Session 3-B: (4:10-5:50) Parsing 1

Beam-Width Prediction for Efficient Context-Free Parsing
Nathan Bodenstab, Aaron Dunlop, Keith Hall and Brian Roark

Optimal Head-Driven Parsing Complexity for Linear Context-Free Rewriting Systems
Pierluigi Crescenzi, Daniel Gildea, Andrea Marino, Gianluca Rossi and Giorgio Satta

Prefix Probability for Probabilistic Synchronous Context-Free Grammars
Mark-Jan Nederhof and Giorgio Satta

A Comparison of Loopy Belief Propagation and Dual Decomposition for Integrated CCG Supertagging and Parsing
Michael Auli and Adam Lopez

Monday, June 20, 2011 (continued)

Session 3-C: (4:10-5:50) Summarization

Jointly Learning to Extract and Compress
Taylor Berg-Kirkpatrick, Dan Gillick and Dan Klein

Discovery of Topically Coherent Sentences for Extractive Summarization
Asli Celikyilmaz and Dilek Hakkani-Tur

Coherent Citation-Based Summarization of Scientific Papers
Amjad Abu-Jbara and Dragomir Radev

A Class of Submodular Functions for Document Summarization
Hui Lin and Jeff Bilmes

Session 3-D: (4:10-5:50) Relation Extraction

Semi-supervised Relation Extraction with Large-scale Word Clustering
Ang Sun, Ralph Grishman and Satoshi Sekine

In-domain Relation Discovery with Meta-constraints via Posterior Regularization
Harr Chen, Edward Benson, Tahira Naseem and Regina Barzilay

Knowledge-Based Weak Supervision for Information Extraction of Overlapping Relations
Raphael Hoffmann, Congle Zhang, Xiao Ling, Luke Zettlemoyer and Daniel S. Weld

Exploiting Syntactico-Semantic Structures for Relation Extraction
Yee Seng Chan and Dan Roth

Monday, June 20, 2011 (continued)

Session 3-E: (4:10-5:50) Semantics

Together We Can: Bilingual Bootstrapping for WSD
Mitesh M. Khapra, Salil Joshi, Arindam Chatterjee and Pushpak Bhattacharyya

Which Noun Phrases Denote Which Concepts?
Jayant Krishnamurthy and Tom Mitchell

Semantic Representation of Negation Using Focus Detection
Eduardo Blanco and Dan Moldovan

Learning Dependency-Based Compositional Semantics
Percy Liang, Michael Jordan and Dan Klein

(6:00-8:30) Poster Session (Long papers)

(6:00-8:30) Poster Session (Short papers)

Tuesday, June 21, 2011

Session 4-A: (9:00-10:30) Best Paper Session

Unsupervised Part-of-Speech Tagging with Bilingual Graph-Based Projections
Dipanjan Das and Slav Petrov

Global Learning of Typed Entailment Rules
Jonathan Berant, Ido Dagan and Jacob Goldberger

Tuesday, June 21, 2011 (continued)

(10:30-11:00) Coffee Break

(3:30-4:00) Coffee Break

Session 7-A: (4:00-5:40) SMT: Phrase-based Models

Incremental Syntactic Language Models for Phrase-based Translation
Lane Schwartz, Chris Callison-Burch, William Schuler and Stephen Wu

An Unsupervised Model for Joint Phrase Alignment and Extraction
Graham Neubig, Taro Watanabe, Eiichiro Sumita, Shinsuke Mori and Tatsuya Kawahara

Learning Hierarchical Translation Structure with Linguistic Annotations
Markos Mylonakis and Khalil Sima'an

Phrase-Based Translation Model for Question Retrieval in Community Question Answer Archives
Guangyou Zhou, Li Cai, Jun Zhao and Kang Liu

Session 7-B: (4:00-5:40) Parsing 2

Neutralizing Linguistically Problematic Annotations in Unsupervised Dependency Parsing Evaluation
Roy Schwartz, Omri Abend, Roi Reichart and Ari Rappoport

Dynamic Programming Algorithms for Transition-Based Dependency Parsers
Marco Kuhlmann, Carlos Gómez-Rodríguez and Giorgio Satta

Shift-Reduce CCG Parsing
Yue Zhang and Stephen Clark

Web-Scale Features for Full-Scale Parsing
Mohit Bansal and Dan Klein

Tuesday, June 21, 2011 (continued)

Session 7-C: (4:00-5:40) Spoken Language Processing

The impact of language models and loss functions on repair disfluency detection
Simon Zwarts and Mark Johnson

Learning Sub-Word Units for Open Vocabulary Speech Recognition
Carolina Parada, Mark Dredze, Abhinav Sethy and Ariya Rastrow

Computing and Evaluating Syntactic Complexity Features for Automated Scoring of Spontaneous Non-Native Speech
Miao Chen and Klaus Zechner

N-Best Rescoring Based on Pitch-accent Patterns
Je Hun Jeon, Wen Wang and Yang Liu

Session 7-D: (4:00-5:40) Natural Language Processing Applications

Lexically-Triggered Hidden Markov Models for Clinical Document Coding
Svetlana Kiritchenko and Colin Cherry

Learning to Grade Short Answer Questions using Semantic Similarity Measures and Dependency Graph Alignments
Michael Mohler, Razvan Bunescu and Rada Mihalcea

Age Prediction in Blogs: A Study of Style, Content, and Online Behavior in Pre- and Post-Social Media Generations
Sara Rosenthal and Kathleen McKeown

Extracting Social Power Relationships from Natural Language
Philip Bramsen, Martha Escobar-Molano, Ami Patel and Rafael Alonso

Tuesday, June 21, 2011 (continued)

Session 7-E: (4:00-5:40) Coreference Resolution

Bootstrapping coreference resolution using word associations
Hamidreza Kobdani, Hinrich Schuetze, Michael Schiehlen and Hans Kamp

Large-Scale Cross-Document Coreference Using Distributed Inference and Hierarchical Models
Sameer Singh, Amarnag Subramanya, Fernando Pereira and Andrew McCallum

A Cross-Lingual ILP Solution to Zero Anaphora Resolution
Ryu Iida and Massimo Poesio

Coreference Resolution with World Knowledge
Altaf Rahman and Vincent Ng

(7:00-11:00) Banquet

Wednesday, June 22, 2011

(9:00-10:00) Invited Talk 2: How do the languages we speak shape the ways we think? by Lera Boroditsky

(10:00-10:30) Coffee Break

Session 5-A: (10:30-12:10) SMT: Tree-based Models

How to train your multi bottom-up tree transducer
Andreas Maletti

Binarized Forest to String Translation
Hao Zhang, Licheng Fang, Peng Xu and Xiaoyun Wu

Learning to Transform and Select Elementary Trees for Improved Syntax-based Machine Translations
Bing Zhao, Young-Suk Lee, Xiaoqiang Luo and Liu Li

Rule Markov Models for Fast Tree-to-String Translation
Ashish Vaswani, Haitao Mi, Liang Huang and David Chiang

Wednesday, June 22, 2011 (continued)

Session 5-B: (10:30-12:10) Morphology/POS Induction

A Hierarchical Pitman-Yor Process HMM for Unsupervised Part of Speech Induction
Phil Blunsom and Trevor Cohn

Using Deep Morphology to Improve Automatic Error Detection in Arabic Handwriting Recognition
Nizar Habash and Ryan Roth

A Discriminative Model for Joint Morphological Disambiguation and Dependency Parsing
John Lee, Jason Naradowsky and David A. Smith

Unsupervised Bilingual Morpheme Segmentation and Alignment with Context-rich Hidden Semi-Markov Models
Jason Naradowsky and Kristina Toutanova

Session 5-C: (10:30-12:10) Error Correction

A Graph Approach to Spelling Correction in Domain-Centric Search
Zhuowei Bao, Benny Kimelfeld and Yunyao Li

Grammatical Error Correction with Alternating Structure Optimization
Daniel Dahlmeier and Hwee Tou Ng

Algorithm Selection and Model Adaptation for ESL Correction Tasks
Alla Rozovskaya and Dan Roth

Automated Whole Sentence Grammar Correction Using a Noisy Channel Model
Y. Albert Park and Roger Levy

Wednesday, June 22, 2011 (continued)

Session 5-D: (10:30-12:10) Information Extraction

A Generative Entity-Mention Model for Linking Entities with Knowledge Base
Xianpei Han and Le Sun

Simple supervised document geolocation with geodesic grids
Benjamin Wing and Jason Baldridge

Piggyback: Using Search Engines for Robust Cross-Domain Named Entity Recognition
Stefan Rüd, Massimiliano Ciaramita, Jens Müller and Hinrich Schütze

Template-Based Information Extraction without the Templates
Nathanael Chambers and Dan Jurafsky

Session 5-E: (10:30-12:10) Discourse

Classifying arguments by scheme
Vanessa Wei Feng and Graeme Hirst

Automatically Evaluating Text Coherence Using Discourse Relations
Ziheng Lin, Hwee Tou Ng and Min-Yen Kan

Underspecifying and Predicting Voice for Surface Realisation Ranking
Sina Zarrieß, Aoife Cahill and Jonas Kuhn

Recognizing Authority in Dialogue with an Integer Linear Programming Constrained Model
Elijah Mayfield and Carolyn Penstein Rosé

Wednesday, June 22, 2011 (continued)

(12:10 - 2:00) Lunch

(1:30-3:00) ACL Business Meeting

(3:00-3:30) Coffee Break

Session 6-A: (3:30-4:45) MT: Reordering Models

Reordering Metrics for MT
Alexandra Birch and Miles Osborne

Reordering with Source Language Collocations
Zhanyi Liu, Haifeng Wang, Hua Wu, Ting Liu and Sheng Li

A Joint Sequence Translation Model with Integrated Reordering
Nadir Durrani, Helmut Schmid and Alexander Fraser

Session 6-B: (3:30-4:45) Grammar

Integrating surprisal and uncertain-input models in online sentence comprehension: formal techniques and empirical results
Roger Levy

Metagrammar engineering: Towards systematic exploration of implemented grammars
Antske Fokkens

Simple Unsupervised Grammar Induction from Raw Text with Cascaded Finite State Models
Elias Ponvert, Jason Baldridge and Katrin Erk

Wednesday, June 22, 2011 (continued)

Session 6-C: (3:30-4:45) Generation/Paraphrasing

Extracting Paraphrases from Definition Sentences on the Web
Chikara Hashimoto, Kentaro Torisawa, Stijn De Saeger, Jun'ichi Kazama and Sadao Kurohashi

Learning From Collective Human Behavior to Introduce Diversity in Lexical Choice
Vahed Qazvinian and Dragomir R. Radev

Ordering Prenominal Modifiers with a Reranking Approach
Jenny Liu and Aria Haghighi

Session 6-D: (3:30-4:45) Event-Role Extraction

Unsupervised Semantic Role Induction via Split-Merge Clustering
Joel Lang and Mirella Lapata

Using Cross-Entity Inference to Improve Event Extraction
Yu Hong, Jianfeng Zhang, Bin Ma, Jianmin Yao, Guodong Zhou and Qiaoming Zhu

Peeling Back the Layers: Detecting Event Role Fillers in Secondary Contexts
Ruihong Huang and Ellen Riloff

Session 6-E: (3:30-4:20) Knowledge Base Extension

Knowledge Base Population: Successful Approaches and Challenges
Heng Ji and Ralph Grishman

Nonlinear Evidence Fusion and Propagation for Hyponymy Relation Mining
Fan Zhang, Shuming Shi, Jing Liu, Shuqi Sun and Chin-Yew Lin

Wednesday, June 22, 2011 (continued)

(5:00-6:10) Life time achievement award and closing

Monday, June 20, 2011

(6:00-8:30) Poster Session (Long papers)

A Pronoun Anaphora Resolution System based on Factorial Hidden Markov Models
Dingcheng Li, Tim Miller and William Schuler

Disentangling Chat with Local Coherence Models
Micha Elsner and Eugene Charniak

An Affect-Enriched Dialogue Act Classification Model for Task-Oriented Dialogue
Kristy Boyer, Joseph Grafsgaard, Eun Young Ha, Robert Phillips and James Lester

Fine-Grained Class Label Markup of Search Queries
Joseph Reisinger and Marius Pasca

Creating a manually error-tagged and shallow-parsed learner corpus
Ryo Nagata, Edward Whittaker and Vera Sheinman

Crowdsourcing Translation: Professional Quality from Non-Professionals
Omar F. Zaidan and Chris Callison-Burch

A Statistical Tree Annotator and Its Applications
Xiaoqiang Luo and Bing Zhao

Consistent Translation using Discriminative Learning - A Translation Memory-inspired Approach
Yanjun Ma, Yifan He, Andy Way and Josef van Genabith

Machine Translation System Combination by Confusion Forest
Taro Watanabe and Eiichiro Sumita

Hypothesis Mixture Decoding for Statistical Machine Translation
Nan Duan, Mu Li and Ming Zhou

Minimum Bayes-risk System Combination
Jesús González-Rubio, Alfons Juan and Francisco Casacuberta

Adjoining Tree-to-String Translation
Yang Liu, Qun Liu and Yajuan Lü

Enhancing Language Models in Statistical Machine Translation with Backward N-grams and Mutual Information Triggers
Deyi Xiong, Min Zhang and Haizhou Li

Translating from Morphologically Complex Languages: A Paraphrase-Based Approach
Preslav Nakov and Hwee Tou Ng

Gappy Phrasal Alignment By Agreement
Mohit Bansal, Chris Quirk and Robert Moore

Translationese and Its Dialects
Moshe Koppel and Noam Ordan

Rare Word Translation Extraction from Aligned Comparable Documents
Emmanuel Prochasson and Pascale Fung

Using Bilingual Parallel Corpora for Cross-Lingual Textual Entailment
Yashar Mehdad, Matteo Negri and Marcello Federico

Using Large Monolingual and Bilingual Corpora to Improve Coordination Disambiguation
Shane Bergsma, David Yarowsky and Kenneth Church

Unsupervised Decomposition of a Document into Authorial Components
Moshe Koppel, Navot Akiva, Idan Dershowitz and Nachum Dershowitz

Invited Talk 1

Building Watson: An Overview of the DeepQA Project

David Ferrucci, Principal Investigator, IBM Research

Monday, June 20, 2011 9:00-10:00

Computer systems that can directly and accurately answer peoples' questions over a broad domain of human knowledge have been envisioned by scientists and writers since the advent of computers themselves. Open domain question answering holds tremendous promise for facilitating informed decision making over vast volumes of natural language content. Applications in business intelligence, healthcare, customer support, enterprise knowledge management, social computing, science and government could all benefit from computer systems capable of deeper language understanding. The DeepQA project is aimed at exploring how advancing and integrating Natural Language Processing (NLP), Information Retrieval (IR), Machine Learning (ML), Knowledge Representation and Reasoning (KR&R) and massively parallel computation can greatly advance the science and application of automatic Question Answering. An exciting proof-point in this challenge was developing a computer system that could successfully compete against top human players at the Jeopardy! quiz show (www.jeopardy.com).

Attaining champion-level performance at Jeopardy! requires a computer to rapidly and accurately answer rich open-domain questions, and to predict its own performance on any given question. The system must deliver high degrees of precision and confidence over a very broad range of knowledge and natural language content with a 3-second response time. To do this, the DeepQA team advanced a broad array of NLP techniques to find, generate, evidence and analyze many competing hypotheses over large volumes of natural language content to build Watson (www.ibmwatson.com). An important contributor to Watson's success is its ability to automatically learn and combine accurate confidences across a wide array of algorithms and over different dimensions of evidence. Watson produced accurate confidences to know when to "buzz in" against its competitors and how much to bet. High precision and accurate confidence computations are critical for real business settings where helping users focus on the right content sooner and with greater confidence can make all the difference. The need for speed and high precision demands a massively parallel computing platform capable of generating, evaluating and combing 1000's of hypotheses and their associated evidence. In this talk, I will introduce the audience to the Jeopardy! Challenge, explain how Watson was built on DeepQA to ultimately defeat the two most celebrated human Jeopardy Champions of all time and I will discuss applications of the Watson technology beyond in areas such as healthcare.

Dr. David Ferrucci is the lead researcher and Principal Investigator (PI) for the Watson/Jeopardy! project. He has been a Research Staff Member at IBM's T.J. Watson's Research Center since 1995 where he heads up the Semantic Analysis and Integration department. Dr. Ferrucci focuses on technologies for automatically discovering valuable knowledge in natural language content and using it to enable better decision making.

Invited Talk 2

How do the languages we speak shape the ways we think?

Lera Boroditsky, Assistant Professor, Stanford University

Wednesday, June 22, 2011 9:00-10:00

Do people who speak different languages think differently? Does learning new languages change the way you think? Do polyglots think differently when speaking different languages? Are some thoughts unthinkable without language? I will describe data from experiments conducted around the world that reveal the powerful and often surprising ways that the languages we speak shape the ways we think.

Lera Boroditsky is an assistant professor of psychology at Stanford University and Editor in Chief of Frontiers in Cultural Psychology. Boroditsky's research centers on how knowledge emerges out of the interactions of mind, world, and language, and the ways that languages and cultures shape human thinking. To this end, Boroditsky's laboratory has collected data around the world, from Indonesia to Chile to Turkey to Aboriginal Australia. Her research has been widely featured in the media and has won multiple awards, including the CAREER award from the National Science Foundation, the Searle Scholars award, and the McDonnell Scholars award.

A Word-Class Approach to Labeling PSCFG Rules for Machine Translation

Andreas Zollmann and **Stephan Vogel**
Language Technologies Institute
School of Computer Science
Carnegie Mellon University
Pittsburgh, PA 15213, USA
{zollmann,vogel+}@cs.cmu.edu

Abstract

In this work we propose methods to label probabilistic synchronous context-free grammar (PSCFG) rules using only word tags, generated by either part-of-speech analysis or unsupervised word class induction. The proposals range from simple tag-combination schemes to a phrase clustering model that can incorporate an arbitrary number of features.

Our models improve translation quality over the single generic label approach of Chiang (2005) and perform on par with the syntactically motivated approach from Zollmann and Venugopal (2006) on the NIST large Chinese-to-English translation task. These results persist when using automatically learned word tags, suggesting broad applicability of our technique across diverse language pairs for which syntactic resources are not available.

1 Introduction

The Probabilistic Synchronous Context Free Grammar (PSCFG) formalism suggests an intuitive approach to model the long-distance and lexically sensitive reordering phenomena that often occur across language pairs considered for statistical machine translation. As in monolingual parsing, nonterminal symbols in translation rules are used to generalize beyond purely lexical operations. *Labels* on these nonterminal symbols are often used to enforce syntactic constraints in the generation of bilingual sentences and imply conditional independence assumptions in the translation model. Several techniques have been recently proposed to automatically identify and estimate parameters for PSCFGs (or related synchronous grammars) from parallel corpora (Galley et al., 2004; Chiang, 2005; Zollmann and Venugopal, 2006; Liu et al., 2006; Marcu et al., 2006).

While all of these techniques rely on word-alignments to suggest lexical relationships, they differ in the way in which they assign labels to nonterminal symbols of PSCFG rules. Chiang (2005) describes a procedure to extract PSCFG rules from word-aligned (Brown et al., 1993) corpora, where all nonterminals share the same generic label X. In Galley et al. (2004) and Marcu et al. (2006), target language parse trees are used to identify rules and label their nonterminal symbols, while Liu et al. (2006) use source language parse trees instead. Zollmann and Venugopal (2006) directly extend the rule extraction procedure from Chiang (2005) to heuristically label any phrase pair based on target language parse trees. Label-based approaches have resulted in improvements in translation quality over the single X label approach (Zollmann et al., 2008; Mi and Huang, 2008); however, all the works cited here rely on stochastic parsers that have been trained on manually created syntactic treebanks. These treebanks are difficult and expensive to produce and exist for a limited set of languages only.

In this work, we propose a labeling approach that is based merely on part-of-speech analysis of the source or target language (or even both). Towards the ultimate goal of building end-to-end machine translation systems without *any* human annotations, we also experiment with automatically inferred word classes using distributional clustering (Kneser and Ney, 1993). Since the number of classes is a parameter of the clustering method and the resulting nonterminal size of our grammar is a function of the number of word classes, the PSCFG grammar complexity can be adjusted to the specific translation task at hand.

Finally, we introduce a more flexible labeling approach based on K-means clustering, which allows

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1–11,
Portland, Oregon, June 19-24, 2011.

the incorporation of an arbitrary number of word-class based features, including phrasal contexts, can make use of multiple tagging schemes, and also allows non-class features such as phrase sizes.

2 PSCFG-based translation

In this work we experiment with PSCFGs that have been automatically learned from word-aligned parallel corpora. PSCFGs are defined by a source terminal set (source vocabulary) $\mathcal{T}_S$, a target terminal set (target vocabulary) $\mathcal{T}_T$, a shared nonterminal set $\mathcal{N}$ and rules of the form: $A \rightarrow \langle \gamma, \alpha, w \rangle$ where

- $A \in \mathcal{N}$ is a labeled nonterminal referred to as the left-hand-side of the rule,
- $\gamma \in (\mathcal{N} \cup \mathcal{T}_S)^*$ is the source side of the rule,
- $\alpha \in (\mathcal{N} \cup \mathcal{T}_T)^*$ is the target side of the rule,
- $w \in [0, \infty)$ is a non-negative real-valued weight assigned to the rule; in our model, w is the product of features ϕ_i raised to the power of weight λ_i.

Chiang (2005) learns a single-nonterminal PSCFG from a bilingual corpus by first identifying initial phrase pairs using the technique from Koehn et al. (2003), and then performing a generalization operation to generate phrase pairs with gaps, which can be viewed as PSCFG rules with generic 'X' nonterminal left-hand-sides and substitution sites. Bilingual features ϕ_i that judge the quality of each rule are estimated based on rule extraction frequency counts.

3 Hard rule labeling from word classes

We now describe a simple method of inducing a multi-nonterminal PSCFG from a parallel corpus with word-tagged target side sentences. The same procedure can straightforwardly be applied to a corpus with tagged source side sentences. We use the simple term 'tag' to stand for any kind of word-level analysis—a syntactic, statistical, or other means of grouping word types or tokens into classes, possibly based on their position and context in the sentence, POS tagging being the most obvious example.

As in Chiang's hierarchical system, we rely on an external phrase-extraction procedure such as the one of Koehn et al. (2003) to provide us with a set of phrase pairs for each sentence pair in the training corpus, annotated with their respective start and end positions in the source and target sentences. Let $\boldsymbol{f} = f_1 \cdots f_m$ be the current source sentence, $\boldsymbol{e} = e_1 \cdots e_n$ the current target sentence, and $\boldsymbol{t} = t_1 \cdots t_n$ its corresponding target tag sequence. We convert each extracted phrase pair, represented by its source span $\langle i, j \rangle$ and target span $\langle k, \ell \rangle$, into an initial rule

$$t_k\text{-}t_\ell \rightarrow f_i \cdots f_j \mid e_k \cdots e_\ell$$

by assigning it a nonterminal "t_k-t_ℓ" constructed by combining the tag of the target phrase's left-most word with the tag of its right-most word.

The creation of complex rules based on all initial rules obtained from the current sentence now proceeds just as in Chiang's model.

Consider the target-tagged example sentence pair:

Ich habe ihn gesehen | I/PRP saw/VBD him/PRP

Then (depending on the extracted phrase pairs), the resulting initial rules could be:

1: PRP-PRP → Ich | I
2: PRP-PRP → ihn | him
3: VBD-VBD → gesehen | saw
4: VBD-PRP → habe ihn gesehen | saw him
5: PRP-PRP → Ich habe ihn gesehen | I saw him

Now, by abstracting-out initial rule 2 from initial rule 4, we obtain the complex rule:

VBD-PRP → habe PRP-PRP$_1$ gesehen | saw PRP-PRP$_1$

Intuitively, the labeling of initial rules with tags marking the boundary of their target sides results in complex rules whose nonterminal occurrences impose weak syntactic constraints on the rules eligible for substitution in a PSCFG derivation: The left and right boundary word tags of the inserted rule's target side have to match the respective boundary word tags of the phrase pair that was replaced by a nonterminal when the complex rule was created from a training sentence pair. Since consecutive words within a rule stem from consecutive words in the training corpus and thus are already consistent, the boundary word tags are more informative than tags of words between the boundaries for the task of combining different rules in a derivation, and are therefore a more appropriate choice for the creation of grammar labels than tags of inside words.

Accounting for phrase size A drawback of the current approach is that a single-word rule such as

PRP-PRP → Ich | I

can have the same left-hand-side nonterminal as a long rule with identical left and right boundary tags, such as (when using target-side tags):

PRP-PRP → Ich habe ihn gesehen | I saw him

We therefore introduce a means of distinguishing between one-word, two-word, and multiple-word phrases as follows: Each one-word phrase with tag T simply receives the label T, instead of T-T. Two-word phrases with tag sequence T_1T_2 are labeled T_1-T_2 as before. Phrases of length greater two with tag sequence $T_1 \cdots T_n$ are labeled $T_1..T_n$ to denote that tags were omitted from the phrase's tag sequence. The resulting number of grammar nonterminals based on a tag vocabulary of size t is thus given by $2t^2 + t$.

An alternative way of accounting for phrase size is presented by Chiang et al. (2008), who introduce *structural distortion features* into a hierarchical phrase-based model, aimed at modeling nonterminal reordering given source span length. Our approach instead uses distinct grammar rules and labels to discriminate phrase size, with the advantage of enabling all translation models to estimate distinct weights for distinct size classes and avoiding the need of additional models in the log-linear framework; however, the increase in the number of labels and thus grammar rules decreases the reliability of estimated models for rare events due to increased data sparseness.

Extension to a bilingually tagged corpus While the availability of syntactic annotations for both source *and* target language is unlikely in most translation scenarios, some form of word tags, be it part-of-speech tags or learned word clusters (cf. Section 3) might be available on both sides. In this case, our grammar extraction procedure can be easily extended to impose both source and target constraints on the eligible substitutions simultaneously.

Let N_f be the nonterminal label that would be assigned to a given initial rule when utilizing the source-side tag sequence, and N_e the assigned label according to the target-side tag sequence. Then our bilingual tag-based model assigns '$N_f + N_e$' to the initial rule. The extraction of complex rules proceeds as before. The number of nonterminals in this model, based on a source tag vocabulary of size s and a target tag vocabulary of size t, is thus given by s^2t^2 for the regular labeling method and $(2s^2 + s)(2t^2 + t)$ when accounting for phrase size.

Consider again our example sentence pair (now also annotated with source-side part-of-speech tags):

Ich/PRP habe/AUX ihn/PRP gesehen/VBN
I/PRP saw/VBD him/PRP

Given the same phrase extraction method as before, the resulting initial rules for our bilingual model, when also accounting for phrase size, are as follows:

1: PRP+PRP → Ich | I
2: PRP+PRP → ihn | him
3: VBN+VBD → gesehen | saw
4: AUX..VBN+VBD-PRP → habe ihn gesehen | saw him
5: PRP..VBN+PRP..PRP → Ich habe ihn gesehen | I saw him

Abstracting-out rule 2 from rule 4, for instance, leads to the complex rule:

AUX..VBN+VBD-PRP → habe PRP+PRP$_1$ gesehen | saw PRP+PRP$_1$

Unsupervised word class assignment by clustering As an alternative to POS tags, we experiment with unsupervised word clustering methods based on the exchange algorithm (Kneser and Ney, 1993). Its objective function is maximizing the likelihood

$$\prod_{i=1}^{n} P(w_i|w_1, \ldots, w_{i-1})$$

of the training data $w = w_1, \ldots, w_n$ given a partially class-based bigram model of the form

$$P(w_i|w_1, \ldots, w_{i-1}) \approx p(c(w_i)|w_{i-1}) \cdot p(w_i|c(w_i))$$

where $c : \mathcal{V} \rightarrow \{1, \ldots, N\}$ maps a word (type, not token) w to its class $c(w)$, $\mathcal{V}$ is the vocabulary, and N the fixed number of classes, which has to be chosen *a priori*. We use the publicly available implementation MKCLS (Och, 1999) to train this model. As training data we use the respective side of the parallel training data for the translation system.

We also experiment with the extension of this model by Clark (2003), who incorporated morphological information by imposing a Bayesian prior on the class mapping c, based on N individual distributions over strings, one for each word class. Each such distribution is a character-based hidden Markov model, thus encouraging the grouping of morphologically similar words into the same class.

4 Clustering phrase pairs directly using the K-means algorithm

Even though we have only made use of the first and last words' classes in the labeling methods described so far, the number of resulting grammar nonterminals quickly explodes. Using a scheme based on source and target phrases with accounting for phrase size, with 36 word classes (the size of the Penn English POS tag set) for both languages, yields a grammar with $(36+2*36^2)^2 = 6.9$m nonterminal labels.

Quite plausibly, phrase labeling should be informed by more than just the classes of the first and last words of the phrase. Taking phrase context into account, for example, can aid the learning of syntactic properties: a phrase beginning with a determiner and ending with a noun, with a verb as right context, is more likely to be a noun phrase than the same phrase with another noun as right context. In the current scheme, there is no way of distinguishing between these two cases. Similarly, it is conceivable that using non-boundary words inside the phrase might aid the labeling process.

When relying on unsupervised learning of the word classes, we are forced to chose a fixed number of classes. A smaller number of word clusters will result in smaller number of grammar nonterminals, and thus more reliable feature estimation, while a larger number has the potential to discover more subtle syntactic properties. Using multiple word clusterings simultaneously, each based on a different number of classes, could turn this global, hard trade-off into a local, soft one, informed by the number of phrase pair instances available for a given granularity.

Lastly, our method of accounting for phrase size is somewhat displeasing: While there is a hard partitioning of one-word and two-word phrases, no distinction is made between phrases of length greater than two. Marking phrase sizes greater than two explicitly by length, however, would create many sparse, low-frequency rules, and one of the strengths of PSCFG-based translation is the ability to substitute flexible-length spans into nonterminals of a derivation. A partitioning where phrase size is instead merely a feature informing the labeling process seems more desirable.

We thus propose to represent each phrase pair instance (including its bilingual one-word contexts) as feature vectors, i.e., points of a vector space. We then use these data points to partition the space into clusters, and subsequently assign each phrase pair instance the cluster of its corresponding feature vector as label.

The feature mapping Consider the phrase pair instance

$$(f_0)f_1 \cdots f_m(f_{m+1}) \mid (e_0)e_1 \cdots e_n(e_{n+1})$$

(where $f_0, f_{m+1}, e_0, e_{n+1}$ are the left and right, source and target side contexts, respectively). We begin with the case of only a single, target-side word class scheme (either a tagger or an unsupervised word clustering/POS induction method). Let $C = \{c_1, \ldots, c_N\}$ be its set of word classes. Further, let c_0 be a short-hand for the result of looking up the class of a word that is out of bounds (e.g., the left context of the first word of a sentence, or the second word of a one-word phrase). We now map our phrase pair instance to the real-valued vector (where $\mathbb{1}_{[P]}$ is the indicator function defined as 1 if property P is true, and 0 otherwise):

$$\Big\langle \mathbb{1}_{[e_1=c_0]}, \ldots, \mathbb{1}_{[e_1=c_N]}, \mathbb{1}_{[e_n=c_0]}, \ldots, \mathbb{1}_{[e_n=c_N]},$$
$$\alpha_{\text{sec}}\mathbb{1}_{[e_2=c_0]}, \ldots, \alpha_{\text{sec}}\mathbb{1}_{[e_2=c_N]},$$
$$\alpha_{\text{sec}}\mathbb{1}_{[e_{n-1}=c_0]}, \ldots, \alpha_{\text{sec}}\mathbb{1}_{[e_{n-1}=c_N]},$$
$$\frac{\alpha_{\text{ins}}\sum_{i=1}^{n}\mathbb{1}_{[e_i=c_0]}}{n}, \ldots, \frac{\alpha_{\text{ins}}\sum_{i=1}^{n}\mathbb{1}_{[e_i=c_N]}}{n},$$
$$\alpha_{\text{cntxt}}\mathbb{1}_{[e_0=c_0]}, \ldots, \alpha_{\text{cntxt}}\mathbb{1}_{[e_0=c_N]},$$
$$\alpha_{\text{cntxt}}\mathbb{1}_{[e_{n+1}=c_0]}, \ldots, \alpha_{\text{cntxt}}\mathbb{1}_{[e_{n+1}=c_N]},$$
$$\alpha_{\text{phrsize}}\sqrt{N+1}\log_{10}(n)\Big\rangle$$

The α parameters determine the influence of the different types of information. The elements in the first line represent the phrase boundary word classes, the next two lines the classes of the second and penultimate word, followed by a line representing the accumulated contents of the whole phrase, followed by two lines pertaining to the context word classes. The final element of the vector is proportional to the logarithm of the phrase length.[1] We chose the logarithm assuming that length deviation of syntactic phrasal units is not constant, but proportional to the average length. Thus, all other features being equal, the distance between a two-word and a four-word phrase is

[1] The $\sqrt{N+1}$ factor serves to make the feature's influence independent of the number of word classes by yielding the same distance (under L_2) as $N+1$ identical copies of the feature.

the same as the distance between a four-word and an eight-word phrase.

We will mainly use the Euclidean (L_2) distance to compare points for clustering purposes. Our feature space is thus the Euclidean vector space $\mathbb{R}^{7N+8}$.

To additionally make use of source-side word classes, we append elements analogous to the ones above to the vector, all further multiplied by a parameter α_{src} that allows trading off the relevance of source-side and target-side information. In the same fashion, we can incorporate multiple tagging schemes (e.g., word clusterings of different granularities) into the same feature vector. As finer-grained schemes have more elements in the feature vector than coarser-grained ones, and thus exert more influence, we set the α parameter for each scheme to $1/N$ (where N is the number of word classes of the scheme).

The K-means algorithm To create the clusters, we chose the K-means algorithm (Steinhaus, 1956; MacQueen, 1967) for both its computational efficiency and ease of implementation and parallelization. Given an initial mapping from the data points to K clusters, the procedure alternates between (i) computing the centroid of each cluster and (ii) reallocating each data point to the closest cluster centroid, until convergence.

We implemented two commonly used initialization methods: Forgy and Random Partition. The Forgy method randomly chooses K observations from the data set and uses these as the initial means. The Random Partition method first randomly assigns a cluster to each observation and then proceeds straight to step (ii). Forgy tends to spread the initial means out, while Random Partition places all of them close to the center of the data set. As the resulting clusters looked similar, and Random Partition sometimes led to a high rate of empty clusters, we settled for Forgy.

5 Experiments

We evaluate our approach by comparing translation quality, as evaluated by the IBM-BLEU (Papineni et al., 2002) metric on the NIST Chinese-to-English translation task using MT04 as development set to train the model parameters λ, and MT05, MT06 and MT08 as test sets. Even though a key advantage of our method is its applicability to resource-poor languages, we used a language pair for which linguistic resources are available in order to determine how close translation performance can get to a fully syntax-based system. Accordingly, we use Chiang's hierarchical phrase based translation model (Chiang, 2007) as a base line, and the syntax-augmented MT model (Zollmann and Venugopal, 2006) as a 'target line', a model that would not be applicable for language pairs without linguistic resources.

We perform PSCFG rule extraction and decoding using the open-source "SAMT" system (Venugopal and Zollmann, 2009), using the provided implementations for the hierarchical and syntax-augmented grammars. Apart from the language model, the lexical, phrasal, and (for the syntax grammar) label-conditioned features, and the rule, target word, and glue operation counters, Venugopal and Zollmann (2009) also provide both the hierarchical and syntax-augmented grammars with a rareness penalty $1/\operatorname{cnt}(r)$, where $\operatorname{cnt}(r)$ is the occurrence count of rule r in the training corpus, allowing the system to learn penalization of low-frequency rules, as well as three indicator features firing if the rule has one, two unswapped, and two swapped nonterminal pairs, respectively.[2] Further, to mitigate badly estimated PSCFG derivations based on low-frequency rules of the much sparser syntax model, the syntax grammar also contains the hierarchical grammar as a backbone (cf. Zollmann and Vogel (2010) for details and empirical analysis).

We implemented our rule labeling approach within the SAMT rule extraction pipeline, resulting in comparable features across all systems. For all systems, we use the bottom-up chart parsing decoder implemented in the SAMT toolkit with a reordering limit of 15 source words, and correspondingly extract rules from initial phrase pairs of maximum source length 15. All rules have at most two nonterminal symbols, which must be non-consecutive on the source side, and rules must contain at least one source-side terminal symbol. The beam settings for the hierarchical system are 600 items per 'X' (generic rule) cell, and 600 per 'S' (glue) cell.[3] Due to memory limitations, the multi-nonterminal grammars have to be pruned more harshly: We al-

[2] Penalization or reward of purely-lexical rules can be indirectly learned by trading off these features with the rule counter feature.

[3] For comparison, Chiang (2007) uses 30 and 15, respectively, and further prunes items that deviate too much in score from the best item. He extracts initial phrases of maximum length 10.

low 100 'S' items, and a total of 500 non-'S' items, but maximally 40 items per nonterminal. For all systems, we further discard non-initial rules occurring only once.[4] For the multi-nonterminal systems, we generally further discard all non-generic non-initial rules occurring less than 6 times, but we additionally give results for a 'slow' version of the Syntax target-line system and our best word class based systems, where only single-occurrences were removed.

For parameter tuning, we use the L_0-regularized minimum-error-rate training tool provided by the SAMT toolkit. Each system is trained separately to adapt the parameters to its specific properties (size of nonterminal set, grammar complexity, features sparseness, reliance on the language model, etc.).

The parallel training data comprises of 9.6M sentence pairs (206M Chinese and 228M English words). The source and target language parses for the syntax-augmented grammar, as well as the POS tags for our POS-based grammars were generated by the Stanford parser (Klein and Manning, 2003).

The results are given in Table 1. Results for the Syntax system are consistent with previous results (Zollmann et al., 2008), indicating improvements over the hierarchical system. Our approach, using target POS tags ('POS-tgt (no phr. s.)'), outperforms the hierarchical system on all three tests sets, and gains further improvements when accounting for phrase size ('POS-tgt'). The latter approach is roughly on par with the corresponding Syntax system, slightly outperforming it on average, but not consistently across all test sets. The same is true for the 'slow' version ('POS-tgt-slow').

The model based on bilingually tagged training instances ('POS-src&tgt') does not gain further improvements over the merely target-based one, but actually performs worse. We assume this is due to the huge number of nonterminals of 'POS-src&tgt' ($(2 * 33^2 + 33)(2 * 36^2 + 36) = 5.8$M in principle) compared to 'POS-tgt' ($2 * 36^2 + 36 = 2628$), increasing the sparseness of the grammar and thus leading to less reliable statistical estimates.

We also experimented with a source-tag based model ('POS-src'). In line with previous findings for syntax-augmented grammars (Zollmann and Vogel, 2010), the source-side-based grammar does not reach the translation quality of its target-based counterpart; however, the model still outperforms the hierarchical system on all test sets. Further, decoding is much faster than for 'POS-ext-tgt' and even slightly faster than 'Hierarchical'. This is due to the fact that for the source-tag based approach, a given chart cell in the CYK decoder, represented by a start and end position in the source sentence, almost uniquely determines the nonterminal any hypothesis in this cell can have: Disregarding part-of-speech tag ambiguity and phrase size accounting, that nonterminal will be the composition of the tags of the start and end source words spanned by that cell. At the same time, this demonstrates that there is hence less of a role for the nonterminal labels to resolve translational ambiguity in the source based model than in the target based model.

Performance of the word-clustering based models To empirically validate the unsupervised clustering approaches, we first need to decide how to determine the number of word classes, N. A straightforward approach is to run experiments and report test set results for many different N. While this would allow us to reliably conclude the optimal number N, a comparison of that best-performing clustering method to the hierarchical, syntax, and POS systems would be tainted by the fact that N was effectively tuned on the test sets. We therefore choose N merely based on development set performance. Unfortunately, variance in development set BLEU scores tends to be higher than test set scores, despite of SAMT MERT's inbuilt algorithms to overcome local optima, such as random restarts and zeroing-out. We have noticed that using an L_0-penalized BLEU score[5] as MERT's objective on the merged n-best lists over all iterations is more stable and will therefore use this score to determine N.

Figure 1 (left) shows the performance of the distributional clustering model ('Clust') and its morphology-sensitive extension ('Clust-morph') according to this score for varying values of $N = 1, \ldots, 36$ (the number Penn treebank POS tags, used for the 'POS' models, is 36).[6] For 'Clust', we see a comfortably wide plateau of nearly-identical scores from $N = 7, \ldots, 15$. Scores for 'Clust-morph' are lower throughout, and peak at $N = 7$.

Looking back at Table 1, we now compare the clustering models chosen by the procedure above—

[4] As shown in Zollmann et al. (2008), the impact of these rules on translation quality is negligible.

[5] Given by: BLEU $-\beta \times |\{i \in \{1, \ldots, K\} | \lambda_i \neq 0\}|$, where $\lambda_1, \ldots, \lambda_K$ are the feature weights and the constant β (which we set to 0.00001) is the regularization penalty.

[6] All these models account for phrase size.

Table 1: Translation quality in % case-insensitive IBM-BLEU (i.e., brevity penalty based on closest reference length) for Chinese-English NIST-large translation tasks, comparing baseline Hierarchical and Syntax systems with POS and clustering based approaches proposed in this work. 'TestAvg' shows the average score over the three test sets. 'Time' is the average decoding time per sentence in seconds on one CPU.

resulting in $N = 7$ for the morphology-unaware model ('Clust-7-tgt') as well as the morphology-aware model ('Clust-7-morph-tgt')—to the other systems. 'Clust-7-tgt' improves over the hierarchical base line on all three test sets and is on par with the corresponding Syntax and POS target lines. The same holds for the 'Clust-7-tgt-slow' version. We also experimented with a model variant based on seven source and seven target language clusters ('Clust-7-src&tgt') and a source-only labeled model ('Clust-7-src')—both performing worse.

Surprisingly, the morphology-sensitive clustering model ('Clust-7-morph-tgt'), while still improving over the hierarchical system, performs worse than the morphology-unaware model. An inspection of the trained word clusters showed that the model, while far superior to the morphology-unaware model in e.g. mapping all numbers to the same class, is overzealous in discovering morphological regularities (such as the '-ed' suffix) to partition functionally only slightly dissimilar words (such present-tense and past-tense verbs) into different classes. While these subtle distinctions make for good partitionings when the number of clusters is large, they appear to lead to inferior results for our task that relies on coarse-grained partitionings of the vocabulary. Note that there are no 'src' or 'src&tgt' systems for 'Clust-morph', as Chinese, being a monosyllabic writing system, does not lend itself to morphology-sensitive clustering.

K-means clustering based models To establish suitable values for the α parameters and investigate the impact of the number of clusters, we looked at the development performance over various parameter combinations for a K-means model based on source and/or target part-of-speech tags.[7] As can be seen from Figure 1 (right), our method reaches its peak performance at around 50 clusters and then levels off slightly. Encouragingly, in contrast to the hard labeling procedure, K-means actually improves when adding source-side information. The optimal ratio of weighting source and target classes is 0.5:1, corresponding to $\alpha_{\text{src}} = .5$. Incorporating context information also helps, and does best for $\alpha_{\text{cntxt}} = 0.25$, i.e. when giving contexts 1/4 the influence of the phrase boundary words.

[7] We set $\alpha_{\text{sec}} = .25$, $\alpha_{\text{ins}} = 0$, and $\alpha_{\text{phrsize}} = .5$ throughout.

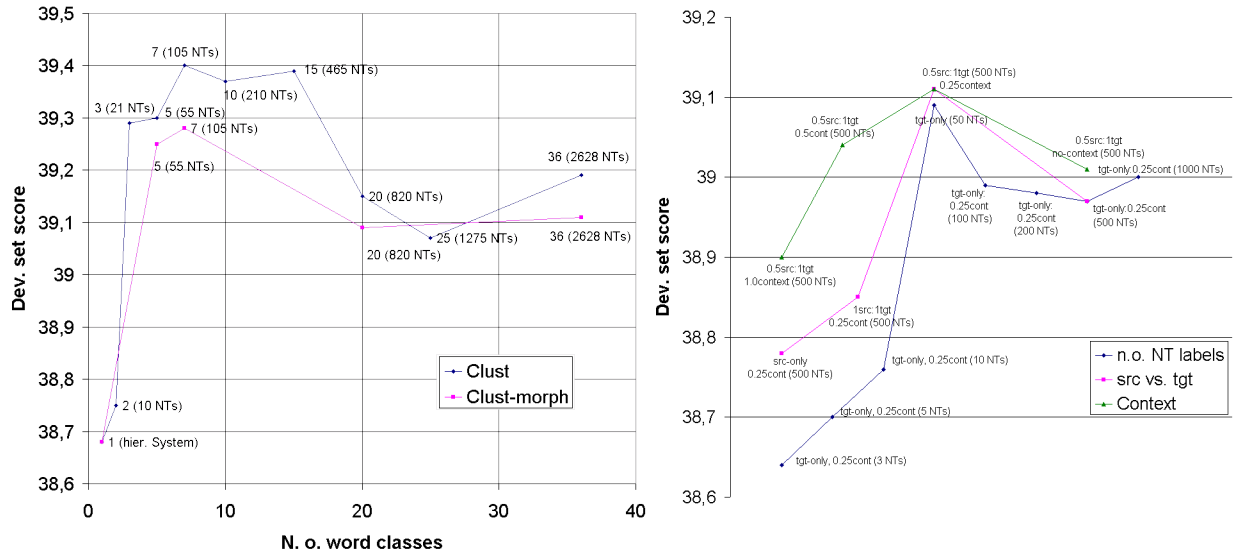

Figure 1: ***Left***: Performance of the distributional clustering model 'Clust' and its morphology-sensitive extension 'Clust-morph' according to L_0-penalized development set BLEU score for varying numbers N of word classes. For each data point N, its corresponding n.o. nonterminals of the induced grammar is stated in parentheses.
Right: Dev. set performance of K-means for various n.o. labels and values of α_{src} and α_{cntxt}.

Entry 'kmeans-POS-src&tgt' in Table 1 shows the test set results for the development-set best K-means configuration (i.e., $\alpha_{\text{src}} = .5$, $\alpha_{\text{cntxt}} = 0.25$, and using 500 clusters). While beating the hierarchical baseline, it is only minimally better than the much simpler target-based hard labeling method 'POS-tgt'. We also tried K-means variants in which the Euclidean distance metric is replaced by the city block distance L_1 and the cosine dissimilarity, respectively, with slightly worse outcomes. Configuration 'kmeans-POS-src&tgt ($\alpha_{\text{ins}} = .5$)' investigates the incorporation of non-boundary word tags inside the phrase. Unfortunately, these features appear to deteriorate performance, presumably because given a fixed number of clusters, accounting for contents inside the phrase comes at the cost of neglect of boundary words, which are more relevant to producing correctly reordered translations.

The two completely unsupervised systems 'kmeans-Clust-7-src&tgt' (based on 7-class MKCLS distributional word clustering) and 'kmeans-Clust-7..36-src&tgt' (using six different word clustering models simultaneously: all the MKCLS models from Figure 1 (left) except for the two-, three- and five-class models) have the best results, outperforming the other K-means models as well as 'Syntax' and 'POS-tgt' on average, but not on all test sets.

Lastly, we give results for 'slow' K-means configurations ('kmeans-POS-src&tgt-slow' and 'kmeans-Clust-7..36-s&t-slow'). Unfortunately (or fortunately, from a pragmatic viewpoint), the models are outperformed by the much simpler 'POS-tgt-slow' and 'Clust-7-tgt-slow' models.

6 Related work

Hassan et al. (2007) improve the statistical phrase-based MT model by injecting *supertags*, lexical information such as the POS tag of the word and its subcategorization information, into the phrase table, resulting in generalized phrases with placeholders in them. The supertags are also injected into the language model. Our approach also generates phrase labels and placeholders based on word tags (albeit in a different manner and without the use of subcategorization information), but produces PSCFG rules for use in a parsing-based decoding system.

Unsupervised *synchronous* grammar induction, apart from the contribution of Chiang (2005) discussed earlier, has been proposed by Wu (1997) for inversion transduction grammars, but as Chiang's model only uses a single generic nonterminal label. Blunsom et al. (2009) present a nonparametric PSCFG translation model that directly induces a grammar from parallel sentences without the use of or constraints from a word-alignment model, and

Cohn and Blunsom (2009) achieve the same for tree-to-string grammars, with encouraging results on small data. Our more humble approach treats the training sentences' word alignments and phrase pairs, obtained from external modules, as ground truth and employs a straight-forward generalization of Chiang's popular rule extraction approach to labeled phrase pairs, resulting in a PSCFG with multiple nonterminal labels.

Our phrase pair clustering approach is similar in spirit to the work of Lin and Wu (2009), who use K-means to cluster (monolingual) phrases and use the resulting clusters as features in discriminative classifiers for a named-entity-recognition and a query classification task. Phrases are represented in terms of their contexts, which can be more than one word long; words within the phrase are not considered. Further, each context contributes one dimension per vocabulary word (not per word class as in our approach) to the feature space, allowing for the discovery of subtle semantic similarities in the phrases, but at much greater computational expense. Another distinction is that Lin and Wu (2009) work with phrase types instead of phrase instances, obtaining a phrase type's contexts by averaging the contexts of all its phrase instances.

Nagata et al. (2006) present a reordering model for machine translation, and make use of clustered phrase pairs to cope with data sparseness in the model. They achieve the clustering by reducing phrases to their head words and then applying the MKCLS tool to these pseudo-words.

Kuhn et al. (2010) cluster the phrase pairs of an SMT phrase table based on their co-occurrence counts and edit distances in order to arrive at semantically similar phrases for the purpose of phrase table smoothing. The clustering proceeds in a bottom-up fashion, gradually merging similar phrases while alternating back and forth between the two languages.

7 Conclusion and discussion

In this work we proposed methods of labeling phrase pairs to create automatically learned PSCFG rules for machine translation. Crucially, our methods only rely on "shallow" lexical tags, either generated by POS taggers or by automatic clustering of words into classes. Evaluated on a Chinese-to-English translation task, our approach improves translation quality over a popular PSCFG baseline—the hierarchical model of Chiang (2005) —and performs on par with the model of Zollmann and Venugopal (2006), using heuristically generated labels from parse trees. Using automatically obtained word clusters instead of POS tags yields essentially the same results, thus making our methods applicable to all languages pairs with parallel corpora, whether syntactic resources are available for them or not.

We also propose a more flexible way of obtaining the phrase labels from word classes using K-means clustering. While currently the simple hard-labeling methods perform just as well, we hope that the ease of incorporating new features into the K-means labeling method will spur interesting future research.

When considering the constraints and independence relationships implied by each labeling approach, we can distinguish between approaches that label rules differently within the context of the sentence that they were extracted from, and those that do not. The Syntax system from Zollmann and Venugopal (2006) is at one end of this extreme. A given target span might be labeled differently depending on the syntactic analysis of the sentence that it is a part of. On the other extreme, the clustering based approach labels phrases based on the contained words alone.[8] The POS grammar represents an intermediate point on this spectrum, since POS tags can change based on surrounding words in the sentence; and the position of the K-means model depends on the influence of the phrase contexts on the clustering process. Context *insensitive* labeling has the advantage that there are less alternative left-hand-side labels for initial rules, producing grammars with less rules, whose weights can be more accurately estimated. This could explain the strong performance of the word-clustering based labeling approach.

Abstract

In this work, we tackle the task of machine translation (MT) without parallel training data. We frame the MT problem as a decipherment task, treating the foreign text as a cipher for English and present novel methods for training translation models from non-parallel text.

1 Introduction

Bilingual corpora are a staple of statistical machine translation (SMT) research. From these corpora, we estimate translation model parameters: word-to-word translation tables, fertilities, distortion parameters, phrase tables, syntactic transformations, etc. Starting with the classic IBM work (Brown et al., 1993), training has been viewed as a maximization problem involving hidden word alignments (a) that are assumed to underlie observed sentence pairs (e, f):

$$\arg\max_{\theta} \prod_{e,f} P_\theta(f|e) \quad (1)$$

$$= \arg\max_{\theta} \prod_{e,f} \sum_{a} P_\theta(f, a|e) \quad (2)$$

Brown et al. (1993) give various formulas that boil $P_\theta(f, a|e)$ down to the specific parameters to be estimated.

Of course, for many language pairs and domains, parallel data is not available. In this paper, we address the problem of *learning a full translation model from non-parallel data*, and we use the learned model to translate new foreign strings. As successful work develops along this line, we expect more domains and language pairs to be conquered by SMT.

How can we learn a translation model from non-parallel data? Intuitively, we try to construct translation model tables which, when applied to observed foreign text, consistently yield sensible English. This is essentially the same approach taken by cryptanalysts and epigraphers when they deal with source texts.

In our case, we observe a large number of foreign strings f, and we apply maximum likelihood training:

$$\arg\max_{\theta} \prod_{f} P_\theta(f) \quad (3)$$

Following Weaver (1955), we imagine that this corpus of foreign strings "is really written in English, but has been coded in some strange symbols," thus:

$$\arg\max_{\theta} \prod_{f} \sum_{e} P(e) \cdot P_\theta(f|e) \quad (4)$$

The variable e ranges over all possible English strings, and $P(e)$ is a language model built from large amounts of English text that is unrelated to the foreign strings. Re-writing for hidden alignments, we get:

$$\arg\max_{\theta} \prod_{f} \sum_{e} P(e) \cdot \sum_{a} P_\theta(f, a|e) \quad (5)$$

Note that this formula has the same free $P_\theta(f, a|e)$ parameters as expression (2). We seek to manipulate these parameters in order to learn the

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 12–21,
Portland, Oregon, June 19-24, 2011.

same full translation model. We note that for each f, not only is the alignment a still hidden, but now the English translation e is hidden as well.

A language model $P(e)$ is typically used in SMT decoding (Koehn, 2009), but here $P(e)$ actually plays a central role in training translation model parameters. To distinguish the two, we refer to (5) as *decipherment*, rather than decoding.

We can now draw on previous decipherment work for solving simpler substitution/transposition ciphers (Bauer, 2006; Knight et al., 2006). We must keep in mind, however, that foreign language is a much more demanding code, involving highly nondeterministic mappings and very large substitution tables.

The contributions of this paper are therefore:

- We give first results for training a full translation model from non-parallel text, and we apply the model to translate previously-unseen text. This work is thus distinguished from prior work on extracting or augmenting partial lexicons using non-parallel corpora (Rapp, 1995; Fung and McKeown, 1997; Koehn and Knight, 2000; Haghighi et al., 2008). It also contrasts with self-training (McClosky et al., 2006), which requires a parallel seed and often does not engage in iterative maximization.

- We develop novel methods to deal with large-scale vocabularies inherent in MT problems.

2 Word Substitution Decipherment

Before we tackle machine translation without parallel data, we first solve a simpler problem—word substitution decipherment. Here, we do not have to worry about hidden alignments since there is only one alignment. In a word substitution cipher, every word in the natural language (plaintext) sequence is substituted by a cipher token, according to a substitution key. The key is deterministic—there exists a 1-to-1 mapping between cipher units and the plaintext words they encode.

For example, the following English plaintext sequences:

```
I SAW THE BOY .
THE BOY RAN .
```

may be enciphered as:

```
xyzz fxyy crqq tmnz lxwz
crqq tmnz gdxx lxwz
```

according to the key:

```
THE → crqq, SAW → fxyy, RAN → gdxx,
.  → lxwz, BOY → tmnz, I → xyzz
```

The goal of word substitution decipherment is to guess the original plaintext from given cipher data without any knowledge of the substitution key.

Word substitution decipherment is a good test-bed for unsupervised statistical NLP techniques for two reasons—(1) we face large vocabularies and corpora sizes typically seen in large-scale MT problems, so our methods need to scale well, (2) similar decipherment techniques can be applied for solving NLP problems such as unsupervised part-of-speech tagging.

Probabilistic decipherment: Our decipherment method follows a noisy-channel approach. We first model the process by which the ciphertext sequence $c = c_1...c_n$ is generated. The generative story for decipherment is described here:

1. Generate an English plaintext sequence $e = e_1...e_n$, with probability $P(e)$.

2. Substitute each plaintext word e_i with a ciphertext token c_i, with probability $P_\theta(c_i|e_i)$ in order to generate the ciphertext sequence $c = c_1...c_n$.

We model $P(e)$ using a statistical word n-gram English language model (LM). During decipherment, our goal is to estimate the channel model parameters θ. Re-writing Equations 3 and 4 for word substitution decipherment, we get:

$$\arg\max_\theta \prod_c P_\theta(c) \tag{6}$$

$$= \arg\max_\theta \prod_c \sum_e P(e) \cdot \prod_{i=1}^{n} P_\theta(c_i|e_i) \tag{7}$$

Challenges: Unlike letter substitution ciphers (having only 26 plaintext letters), here we have to deal with large-scale vocabularies (10k-1M word types) and corpora sizes (100k cipher tokens). This poses some serious scalability challenges for word substitution decipherment.

We propose novel methods that can deal with these challenges effectively and solve word substitution ciphers:

1. *EM solution:* We would like to use the Expectation Maximization (EM) algorithm (Dempster et al., 1977) to estimate θ from Equation 7, but EM training is not feasible in our case. First, EM cannot scale to such large vocabulary sizes (running the forward-backward algorithm for each iteration requires $O(V^2)$ time). Secondly, we need to instantiate the entire channel and resulting derivation lattice before we can run EM, and this is too big to be stored in memory. So, we introduce a new training method (*Iterative EM*) that fixes these problems.

2. *Bayesian decipherment:* We also propose a novel decipherment approach using Bayesian inference. Typically, Bayesian inference is very slow when applied to such large-scale problems. Our method overcomes these challenges and does fast, efficient inference using (a) a novel strategy for selecting sampling choices, and (b) a parallelized sampling scheme.

In the next two sections, we describe these methods in detail.

2.1 Iterative EM

We devise a method which overcomes memory and running time efficiency issues faced by EM. Instead of instantiating the entire channel model (with all its parameters), we iteratively train the model in small steps. The training procedure is described here:

1. Identify the top K frequent word types in both the plaintext and ciphertext data. Replace all other word tokens with *Unknown*. Now, instantiate a small channel with just $(K+1)^2$ parameters and use the EM algorithm to train this model to maximize likelihood of cipher data.

2. Extend the plaintext and ciphertext vocabularies from the previous step by adding the next K most frequent word types (so the new vocabulary size becomes $2K+1$). Regenerate the plaintext and ciphertext data.

3. Instantiate a new $(2K+1) \times (2K+1)$ channel model. From the previous EM-trained channel, identify all the $e \rightarrow c$ mappings that were assigned a probability $P(c|e) > 0.5$. Fix these mappings in the new channel, i.e. set $P(c|e) = 1.0$. From the new channel, eliminate all other parameters $e \rightarrow c_j$ associated with the plaintext word type e (where $c_j \neq c$). This yields a much smaller channel with size $< (2K+1)^2$. Retrain the new channel using EM algorithm.

4. Goto Step 2 and repeat the procedure, extending the channel size iteratively in each stage.

Finally, we decode the given ciphertext c by using the Viterbi algorithm to choose the plaintext decoding e that maximizes $P(e) \cdot P_{\theta_{trained}}(c|e)^3$, stretching the channel probabilities (Knight et al., 2006).

2.2 Bayesian Decipherment

Bayesian inference methods have become popular in natural language processing (Goldwater and Griffiths, 2007; Finkel et al., 2005; Blunsom et al., 2009; Chiang et al., 2010; Snyder et al., 2010). These methods are attractive for their ability to manage uncertainty about model parameters and allow one to incorporate prior knowledge during inference.

Here, we propose a novel decipherment approach using Bayesian learning. Our method holds several other advantages over the EM approach—(1) inference using smart sampling strategies permits efficient training, allowing us to scale to large data/vocabulary sizes, (2) incremental scoring of derivations during sampling allows efficient inference even when we use higher-order n-gram LMs, (3) there are no memory bottlenecks since the full channel model and derivation lattice are never instantiated during training, and (4) prior specification allows us to learn *skewed* distributions that are useful here—word substitution ciphers exhibit 1-to-1 correspondence between plaintext and cipher types.

We use the same generative story as before for decipherment, except that we use Chinese Restaurant Process (CRP) formulations for the source and channel probabilities. We use an English word bigram LM as the base distribution (P_0) for the source model and specify a uniform P_0 distribution for the

channel.[1] We perform inference using point-wise Gibbs sampling (Geman and Geman, 1984). We define a sampling operator that samples plaintext word choices for every cipher token, one at a time. Using the exchangeability property, we efficiently score the probability of each derivation in an incremental fashion. In addition, we make further improvements to the sampling procedure which makes it faster.

Smart sample-choice selection: In the original sampling step, for each cipher token we have to sample from a list of all possible plaintext choices (10k-1M English words). There are 100k cipher tokens in our data which means we have to perform $\sim 10^9$ sampling operations to make one entire pass through the data. We have to then repeat this process for 2000 iterations. Instead, we now reduce our choices in each sampling step.

Say that our current plaintext hypothesis contains English words X, Y and Z at positions $i-1$, i and $i+1$ respectively. In order to sample at position i, we choose the top K English words Y ranked by $P(\text{X Y Z})$, which can be computed offline from a statistical word bigram LM. If this probability is 0 (i.e., X and Z never co-occurred), we randomly pick K words from the plaintext vocabulary. We set K = 100 in our experiments. This significantly reduces the sampling possibilities (10k-1M reduces to 100) at each step and allows us to scale to large plaintext vocabulary sizes without enumerating all possible choices at every cipher position.[2]

Parallelized Gibbs sampling: Secondly, we parallelize our sampling step using a Map-Reduce framework. In the past, others have proposed parallelized sampling schemes for topic modeling applications (Newman et al., 2009). In our method, we split the entire corpus into separate chunks and we run the sampling procedure on each chunk in parallel. At the end of each sampling iteration, we combine the samples corresponding to each chunk and collect the counts of all events—this forms our cache for the next sampling iteration. In practice, we observe that the parallelized sampling run converges quickly and runs much faster than the conventional point-wise sampling—for example, 3.1 hours (using 10 nodes) versus 11 hours for one of the word substitution experiments. We also notice a higher speedup when scaling to larger vocabularies.[3]

Decoding the ciphertext: After the sampling run has finished, we choose the final sample and extract a trained version of the channel model $P_\theta(c|e)$ from this sample following the technique of Chiang et al. (2010). We then use the Viterbi algorithm to choose the English plaintext e that maximizes $P(e) \cdot P_{\theta_{trained}}(c|e)^3$.

2.3 Experiments and Results

Data: For the word substitution experiments, we use two corpora:

- *Temporal expression corpus* containing short English temporal expressions such as "THE NEXT MONTH", "THE LAST THREE YEARS", etc. The cipher data contains 5000 expressions (9619 tokens, 153 word types). We also have access to a separate English corpus (which is not parallel to the ciphertext) containing 125k temporal expressions (242k word tokens, 201 word types) for LM training.
- *Transtac corpus* containing full English sentences. The data consists of 10k cipher sentences (102k tokens, 3397 word types); and a plaintext corpus of 402k English sentences (2.7M word tokens, 25761 word types) for LM training. We use all the cipher data for decipherment training but evaluate on the first 1000 cipher sentences.

The cipher data was originally generated from English text by substituting each English word with a unique cipher word. We use the plaintext corpus to

[1] For word substitution decipherment, we want to keep the language model probabilities fixed during training, and hence we set the prior on that model to be high ($\alpha = 10^4$). We use a sparse Dirichlet prior for the channel ($\beta = 0.01$). We use the output from Iterative EM decoding (using 101 x 101 channel) as initial sample and run the sampler for 2000 iterations. During sampling, we use a linear annealing schedule decreasing the temperature from $1 \rightarrow 0.08$.

[2] Since we now sample from an approximate distribution, we have to correct this with the Metropolis-Hastings algorithm. But in practice we observe that samples from our proposal distribution are accepted with probability > 0.99, so we skip this step.

[3] *Type sampling* could be applied on top of our methods to further optimize performance. But more complex problems like MT do not follow the same principles (1-to-1 key mappings) as seen in word substitution ciphers, which makes it difficult to identify type dependencies.

Method	Decipherment Accuracy (%)		
	Temporal expr.	*Transtac*	
		9k	100k
0. EM with 2-gram LM	87.8	Intractable	
1. Iterative EM with 2-gram LM	87.8	70.5	71.8
2. Bayesian with 2-gram LM	**88.6**	60.1	80.0
with 3-gram LM	-		**82.5**

Figure 1: Comparison of word substitution decipherment results using (1) Iterative EM, and (2) Bayesian method. For the *Transtac* corpus, decipherment performance is also shown for different training data sizes (9k versus 100k cipher tokens).

build an English word n-gram LM, which is used in the decipherment process.

Evaluation: We compute the accuracy of a particular decipherment as the percentage of cipher tokens that were correctly deciphered from the whole corpus. We run the two methods (Iterative EM[4] and Bayesian) and then compare them in terms of word substitution decipherment accuracies.

Results: Figure 1 compares the word substitution results from Iterative EM and Bayesian decipherment. Both methods achieve high accuracies, decoding 70-90% of the two word substitution ciphers. Overall, Bayesian decipherment (with sparse priors) performs better than Iterative EM and achieves the best results on this task. We also observe that both methods benefit from better LMs and more (cipher) training data. Figure 2 shows sample outputs from Bayesian decipherment.

3 Machine Translation as a Decipherment Task

We now turn to the problem of MT without parallel data. From a decipherment perspective, machine translation is a much more complex task than word substitution decipherment and poses several technical challenges: (1) scalability due to large corpora sizes and huge translation tables, (2) nondeterminism in translation mappings (a word can have multiple translations), (3) re-ordering of words

[4]For Iterative EM, we start with a channel of size 101x101 (K=100) and in every pass we iteratively increase the vocabulary sizes by 50, repeating the training procedure until the channel size becomes 351x351.

or phrases, (4) a single word can translate into a phrase, and (5) insertion/deletion of words.

Problem Formulation: We formulate the MT decipherment problem as—given a foreign text f (i.e., foreign word sequences $f_1 ... f_m$) and a monolingual English corpus, our goal is to decipher the foreign text and produce an English translation.

Probabilistic decipherment: Unlike parallel training, here we have to estimate the translation model $P_\theta(f|e)$ parameters using only monolingual data. During decipherment training, our objective is to estimate the model parameters θ in order to maximize the probability of the foreign corpus f. From Equation 4 we have:

$$\arg\max_\theta \prod_f \sum_e P(e) \cdot P_\theta(f|e)$$

For $P(e)$, we use a word n-gram LM trained on monolingual English data. We then estimate parameters of the translation model $P_\theta(f|e)$ during training. Next, we present two novel decipherment approaches for MT training without parallel data.

1. *EM Decipherment:* We propose a new translation model for MT decipherment which can be efficiently trained using the EM algorithm.

2. *Bayesian Decipherment:* We introduce a novel method for estimating IBM Model 3 parameters without parallel data, using Bayesian learning. Unlike EM, this method does not face any

memory issues and we use sampling to perform efficient inference during training.

3.1 EM Decipherment

For the translation model $P_\theta(f|e)$, we would like to use a well-known statistical model such as IBM Model 3 and subsequently train it using the EM algorithm. But without parallel training data, EM training for IBM Model 3 becomes intractable due to (1) scalability and efficiency issues because of large-sized fertility and distortion parameter tables, and (2) the resulting derivation lattices become too big to be stored in memory.

Instead, we propose a simpler generative story for MT without parallel data. Our model accounts for (word) substitutions, insertions, deletions and local re-ordering during the translation process but does not incorporate fertilities or global re-ordering. We describe the generative process here:

1. Generate an English string $e = e_1...e_l$, with probability $P(e)$.
2. Insert a NULL word at any position in the English string, with uniform probability.
3. For each English word token e_i (including NULLs), choose a foreign word translation f_i, with probability $P_\theta(f_i|e_i)$. The foreign word may be NULL.
4. Swap any pair of adjacent foreign words f_{i-1}, f_i, with probability $P_\theta(swap)$. We set this value to 0.1.
5. Output the foreign string $f = f_1...f_m$, skipping over NULLs.

We use the EM algorithm to estimate all the parameters θ in order to maximize likelihood of the foreign corpus. Finally, we use the Viterbi algorithm to decode the foreign sentence f and produce an English translation e that maximizes $P(e) \cdot P_{\theta_{trained}}(f|e)$.

Linguistic knowledge for decipherment: To help limit translation model size and deal with data sparsity problem, we use prior linguistic knowledge. We use identity mappings for numeric values (for example, "8" maps to "8"), and we split nouns into morpheme units prior to decipherment training (for example, "YEARS" → "YEAR" "+S").

Whole-segment Language Models: When using word n-gram models of English for decipherment, we find that some of the foreign sentences are decoded into sequences (such as "THANK YOU TALKING ABOUT ?") that are not good English. This stems from the fact that n-gram LMs have no global information about what constitutes a valid English segment. To learn this information automatically, we build a $P(e)$ model that only recognizes English whole-segments (entire sentences or expressions) observed in the monolingual training data. We then use this model (in place of word n-gram LMs) for decipherment training and decoding.

3.2 Bayesian Method

Brown et al. (1993) provide an efficient algorithm for training IBM Model 3 translation model when parallel sentence pairs are available. But we wish to perform IBM Model 3 training under non-parallel conditions, which is intractable using EM training. Instead, we take a Bayesian approach.

Following Equation 5, we represent the translation model as $P_\theta(f, a|e)$ in terms of hidden alignments a. Recall the generative story for IBM Model 3 translation which has the following formula:

$$\begin{aligned} P_\theta(f,a|e) &= \prod_{i=0}^{l} t_\theta(f_{a_j}|e_i) \cdot \prod_{i=1}^{l} n_\theta(\phi_i|e_i) \\ &\cdot \prod_{a_j \neq 0, j=1}^{m} d_\theta(a_j|i,l,m) \cdot \prod_{i=0}^{l} \phi_i! \\ &\cdot \frac{1}{\phi_0!} \cdot \binom{m-\phi_0}{\phi_0} \\ &\cdot p_{1_\theta}^{\phi_0} \cdot p_{0_\theta}^{m-2\phi_0} \end{aligned} \quad (8)$$

The alignment a is represented as a vector; $a_j = i$ implies that the foreign word f_j is produced by the English word e_i during translation.

Bayesian Formulation: Our goal is to learn the probability tables t (translation parameters) n (fertility parameters), d (distortion parameters), and p (English NULL word probabilities) without parallel data. In order to apply Bayesian inference for decipherment, we model each of these tables using a

Chinese Restaurant Process (CRP) formulation. For example, to model the translation probabilities, we use the formula:

$$t_\theta(f_j|e_i) = \frac{\alpha \cdot P_0(f_j|e_i) + C_{history}(e_i, f_j)}{\alpha + C_{history}(e_i)} \quad (9)$$

where, P_0 represents the base distribution (which is set to uniform) and $C_{history}$ represents the count of events occurring in the history (cache). Similarly, we use CRP formulations for the other probabilities (n, d and p). We use sparse Dirichlet priors for all these models (i.e., low values for α) and plug these probabilities into Equation 8 to get $P_\theta(f, a|e)$.

Sampling IBM Model 3: We use point-wise Gibbs sampling to estimate the IBM Model 3 parameters. The sampler is seeded with an initial English sample translation and a corresponding alignment for every foreign sentence. We define several sampling operators, which are applied in sequence one after the other to generate English samples for the entire foreign corpus. Some of the sampling operators are described below:

- TranslateWord(j): Sample a new English word translation for foreign word f_j, from all possibilities (including NULL).
- SwapSegment(i_1, i_2): Swap the alignment links for English words e_{i_1} and e_{i_2}.
- JoinWords(i_1, i_2): Eliminate the English word e_{i_1} and transfer its links to the word e_{i_2}.

During sampling, we apply each of these operators to generate a new derivation e, a for the foreign text f and compute its score as $P(e) \cdot P_\theta(f, a|e)$. These small-change operators are similar to the heuristic techniques used for greedy decoding by German et al. (2001). But unlike the greedy method, which can easily get stuck, our Bayesian approach guarantees that once the sampler converges we will be sampling from the true *posterior* distribution.

As with Bayesian decipherment for word substitution, we compute the probability of each new derivation incrementally, which makes sampling efficient. We also apply blocked sampling on top of point-wise sampling—we treat all occurrences of a particular foreign sentence as a single block and sample a single derivation for the entire block. We also parallelize the sampling procedure (as described in Section 2.2).[5]

Choosing the best translation: Once the sampling run finishes, we select the final sample and extract the corresponding English translations for every foreign sentence. This yields the final decipherment output.

3.3 MT Experiments and Results

Data: We work with the Spanish/English language pair and use the following corpora in our MT experiments:

- *Time corpus:* We mined English newswire text on the Web and collected 295k temporal expressions such as "LAST YEAR", "THE FOURTH QUARTER", "IN JAN 1968", etc. We first process the data and normalize numbers and names of months/weekdays—for example, "1968" is replaced with "NNNN", "JANUARY" with "[MONTH]", and so on. We then translate the English temporal phrases into Spanish using an automatic translation software (Google Translate) followed by manual annotation to correct mistakes made by the software. We create the following splits out of the resulting parallel corpus:

  TRAIN (English): 195k temporal expressions (7588 unique), 382k word tokens, 163 types.

  TEST (Spanish): 100k temporal expressions (2343 unique), 204k word tokens, 269 types.

- *OPUS movie subtitle corpus:* This is a large open source collection of parallel corpora available for multiple language pairs (Tiedemann, 2009). We downloaded the parallel Spanish/English subtitle corpus which consists of aligned Spanish/English sentences from a collection of movie subtitles. For our MT experiments, we select only Spanish/English sentences with frequency > 10 and create the following train/test splits:

[5] For Bayesian MT decipherment, we set a high prior value on the language model (10^4) and use sparse priors for the IBM 3 model parameters t, n, d, p $(0.01, 0.01, 0.01, 0.01)$. We use the output from EM decipherment as the initial sample and run the sampler for 2000 iterations, during which we apply annealing with a linear schedule ($2 \rightarrow 0.08$).

with 2-gram LM	37.6 (44.6)	67.2 (15.3)
with whole-segment LM	28.7 (48.7)	65.1 (19.3)
2b. *Decipherment* (Bayesian IBM 3)		
with 2-gram LM	34.0 (30.2)	66.6 (15.1)

Figure 3: Comparison of Spanish/English MT performance on the *Time* and *OPUS* test corpora achieved by various MT systems trained under (1) **parallel**—(a) MOSES, (b) IBM 3 without distortion, and (2) **decipherment** settings—(a) EM, (b) Bayesian. The scores reported here are normalized edit distance values with BLEU scores shown in parentheses.

> **TRAIN** (English): 19770 sentences (1128 unique), 62k word tokens, 411 word types.
>
> **TEST** (Spanish): 13181 sentences (1127 unique), 39k word tokens, 562 word types.

Both Spanish/English sides of **TRAIN** are used for parallel MT training, whereas decipherment uses only monolingual English data for training LMs.

MT Systems: We build and compare different MT systems under two training scenarios:

1. *Parallel training* using: (a) **MOSES**, a phrase translation system (Koehn et al., 2007) widely used in MT literature, and (b) a simpler version of **IBM Model 3 (without distortion parameters)** which can be trained tractably using the strategy of Knight and Al-Onaizan (1998).
2. *Decipherment without parallel data* using: (a) **EM method** (from Section 3.1), and (b) **Bayesian method** (from Section 3.2).

Evaluation: All the MT systems are run on the Spanish test data and the quality of the resulting English translations are evaluated using two different measures—(1) Normalized edit distance score (Navarro, 2001),[6] and (2) BLEU (Papineni et al., 2002), a standard MT evaluation measure.

Results: Figure 3 compares the results of various MT systems (using parallel versus decipherment training) on the two test corpora in terms of edit distance scores (a lower score indicates closer match to the gold translation). The figure also shows the corresponding BLEU scores in parentheses for comparison (higher scores indicate better MT output).

We observe that even without parallel training data, our decipherment strategies achieve MT accuracies comparable to parallel-trained systems. On the *Time* corpus, the best decipherment (Method 2a in the figure) achieves an edit distance score of 28.7 (versus 4.7 for MOSES). Better LMs yield better MT results for both parallel and decipherment training—for example, using a segment-based English LM instead of a 2-gram LM yields a 24% reduction in edit distance and a 9% improvement in BLEU score for EM decipherment.

We also investigate how the performance of different MT systems vary with the size of the training data. Figure 4 plots the BLEU scores versus training sizes for different MT systems on the *Time* corpus. Clearly, using more training data yields better performance for all systems. However, higher improvements are observed when using parallel data in comparison to decipherment training which only uses monolingual data. We also notice that the scores do not improve much when going beyond 10,000 train-

[6] When computing edit distance, we account for substitutions, insertions, deletions as well as local-swap edit operations required to convert a given English string into the (gold) reference translation.

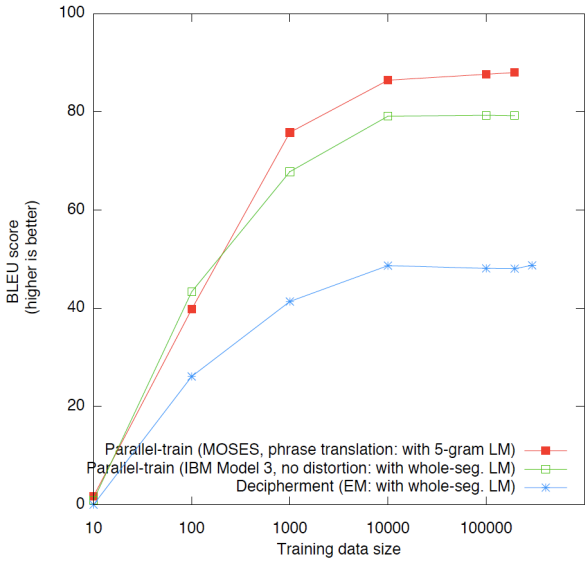

Figure 4: Comparison of *training data size* versus *MT accuracy* in terms of BLEU score under different training conditions: (1) **Parallel training**—(a) MOSES, (b) IBM Model 3 without distortion, and (2) **Decipherment** without parallel data using EM method (from Section 3.1).

ing instances for this domain.

It is interesting to quantify the value of parallel versus non-parallel data for any given MT task. In other words, "*how much non-parallel data is worth how much parallel data in order to achieve the same MT accuracy?*" Figure 4 provides a reasonable answer to this question for the Spanish/English MT task described here. We see that deciphering with 10k monolingual Spanish sentences yields the same performance as training with around 200-500 parallel English/Spanish sentence pairs. This is the first attempt at such a quantitative comparison for MT and our results are encouraging. We envision that further developments in unsupervised methods will help reduce this gap further.

4 Conclusion

Our work is the first attempt at doing MT without parallel data. We discussed several novel decipherment approaches for achieving this goal. Along the way, we developed efficient training methods that can deal with large-scale vocabularies and data sizes. For future work, it will be interesting to see if we can exploit both parallel and non-parallel data to improve on both.

Abstract

In the present paper, we propose the effective usage of function words to generate generalized translation rules for forest-based translation. Given aligned forest-string pairs, we extract composed tree-to-string translation rules that account for multiple interpretations of both aligned and unaligned target function words. In order to constrain the exhaustive attachments of function words, we limit to bind them to the nearby syntactic chunks yielded by a target dependency parser. Therefore, the proposed approach can not only capture source-tree-to-target-chunk correspondences but can also use forest structures that compactly encode an exponential number of parse trees to properly generate target function words during decoding. Extensive experiments involving large-scale English-to-Japanese translation revealed a significant improvement of 1.8 points in BLEU score, as compared with a strong forest-to-string baseline system.

1 Introduction

Rule generalization remains a key challenge for current syntax-based statistical machine translation (SMT) systems. On the one hand, there is a tendency to integrate richer syntactic information into a translation rule in order to better express the translation phenomena. Thus, flat phrases (Koehn et al., 2003), hierarchical phrases (Chiang, 2005), and syntactic tree fragments (Galley et al., 2006; Mi and Huang, 2008; Wu et al., 2010) are gradually used in SMT. On the other hand, the use of syntactic phrases continues due to the requirement for phrase coverage in most syntax-based systems. For example, Mi et al. (2008) achieved a 3.1-point improvement in BLEU score (Papineni et al., 2002) by including bilingual syntactic phrases in their forest-based system. Compared with flat phrases, syntactic rules are good at capturing global reordering, which has been reported to be essential for translating between languages with substantial structural differences, such as English and Japanese, which is a subject-object-verb language (Xu et al., 2009).

Forest-based translation frameworks, which make use of packed parse forests on the source and/or target language side(s), are an increasingly promising approach to syntax-based SMT, being both algorithmically appealing (Mi et al., 2008) and empirically successful (Mi and Huang, 2008; Liu et al., 2009). However, forest-based translation systems, and, in general, most linguistically syntax-based SMT systems (Galley et al., 2004; Galley et al., 2006; Liu et al., 2006; Zhang et al., 2007; Mi et al., 2008; Liu et al., 2009; Chiang, 2010), are built upon word aligned parallel sentences and thus share a critical dependence on word alignments. For example, even a single spurious word alignment can invalidate a large number of otherwise extractable rules, and unaligned words can result in an exponentially large set of extractable rules for the interpretation of these unaligned words (Galley et al., 2006).

What makes word alignment so fragile? In order to investigate this problem, we manually analyzed the alignments of the first 100 parallel sentences in our English-Japanese training data (to be shown in Table 2). The alignments were generated by running GIZA++ (Och and Ney, 2003) and the *grow-diag-final-and* symmetrizing strategy (Koehn et al., 2007) on the training set. Of the 1,324 word alignment pairs, there were 309 error pairs, among

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 22–31,
Portland, Oregon, June 19-24, 2011.

which there were 237 target function words, which account for 76.7% of the error pairs[1]. This indicates that the alignments of the function words are more easily to be mistaken than content words. Moreover, we found that most Japanese function words tend to align to a few English words such as 'of' and 'the', which may appear anywhere in an English sentence. Following these problematic alignments, we are forced to make use of relatively large English tree fragments to construct translation rules that tend to be ill-formed and less generalized.

This is the motivation of the present approach of re-aligning the target function words to source tree fragments, so that the influence of incorrect alignments is reduced and the function words can be generated by tree fragments on the fly. However, the current dominant research only uses 1-best trees for syntactic realignment (Galley et al., 2006; May and Knight, 2007; Wang et al., 2010), which adversely affects the rule set quality due to parsing errors. Therefore, we realign target function words to a packed forest that compactly encodes exponentially many parses. Given aligned forest-string pairs, we extract composed tree-to-string translation rules that account for multiple interpretations of both aligned and unaligned target function words. In order to constrain the exhaustive attachments of function words, we further limit the function words to bind to their surrounding chunks yielded by a dependency parser. Using the composed rules of the present study in a baseline forest-to-string translation system results in a 1.8-point improvement in the BLEU score for large-scale English-to-Japanese translation.

2 Backgrounds

2.1 Japanese function words

In the present paper, we limit our discussion on Japanese particles and auxiliary verbs (Martin, 1975). Particles are suffixes or tokens in Japanese grammar that immediately follow modified content words or sentences. There are eight types of Japanese function words, which are classified depending on what function they serve: case markers, parallel markers, sentence ending particles, interjectory particles, adverbial particles, binding particles, conjunctive particles, and phrasal particles.

Japanese grammar also uses auxiliary verbs to give further semantic or syntactic information about the preceding main or full verb. Alike English, the extra meaning provided by a Japanese auxiliary verb alters the basic meaning of the main verb so that the main verb has one or more of the following functions: passive voice, progressive aspect, perfect aspect, modality, dummy, or emphasis.

2.2 HPSG forests

Following our precious work (Wu et al., 2010), we use head-drive phrase structure grammar (HPSG) forests generated by Enju[2] (Miyao and Tsujii, 2008), which is a state-of-the-art HPSG parser for English. HPSG (Pollard and Sag, 1994; Sag et al., 2003) is a lexicalist grammar framework. In HPSG, linguistic entities such as words and phrases are represented by a data structure called a *sign*. A sign gives a factored representation of the syntactic features of a word/phrase, as well as a representation of their semantic content. Phrases and words represented by signs are collected into larger phrases by the applications of *schemata*. The semantic representation of the new phrase is calculated at the same time. As such, an HPSG parse forest can be considered to be a forest of signs. Making use of these signs instead of part-of-speech (POS)/phrasal tags in PCFG results in a fine-grained rule set integrated with deep syntactic information.

For example, an aligned HPSG forest[3]-string pair is shown in Figure 1. For simplicity, we only draw the identifiers for the signs of the nodes in the HPSG forest. Note that the identifiers that start with 'c' denote non-terminal nodes (e.g., c0, c1), and the identifiers that start with 't' denote terminal nodes (e.g., t3, t1). In a complete HPSG forest given in (Wu et al., 2010), the terminal signs include features such as the POS tag, the tense, the auxiliary, the voice of a verb, etc.. The non-terminal signs include features such as the phrasal category, the name of the schema

[1]These numbers are language/corpus-dependent and are not necessarily to be taken as a general reflection of the overall quality of the word alignments for arbitrary language pairs.

[2]http://www-tsujii.is.s.u-tokyo.ac.jp/enju/index.html

[3]The forest includes three parse trees rooted at c0, c1, and c2. In the 1-best tree, 'by' modifies the passive verb 'verified'. Yet in the 2- and 3-best tree, 'by' modifies 'this result was verified'. Furthermore, 'verified' is an adjective in the 2-best tree and a passive verb in the 3-best tree.

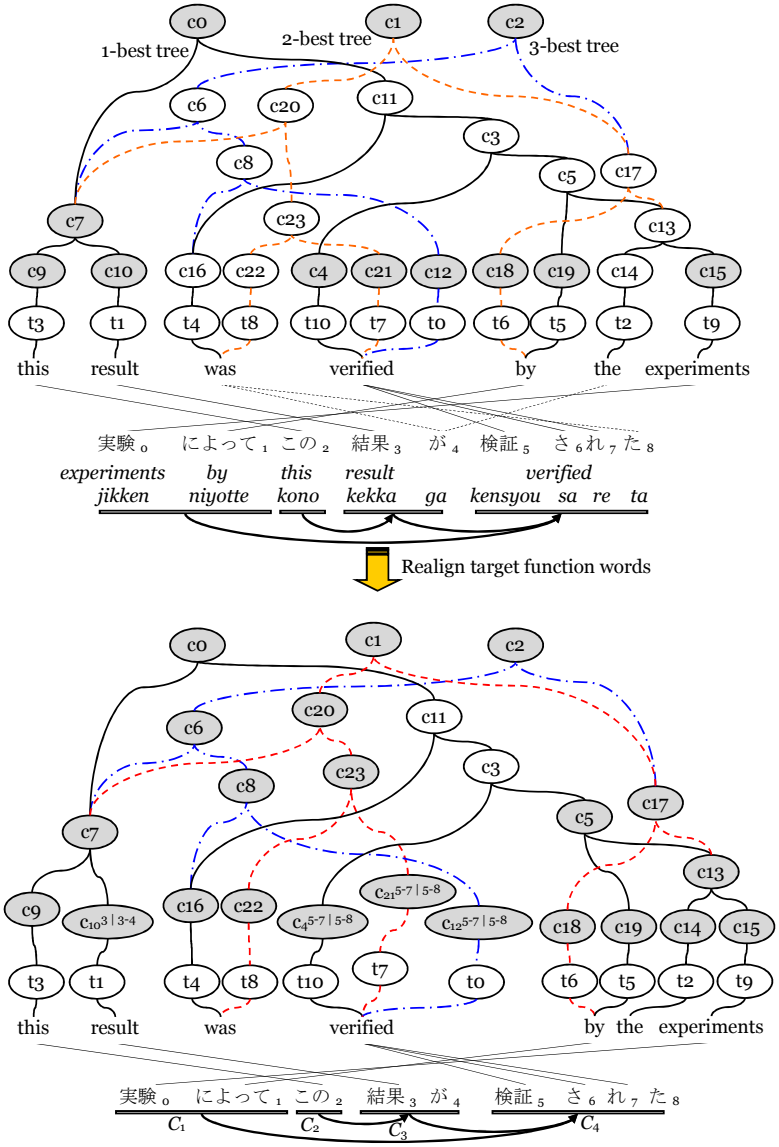

Figure 1: Illustration of an aligned HPSG forest-string pair for English-to-Japanese translation. The chunk-level dependency tree for the Japanese sentence is shown as well.

applied in the node, etc..

3 Composed Rule Extraction

In this section, we first describe an algorithm that attaches function words to a packed forest guided by target chunk information. That is, given a triple $\langle F_S, T, A \rangle$, namely an aligned ($A$) source forest ($F_S$) to target sentence ($T$) pair, we 1) tailor the alignment A by removing the alignments for target function words, 2) seek attachable nodes in the source forest F_S for each function word, and 3) construct a derivation forest by topologically traversing F_S. Then, we identify minimal and composed rules from the derivation forest and estimate the probabilities of rules and scores of derivations using the expectation-maximization (EM) (Dempster et al., 1977) algorithm.

3.1 Definitions

In the proposed algorithm, we make use of the following definitions, which are similar to those described in (Galley et al., 2004; Mi and Huang, 2008):

- $s(\cdot)$: the *span* of a (source) node v or a (target) chunk $\mathcal{C}$, which is an index set of the words that

v or $\mathcal{C}$ covers;

- $t(v)$: the *corresponding span* of v, which is an index set of aligned words on another side;
- $c(v)$: the *complement span* of v, which is the union of corresponding spans of nodes v' that share an identical parse tree with v but are neither antecedents nor descendants of v;
- $\mathcal{P}_A$: the *frontier set* of F_S, which contains nodes that are *consistent* with an alignment A (gray nodes in Figure 1), i.e., $t(v) \neq \varnothing$ and $closure(t(v)) \cap c(v) = \varnothing$.

The function $closure$ covers the gap(s) that may appear in the interval parameter. For example, $closure(t(\text{c3})) = closure(\{\text{0-1, 4-7}\}) = \{\text{0-7}\}$. Examples of the applications of these functions can be found in Table 1. Following (Galley et al., 2006), we distinguish between *minimal* and *composed* rules. The composed rules are generated by combining a sequence of minimal rules.

3.2 Free attachment of target function words

3.2.1 Motivation

We explain the motivation for the present research using an example that was extracted from our training data, as shown in Figure 1. In the alignment of this example, three lines (in dot lines) are used to align *was* and *the* with *ga* (subject particle), and *was* with *ta* (past tense auxiliary verb). Under this alignment, we are forced to extract rules with relatively large tree fragments. For example, by applying the GHKM algorithm (Galley et al., 2004), a rule rooted at c0 will take c7, t4, c4, c19, t2, and c15 as the leaves. The final tree fragment, with a height of 7, contains 13 nodes. In order to ensure that this rule is used during decoding, we must generate subtrees with a height of 7 for c0. Suppose that the input forest is binarized and that $|E|$ is the average number of hyperedges of each node, then we must generate $O(|E|^{2^6-1})$ subtrees[4] for c0 in the worst case. Thus, the existence of these rules prevents the generalization ability of the final rule set that is extracted.

In order to address this problem, we tailor the alignment by ignoring these three alignment pairs in dot lines. For example, by ignoring the ambiguous alignments on the Japanese function words, we enlarge the frontier set to include from 12 to 19 of the 24 non-terminal nodes. Consequently, the number of extractable minimal rules increases from 12 (with three reordering rules rooted at c0, c1, and c2) to 19 (with five reordering rules rooted at c0, c1, c2, c5, and c17). With more nodes included in the frontier set, we can extract more minimal and composed monotonic/reordering rules and avoid extracting the less generalized rules with extremely large tree fragments.

3.2.2 Why chunking?

In the proposed algorithm, we use a target chunk set to constrain the *attachment explosion problem* because we use a packed parse forest instead of a 1-best tree, as in the case of (Galley et al., 2006). Multiple interpretations of unaligned function words for an aligned tree-string pair result in a derivation forest. Now, we have a packed parse forest in which each tree corresponds to a derivation forest. Thus, pruning free attachments of function words is practically important in order to extract composed rules from this "(derivation) forest of (parse) forest".

In the English-to-Japanese translation test case of the present study, the target chunk set is yielded by a state-of-the-art Japanese dependency parser, Cabocha v0.53[5] (Kudo and Matsumoto, 2002). The output of Cabocha is a list of *chunks*. A chunk contains roughly one content word (usually the head) and affixed function words, such as case markers (e.g., *ga*) and verbal morphemes (e.g., *sa re ta*, which indicate past tense and passive voice). For example, the Japanese sentence in Figure 1 is separated into four chunks, and the dependencies among these chunks are identified by arrows. These arrows point out the head chunk that the current chunk modifies. Moreover, we also hope to gain a fine-grained alignment among these syntactic chunks and source tree fragments. Thereby, during decoding, we are binding the generation of function words with the generation of target chunks.

[4] For one (binarized) hyperedge e of a node, suppose there are x subtrees in the left tail node and y subtrees in the right tail node. Then the number of subtrees guided by e is $(x+1) \times (y+1)$. Thus, the recursive formula is $N_h = |E|(N_{h-1}+1)^2$, where h is the height of the hypergraph and N_h is the number of subtrees. When $h = 1$, we let $N_h = 0$.

Algorithm 1 Aligning function words to the forest

Input: HPSG forest F_S, target sentence T, word alignment $A = \{(i, j)\}$, target function word set $\{f_w\}$ appeared in T, and target chunk set $\{\mathcal{C}\}$
Output: a derivation forest DF

$A' \leftarrow A \setminus \{(i, s(f_w))\}$ ▷ $f_w \in \{f_w\}$
for each node $v \in \mathcal{P}_{A'}$ in topological order **do**
  $\mathcal{T}_v \leftarrow \varnothing$ ▷ store the corresponding spans of v
  for each function word $f_w \in \{f_w\}$ **do**
    if $f_w \in \mathcal{C}$ and $t(v) \cap (\mathcal{C}) \neq \varnothing$ and f_w are not attached to descendants of v **then**
      append $t(v) \cup \{s(f_w)\}$ to $\mathcal{T}_v$
    end if
  end for
  for each corresponding span $t(v) \in \mathcal{T}_v$ **do**
    $\mathcal{R} \leftarrow$ IDENTIFYMINRULES$(v, t(v), T)$ ▷ range over the hyperedges of v, and discount the factional count of each rule $r \in \mathcal{R}$ by $1/|\mathcal{T}_v|$
    create a node n in DF for each rule $r \in \mathcal{R}$
    create a shared parent node $\oplus$ when $|\mathcal{R}| > 1$
  end for
end for

3.2.3 The algorithm

Algorithm 1 outlines the proposed approach to constructing a derivation forest to include multiple interpretations of target function words. The derivation forest is a hypergraph as previously used in (Galley et al., 2006), to maintain the constraint that one unaligned target word be attached to some node v exactly once in one derivation tree. Starting from a triple $\langle F_S, T, A\rangle$, we first tailor the alignment A to A' by removing the alignments for target function words. Then, we traverse the nodes $v \in \mathcal{P}_{A'}$ in topological order. During the traversal, a function word f_w will be attached to v if 1) $t(v)$ overlaps with the span of the chunk to which f_w belongs, and 2) f_w has not been attached to the descendants of v.

We identify translation rules that take v as the root of their tree fragments. Each tree fragment is a *frontier tree* that takes a node in the frontier set $\mathcal{P}_{\mathcal{A}'}$ of F_S as the root node and non-lexicalized frontier nodes or lexicalized non-frontier nodes as the leaves. Also, a *minimal frontier tree* used in a minimal rule is limited to be a frontier tree such that all nodes other than the root and leaves are non-frontier nodes. We use Algorithm 1 described in (Mi and Huang, 2008) to collect minimal frontier trees rooted at v in F_S. That is, we range over each hyperedges headed at v and continue to expand downward until the current set of hyperedges forms a minimal frontier tree.

	$A \rightarrow (A')$			
node	$s(\cdot)$	$t(\cdot)$	$c(\cdot)$	consistent

Table 1: Change of node attributes after alignment modification from A to A' of the example in Figure 1. Nodes with * superscripts are consistent with A' but not consistent with A.

In the derivation forest, we use $\oplus$ nodes to manage minimal/composed rules that share the same node and the same corresponding span. Figure 2 shows some minimal rule and $\oplus$ nodes derived from the example in Figure 1.

Even though we bind function words to their nearby chunks, these function words may still be attached to relative large tree fragments, so that richer syntactic information can be used to predict the function words. For example, in Figure 2, the tree fragments rooted at node c_0^{0-8} can predict *ga* and/or *ta*. The syntactic foundation behind is that, whether to use *ga* as a subject particle or to use *wo* as an object particle depends on both the left-hand-side noun phrase (*kekka*) and the right-hand-side verb (*kensyou sa re ta*). This type of node v' (such as c_0^{0-8}) should satisfy the following two heuristic conditions:

- v' is included in the frontier set $\mathcal{P}_{\mathcal{A}'}$ of F_S, and
- $t(v')$ covers the function word, or v' is the root node of F_S if the function word is the beginning or ending word in the target sentence T.

Starting from this derivation forest with minimal

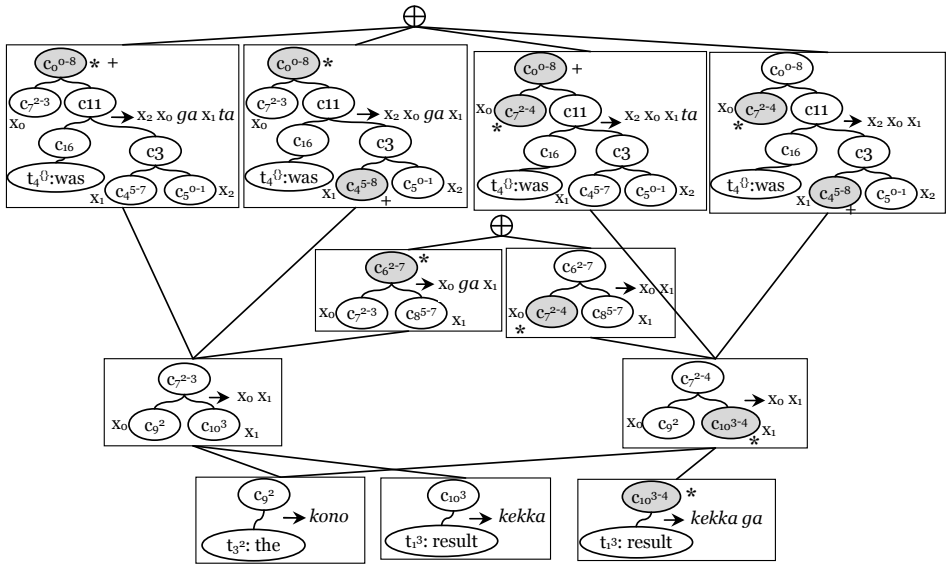

Figure 2: Illustration of a (partial) derivation forest. Gray nodes include some unaligned target function word(s). Nodes annotated by "*" include *ga*, and nodes annotated by "+" include *ta*.

rules as nodes, we can further combine two or more minimal rules to form composed rules nodes and can append these nodes to the derivation forest.

3.3 Estimating rule probabilities

We use the EM algorithm to jointly estimate 1) the translation probabilities and fractional counts of rules and 2) the scores of derivations in the derivation forests. As reported in (May and Knight, 2007), EM, as has been used in (Galley et al., 2006) to estimate rule probabilities in derivation forests, is an iterative procedure and prefers shorter derivations containing large rules over longer derivations containing small rules. In order to overcome this bias problem, we discount the fractional count of a rule by the product of the probabilities of parse hyperedges that are included in the tree fragment of the rule.

4 Experiments

4.1 Setup

We implemented the forest-to-string decoder described in (Mi et al., 2008) that makes use of forest-based translation rules (Mi and Huang, 2008) as the baseline system for translating English HPSG forests into Japanese sentences. We analyzed the performance of the proposed translation rule sets by using the same decoder.

	Train	Dev.	Test
# sentence pairs	994K	2K	2K
# En 1-best trees	987,401	1,982	1,984
# En forests	984,731	1,979	1,983
# En words	24.7M	50.3K	49.9K
# Jp words	28.2M	57.4K	57.1K
# Jp function words	8.0M	16.1K	16.1K

Table 2: Statistics of the JST corpus. Here, En = English and Jp = Japanese.

The JST Japanese-English paper abstract corpus[6] (Utiyama and Isahara, 2007), which consists of one million parallel sentences, was used for training, tuning, and testing. Table 2 shows the statistics of this corpus. Note that Japanese function words occupy more than a quarter of the Japanese words. Making use of Enju 2.3.1, we generated 987,401 1-best trees and 984,731 parse forests for the English sentences in the training set, with successful parse rates of 99.3% and 99.1%, respectively. Using the pruning criteria expressed in (Mi and Huang, 2008), we continue to prune a parse forest by setting p_e to be 8, 5, and 2, until there are no more than $e^{10} = 22,026$ trees in a forest. After pruning, there are an average of 82.3 trees in a parse forest.

BLEU (%)	26.15	27.07	27.93	**28.89**

Table 3: Statistics and translation results for four types of tree-to-string rules. With the exception of '# nodes/tree', the numbers in the table are in millions and the time is in hours. Here, fw denotes function word, and DT denotes the decoding time, and the BLEU scores were computed on the test set.

We performed GIZA++ (Och and Ney, 2003) and the *grow-diag-final-and* symmetrizing strategy (Koehn et al., 2007) on the training set to obtain alignments. The SRI Language Modeling Toolkit (Stolcke, 2002) was employed to train a five-gram Japanese LM on the training set. We evaluated the translation quality using the BLEU-4 metric (Papineni et al., 2002).

Joshua v1.3 (Li et al., 2009), which is a freely available decoder for hierarchical phrase-based SMT (Chiang, 2005), is used as an external baseline system for comparison. We extracted 4.5M translation rules from the training set for the 4K English sentences in the development and test sets. We used the default configuration of Joshua, with the exception of the maximum number of items/rules, and the value of k (of the k-best outputs) is set to be 200.

4.2 Results

Table 3 lists the statistics of the following translation rule sets:

- C3-T: a composed rule set extracted from the derivation forests of 1-best HPSG trees that were constructed using the approach described in (Galley et al., 2006). The maximum number of internal nodes is set to be three when generating a composed rule. We free attach target function words to derivation forests;

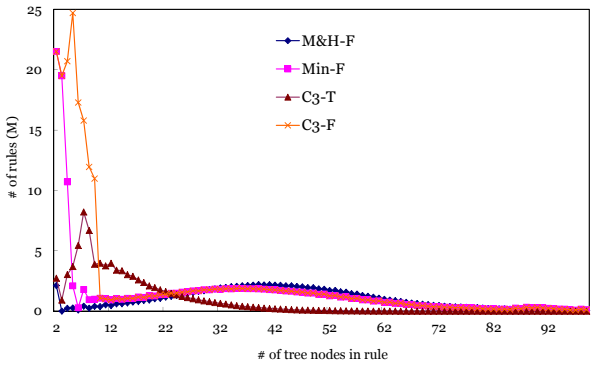

Figure 3: Distributions of the number of tree nodes in the translation rule sets. Note that the curves of Min-F and C3-F are duplicated when the number of tree nodes being larger than 9.

- M&H-F: a minimal rule set extracted from HPSG forests using the extracting algorithm of (Mi and Huang, 2008). Here, we make use of the original alignments. We use the two heuristic conditions described in Section 3.2.3 to attach unaligned words to some node(s) in the forest;

- Min-F: a minimal rule set extracted from the derivation forests of HPSG forests that were constructed using Algorithm 1 (Section 3).

- C3-F: a composed rule set extracted from the derivation forests of HPSG forests. Similar to C3-T, the maximum number of internal nodes during combination is three.

We investigate the generalization ability of these rule sets through the following aspects:

1. the number of rules, the number of reordering rules, and the distributions of the number of tree nodes (Figure 3), i.e., more rules with relatively small tree fragments are preferred;

2. the number of rules that are applicable to the development and test sets (Table 3); and

3. the final translation accuracies.

Table 3 and Figure 3 reflect that the generalization abilities of these four rule sets increase in the order of C3-T $<$ M&H-F $<$ Min-F $<$ C3-F. The advantage of using a packed forest for re-alignment is verified by comparing the statistics of the rules and

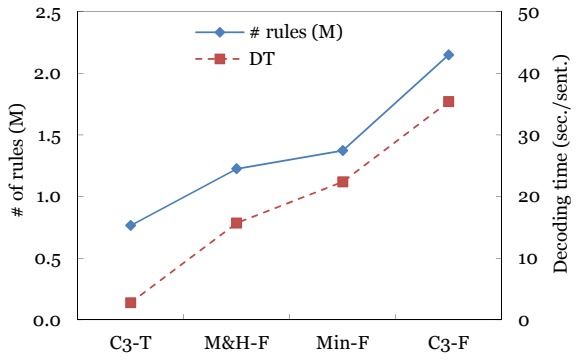

Figure 4: Comparison of decoding time and the number of rules used for translating the test set.

the final BLEU scores of C3-T with Min-F and C3-F. Using the composed rule set C3-F in our forest-based decoder, we achieved an optimal BLEU score of 28.89 (%). Taking M&H-F as the baseline translation rule set, we achieved a significant improvement ($p < 0.01$) of 1.81 points.

In terms of decoding time, even though we used Algorithm 3 described in (Huang and Chiang, 2005), which lazily generated the N-best translation candidates, the decoding time tended to be increased because more rules were available during cube-pruning. Figure 4 shows a comparison of decoding time (seconds per sentence) and the number of rules used for translating the test set. Easy to observe that, decoding time increases in a nearly linear way following the increase of the number of rules used during decoding.

Finally, compared with Joshua, which achieved a BLEU score of 24.79 (%) on the test set with a decoding speed of 8.8 seconds per sentence, our forest-based decoder achieved a significantly better ($p < 0.01$) BLEU score by using either of the four types of translation rules.

5 Related Research

Galley et al. (2006) first used derivation forests of aligned tree-string pairs to express multiple interpretations of unaligned target words. The EM algorithm was used to jointly estimate 1) the translation probabilities and fractional counts of rules and 2) the scores of derivations in the derivation forests. By dealing with the ambiguous word alignment instead of unaligned target words, syntax-based re-alignment models were proposed by (May and Knight, 2007; Wang et al., 2010) for tree-based translations.

Free attachment of the unaligned target word problem was ignored in (Mi and Huang, 2008), which was the first study on extracting tree-to-string rules from aligned forest-string pairs. This inspired the idea to re-align a packed forest and a target sentence. Specially, we observed that most incorrect or ambiguous word alignments are caused by function words rather than content words. Thus, we focus on the realignment of target function words to source tree fragments and use a dependency parser to limit the attachments of unaligned target words.

6 Conclusion

We have proposed an effective use of target function words for extracting generalized transducer rules for forest-based translation. We extend the unaligned word approach described in (Galley et al., 2006) from the 1-best tree to the packed parse forest. A simple yet effective modification is that, during rule extraction, we account for multiple interpretations of both aligned and unaligned target function words. That is, we chose to loose the ambiguous alignments for all of the target function words. The consideration behind is in order to generate target function words in a robust manner. In order to avoid generating too large a derivation forest for a packed forest, we further used chunk-level information yielded by a target dependency parser. Extensive experiments on large-scale English-to-Japanese translation resulted in a significant improvement in BLEU score of 1.8 points ($p < 0.01$), as compared with our implementation of a strong forest-to-string baseline system (Mi et al., 2008; Mi and Huang, 2008).

The present work only re-aligns target function words to source tree fragments. It will be valuable to investigate the feasibility to re-align all the target words to source tree fragments. Also, it is interesting to automatically learn a word set for re-aligning[7]. Given source parse forests and a target word set for re-aligning beforehand, we argue our approach is generic and applicable to any language pairs. Finally, we intend to extend the proposed approach to tree-to-tree translation frameworks by

[7]This idea comes from one reviewer, we express our thankfulness here.

re-aligning subtree pairs (Liu et al., 2009; Chiang, 2010) and consistency-to-dependency frameworks by re-aligning consistency-tree-to-dependency-tree pairs (Mi and Liu, 2010) in order to tackle the rule-sparseness problem.

Combining Morpheme-based Machine Translation with Post-processing Morpheme Prediction

Abstract

This paper extends the training and tuning regime for phrase-based statistical machine translation to obtain fluent translations *into* morphologically complex languages (we build an English to Finnish translation system). Our methods use unsupervised morphology induction. Unlike previous work we focus on morphologically productive phrase pairs – our decoder can combine morphemes across phrase boundaries. Morphemes in the target language may not have a corresponding morpheme or word in the source language. Therefore, we propose a novel combination of post-processing morphology prediction with morpheme-based translation. We show, using both automatic evaluation scores and linguistically motivated analyses of the output, that our methods outperform previously proposed ones and provide the best known results on the English-Finnish Europarl translation task. Our methods are mostly language independent, so they should improve translation into other target languages with complex morphology.

1 Translation and Morphology

Languages with rich morphological systems present significant hurdles for statistical machine translation (SMT), most notably data sparsity, source-target asymmetry, and problems with automatic evaluation.

In this work, we propose to address the problem of morphological complexity in an English-to-Finnish MT task within a phrase-based translation framework. We focus on unsupervised segmentation methods to derive the morphological information supplied to the MT model in order to provide coverage on very large datasets and for languages with few hand-annotated resources. In fact, in our experiments, unsupervised morphology always outperforms the use of a hand-built morphological analyzer. Rather than focusing on a few linguistically motivated aspects of Finnish morphological behaviour, we develop techniques for handling morphological complexity in general. We chose Finnish as our target language for this work, because it exemplifies many of the problems morphologically complex languages present for SMT. Among all the languages in the Europarl data-set, Finnish is the most difficult language to translate from and into, as was demonstrated in the MT Summit shared task (Koehn, 2005). Another reason is the current lack of knowledge about how to apply SMT successfully to agglutinative languages like Turkish or Finnish.

Our main contributions are: 1) the introduction of the notion of segmented translation where we explicitly allow phrase pairs that can end with a dangling morpheme, which can connect with other morphemes as part of the translation process, and 2) the use of a fully segmented translation model in combination with a post-processing morpheme prediction system, using unsupervised morphology induction. Both of these approaches beat the state of the art on the English-Finnish translation task. Morphology can express both content and function categories, and our experiments show that it is important to use morphology both within the translation model (for morphology with content) and outside it (for morphology contributing to fluency).

Automatic evaluation measures for MT, BLEU (Papineni et al., 2002), WER (Word Error Rate) and PER (Position Independent Word Error Rate) use the word as the basic unit rather than morphemes. In a word com-

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 32–42,
Portland, Oregon, June 19-24, 2011.

prised of multiple morphemes, getting even a single morpheme wrong means the entire word is wrong. In addition to standard MT evaluation measures, we perform a detailed linguistic analysis of the output. Our proposed approaches are significantly better than the state of the art, achieving the highest reported BLEU scores on the English-Finnish Europarl version 3 data-set. Our linguistic analysis shows that our models have fewer morpho-syntactic errors compared to the word-based baseline.

2 Models

2.1 Baseline Models

We set up three baseline models for comparison in this work. The first is a basic word-based model (called Baseline in the results); we trained this on the original unsegmented version of the text. Our second baseline is a factored translation model (Koehn and Hoang, 2007) (called Factored), which used as factors the word, "stem"[1] and suffix. These are derived from the same unsupervised segmentation model used in other experiments. The results (Table 3) show that a factored model was unable to match the scores of a simple word-based baseline. We hypothesize that this may be an inherently difficult representational form for a language with the degree of morphological complexity found in Finnish. Because the morphology generation must be precomputed, for languages with a high degree of morphological complexity, the combinatorial explosion makes it unmanageable to capture the full range of morphological productivity. In addition, because the morphological variants are generated on a per-word basis within a given phrase, it excludes productive morphological combination across phrase boundaries and makes it impossible for the model to take into account any long-distance dependencies between morphemes. We conclude from this result that it may be more useful for an agglutinative language to use morphology beyond the confines of the phrasal unit, and condition its generation on more than just the local target stem. In order to compare the performance of unsupervised segmentation for translation, our third baseline is a segmented translation model based on a supervised segmentation model (called Sup), using the hand-built Omorfi morphological analyzer (Pirinen and Listenmaa, 2007), which provided slightly higher BLEU scores than the word-based baseline.

[1] see Section 2.2.

2.2 Segmented Translation

For segmented translation models, it cannot be taken for granted that greater linguistic accuracy in segmentation yields improved translation (Chang et al., 2008). Rather, the goal in segmentation for translation is instead to maximize the amount of lexical content-carrying morphology, while generalizing over the information not helpful for improving the translation model. We therefore trained several different segmentation models, considering factors of granularity, coverage, and source-target symmetry.

We performed unsupervised segmentation of the target data, using Morfessor (Creutz and Lagus, 2005) and Paramor (Monson, 2008), two top systems from the Morpho Challenge 2008 (their combined output was the Morpho Challenge winner). However, translation models based upon either Paramor alone or the combined systems output could not match the word-based baseline, so we concentrated on Morfessor. Morfessor uses minimum description length criteria to train a HMM-based segmentation model. When tested against a human-annotated gold standard of linguistic morpheme segmentations for Finnish, this algorithm outperforms competing unsupervised methods, achieving an F-score of 67.0% on a 3 million sentence corpus (Creutz and Lagus, 2006). Varying the perplexity threshold in Morfessor does not segment more word types, but rather over-segments the same word types. In order to get robust, common segmentations, we trained the segmenter on the 5000 most frequent words[2]; we then used this to segment the entire data set. In order to improve coverage, we then further segmented

[2] For the factored model baseline we also used the same setting *perplexity* = 30, 5,000 most frequent words, but with all but the last suffix collapsed and called the "stem".

	Training Set	Test Set
Total	64,106,047	21,938
Morph	30,837,615	5,191
Hanging Morph	10,906,406	296

Table 1: Morpheme occurences in the phrase table and in translation.

any word type that contained a match from the most frequent suffix set, looking for the longest matching suffix character string. We call this method Unsup L-match.

After the segmentation, word-internal morpheme boundary markers were inserted into the segmented text to be used to reconstruct the surface forms in the MT output. We then trained the Moses phrase-based system (Koehn et al., 2007) on the segmented and marked text. After decoding, it was a simple matter to join together all adjacent morphemes with word-internal boundary markers to reconstruct the surface forms. Figure 1(a) gives the full model overview for all the variants of the segmented translation model (supervised/unsupervised; with and without the Unsup L-match procedure).

Table 1 shows how morphemes are being used in the MT system. Of the phrases that included segmentations ('Morph' in Table 1), roughly a third were 'productive', i.e. had a hanging morpheme (with a form such as *stem+*) that could be joined to a suffix ('Hanging Morph' in Table 1). However, in phrases used while decoding the development and test data, roughly a quarter of the phrases that generated the translated output included segmentations, but of these, only a small fraction (6%) had a hanging morpheme; and while there are many possible reasons to account for this we were unable to find a single convincing cause.

2.3 Morphology Generation

Morphology generation as a post-processing step allows major vocabulary reduction in the translation model, and allows the use of morphologically targeted features for modeling inflection. A possible disadvantage of this approach is that in this model there is no opportunity to consider the morphology in translation since it is removed prior to training the translation model. Morphology generation models can use a variety of bilingual and contextual information to capture dependencies between morphemes, often more long-distance than what is possible using n-gram language models over morphemes in the segmented model.

Similar to previous work (Minkov et al., 2007; Toutanova et al., 2008), we model morphology generation as a sequence learning problem. Unlike previous work, we use unsupervised morphology induction and use automatically generated suffix classes as tags. The first phase of our morphology prediction model is to train a MT system that produces morphologically simplified word forms in the target language. The output word forms are complex stems (a stem and some suffixes) but still missing some important suffix morphemes. In the second phase, the output of the MT decoder is then tagged with a sequence of abstract suffix tags. In particular, the output of the MT decoder is a sequence of complex stems denoted by $\boldsymbol{x}$ and the output is a sequence of suffix class tags denoted by $\boldsymbol{y}$. We use a list of parts from ($\boldsymbol{x}$,$\boldsymbol{y}$) and map to a d-dimensional feature vector $\Phi(\boldsymbol{x}, \boldsymbol{y})$, with each dimension being a real number. We infer the best sequence of tags using:

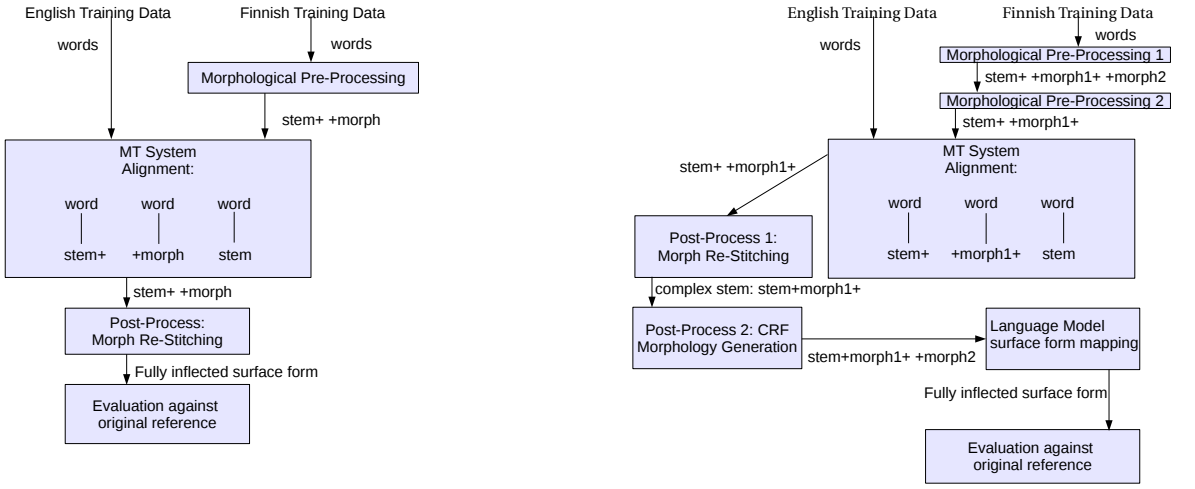
$$F(\boldsymbol{x}) = \underset{\boldsymbol{y}}{\operatorname{argmax}}\, p(\boldsymbol{y} \mid \boldsymbol{x}, \mathbf{w})$$

where $F(\boldsymbol{x})$ returns the highest scoring output $\boldsymbol{y}^*$. A *conditional random field* (CRF) (Lafferty et al., 2001) defines the conditional probability as a linear score for each candidate $\boldsymbol{y}$ and a *global* normalization term:

$$\log p(\boldsymbol{y} \mid \boldsymbol{x}, \mathbf{w}) = \Phi(\boldsymbol{x}, \boldsymbol{y}) \cdot \mathbf{w} - \log Z$$

where $Z = \sum_{\boldsymbol{y'} \in GEN(\boldsymbol{x})} \exp(\Phi(\boldsymbol{x}, \boldsymbol{y'}) \cdot \mathbf{w})$. We use stochastic gradient descent (using *crfsgd*[3]) to train the weight vector $\mathbf{w}$. So far, this is all off-the-shelf sequence learning. However, the output $\boldsymbol{y}^*$ from the CRF decoder is still only a sequence of abstract suffix tags. The third and final phase in our morphology prediction model

[3] *http://leon.bottou.org/projects/sgd*



(a) Segmented Translation Model (b) Post-Processing Model Translation & Generation

Figure 1: Training and testing pipelines for the SMT models.

is to take the abstract suffix tag sequence $\boldsymbol{y}^*$ and then map it into fully inflected word forms, and rank those outputs using a morphemic language model. The abstract suffix tags are extracted from the unsupervised morpheme learning process, and are carefully designed to enable CRF training and decoding. We call this model CRF-LM for short. Figure 1(b) shows the full pipeline and Figure 2 shows a worked example of all the steps involved.

We use the morphologically segmented training data (obtained using the segmented corpus described in Section 2.2[4]) and remove selected suffixes to create a morphologically simplified version of the training data. The MT model is trained on the morphologically simplified training data. The output from the MT system is then used as input to the CRF model. The CRF model was trained on a ∼210,000 Finnish sentences, consisting of ∼1.5 million tokens; the 2,000 sentence Europarl test set consisted of 41,434 stem tokens. The labels in the output sequence $\mathbf{y}$ were obtained by selecting the most productive 150 stems, and then collapsing certain vowels into equivalence classes corresponding to Finnish vowel harmony patterns. Thus variants -kö and -ko become vowel-generic enclitic particle -kO, and variants -ssä and -ssa become the vowel-generic inessive case marker -ssA, etc. This is the only language-specific component of our translation model. However, we expect this approach to work for other agglutinative languages as well. For fusional languages like Spanish, another mapping from suffix to abstract tags might be needed. These suffix transformations to their equivalence classes prevent morphophonemic variants of the same morpheme from competing against each other in the prediction model. This resulted in 44 possible label outputs per stem which was a reasonable sized tag-set for CRF training. The CRF was trained on monolingual features of the segmented text for suffix prediction, where t is the current token:

Word Stem	$s_{t-n}, .., s_t, .., s_{t+n} (n = 4)$
Morph Prediction	y_{t-2}, y_{t-1}, y_t

With this simple feature set, we were able to use features over longer distances, resulting in a total of 1,110,075 model features. After CRF based recovery of the suffix tag sequence, we use a bigram language model trained on a full segmented version on the training data to recover the original vowels. We used bigrams only, because the suffix vowel harmony alternation depends only upon the preceding phonemes in the word from which it was segmented.

[4]Note that unlike Section 2.2 we do not use Unsup L-match because when evaluating the CRF model on the suffix prediction task it obtained 95.61% without using Unsup L-match and 82.99% when using Unsup L-match.

map final suffix to abstract tag-set:
koske+ +va+ +A mietintö+ +A käsi+ +te+ +llä+ +ä+ +n
(train CRF model to predict the final suffix)
peeling of final suffix:
koske+ +va+ mietintö+ käsi+ +te+ +llä+ +ä+
(train SMT model on this transformation of training data)

(a) Training

decoder output:
koske+ +va+ mietintö+ käsi+ +te+ +llä+ +ä+
decoder output stitched up:
koskeva+ mietintö+ käsitellää+
CRF model prediction:
$\boldsymbol{x}$ = 'koskeva+ mietintö+ käsitellää+', $\boldsymbol{y}$ = '+A +A +n'
koskeva+ +A mietintö+ +A käsitellää+ +n
unstitch morphemes:
koske+ +va+ +A mietintö+ +A käsi+ +te+ +llä+ +ä+ +n
language model disambiguation:
koske+ +va+ +a mietintö+ +ä käsi+ +te+ +llä+ +ä+ +n
final stitching:
koskevaa mietintöä käsitellään
(the output is then compared to the reference translation)

(b) Decoding

Figure 2: Worked example of all steps in the post-processing morphology prediction model.

3 Experimental Results

For all of the models built in this paper, we used the Europarl version 3 corpus (Koehn, 2005) English-Finnish training data set, as well as the standard development and test data sets. Our parallel training data consists of ∼1 million sentences of 40 words or less, while the development and test sets were each 2,000 sentences long. In all the experiments conducted in this paper, we used the Moses[5] phrase-based translation system (Koehn et al., 2007), 2008 version. We trained all of the Moses systems herein using the standard features: language model, reordering model, translation model, and word penalty; in addition to these, the factored experiments called for additional translation and generation features for the added factors as noted above. We used in all experiments the following settings: a hypothesis stack size 100, distortion limit 6, phrase translations limit 20, and maximum phrase length 20. For the language models, we used SRILM 5-gram language models (Stolcke, 2002) for all factors. For our word-based Baseline system, we trained a word-based model using the same Moses system with identical settings. For evaluation against segmented translation systems in segmented forms before word reconstruction, we also segmented the baseline system's word-based output. All the BLEU scores reported are for lowercase evaluation.

We did an initial evaluation of the segmented output translation for each system using the notion of m-BLEU score (Luong et al., 2010) where the BLEU score is computed by comparing the segmented output with a segmented reference translation. Table 2 shows the m-BLEU scores for various systems. We also show the m-BLEU score without unigrams, since over-segmentation could lead to artificially high m-BLEU scores. In fact, if we compare the relative improvement of our m-BLEU scores for the Unsup L-match system we see a relative improvement of 39.75% over the baseline. Luong et. al. (2010) report an m-BLEU score of 55.64% but obtain a relative improvement of 0.6% over their baseline m-BLEU score. We find that when using a good segmentation model, segmentation of the morphologically complex target language improves model performance over an unsegmented baseline (the confidence scores come from bootstrap resampling). Table 3 shows the evaluation scores for all the baselines and the methods introduced in this paper using standard word-based lowercase BLEU, WER and PER. We do

Segmentation	m-BLEU	No Uni
Baseline	14.84±0.69	9.89
Sup	18.41±0.69	13.49
Unsup L-match	**20.74±0.68**	15.89

Table 2: Segmented Model Scores. Sup refers to the supervised segmentation baseline model. m-BLEU indicates that the segmented output was evaluated against a segmented version of the reference (this measure does not have the same correlation with human judgement as BLEU). No Uni indicates the segmented BLEU score without unigrams.

[5] http://www.statmt.org/moses/

Model	BLEU	WER	TER
Baseline	14.68	74.96	72.42
Factored	14.22	76.68	74.15
(Luong et.al, 2010)	14.82	-	-
Sup	14.90	74.56	71.84
Unsup L-match	**15.09***	74.46	71.78
CRF-LM	14.87	**73.71**	**71.15**

Table 3: Test Scores: lowercase BLEU, WER and TER. The $*$ indicates a statistically significant improvement of BLEU score over the Baseline model. The boldface scores are the best performing scores per evaluation measure.

better than (Luong et al., 2010), the previous best score for this task. We also show a better relative improvement over our baseline when compared to (Luong et al., 2010): a relative improvement of 4.86% for Unsup L-match compared to our baseline word-based model, compared to their 1.65% improvement over their baseline word-based model. Our best performing method used unsupervised morphology with L-match (see Section 2.2) and the improvement is significant: bootstrap resampling provides a confidence margin of ± 0.77 and a t-test (Collins et al., 2005) showed significance with $p = 0.001$.

3.1 Morphological Fluency Analysis

To see how well the models were doing at getting morphology right, we examined several patterns of morphological behavior. While we wish to explore minimally supervised morphological MT models, and use as little language specific information as possible, we do want to use linguistic analysis on the output of our system to see how well the models capture essential morphological information in the target language. So, we ran the word-based baseline system, the segmented model (Unsup L-match), and the prediction model (CRF-LM) outputs, along with the reference translation through the supervised morphological analyzer Omorfi (Pirinen and Listenmaa, 2007). Using this analysis, we looked at a variety of linguistic constructions that might reveal patterns in morphological behavior. These were: (a) explicitly marked noun forms, (b) noun-adjective case agreement, (c) subject-verb person/number agreement, (d) transitive object case marking, (e) postpositions, and (f) possession. In each of these categories, we looked for construction matches on a per-sentence level between the models' output and the reference translation.

Table 4 shows the models' performance on the constructions we examined. In all of the categories, the CRF-LM model achieves the best precision score, as we explain below, while the Unsup L-match model most frequently gets the highest recall score.

A general pattern in the most prevalent of these constructions is that the baseline tends to prefer the least marked form for noun cases (corresponding to the nominative) more than the reference or the CRF-LM model. The baseline leaves nouns in the (unmarked) nominative far more than the reference, while the CRF-LM model comes much closer, so it seems to fare better at explicitly marking forms, rather than defaulting to the more frequent unmarked form.

Finnish adjectives must be marked with the same case as their head noun, while verbs must agree in person and number with their subject. We saw that in both these categories, the CRF-LM model outperforms for precision, while the segmented model gets the best recall.

In addition, Finnish generally marks direct objects of verbs with the accusative or the partitive case; we observed more accusative/partitive-marked nouns following verbs in the CRF-LM output than in the baseline, as illustrated by example (1) in Fig. 3. While neither translation picks the same verb as in the reference for the input 'clarify,' the CRF-LM-output paraphrases it by using a grammatical construction of the transitive verb followed by a noun phrase inflected with the accusative case, correctly capturing the transitive construction. The baseline translation instead follows 'give' with a direct object in the nominative case.

To help clarify the constructions in question, we have used Google Translate[6] to provide back-

[6] *http://translate.google.com/*

Construction	Freq.	Baseline			Unsup L-match			CRF-LM		
		P	R	F	P	R	F	P	R	F

Postpositions	0.1138	43.31	29.89	35.37	39.31	**36.96**	**38.10**	**47.16**	31.52	37.79
Possession	0.0287	66.67	**70.00**	68.29	75.68	**70.00**	**72.73**	**78.79**	60.00	68.12

Table 4: Model Accuracy: Morphological Constructions. Freq. refers to the construction's average number of occurrences per sentence, also averaged over the various translations. P, R and F stand for precision, recall and F-score. The constructions are listed in descending order of their frequency in the texts. The highlighted value in each column is the most accurate with respect to the reference value.

translations of our MT output into English; to contextualize these back-translations, we have provided Google's back-translation of the reference.

The use of postpositions shows another difference between the models. Finnish postpositions require the preceding noun to be in the genitive or sometimes partitive case, which occurs correctly more frequently in the CRF-LM than the baseline. In example (2) in Fig. 3, all three translations correspond to the English text, 'with the basque nationalists.' However, the CRF-LM output is more grammatical than the baseline, because not only do the adjective and noun agree for case, but the noun 'baskien' to which the postposition 'kanssa' belongs is marked with the correct genitive case. However, this well-formedness is not rewarded by BLEU, because 'baskien' does not match the reference.

In addition, while Finnish may express possession using case marking alone, it has another construction for possession; this can disambiguate an otherwise ambiguous clause. This alternate construction uses a pronoun in the genitive case followed by a possessive-marked noun; we see that the CRF-LM model correctly marks this construction more frequently than the baseline. As example (3) in Fig. 3 shows, while neither model correctly translates 'matkan' ('trip'), the baseline's output attributes the inessive 'yhteydess' ('connection') as belonging to 'tulokset' ('results'), and misses marking the possession linking it to 'Commissioner Fischler'.

Our manual evaluation shows that the CRF-LM model is producing output translations that are more morphologically fluent than the word-based baseline and the segmented translation Unsup L-match system, even though the word choices lead to a lower BLEU score overall when compared to Unsup L-match.

4 Related Work

The work on morphology in MT can be grouped into three categories, factored models, segmented translation, and morphology generation.

Factored models (Koehn and Hoang, 2007) factor the phrase translation probabilities over additional information annotated to each word, allowing for text to be represented on multiple levels of analysis. We discussed the drawbacks of factored models for our task in Section 2.1. While (Koehn and Hoang, 2007; Yang and Kirchhoff, 2006; Avramidis and Koehn, 2008) obtain improvements using factored models for translation into English, German, Spanish, and Czech, these models may be less useful for capturing long-distance dependencies in languages with much more complex morphological systems such as Finnish. In our experiments factored models did worse than the baseline.

Segmented translation performs morphological analysis on the morphologically complex text for use in the translation model (Brown et al., 1993; Goldwater and McClosky, 2005; de Gispert and Mariño, 2008). This method unpacks complex forms into simpler, more frequently occurring components, and may also increase the symmetry of the lexically realized content be-

(1) Input: 'the charter we are to approve today both strengthens and gives visible shape to the common fundamental rights and values our community is to be based upon.'

   a. Reference: perusoikeuskirja , jonka tänään aiomme hyväksyä , sekä vahvistaa että **selventää** (selventää/VERB/ACT/INF/SG/LAT-clarify) **niitä** (ne/PRONOUN/PL/PAR-them) yhteisiä perusoikeuksia ja -arvoja , joiden on oltava yhteisömme perusta.
   Back-translation: 'Charter of Fundamental Rights, which today we are going to accept that clarify and strengthen the common fundamental rights and values, which must be community based.'
   b. Baseline: perusoikeuskirja me hyväksymme tänään molemmat vahvistaa ja **antaa** (antaa/VERB/INF/SG/LAT-give) **näkyvä** (näkyä/VERB/ACT/PCP/SG/NOM-visible) muokata yhteistä perusoikeuksia ja arvoja on perustuttava.
   Back-translation: 'Charter today, we accept both confirm and modify to make a visible and common values, fundamental rights must be based.'
   c. CRF-LM: perusoikeuskirja on hyväksytty tänään , sekä vahvistaa ja **antaa** (antaa/VERB/ACT/INF/SG/LAT-give) **konkreettisen** (konkreettinen/ADJECTIVE/SG/GEN,ACC-concrete) **muodon** (muoto/NOUN/SG/GEN,ACC-shape) yhteisiä perusoikeuksia ja perusarvoja , yhteisön on perustuttava.
   Back-translation: 'Charter has been approved today, and to strengthen and give concrete shape to the common basic rights and fundamental values, the Community must be based.'

   c. CRF-LM: kansallismielisten baskien kanssa
   nationalists-PL/GEN basques-PL/GEN with-POST

(3) Input: 'and in this respect we should value the latest measures from commissioner fischler , the results of **his trip to morocco on the 26th of last month** and the high level meetings that took place, including the one with the king himself'

   a. Reference: ja tässä mielessä osaamme myös arvostaa komission jäsen fischlerin viimeisimpiä toimia , jotka ovat **hänen** (hänen/GEN-his) **marokkoon 26 lokakuuta tekemns** (tekemänsä/POSS-his) **matkan** (matkan/GEN-tour) ja korkean tason kokousten jopa itsensä kuninkaan kanssa tulosta
   Back-translation: 'and in this sense we can also appreciate the Commissioner Fischler's latest actions, which are **his to Morocco 26 October trip** to high-level meetings and even the king himself with the result
   b. Baseline: ja tässä yhteydessä olisi arvoa viimeisin toimia komission jäsen fischler , tulokset monitulkintaisia **marokon yhteydessä** (yhteydess/INE-connection) , ja viime kuussa pidettiin korkean tason kokouksissa , mukaan luettuna kuninkaan kanssa
   Back-translation: 'and in this context would be the value of the last act, Commissioner Fischler, the results of **the Moroccan context**, ambiguous, and last month held high level meetings, including with the king'
   c. CRF-LM: ja tässä yhteydessä meidän olisi lisäarvoa viimeistä toimenpiteitä kuin komission jäsen fischler , että **hänen** (hänen/GEN-his) **kokemuksensa** (kokemuksensa/POSS-experience) **marokolle** (marokolle-Moroccan) viime kuun 26 ja korkean tason tapaamiset järjestettiin, kuninkaan kanssa
   Back-translation: 'and in this context, we should value the last measures as the Commissioner Fischler, that **his experience in Morocco** has on the 26th and high-level meetings took place, including with the king.'

Figure 3: Morphological fluency analysis (see Section 3.1).

tween source and target. In a somewhat orthogonal approach to ours, (Ma et al., 2007) use alignment of a parallel text to pack together adjacent segments in the alignment output, which are then fed back to the word aligner to bootstrap an improved alignment, which is then used in the translation model. We compared our results against (Luong et al., 2010) in Table 3 since their results are directly comparable to ours. They use a segmented phrase table and language model along with the word-based versions in the decoder and in tuning a Finnish target. Their approach requires segmented phrases to match word boundaries, eliminating morphologically productive phrases. In their work a segmented language model can score a translation, but cannot insert morphology that does not show source-side reflexes. In order to perform a similar experiment that still allowed for morphologically productive phrases, we tried training a segmented translation model, the output of which we stitched up in tuning so as to tune to a word-based reference. The goal of this experiment was to control the segmented model's tendency to overfit by rewarding it for using correct whole-word forms. However, we found

that this approach was less successful than using the segmented reference in tuning, and could not meet the baseline (13.97% BLEU best tuning score, versus 14.93% BLEU for the baseline best tuning score). Previous work in segmented translation has often used linguistically motivated morphological analysis selectively applied based on a language-specific heuristic. A typical approach is to select a highly inflecting class of words and segment them for particular morphology (de Gispert and Mariño, 2008; Ramanathan et al., 2009). Popoviç and Ney (2004) perform segmentation to reduce morphological complexity of the source to translate into an isolating target, reducing the translation error rate for the English target. For Czech-to-English, Goldwater and McClosky (2005) lemmatized the source text and inserted a set of 'pseudowords' expected to have lexical reflexes in English.

Minkov et. al. (2007) and Toutanova et. al. (2008) use a Maximum Entropy Markov Model for morphology generation. The main drawback to this approach is that it removes morphological information from the translation model (which only uses stems); this can be a problem for languages in which morphology expresses lexical content. de Gispert (2008) uses a language-specific targeted morphological classifier for Spanish verbs to avoid this issue. Talbot and Osborne (2006) use clustering to group morphological variants of words for word alignments and for smoothing phrase translation tables. Habash (2007) provides various methods to incorporate morphological variants of words in the phrase table in order to help recognize out of vocabulary words in the source language.

5 Conclusion and Future Work

We found that using a segmented translation model based on unsupervised morphology induction and a model that combined morpheme segments in the translation model with a post-processing morphology prediction model gave us better BLEU scores than a word-based baseline. Using our proposed approach we obtain better scores than the state of the art on the English-Finnish translation task (Luong et al., 2010): from 14.82% BLEU to 15.09%, while using a simpler model. We show that using morphological segmentation in the translation model can improve output translation scores. We also demonstrate that for Finnish (and possibly other agglutinative languages), phrase-based MT benefits from allowing the translation model access to morphological segmentation yielding productive morphological phrases. Taking advantage of linguistic analysis of the output we show that using a post-processing morphology generation model can improve translation fluency on a sub-word level, in a manner that is not captured by the BLEU word-based evaluation measure.

In order to help with replication of the results in this paper, we have run the various morphological analysis steps and created the necessary training, tuning and test data files needed in order to train, tune and test any phrase-based machine translation system with our data. The files can be downloaded from *natlang.cs.sfu.ca*.

In future work we hope to explore the utility of phrases with productive morpheme boundaries and explore why they are not used more pervasively in the decoder. Evaluation measures for morphologically complex languages and tuning to those measures are also important future work directions. Also, we would like to explore a non-pipelined approach to morphological pre- and post-processing so that a globally trained model could be used to remove the target side morphemes that would improve the translation model and then predict those morphemes in the target language.

Evaluating the Impact of Coder Errors on Active Learning

Abstract

Active Learning (AL) has been proposed as a technique to reduce the amount of annotated data needed in the context of supervised classification. While various simulation studies for a number of NLP tasks have shown that AL works well on goldstandard data, there is some doubt whether the approach can be successful when applied to noisy, real-world data sets. This paper presents a thorough evaluation of the impact of annotation noise on AL and shows that systematic noise resulting from biased coder decisions can seriously harm the AL process. We present a method to filter out inconsistent annotations during AL and show that this makes AL far more robust when applied to noisy data.

1 Introduction

Supervised machine learning techniques are still the mainstay for many NLP tasks. There is, however, a well-known bottleneck for these approaches: the amount of high-quality data needed for training, mostly obtained by human annotation. Active Learning (AL) has been proposed as a promising approach to reduce the amount of time and cost for human annotation. The idea behind active learning is quite intuitive: instead of annotating a large number of randomly picked instances we carefully select a small number of instances that are maximally informative for the machine learning classifier. Thus a smaller set of data points is able to boost classifier performance and to yield an accuracy comparable to the one obtained when training the same system on a larger set of randomly chosen data.

Active learning has been applied to several NLP tasks like part-of-speech tagging (Ringger et al., 2007), chunking (Ngai and Yarowsky, 2000), syntactic parsing (Osborne and Baldridge, 2004; Hwa, 2004), Named Entity Recognition (Shen et al., 2004; Laws and Schütze, 2008; Tomanek and Hahn, 2009), Word Sense Disambiguation (Chen et al., 2006; Zhu and Hovy, 2007; Chan and Ng, 2007), text classification (Tong and Koller, 1998) or statistical machine translation (Haffari and Sarkar, 2009), and has been shown to reduce the amount of annotated data needed to achieve a certain classifier performance, sometimes by as much as half. Most of these studies, however, have only simulated the active learning process using goldstandard data. This setting is crucially different from a real world scenario where we have to deal with erroneous data and inconsistent annotation decisions made by the human annotators. While simulations are an indispensable instrument to test different parameters and settings, it has been shown that when applying AL to highly ambiguous tasks like e.g. Word Sense Disambiguation (WSD) with fine-grained sense distinctions, AL can actually harm the learning process (Dang, 2004; Rehbein et al., 2010). Dang suggests that the lack of a positive effect of AL might be due to inconsistencies in the human annotations and that AL cannot efficiently be applied to tasks which need double blind annotation with adjudication to insure a sufficient data quality. Even if we take a more optimistic view and assume that AL might still be useful even for tasks featuring a high degree of ambiguity, it remains crucial to address the problem of annotation noise and its impact on AL.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 43–51,
Portland, Oregon, June 19-24, 2011.

In this paper we present a thorough evaluation of the impact of annotation noise on AL. We simulate different types of coder errors and assess the effect on the learning process. We propose a method to detect inconsistencies and remove them from the training data, and show that our method does alleviate the problem of annotation noise in our experiments.

The paper is structured as follows. Section 2 reports on recent research on the impact of annotation noise in the context of supervised classification. Section 3 describes the experimental setup of our simulation study and presents results. In Section 4 we present our filtering approach and show its impact on AL performance. Section 5 concludes and outlines future work.

2 Related Work

We are interested in the question whether or not AL can be successfully applied to a supervised classification task where we have to deal with a considerable amount of inconsistencies and noise in the data, which is the case for many NLP tasks (e.g. sentiment analysis, the detection of metaphors, WSD with fine-grained word senses, to name but a few). Therefore we do not consider part-of-speech tagging or syntactic parsing, where coders are expected to agree on most annotation decisions. Instead, we focus on work on AL for WSD, where inter-coder agreement (at least for fine-grained annotation schemes) usually is much lower than for the former tasks.

2.1 Annotation Noise

Studies on active learning for WSD have been limited to running simulations of AL using gold standard data and a coarse-grained annotation scheme (Chen et al., 2006; Chan and Ng, 2007; Zhu and Hovy, 2007). Two exceptions are Dang (2004) and Rehbein et al. (2010) who both were not able to replicate the positive findings obtained for AL for WSD on coarse-grained sense distinctions. A possible reason for this failure is the amount of annotation noise in the training data which might mislead the classifier during the AL process. Recent work on the impact of annotation noise on a machine learning task (Reidsma and Carletta, 2008) has shown that random noise can be tolerated in supervised learning, while systematic errors (as caused by biased annotators) can seriously impair the performance of a supervised classifier even if the observed accuracy of the classifier on a test set coming from the same population as the training data is as high as 0.8.

Related work (Beigman Klebanov et al., 2008; Beigman Klebanov and Beigman, 2009) has been studying annotation noise in a multi-annotator setting, distinguishing between *hard* cases (unreliably annotated due to genuine ambiguity) and *easy* cases (reliably annotated data). The authors argue that even for those data points where the annotators agreed on one particular class, a proportion of the agreement might be merely due to chance. Following this assumption, the authors propose a measure to estimate the amount of annotation noise in the data after removing all hard cases. Klebanov et al. (2008; 2009) show that, according to their model, high inter-annotator agreement (κ) achieved in an annotation scenario with two annotators is no guarantee for a high-quality data set. Their model, however, assumes that a) all instances where annotators disagreed are in fact hard cases, and b) that for the hard cases the annotators decisions are obtained by coin-flips. In our experience, some amount of disagreement can also be observed for easy cases, caused by attention slips or by a deviant interpretation of some class(es) by one of the annotators, and the annotation decision of an individual annotator cannot so much be described as random choice (coin-flip) but as systematically biased selection, causing the types of errors which have been shown to be problematic for supervised classification (Reidsma and Carletta, 2008).

Further problems arise in the AL scenario where the instances to be annotated are selected as a function of the sampling method and the annotation judgements made before. Therefore, Beigman and Klebanov Beigman (2009)'s approach of identifying unreliably annotated instances by disagreement is not applicable to AL, as most instances are annotated only once.

2.2 Annotation Noise and Active Learning

For AL to be succesful, we need to remove systematic noise in the training data. The challenge we face is that we only have a small set of seed data and no information about the reliability of the annotations

assigned by the human coders.

Zhu et al. (2008) present a method for detecting outliers in the pool of unannotated data to prevent these instances from becoming part of the training data. This approach is different from ours, where we focus on detecting annotation noise in the manually labelled training data produced by the human coders.

Schein and Ungar (2007) provide a systematic investigation of 8 different sampling methods for AL and their ability to handle different types of noise in the data. The types of noise investigated are a) prediction residual error (the portion of squared error that is independent of training set size), and b) different levels of confusion among the categories. Type a) models the presence of unknown features that influence the true probabilities of an outcome: a form of noise that will increase residual error. Type b) models categories in the data set which are intrinsically hard to disambiguate, while others are not. Therefore, type b) errors are of greater interest to us, as it is safe to assume that intrinsically ambiguous categories will lead to biased coder decisions and result in the systematic annotation noise we are interested in.

Schein and Ungar observe that none of the 8 sampling methods investigated in their experiment achieved a significant improvement over the random sampling baseline on type b) errors. In fact, entropy sampling and margin sampling even showed a decrease in performance compared to random sampling. For AL to work well on noisy data, we need to identify and remove this type of annotation noise during the AL process. To the best of our knowledge, there is no work on detecting and removing annotation noise by human coders during AL.

3 Experimental Setup

To make sure that the data we use in our simulation is as close to real-world data as possible, we do not create an artificial data set as done in (Schein and Ungar, 2007; Reidsma and Carletta, 2008) but use real data from a WSD task for the German verb *drohen* (threaten).[1] *Drohen* has three different word senses which can be disambiguated by humans with a high accuracy.[2] This point is crucial to our setup. To control the amount of noise in the data, we need to be sure that the initial data set is noise-free.

For classification we use a maximum entropy classifier.[3] Our sampling method is uncertainty sampling (Lewis and Gale, 1994), a standard sampling heuristic for AL where new instances are selected based on the confidence of the classifier for predicting the appropriate label. As a measure of uncertainty we use Shannon entropy (1) (Zhang and Chen, 2002) and the *margin* metric (2) (Schein and Ungar, 2007). The first measure considers the model's predictions q for each class c and selects those instances from the pool where the Shannon entropy is highest.

$$-\sum_{c} q_c \, log \, q_c \tag{1}$$

The second measure looks at the difference between the largest two values in the prediciton vector q, namely the two predicted classes c, c' which are, according to our model, the most likely ones for instance x_n, and selects those instances where the difference (*margin*) between the two predicted probabilities is the smallest. We discuss some details of this metric in Section 4.

$$M_n = |P(c|x_n) - P(c'|x_n)| \tag{2}$$

The features we use for WSD are a combination of context features (word token with window size 11 and POS context with window size 7), syntactic features based on the output of a dependency parser[4] and semantic features based on GermaNet hyperonyms. These settings were tuned to the target verb by (Rehbein et al., 2009). All results reported below are averages over a 5-fold cross validation.

3.1 Simulating Coder Errors in AL

Before starting the AL trials we automatically separate the 2,500 sentences into test set (498 sentences) and pool (2,002 sentences),[5] retaining the overall distribution of word senses in the data set. We insert a varying amount of noise into the pool data,

[1] The data has been provided by the SALSA project: `http://www.coli.uni-saarland.de/projects/salsa`

[2] In a pilot study where two human coders assigned labels to a set of 100 sentences, the coders agreed on 99% of the data.

[3] `http://maxent.sourceforge.net`

[4] The MaltParser: `http://maltparser.org`

[5] The split has been made automatically, the unusual numbers are caused by rounding errors.

	test	pool		
% errors	**0%**	**0%**	**ALrand 30%**	**ALbias 30%**
drohen1-salsa	126	506	524	514
Comittment	129	520	522	327
Run_risk	243	976	956	1161
Total	498	2002	2002	2002

Table 1: Distribution of word senses in pool and test sets

starting from 0% up to 30% of noise, increasing by 2% in each trial.

We assess the impact of annotation noise on active learning in three different settings. In the first setting, we randomly select new instances from the pool (random sampling; *rand*). In the second setting, we randomly replace n percent of all labels (from 0 to 30) in the pool by another label before starting the active learning trial, but retain the distribution of the different labels in the pool data (active learning with random errors); (Table 1, *ALrand*, 30%). In the third setting we simulate biased decisions by a human annotator. For a certain fraction (0 to 30%) of instances of a particular non-majority class, we substitute the majority class label for the gold label, thereby producing a more skewed distribution than in the original pool (active learning with biased errors); (Table 1, *ALbias*, 30%).

For all three settings (*rand, ALrand, ALbias*) and each degree of noise (0-30%), we run active learning simulations on the already annotated data, simulating the annotation process by selecting one new, prelabelled instance per trial from the pool and, instead of handing them over to a human coder, assigning the known (possibly erroneous) label to the instance and adding it to the training set. We use the same split (test, pool) for all three settings and all degrees of noise, with identical test sets for all trials.

3.2 Results

Figure 1 shows active learning curves for the different settings and varying degrees of noise. The horizontal black line slightly below 0.5 accuracy shows the majority baseline (the performance obtained when always assigning the majority class). For all degrees of randomly inserted noise, active learning (*ALrand*) outperforms random sampling (*rand*) at an early stage in the learning process. Looking at the biased errors (*ALbias*), we see a different picture. With a low degree of noise, the curves for *ALrand* and *ALbias* are very similar. When inserting more noise, performance for *ALbias* decreases, and with around 20% of biased errors in the pool AL performs worse than our random sampling baseline. In the random noise setting (*ALrand*), even after inserting 30% of errors AL clearly outperforms random sampling. Increasing the size of the seed data reduces the effect slightly, but does not prevent it (not shown here due to space limitations). This confirms the findings that under certain circumstances AL performs worse than random sampling (Dang, 2004; Schein and Ungar, 2007; Rehbein et al., 2010). We could also confirm Schein and Ungar (2007)'s observation that margin sampling is less sensitive to certain types of noise than entropy sampling (Table 2). Because of space limitations we only show curves for margin sampling. For entropy sampling, the general trend is the same, with results being slightly lower than for margin sampling.

4 Detecting Annotation Noise

Uncertainty sampling using the margin metric selects instances for which the difference between classifier predictions for the two most probable classes c, c' is very small (Section 3, Equation 2). When selecting unlabelled instances from the pool, this metric picks examples which represent regions of uncertainty between classes which have yet to be learned by the classifier and thus will advance the learning process. Our human coder, however, is not the perfect oracle assumed in most AL simulations, and might also assign incorrect labels. The filter approach has two objectives: a) to detect incorrect labels assigned by human coders, and b) to prevent the *hard* cases (following the terminology of Klebanov et al. (2008)) from becoming part of the training data.

We proceed as follows. Our approach makes use of the limited set of seed data S and uses heuristics to detect unreliably annotated instances. We assume that the instances in S have been validated thoroughly. We train an ensemble of classifiers E on subsets of S, and use E to decide whether or not a newly annotated instance should be added to the seed.

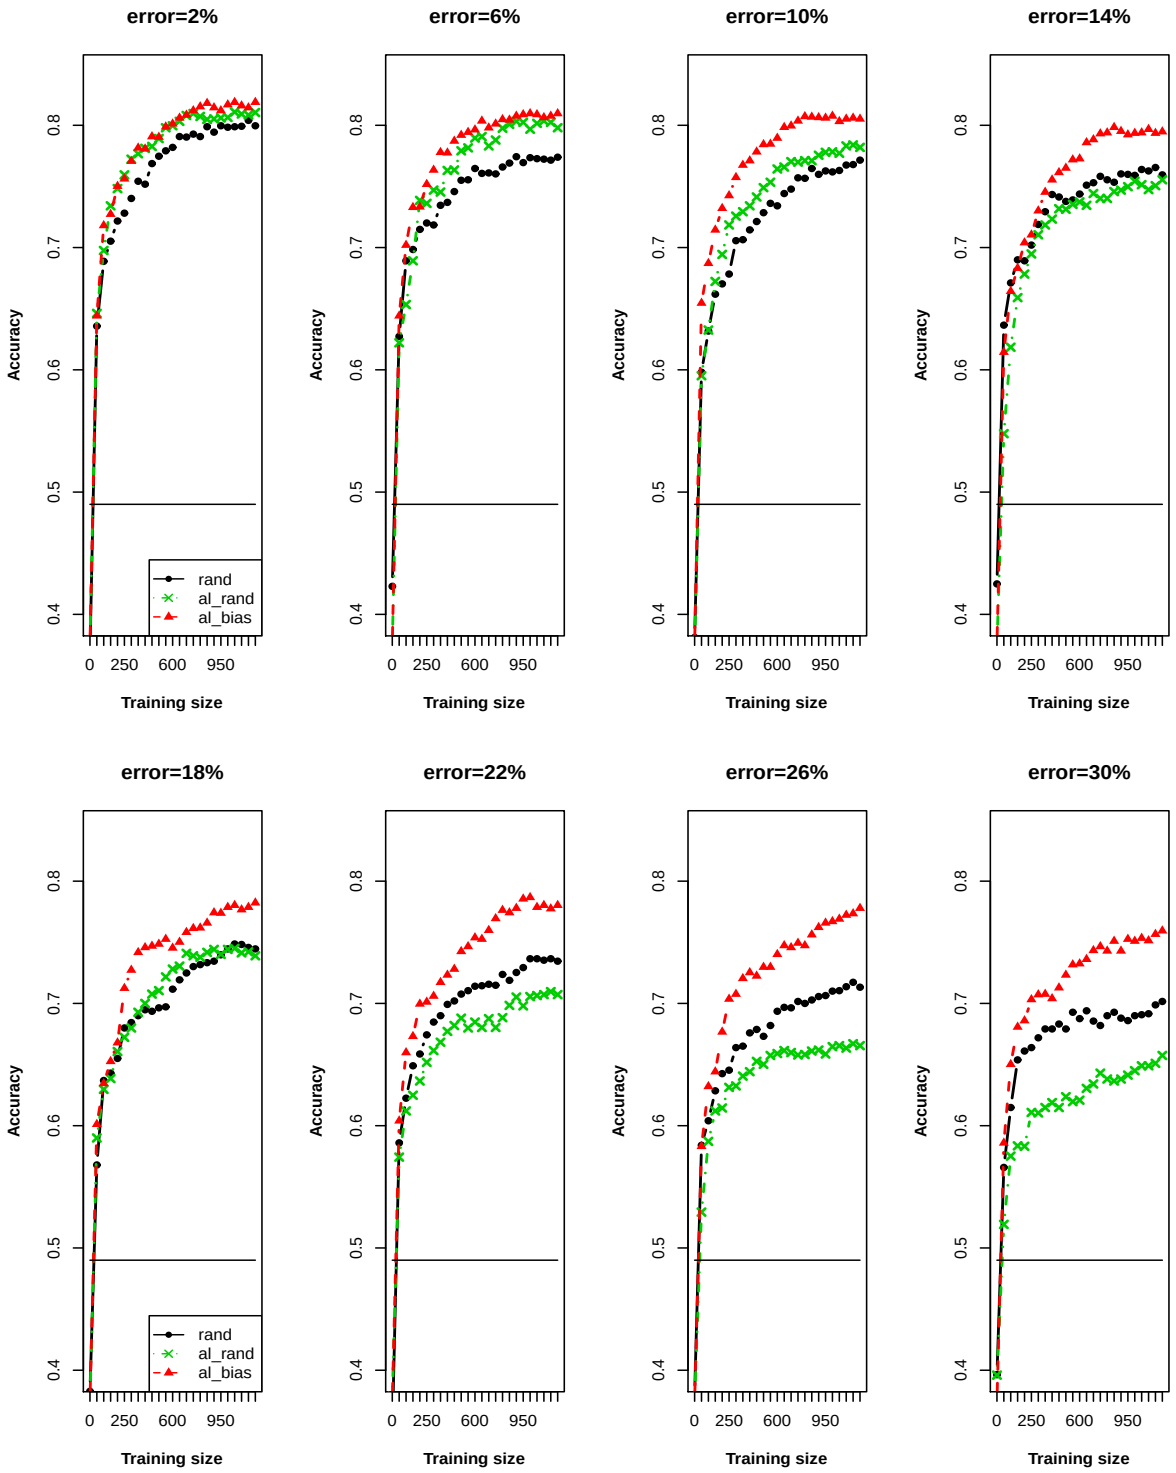

Figure 1: Active learning curves for varying degrees of noise, starting from 0% up to 30% for a training size up to 1200 instances (solid circle (black): random sampling; filled triangle point-up (red): AL with random errors; cross (green): AL with biased errors)

	filter	% error	0	4	8	12	16	20	24	28	30

Table 2: Accuracy for the different sampling methods without and with filtering after adding 500 instances to the seed data

There are a number of problems with this approach. First, there is the risk of overfitting S. Second, we know that classifier accuracy in the early phase of AL is low. Therefore, using classifier predictions at this stage to accept or reject new instances could result in poor choices that might harm the learning proceess. To avoid this and to generalise over S to prevent overfitting, we do not directly train our ensemble on instances from S. Instead, we create new feature vectors F_{gen} on the basis of the feature vectors F_{seed} in S. For each class in S, we extract all attribute-value pairs from the feature vectors for this particular class. For each class, we randomly select features (with replacement) from F_{seed} and combine them into a new feature vector F_{gen}, retaining the distribution of the different classes in the data. As a result, we obtain a more general set of feature vectors F_{gen} with characteristic features being distributed more evenly over the different feature vectors.

In the next step we train $n = 5$ maximum entropy classifiers on subsets of F_{gen}, excluding the instances last annotated by the oracle. Each subset is half the size of the current S. We use the ensemble to predict the labels for the new instances and, based on the predictions, accept or reject these, following the two heuristics below (also see Figure 2).

1. If all n ensemble classifiers agree on one label but disagree with the oracle $\Rightarrow$ reject.

2. If the sum of the margins predicted by the ensemble classifiers is below a particular theshold $t_{margin} \Rightarrow$ reject.

The threshold t_{margin} was set to 0.01, based on a qualitative data analysis.

AL with Filtering:

Input: annotated seed data S,
unannotated pool P
AL loop:

- train classifier C on S
- let C predict labels for data in P
- select new instances from P according to sampling method, hand over to oracle for annotation

Repeat: after every c new instances annotated by the oracle

- for each class in S, extract sets of features F_{seed}
- create new, more general feature vectors F_{gen} from this set (with replacement)
- train an ensemble E of n classifiers on different subsets of F_{gen}

  Filtering Heuristics:

  - **if** all n classifier in E agree on label but disagree with oracle:
    $\Rightarrow$ *remove instance from seed*
  - **if** margin is less than threshold t_{margin}:
    $\Rightarrow$ *remove instance from seed*

Until done

Figure 2: Heuristics for filtering unreliable data points (parameters used: initial seed size: 9 sentences, $c = 10$, $n = 5$, $t_{margin} = 0.01$)

In each iteration of the AL process, one new instance is selected using margin sampling. The instance is presented to the oracle who assigns a label. Then the instance is added to the seed data, thus influencing the selection of the next data point to be annotated. After 10 new instances have been added, we apply the filter technique which finally decides whether the newly added instances will remain in the seed data or will be removed.

Figure 3 shows learning curves for the filter approach. With increasing amount of errors in the pool, a clear pattern emerges. For both sampling methods (ALrand, ALbias), the filtering step clearly improves results. Even for the noisier data sets with up to 26% of errors, ALbias with filtering performs at least as well as random sampling.

4.1 Error Analysis

Next we want to find out what kind of errors the system could detect. We want to know whether the approach is able to detect the errors previously inserted into the data, and whether it manages to identify hard cases representing true ambiguities.

To answer these questions we look at one fold of the ALbias data with 10% of noise. In 1,200 AL iterations the system rejected 116 instances (Table 3). The major part of the rejections was due to the majority vote of the ensemble classifiers (first heuristic, H1) which rejects all instances where the ensemble classifiers agree with each other but disagree with the human judgement. Out of the 105 instances rejected by H1, 41 were labelled incorrectly. This means that we were able to detect around half of the incorrect labels inserted in the pool.

11 instances were filtered out by the margin threshold (H2). None of these contained an incorrect label. On first glance H2 seems to be more lenient than H1, considering the number of rejected sentences. This, however, could also be an effect of the order in which we apply the filters.

errors inserted in pool	173
err. instances selected by AL	93
instances rejected by H1+H2	116
instances rejected by H1	105
true errors rejected by H1	41
instances rejected by H2	11
true errors rejected by H2	0

Table 3: Error analysis of the instances rejected by the filtering approach

The different word senses are evenly distributed over the rejected instances (H1: Commitment 30, drohen1-salsa 38, Run_risk 36; H2: Commitment 3, drohen1-salsa 4, Run_risk 4). This shows that there is less uncertainty about the majority word sense, Run_risk.

It is hard to decide whether the correctly labelled instances rejected by the filtering method would have helped or hurt the learning process. Simply adding them to the seed data after the conclusion of AL would not answer this question, as it would merely tell us whether they improve classification accuracy further, but we still would not know what impact these instances would have had on the selection of instances during the AL process.

5 Conclusions

This paper shows that certain types of annotation noise cause serious problems for active learning approaches. We showed how biased coder decisions can result in an accuracy for AL approaches which is below the one for random sampling. In this case, it is necessary to apply an additional filtering step to remove the noisy data from the training set. We presented an approach based on a resampling of the features in the seed data and guided by an ensemble of classifiers trained on the resampled feature vectors. We showed that our approach is able to detect a certain amount of noise in the data.

Future work should focus on finding optimal parameter settings to make the filtering method more robust even for noisier data sets. We also plan to improve the filtering heuristics and to explore further ways of detecting human coder errors. Finally, we plan to test our method in a real-world annotation scenario.

Abstract

This paper proposes a new method for approximate string search, specifically candidate generation in spelling error correction, which is a task as follows. Given a misspelled word, the system finds words in a dictionary, which are most "similar" to the misspelled word. The paper proposes a probabilistic approach to the task, which is both accurate and efficient. The approach includes the use of a log linear model, a method for training the model, and an algorithm for finding the top k candidates. The log linear model is defined as a conditional probability distribution of a corrected word and a rule set for the correction conditioned on the misspelled word. The learning method employs the criterion in candidate generation as loss function. The retrieval algorithm is efficient and is guaranteed to find the optimal k candidates. Experimental results on large scale data show that the proposed approach improves upon existing methods in terms of accuracy in different settings.

1 Introduction

This paper addresses the following problem, referred to as approximate string search. Given a query string, a dictionary of strings (vocabulary), and a set of operators, the system returns the top k strings in the dictionary that can be transformed from the query string by applying several operators in the operator set. Here each operator is a rule that can replace a substring in the query string with another substring. The top k results are defined in terms of an evaluation measure employed in a specific application. The requirement is that the task must be conducted very efficiently.

Approximate string search is useful in many applications including spelling error correction, similar terminology retrieval, duplicate detection, etc. Although certain progress has been made for addressing the problem, further investigation on the task is still necessary, particularly from the viewpoint of *enhancing both accuracy and efficiency*.

Without loss of generality, in this paper we address candidate generation in spelling error correction. Candidate generation is to find the most possible corrections of a misspelled word. In such a problem, strings are words, and the operators represent insertion, deletion, and substitution of characters with or without surrounding characters, for example, "a"→"e" and "lly"→"ly". Note that candidate generation is concerned with a single word; after candidate generation, the words surrounding it in the text can be further leveraged to make the final *candidate selection*, e.g., Li et al. (2006), Golding and Roth (1999).

In spelling error correction, Brill and Moore (2000) proposed employing a generative model for candidate generation and a hierarchy of trie structures for fast candidate retrieval. Our approach is a discriminative approach and is aimed at improving Brill and Moore's method. Okazaki *et al.* (2008) proposed using a logistic regression model for approximate dictionary matching. Their method is also a discriminative approach, but it is largely different from our approach in the following points. It formalizes the problem as binary classification and

* Contribution during internship at Microsoft Research Asia.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 52–61,
Portland, Oregon, June 19-24, 2011.

assumes that there is only one rule applicable each time in candidate generation. Efficiency is also not a major concern for them, because it is for offline text mining.

There are two fundamental problems in research on approximate string search: (1) how to build a model that can archive both high accuracy and efficiency, and (2) how to develop a data structure and algorithm that can facilitate efficient retrieval of the top k candidates.

In this paper, we propose a probabilistic approach to the task. Our approach is novel and unique in the following aspects. It employs (a) a log-linear (discriminative) model for candidate generation, (b) an effective algorithm for model learning, and (c) an efficient algorithm for candidate retrieval.

The log linear model is defined as a conditional probability distribution of a corrected word and a rule set for the correction given the misspelled word. The learning method employs, in the training process, a criterion that represents the goal of making both accurate and efficient prediction (candidate generation). As a result, the model is optimally trained toward its objective. The retrieval algorithm uses special data structures and efficiently performs the top k candidates finding. It is guaranteed to find the best k candidates without enumerating all the possible ones.

We empirically evaluated the proposed method in spelling error correction of web search queries. The experimental results have verified that the accuracy of the top candidates given by our method is significantly higher than those given by the baseline methods. Our method is more accurate than the baseline methods in different settings such as large rule sets and large vocabulary sizes. The efficiency of our method is also very high in different experimental settings.

2 Related Work

Approximate string search has been studied by many researchers. Previous work mainly focused on efficiency rather than model. Usually, it is assumed that the model (similarity distance) is fixed and the goal is to efficiently find all the strings in the collection whose similarity distances are within a threshold. Most existing methods employ n-gram based algorithms (Behm et al., 2009; Li et al., 2007; Yang et al., 2008) or filtering algorithms (Mihov and Schulz, 2004; Li et al., 2008). Instead of finding all the candidates in a fixed range, methods for finding the top k candidates have also been developed. For example, the method by Vernica and Li (2009) utilized n-gram based inverted lists as index structure and a similarity function based on n-gram overlaps and word frequencies. Yang et al. (2010) presented a general framework for top k retrieval based on n-grams. In contrast, our work in this paper aims to learn a ranking function which can achieve both high accuracy and efficiency.

Spelling error correction normally consists of candidate generation and candidate final selection. The former task is an example of approximate string search. Note that candidate generation is only concerned with a single word. For single-word candidate generation, rule-based approach is commonly used. The use of edit distance is a typical example, which exploits operations of character deletion, insertion and substitution. Some methods generate candidates within a fixed range of edit distance or different ranges for strings with different lengths (Li et al., 2006; Whitelaw et al., 2009). Other methods make use of weighted edit distance to enhance the representation power of edit distance (Ristad and Yianilos, 1998; Oncina and Sebban, 2005; McCallum et al., 2005; Ahmad and Kondrak, 2005).

Conventional edit distance does not take in consideration context information. For example, people tend to misspell "c" to "s" or "k" depending on contexts, and a straightforward application of edit distance cannot deal with the problem. To address the challenge, some researchers proposed using a large number of substitution rules containing context information (at character level). For example, Brill and Moore (2000) developed a generative model including contextual substitution rules; and Toutanova and Moore (2002) further improved the model by adding pronunciation factors into the model. Schaback and Li (2007) proposed a multi-level feature-based framework for spelling error correction including a modification of Brill and Moore's model (2000). Okazaki et al. (2008) utilized substring substitution rules and incorporated the rules into a L_1-regularized logistic regression model. Okazaki et al.'s model is largely different

from the model proposed in this paper, although both of them are discriminative models. Their model is a binary classification model and it is assumed that only a single rule is applied in candidate generation.

Since users' behavior of misspelling and correction can be frequently observed in web search log data, it has been proposed to mine spelling-error and correction pairs by using search log data. The mined pairs can be directly used in spelling error correction. Methods of selecting spelling and correction pairs with maximum entropy model (Chen et al., 2007) or similarity functions (Islam and Inkpen, 2009; Jones et al., 2006) have been developed. The mined pairs *can only be used in candidate generation of high frequency typos*, however. In this paper, we work on candidate generation *at the character level*, which can be applied to spelling error correction for both high and low frequency words.

3 Model for Candidate Generation

As an example of approximate string search, we consider candidate generation in spelling correction. Suppose that there is a vocabulary $\mathcal{V}$ and a misspelled word, the objective of candidate generation is to select the best corrections from the vocabulary $\mathcal{V}$. We care about both accuracy and efficiency of the process. The problem is very challenging when the size of vocabulary is large, because there are a large number of potential candidates to be verified.

In this paper, we propose a probabilistic approach to candidate generation, which can achieve both high accuracy and efficiency, and is particularly powerful when the scale is large.

In our approach, it is assumed that a large number of misspelled words and their best corrections are given as training data. A probabilistic model is then trained by using the training data, which can assign ranking scores to candidates. The best candidates for correction of a misspelled word are thus defined as those candidates having the highest probabilistic scores with respect to the training data and the operators.

Hereafter, we will describe the probabilistic model for candidate generation, as well as training and exploitation of the model.

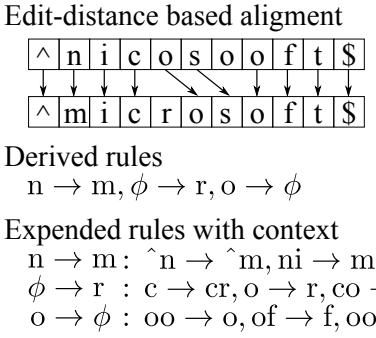

Figure 1: Example of rule extraction from word pair

3.1 Model

The operators (rules) represent insertion, deletion, and substitution of characters in a word with or without surrounding context (characters), which are similar to those defined in (Brill and Moore, 2000; Okazaki et al., 2008). An operator is formally represented a rule $\alpha \rightarrow \beta$ that replaces a substring α in a misspelled word with β, where $\alpha, \beta \in \{s | s = t, s = \hat{}t$, or $s = t\$\}$ and $t \in \Sigma^*$ is the set of all possible strings over the alphabet. Obviously, $\mathcal{V} \subset \Sigma^*$. We actually derive all the possible rules from the training data using a similar approach to (Brill and Moore, 2000) as shown in Fig. 1. First we conduct the letter alignment based on the minimum edit-distance, and then derive the rules from the alignment. Furthermore we expand the derived rules with surrounding words. Without loss of generality, we only consider using $+2, +1, 0, -1, -2$ characters as contexts in this paper.

If we can apply a set of rules to transform the misspelled word w_m to a correct word w_c in the vocabulary, then we call the rule set a "transformation" for the word pair w_m and w_c. Note that for a given word pair, it is likely that there are multiple possible transformations for it. For example, both "n"→"m" and "ni"→"mi" can transform "nicrosoft" to "microsoft".

Without loss of generality, we set the maximum number of rules applicable to a word pair to be a fixed number. As a result, the number of possible transformations for a word pair is finite, and usually limited. This is equivalent to the assumption that the number of spelling errors in a word is small.

Given word pair (w_m, w_c), let $R(w_m, w_c)$ denote one transformation (a set of rules) that can rewrite

w_m to w_c. We consider that there is a probabilistic mapping between the misspelled word w_m and correct word w_c plus transformation $R(w_m, w_c)$. We define the conditional probability distribution of w_c and $R(w_m, w_c)$ given w_m as the following log linear model:

$$P(w_c, R(w_m, w_c)|w_m) \quad (1)$$
$$= \frac{\exp\left(\sum_{r \in R(w_m, w_c)} \lambda_r\right)}{\sum_{(w'_c, R(w_m, w'_c)) \in \mathcal{Z}(w_m)} \exp\left(\sum_{o \in R(w_m, w'_c)} \lambda_o\right)}$$

where r or o denotes a rule in rule set R, λ_r or λ_o denotes a weight, and the normalization is carried over $\mathcal{Z}(w_m)$, all pairs of word w'_c in $\mathcal{V}$ and transformation $R(w_m, w'_c)$, such that w_m can be transformed to w'_c by $R(w_m, w'_c)$. The log linear model actually uses binary features indicating whether or not a rule is applied.

In general, the weights in Equ. (1) can be any real numbers. To improve efficiency in retrieval, we further assume that all the weights are non-positive, i.e., $\forall \lambda_r \leq 0$. It introduces monotonicity in rule application and implies that applying additional rules cannot lead to generation of better candidates. For example, both "office" and "officer" are correct candidates of "ofice". We view "office" a better candidate (with higher probability) than "officer", as it needs one less rule. The assumption is reasonable because the chance of making more errors should be lower than that of making less errors. Our experimental results have shown that the change in accuracy by making the assumption is negligible, but the gain in efficiency is very large.

3.2 Training of Model

Training data is given as a set of pairs $\mathcal{T} = \left\{(w_m^i, w_c^i)\right\}_{i=1}^N$, where w_m^i is a misspelled word and $w_c^i \in \mathcal{V}$ is a correction of w_m^i. The objective of training would be to maximize the conditional probability $P(w_c^i, R(w_m^i, w_c^i)|w_m^i)$ over the training data.

This is not a trivial problem, however, because the "true" transformation $R^*(w_m^i, w_c^i)$ for each word pair w_m^i and w_c^i is not given in the training data. It is often the case that there are multiple transformations applicable, and it is not realistic to assume that such information can be provided by humans or automatically derived. (It is relatively easy to automatically find the pairs w_m^i and w_c^i as explained in Section 5.1).

In this paper, we assume that the transformation that actually generates the correction among all the possible transformations is the one that can give the maximum conditional probability; the exactly same criterion is also used for fast prediction. Therefore we have the following objective function

$$\lambda^* = \arg\max_{\lambda} L(\lambda) \quad (2)$$
$$= \arg\max_{\lambda} \sum_i \max_{R(w_m^i, w_c^i)} \log P(w_c^i, R(w_m^i, w_c^i)|w_m^i)$$

where λ denotes the weight parameters and the $\max$ is taken over the set of transformations that can transform w_m^i to w_c^i.

We employ gradient ascent in the optimization in Equ. (2). At each step, we first find the best transformation for each word pair based on the current parameters $\lambda^{(t)}$

$$R^*(w_m^i, w_c^i) \quad (3)$$
$$= \arg\max_{R(w_m^i, w_c^i)} \log P_{\lambda^{(t)}}(w_c^i, R(w_m^i, w_c^i)|w_m^i)$$

Next, we calculate the gradients,

$$\frac{\partial L}{\partial \lambda_r} = \frac{\sum_i \log P_{\lambda^{(t)}}(w_c^i, R^*(w_m^i, w_c^i)|w_m^i)}{\partial \lambda_r} \quad (4)$$

In this paper, we employ the bounded L-BFGS (Behm et al., 2009) algorithm for the optimization task, which works well even when the number of weights λ is large.

3.3 Candidate Generation

In candidate generation, given a misspelled word w_m, we find the k candidates from the vocabulary, that can be transformed from w_m and have the largest probabilities assigned by the learned model.

We only need to utilize the following ranking function to rank a candidate w_c given a misspelled word w_m, by taking into account Equs. (1) and (2)

$$\text{rank}(w_c|w_m) = \max_{R(w_m, w_c)} \left(\sum_{r \in R(w_m, w_c)} \lambda_r \right) \quad (5)$$

For each possible transformation, we simply take summation of the weights of the rules used in the transformation. We then choose the sum as a ranking score, which is equivalent to ranking candidates based on their largest conditional probabilities.

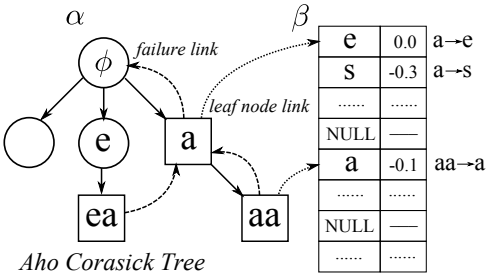

Figure 2: Rule Index based on Aho Corasick Tree.

4 Efficient Retrieval Algorithm

In this section, we introduce how to efficiently perform top k candidate generation. Our retrieval algorithm is guaranteed to find the optimal k candidates with some "pruning" techniques. We first introduce the data structures and then the retrieval algorithm.

4.1 Data Structures

We exploit two data structures for candidate generation. One is a trie for storing and matching words in the vocabulary, referred to as vocabulary trie, and the other based on what we call an Aho-Corasick tree (AC tree) (Aho and Corasick, 1975), which is used for storing and applying correction rules, referred to as rule index. The vocabulary trie is the same as that used in existing work and it will be traversed when searching the top k candidates.

Our rule index is unique because it indexes all the rules based on an AC tree. The AC tree is a trie with "failure links", on which the Aho-Corasick string matching algorithm can be executed. Aho-Corasick algorithm is a well known dictionary-matching algorithm which can quickly locate all the words in a dictionary within an input string. Time complexity of the algorithm is of linear order in length of input string plus number of matched entries.

We index all the α's in the rules on the AC tree. Each α corresponds to a leaf node, and the β's of the α are stored in an associated list in decreasing order of rule weights λ, as illustrated in Fig. 2. [1]

[1]One may further improve the index structure by using a trie rather than a ranking list to store βs associated with the same α. However the improvement would not be significant because the number of βs associated with each α is usually very small.

4.2 Algorithm

One could employ a naive algorithm that applies all the possible combinations of rules (α's) to the current word w_m, verifies whether the resulting words (candidates) are in the vocabulary, uses the function in Equ. (5) to calculate the ranking scores of the candidates, and find the top k candidates. This algorithm is clearly inefficient.

Our algorithm first employs the Aho-Corasick algorithm to locate all the applicable α's within the input word w_m, from the rule index. The corresponding β's are retrieved as well. Then all the applicable rules are identified and indexed by the applied positions of word w_m.

Our algorithm next traverses the vocabulary trie and searches the top k candidates with some pruning techniques. The algorithm starts from the root node of the vocabulary trie. At each step, it has multiple search branches. It tries to match at the next position of w_m, or apply a rule at the current position of w_m. The following two pruning criteria are employed to significantly accelerate the search process.

1) If the current sum of weights of applied rules is smaller than the smallest weight in the top k list, the search branch is pruned. This criterion is derived from the non-negative constraint on rule weights λ. It is easy to verify that the sum of weights will not become larger if one continues to search the branch because all the weights are non-positive.
2) If two search branches merge at the same node in the vocabulary trie as well as the same position on w_m, the search branches with smaller sum of weights will be pruned. It is based on the dynamic programming technique because we take $\max$ in the ranking function in Equ. 5.

It is not difficult to prove that our algorithm is guaranteed to find the best k candidates in terms of the ranking scores, because we only prune those candidates that cannot give better scores than the ones in the current top k list. Due to the limitation of space, we omit the proof of the theorem that if the weights of rules λ are non-positive and the ranking function is defined as in Equ. 5, then the top k candidates obtained with the pruning criteria are the same as the top k candidates obtained without pruning.

5 Experimental Results

We have experimentally evaluated our approach in spelling error correction of queries in web search. The problem is more challenging than usual due to the following reasons. (1) The vocabulary of queries in web search is extremely large due to the scale, diversity, and dynamics of the Internet. (2) Efficiency is critically important, because the response time of top k candidate retrieval for web search must be kept very low. Our approach for candidate generation is in fact motivated by the application.

5.1 Word Pair Mining

In web search, a search session is comprised of a sequence of queries from the same user within a time period. It is easy to observe from search session data that there are many spelling errors and their corrections occurring in the same sessions. We employed heuristics to automatically mine training pairs from search session data at a commercial search engine.

First, we segmented the query sequence from each user into sessions. If two queries were issued more than 5 minutes apart, then we put a session boundary between them. We used short sessions here because we found that search users usually correct their misspelled queries very quickly after they find the misspellings. Then the following heuristics were employed to identify pairs of misspelled words and their corrections from two consecutive queries within a session:

1) Two queries have the same number of words.
2) There is only one word difference between two queries.
3) For the two distinct words, the word in the first query is considered as misspelled and the second one as its correction.

Finally, we aggregated the identified training pairs across sessions and users and discarded the pairs with low frequencies. Table 1 shows some examples of the mined word pairs.

Misspelled	Correct	Misspelled	Correct
aacoustic	acoustic	chevorle	chevrolet
liyerature	literature	tournemen	tournament
shinngle	shingle	newpape	newspaper
finlad	finland	ccomponet	component
reteive	retrieve	olimpick	olympic

Table 1: Examples of Word Pairs

5.2 Experiments on Accuracy

Two representative methods were used as baselines: the generative model proposed by (Brill and Moore, 2000) referred to as *generative* and the logistic regression model proposed by (Okazaki et al., 2008) referred to as *logistic*. Note that Okazaki et al. (2008)'s model is not particularly for spelling error correction, but it can be employed in the task. When using their method for ranking, we used outputs of the logistic regression model as rank scores.

We compared our method with the two baselines in terms of top k accuracy, which is ratio of the true corrections among the top k candidates generated by a method. All the methods shared the same settings: 973,902 words in the vocabulary, 10,597 rules for correction, and up to two rules used in one transformation. We made use of 100,000 word pairs mined from query sessions for training, and 10,000 word pairs for testing.

The experimental results are shown in Fig. 3. We can see that our method always performs the best when compared with the baselines and the improvements are statistically significant ($p < 0.01$). The *logistic* method works better than *generative*, when k is small, but its performance becomes saturated, when k is large. Usually a discriminative model works better than a generative model, and that seems to be what happens with small k's. However, *logistic* cannot work so well for large k's, because it only allows the use of one rule each time. We observe that there are many word pairs in the data that need to be transformed with multiple rules.

Next, we conducted experiments to investigate how the top k accuracy changes with different sizes of vocabularies, maximum numbers of applicable rules and sizes of rule set for the three methods. The experimental results are shown in Fig. 4, Fig. 5 and Fig. 6.

For the experiment in Fig. 4, we enlarged the vocabulary size from 973,902 (smallVocab) to 2,206,948 (largeVocab) and kept the other settings the same as in the previous experiment. Because more candidates can be generated with a larger vocabulary, the performances of all the methods de-

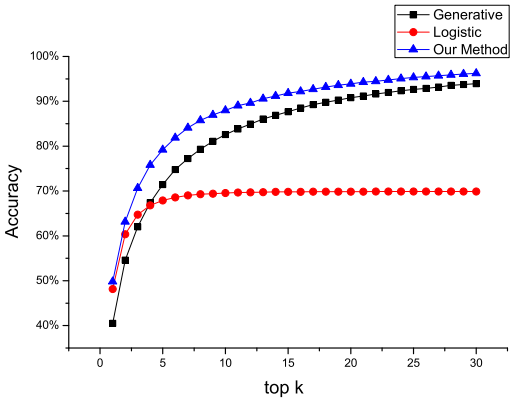

Figure 3: Accuracy Comparison between Our Method and Baselines

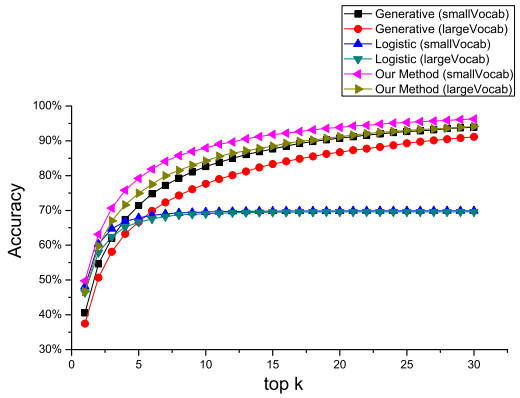

Figure 4: Accuracy Comparisons between Baselines and Our Method with Different Vocabulary Sizes

cline. However, the drop of accuracy by our method is much smaller than that by *generative*, which means our method is more powerful when the vocabulary is large, e.g., for web search. For the experiment in Fig. 5, we changed the maximum number of rules that can be applied to a transformation from 2 to 3. Because *logistic* can only use one rule at a time, it is not included in this experiment. When there are more applicable rules, more candidates can be generated and thus ranking of them becomes more challenging. The accuracies of both methods drop, but our method is constantly better than *generative*. Moreover, the decrease in accuracy by our method is clearly less than that by *generative*. For the experiment in Fig. 6, we enlarged the number of rules from 10,497 (smallRuleNum) to 24,054 (largeRuleNum). The performance of our method and those of the two baselines did not change so much, and our method still visibly outperform the baselines when more rules are exploited.

5.3 Experiments on Efficiency

We have also experimentally evaluated the efficiency of our approach. Because most existing work uses a predefined ranking function, it is not fair to make a comparison with them. Moreover, Okazaki et al.' method does not consider efficiency, and Brill and Moore's method is based a complicated retrieve algorithm which is very hard to implement. Instead of making comparison with the existing methods in terms of efficiency, we evaluated the efficiency of our method by looking at how efficient it becomes with its data structure and pruning technique.

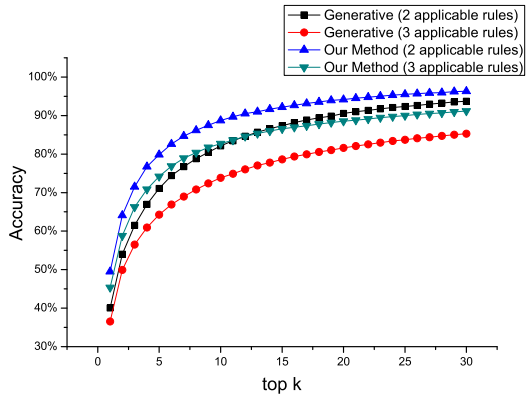

Figure 5: Accuracy Comparison between Generative and Our Method with Different Maximum Numbers of Applicable Rules

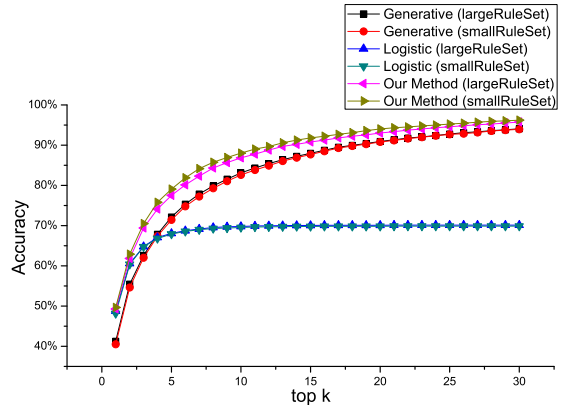

Figure 6: Accuracy Comparison between Baselines and Our Method with Different Numbers of Rules

First, we tested the efficiency of using Aho-Corasick algorithm (the rule index). Because the

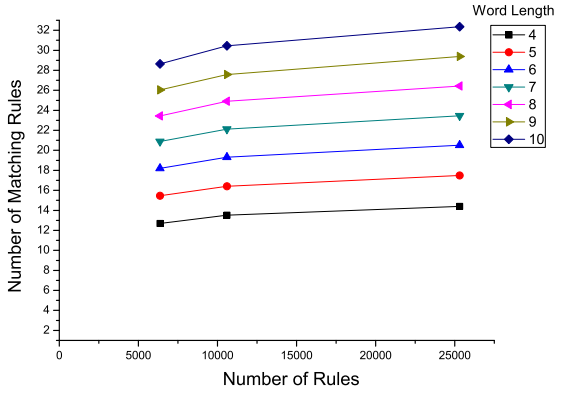

Figure 7: Number of Matching Rules v.s. Number of Rules

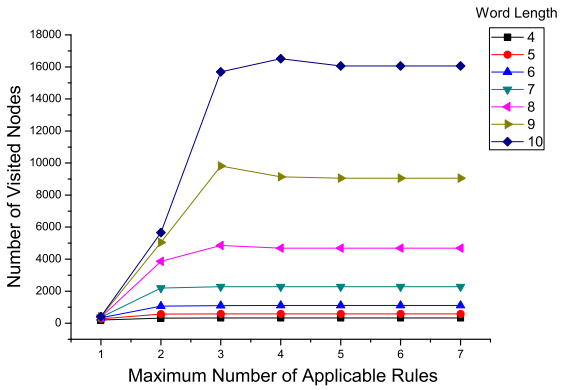

Figure 8: Efficiency Evaluation with Different Maximum Numbers of Applicable Rules

time complexity of Aho-Corasick algorithm is determined by the lengths of query strings and the number of matches, we examined how the number of matches on query strings with different lengths changes when the number of rules increases. The experimental results are shown in Fig. 7. We can see that the number of matches is not largely affected by the number of rules in the rule index. It implies that the time for searching applicable rules is close to a constant and does not change much with different numbers of rules.

Next, since the running time of our method is proportional to the number of visited nodes on the vocabulary trie, we evaluated the efficiency of our method in terms of number of visited nodes. The result reported here is that when k is 10.

Specifically, we tested how the number of visited nodes changes according to three factors: maximum number of applicable rules in a transformation, vocabulary size and rule set size. The experimental results are shown in Fig. 8, Fig. 9 and Fig. 10 respectively. From Fig. 8, with increasing maximum number of applicable rules in a transformation, number of visited nodes increases first and then stabilizes, especially when the words are long. Note that pruning becomes even more effective because number of visited nodes without pruning grows much faster. It demonstrates that our method is very efficient when compared to the non-pruning method. Admittedly, the efficiency of our method also deteriorates somewhat. This would not cause a noticeable issue in real applications, however. In the previous section,

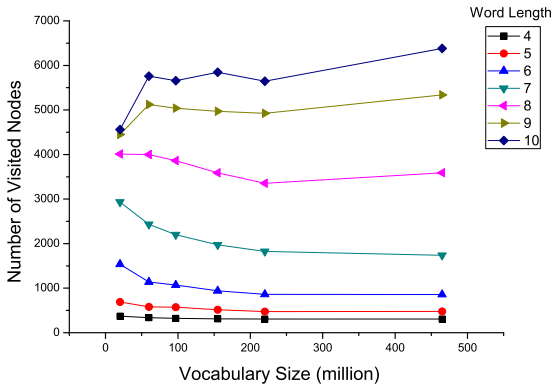

Figure 9: Efficiency Evaluation with Different Sizes of Vocabulary

we have seen that using up to two rules in a transformation can bring a very high accuracy. From Fig. 8 and Fig. 9, we can conclude that the numbers of visited nodes are stable and thus the efficiency of our method keeps high with larger vocabulary size and number of rules. It indicates that our pruning strategy is very effective. From all the figures, we can see that our method is always efficient especially when the words are relatively short.

5.4 Experiments on Model Constraints

In Section 3.1, we introduce the non-positive constraints on the parameters, i.e., $\forall \lambda_r \leq 0$, to enable the pruning technique for efficient top k retrieval. We experimentally verified the impact of the constraints to both the accuracy and efficiency. For ease of reference, we name the model with the non-positive constraints as *bounded*, and the origi-

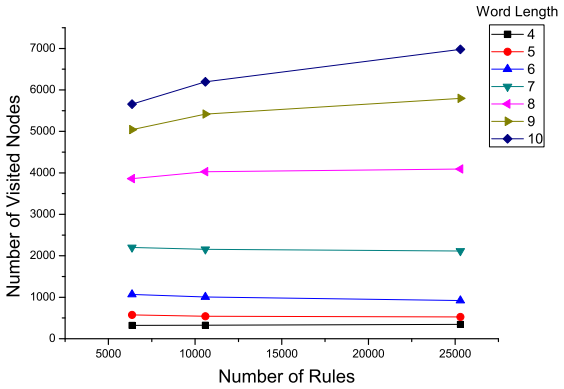

Figure 10: Efficiency Evaluation with Different Number of Rules

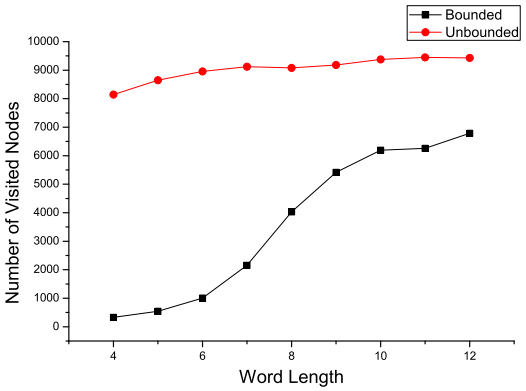

Figure 12: Efficiency Comparison between Bounded and Unbounded Models

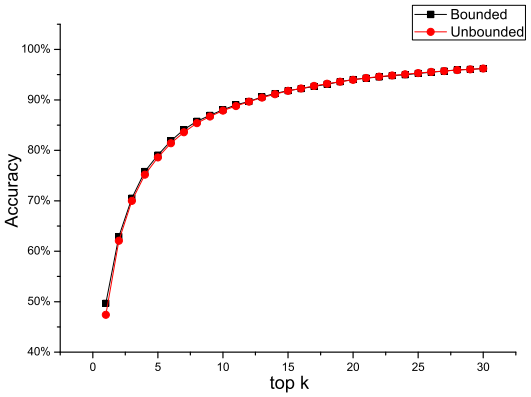

Figure 11: Accuracy Comparison between Bounded and Unbounded Models

nal model as *unbounded*. The experimental results are shown in Fig. 11 and Fig. 12. All the experiments were conducted based on the typical setting of our experiments: 973,902 words in the vocabulary, 10,597 rules, and up to two rules in one transformation. In Fig. 11, we can see that the difference between *bounded* and *unbounded* in terms of accuracy is negligible, and we can draw a conclusion that adding the constraints does not hurt the accuracy. From Fig. 12, it is easy to note that *bounded* is much faster than *unbounded* because our pruning strategy can be applied to *bounded*.

6 Conclusion

In this paper, we have proposed a new method for approximate string search, including spelling error correction, which is both accurate and efficient. Our method is novel and unique in its model, learning algorithm, and retrieval algorithm. Experimental results on a large data set show that our method improves upon existing methods in terms of accuracy, and particularly our method can perform better when the dictionary is large and when there are many rules. Experimental results have also verified the high efficiency of our method. As future work, we plan to add contextual features into the model and apply our method to other data sets in other tasks.

Domain Adaptation by Constraining Inter-Domain Variability of Latent Feature Representation

Ivan Titov
Saarland University
Saarbruecken, Germany
titov@mmci.uni-saarland.de

Abstract

We consider a semi-supervised setting for domain adaptation where only unlabeled data is available for the target domain. One way to tackle this problem is to train a generative model with latent variables on the mixture of data from the source and target domains. Such a model would cluster features in both domains and ensure that at least some of the latent variables are predictive of the label on the source domain. The danger is that these predictive clusters will consist of features specific to the source domain only and, consequently, a classifier relying on such clusters would perform badly on the target domain. We introduce a constraint enforcing that marginal distributions of each cluster (i.e., each latent variable) do not vary significantly across domains. We show that this constraint is effective on the sentiment classification task (Pang et al., 2002), resulting in scores similar to the ones obtained by the structural correspondence methods (Blitzer et al., 2007) without the need to engineer auxiliary tasks.

1 Introduction

Supervised learning methods have become a standard tool in natural language processing, and large training sets have been annotated for a wide variety of tasks. However, most learning algorithms operate under assumption that the learning data originates from the same distribution as the test data, though in practice this assumption is often violated. This difference in the data distributions normally results in a significant drop in accuracy. To address this problem a number of *domain-adaptation* methods has recently been proposed (see e.g., (Daumé and Marcu, 2006; Blitzer et al., 2006; Bickel et al., 2007)). In addition to the labeled data from the source domain, they also exploit small amounts of labeled data and/or unlabeled data from the target domain to estimate a more predictive model for the target domain.

In this paper we focus on a more challenging and arguably more realistic version of the domain-adaptation problem where only unlabeled data is available for the target domain. One of the most promising research directions on domain adaptation for this setting is based on the idea of inducing a *shared feature representation* (Blitzer et al., 2006), that is mapping from the initial feature representation to a new representation such that (1) examples from both domains 'look similar' and (2) an accurate classifier can be trained in this new representation. Blitzer et al. (2006) use auxiliary tasks based on unlabeled data for both domains (called pivot features) and a dimensionality reduction technique to induce such shared representation. The success of their domain-adaptation method (Structural Correspondence Learning, SCL) crucially depends on the choice of the auxiliary tasks, and defining them can be a non-trivial engineering problem for many NLP tasks (Plank, 2009). In this paper, we investigate methods which do not use auxiliary tasks to induce a shared feature representation.

We use generative latent variable models (LVMs) learned on all the available data: unlabeled data for both domains and on the labeled data for the source domain. Our LVMs use vectors of latent features

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 62–71,
Portland, Oregon, June 19-24, 2011.

to represent examples. The latent variables encode regularities observed on unlabeled data from both domains, and they are learned to be predictive of the labels on the source domain. Such LVMs can be regarded as composed of two parts: a mapping from initial (normally, word-based) representation to a new shared distributed representation, and also a classifier in this representation. The danger of this semi-supervised approach in the domain-adaptation setting is that some of the latent variables will correspond to clusters of features specific only to the source domain, and consequently, the classifier relying on this latent variable will be badly affected when tested on the target domain. Intuitively, one would want the model to induce only those features which generalize between domains. We encode this intuition by introducing a term in the learning objective which regularizes inter-domain difference in marginal distributions of each latent variable.

Another, though conceptually similar, argument for our method is coming from theoretical results which postulate that the drop in accuracy of an adapted classifier is dependent on the *discrepancy distance* between the source and target domains (Blitzer et al., 2008; Mansour et al., 2009; Ben-David et al., 2010). Roughly, the discrepancy distance is small when linear classifiers cannot distinguish between examples from different domains. A necessary condition for this is that the feature expectations do not vary significantly across domains. Therefore, our approach can be regarded as minimizing a coarse approximation of the discrepancy distance.

The introduced term regularizes model expectations and it can be viewed as a form of a generalized expectation (GE) criterion (Mann and McCallum, 2010). Unlike the standard GE criterion, where a model designer defines the prior for a model expectation, our criterion postulates that the model expectations should be similar across domains.

In our experiments, we use a form of Harmonium Model (Smolensky, 1986) with a single layer of binary latent variables. Though exact inference with this class of models is infeasible we use an efficient approximation (Bengio and Delalleau, 2007), which can be regarded either as a mean-field approximation to the reconstruction error or a deterministic version of the Contrastive Divergence sampling method (Hinton, 2002). Though such an estimator is biased, in practice, it yields accurate models. We explain how the introduced regularizer can be integrated into the stochastic gradient descent learning algorithm for our model.

We evaluate our approach on adapting sentiment classifiers on 4 domains: books, DVDs, electronics and kitchen appliances (Blitzer et al., 2007). The loss due to transfer to a new domain is very significant for this task: in our experiments it was approaching 9%, in average, for the non-adapted model. Our regularized model achieves 35% average relative error reduction with respect to the non-adapted classifier, whereas the non-regularized version demonstrates a considerably smaller reduction of 26%. Both the achieved error reduction and the absolute score match the results reported in (Blitzer et al., 2007) for the best version[1] of the SCL method (SCL-MI, 36%), suggesting that our approach is a viable alternative to SCL.

The rest of the paper is structured as follows. In Section 2 we introduce a model which uses vectors of latent variables to model statistical dependencies between the elementary features. In Section 3 we discuss its applicability in the domain-adaptation setting, and introduce constraints on inter-domain variability as a way to address the discovered limitations. Section 4 describes approximate learning and inference algorithms used in our experiments. In Section 5 we provide an empirical evaluation of the proposed method. We conclude in Section 6 with further examination of the related work.

2 The Latent Variable Model

The adaptation method advocated in this paper is applicable to any joint probabilistic model which uses *distributed representations*, i.e. vectors of latent variables, to abstract away from hand-crafted features. These models, for example, include Restricted Boltzmann Machines (Smolensky, 1986; Hinton, 2002) and Sigmoid Belief Networks (SBNs) (Saul et al., 1996) for classification and regression tasks, Factorial HMMs (Ghahramani and Jordan, 1997) for sequence labeling problems, Incremental SBNs for parsing problems (Titov and Henderson, 2007a),

[1] Among the versions which do not exploit labeled data from the target domain.

as well as different types of Deep Belief Networks (Hinton and Salakhutdinov, 2006). The power of these methods is in their ability to automatically construct new features from elementary ones provided by the model designer. This feature induction capability is especially desirable for problems where engineering features is a labor-intensive process (e.g., multilingual syntactic parsing (Titov and Henderson, 2007b)), or for multitask learning problems where the nature of interactions between the tasks is not fully understood (Collobert and Weston, 2008; Gesmundo et al., 2009).

In this paper we consider classification tasks, namely prediction of sentiment polarity of a user review (Pang et al., 2002), and model the joint distribution of the binary sentiment label $y \in \{0,1\}$ and the multiset of text features $\boldsymbol{x}, x_i \in \mathcal{X}$. The hidden variable vector $\boldsymbol{z}$ ($z_i \in \{0,1\}$, $i = 1,\dots,m$) encodes statistical dependencies between components of $\boldsymbol{x}$ and also dependencies between the label y and the features $\boldsymbol{x}$. Intuitively, the model can be regarded as a logistic regression classifier with latent features.

The model assumes that the features and the latent variable vector are generated jointly from a globally-normalized model and then the label y is generated from a conditional distribution dependent on $\boldsymbol{z}$. Both of these distributions, $P(\boldsymbol{x},\boldsymbol{z})$ and $P(y|\boldsymbol{z})$, are parameterized as log-linear models and, consequently, our model can be seen as a combination of an undirected Harmonium model (Smolensky, 1986) and a directed SBN model (Saul et al., 1996). The formal definition is as follows:

(1) Draw $(\boldsymbol{x},\boldsymbol{z}) \sim P(\boldsymbol{x},\boldsymbol{z}|\boldsymbol{v})$,
(2) Draw label $y \sim \sigma(w_0 + \sum_{i=1}^{m} w_i z_i)$,

where $\boldsymbol{v}$ and $\boldsymbol{w}$ are parameters, σ is the logistic sigmoid function, $\sigma(t) = 1/(1+e^{-t})$, and the joint distribution of $(\boldsymbol{x},\boldsymbol{z})$ is given by the Gibbs distribution:

$$P(\boldsymbol{x},\boldsymbol{z}|\boldsymbol{v}) \propto \exp(\sum_{j=1}^{|x|} v_{x_j 0} + \sum_{i=1}^{n} v_{0i} z_i + \sum_{j,i=1}^{|x|,n} v_{x_j i} z_i).$$

Figure 1 presents the corresponding graphical model. Note that the arcs between $\boldsymbol{x}$ and $\boldsymbol{z}$ are undirected, whereas arcs between y and $\boldsymbol{z}$ are directed.

The parameters of this model $\theta = (\boldsymbol{v},\boldsymbol{w})$ can be estimated by maximizing joint likelihood $L(\theta)$ of labeled data for the source domain $\{\boldsymbol{x}^{(l)}, y^{(l)}\}_{l \in S_L}$

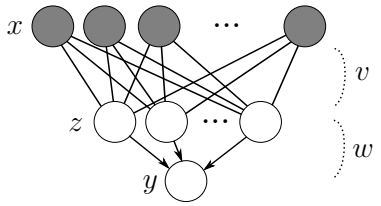

Figure 1: The latent variable model: $\boldsymbol{x}$, $\boldsymbol{z}$, y are random variables, dependencies between $\boldsymbol{x}$ and $\boldsymbol{z}$ are parameterized by matrix $\boldsymbol{v}$, and dependencies between $\boldsymbol{z}$ and y - by vector $\boldsymbol{w}$.

and unlabeled data for the source and target domain $\{\boldsymbol{x}^{(l)}\}_{l \in S_U \cup T_U}$, where S_U and T_U stand for the unlabeled datasets for the source and target domains, respectively. However, given that, first, amount of unlabeled data $|S_U \cup T_U|$ normally vastly exceeds the amount of labeled data $|S_L|$ and, second, the number of features for each example $|\boldsymbol{x}^{(l)}|$ is usually large, the label y will have only a minor effect on the mapping from the initial features $\boldsymbol{x}$ to the latent representation $\boldsymbol{z}$ (i.e. on the parameters $\boldsymbol{v}$). Consequently, the latent representation induced in this way is likely to be inappropriate for the classification task in question. Therefore, we follow (McCallum et al., 2006) and use a multi-conditional objective, a specific form of hybrid learning, to emphasize the importance of labels y:

$$L(\theta,\alpha) = \alpha \sum_{l \in S_L} \log P(y^{(l)}|x^{(l)},\theta) + \sum_{l \in S_U \cup T_U \cup S_L} \log P(x^{(l)}|\theta),$$

where α is a weight, $\alpha > 1$.

Direct maximization of the objective is problematic, as it would require summation over all the 2^m latent vectors $\boldsymbol{z}$. Instead we use a mean-field approximation. Similarly, an efficient approximate inference algorithm is used to compute $\arg\max_y P(y|x,\theta)$ at testing time. The approximations are described in Section 4.

3 Constraints on Inter-Domain Variability

As we discussed in the introduction, our goal is to provide a method for domain adaptation based on semi-supervised learning of models with distributed representations. In this section, we first discuss the shortcomings of domain adaptation with the above-described semi-supervised approach and motivate constraints on inter-domain variability of

the induced shared representation. Then we propose a specific form of this constraint based on the Kullback-Leibler (KL) divergence.

3.1 Motivation for the Constraints

Each latent variable z_i encodes a cluster or a combination of elementary features x_j. At least some of these clusters, when induced by maximizing the likelihood $L(\theta, \alpha)$ with sufficiently large α, will be useful for the classification task on the source domain. However, when the domains are substantially different, these predictive clusters are likely to be specific only to the source domain. For example, consider moving from reviews of electronics to book reviews: the cluster of features related to equipment reliability and warranty service will not generalize to books. The corresponding latent variable will always be inactive on the books domain (or always active, if negative correlation is induced during learning). Equivalently, the marginal distribution of this variable will be very different for both domains. Note that the classifier, defined by the vector $\boldsymbol{w}$, is only trained on the labeled source examples $\{\boldsymbol{x}^{(l)}, y^{(l)}\}_{l \in S_L}$ and therefore it will rely on such latent variables, even though they do not generalize to the target domain. Clearly, the accuracy of such classifier will drop when it is applied to target domain examples. To tackle this issue, we introduce a regularizing term which penalizes differences in the marginal distributions between the domains.

In fact, we do not need to consider the behavior of the classifier to understand the rationale behind the introduction of the regularizer. Intuitively, when adapting between domains, we are interested in representations $\boldsymbol{z}$ which explain domain-independent regularities rather than in modeling inter-domain differences. The regularizer favors models which focus on the former type of phenomena rather than the latter.

Another motivation for the form of regularization we propose originates from theoretical analysis of the domain adaptation problems (Ben-David et al., 2010; Mansour et al., 2009; Blitzer et al., 2007). Under the assumption that there exists a domain-independent scoring function, these analyses show that the drop in accuracy is upper-bounded by the quantity called discrepancy distance. The discrepancy distance is dependent on the feature representation $\boldsymbol{z}$, and the input distributions for both domains $P_S(\boldsymbol{z})$ and $P_T(\boldsymbol{z})$, and is defined as

$$d_{\boldsymbol{z}}(S,T) = \max_{f,f'} |E_{P_S}[f(\boldsymbol{z}) \neq f'(\boldsymbol{z})] - E_{P_T}[f(\boldsymbol{z}) \neq f'(\boldsymbol{z})]|,$$

where f and f' are arbitrary linear classifiers in the feature representation $\boldsymbol{z}$. The quantity $E_P[f(\boldsymbol{z}) \neq f'(\boldsymbol{z})]$ measures the probability mass assigned to examples where f and f' disagree. Then the discrepancy distance is the maximal change in the size of this disagreement set due to transfer between the domains. For a more restricted class of classifiers which rely only on any single feature[2] z_i, the distance is equal to the maximum over the change in the distributions $P(z_i)$. Consequently, for arbitrary linear classifiers we have:

$$d_{\boldsymbol{z}}(S,T) \geq \max_{i=1,\ldots,m} |E_{P_S}[z_i = 1] - E_{P_T}[z_i = 1]|.$$

It follows that low inter-domain variability of the marginal distributions of latent variables is a necessary condition for low discrepancy distance. Minimizing the difference in the marginal distributions can be regarded as a coarse approximation to the minimization of the distance. However, we have to concede that the above argument is fairly informal, as the generalization bounds do not directly apply to our case: (1) our feature representation is learned from the same data as the classifier, (2) we cannot guarantee that the existence of a domain-independent scoring function is preserved under the learned transformation $\boldsymbol{x} \rightarrow \boldsymbol{z}$ and (3) in our setting we have access not only to samples from $P(\boldsymbol{z}|\boldsymbol{x}, \theta)$ but also to the distribution itself.

3.2 The Expectation Criterion

Though the above argument suggests a specific form of the regularizing term, we believe that the penalizer should not be very sensitive to small differences in the marginal distributions, as useful variables (clusters) are likely to have somewhat different marginal distributions in different domains, but it should severely penalize extreme differences.

To achieve this goal we instead propose to use the symmetrized Kullback-Leibler (KL) divergence between the marginal distributions as the penalty. The

[2] We consider only binary features here.

derivative of the symmetrized KL divergence is large when one of the marginal distributions is concentrated at 0 or 1 with another distribution still having high entropy, and therefore such configurations are severely penalized.[3] Formally, the regularizer $G(\theta)$ is defined as

$$G(\theta) = \sum_{i=1}^{m} D(P_S(z_i|\theta)||P_T(z_i|\theta)) + D(P_T(z_i|\theta)||P_S(z_i|\theta)), \quad (1)$$

where $P_S(z_i)$ and $P_T(z_i)$ stand for the training sample estimates of the marginal distributions of latent features, for instance:

$$P_T(z_i = 1|\theta) = \frac{1}{|T_U|} \sum_{l \in T_U} P(z_i = 1|\boldsymbol{x}^{(l)}, \theta).$$

We augment the multi-conditional log-likelihood $L(\theta, \alpha)$ with the weighted regularization term $G(\theta)$ to get the composite objective function:

$$L_R(\theta, \alpha, \beta) = L(\theta, \alpha) - \beta G(\theta), \quad \beta > 0.$$

Note that this regularization term can be regarded as a form of the generalized expectation (GE) criteria (Mann and McCallum, 2010), where GE criteria are normally defined as KL divergences between a prior expectation of some feature and the expectation of this feature given by the model, where the prior expectation is provided by the model designer as a form of weak supervision. In our case, both expectations are provided by the model but on different domains.

Note that the proposed regularizer can be trivially extended to support the multi-domain case (Mansour et al., 2008) by considering symmetrized KL divergences for every pair of domains or regularizing the distributions for every domain towards their average.

More powerful regularization terms can also be motivated by minimization of the discrepancy distance but their optimization is likely to be expensive, whereas $L_R(\theta, \alpha, \beta)$ can be optimized efficiently.

[3] An alternative is to use the Jensen-Shannon (JS) divergence, however, our preliminary experiments seem to suggest that the symmetrized KL divergence is preferable. Though the two divergences are virtually equivalent when the distributions are very similar (their ratio tends to a constant as the distributions go closer), the symmetrized KL divergence stronger penalizes extreme differences and this is important for our purposes.

4 Learning and Inference

In this section we describe an approximate learning algorithm based on the mean-field approximation. Though we believe that our approach is independent of the specific learning algorithm, we provide the description for completeness. We also describe a simple approximate algorithm for computing $P(y|\boldsymbol{x}, \theta)$ at test time.

The stochastic gradient descent algorithm iterates over examples and updates the weight vector based on the contribution of every considered example to the objective function $L_R(\theta, \alpha, \beta)$. To compute these updates we need to approximate gradients of $\nabla_\theta \log P(y^{(l)}|\boldsymbol{x}^{(l)}, \theta)$ ($l \in S_L$), $\nabla_\theta \log P(\boldsymbol{x}^{(l)}|\theta)$ ($l \in S_L \cup S_U \cup T_U$) as well as to estimate the contribution of a given example to the gradient of the regularizer $\nabla_\theta G(\theta)$. In the next sections we will describe how each of these terms can be estimated.

4.1 Conditional Likelihood Term

We start by explaining the mean-field approximation of $\log P(y|\boldsymbol{x}, \theta)$. First, we compute the means $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_m)$:

$$\mu_i = P(z_i = 1|\boldsymbol{x}, \boldsymbol{v}) = \quad \sigma(v_{0i} + \textstyle\sum_{j=1}^{|\boldsymbol{x}|} v_{x_j i}).$$

Now we can substitute them instead of $\boldsymbol{z}$ to approximate the conditional probability of the label:

$$\begin{aligned} P(y = 1|\boldsymbol{x}, \theta) \quad &= \textstyle\sum_{\boldsymbol{z}} P(y|\boldsymbol{z}, \boldsymbol{w}) P(\boldsymbol{z}|\boldsymbol{x}, \boldsymbol{v}) \\ &\propto \sigma(w_0 + \textstyle\sum_{i=1}^{m} w_i \mu_i). \end{aligned}$$

We use this estimate both at testing time and also to compute gradients $\nabla_\theta \log P(y^{(l)}|\boldsymbol{x}^{(l)}, \theta)$ during learning. The gradients can be computed efficiently using a form of back-propagation. Note that with this approximation, we do not need to normalize over the feature space, which makes the model very efficient at classification time.

This approximation is equivalent to the computation of the two-layer perceptron with the soft-max activation function (Bishop, 1995). However, the above derivation provides a probabilistic interpretation of the hidden layer.

4.2 Unlabeled Likelihood Term

In this section, we describe how the unlabeled likelihood term is optimized in our stochastic learning

algorithm. First, we note that, given the directed nature of the arcs between $\boldsymbol{z}$ and y, the weights $\boldsymbol{w}$ do not affect the probability of input $\boldsymbol{x}$, that is $P(\boldsymbol{x}|\theta) = P(\boldsymbol{x}|\boldsymbol{v})$.

Instead of directly approximating the gradient $\nabla_{\boldsymbol{v}} \log P(\boldsymbol{x}^{(l)}|\boldsymbol{v})$, we use a deterministic version of the Contrastive Divergence (CD) algorithm, equivalent to the mean-field approximation of the reconstruction error used in training autoassociaters (Bengio and Delalleau, 2007). The CD-based estimators are biased estimators but are guaranteed to converge. Intuitively, maximizing the likelihood of unlabeled data is closely related to minimizing the reconstruction error, that is training a model to discover such mapping parameters $\boldsymbol{u}$ that $\boldsymbol{z}$ encodes all the necessary information to accurately reproduce $\boldsymbol{x}^{(l)}$ from $\boldsymbol{z}$ for every training example $\boldsymbol{x}^{(l)}$. Formally, the mean-field approximation to the negated reconstruction error is defined as

$$\hat{L}(\boldsymbol{x}^{(l)}, \boldsymbol{v}) = \log P(\boldsymbol{x}^{(l)}|\boldsymbol{\mu}, \boldsymbol{v}),$$

where the means, $\mu_i = P(z_i = 1|\boldsymbol{x}^{(l)}, \boldsymbol{v})$, are computed as in the preceding section. Note that when computing the gradient of $\nabla_{\boldsymbol{v}}\hat{L}$, we need to take into account both the forward and backward mappings: the computation of the means $\boldsymbol{\mu}$ from $\boldsymbol{x}^{(\boldsymbol{l})}$ and the computation of the log-probability of $\boldsymbol{x}^{(\boldsymbol{l})}$ given the means $\boldsymbol{\mu}$:

$$\frac{d\hat{L}}{dv_{ki}} = \frac{\partial \hat{L}}{\partial v_{ki}} + \frac{\partial \hat{L}}{\partial \mu_i}\frac{d\mu_i}{dv_{ki}}.$$

4.3 Regularization Term

The criterion $G(\theta)$ is also independent of the classifier parameters $\boldsymbol{w}$, i.e. $G(\theta) = G(\boldsymbol{v})$, and our goal is to compute the contribution of a considered example l to the gradient $\nabla_{\boldsymbol{v}} G(\boldsymbol{v})$.

The regularizer $G(\boldsymbol{v})$ is defined as in equation (1) and it is a function of the sample-based domain-specific marginal distributions of latent variables P_S and P_T:

$$P_T(z_i = 1|\theta) = \frac{1}{|T_U|}\sum_{l \in T_U} \mu_i^{(l)},$$

where the means $\mu_i^{(l)} = P(z_i = 1|x^{(l)}, \boldsymbol{v})$; P_S can be re-written analogously. $G(\boldsymbol{v})$ is dependent on the parameters $\boldsymbol{v}$ only via the mean activations of the latent variables $\boldsymbol{\mu}^{(l)}$, and contribution of each example l can be computed by straightforward differentiation:

$$\frac{dG^{(l)}(\boldsymbol{v})}{dv_{ki}} = (\log\frac{p}{p'} - \log\frac{1-p}{1-p'} - \frac{p'}{p} + \frac{1-p'}{1-p})\frac{d\mu_i^{(l)}}{dv_{ki}},$$

where $p = P_S(z_i = 1|\theta)$ and $p' = P_T(z_i = 1|\theta)$ if l is from the source domain, and, inversely, $p = P_T(z_i = 1|\theta)$ and $p' = P_S(z_i = 1|\theta)$, otherwise.

One problem with the above expression is that the exact computation of P_S and P_T requires recomputation of the means $\boldsymbol{\mu}^{(l)}$ for all the examples after each update of the parameters, resulting in $O(|S_L \cup S_U \cup T_U|^2)$ complexity of each iteration of stochastic gradient descent. Instead, we shuffle examples and use amortization; we approximate P_S at update t by:

$$\hat{P}_S^{(t)}(z_i = 1) = \begin{cases} (1-\gamma)\hat{P}_S^{(t-1)}(z_i = 1) + \gamma\mu_i^{(l)}, & l \in S_L \cup S_U \\ \hat{P}_S^{(t-1)}(z_i = 1), & \text{otherwise,} \end{cases}$$

where l is an example considered at update t. The approximation $\hat{P}_T$ is computed analogously.

5 Empirical Evaluation

In this section we empirically evaluate our approach on the sentiment classification task. We start with the description of the experimental set-up and the baselines, then we present the results and discuss the utility of the constraint on inter-domain variability.

5.1 Experimental setting

To evaluate our approach, we consider the same dataset as the one used to evaluate the SCL method (Blitzer et al., 2007). The dataset is composed of labeled and unlabeled reviews of four different product types: books, DVDs, electronics and kitchen appliances. For each domain, the dataset contains 1,000 labeled positive reviews and 1,000 labeled negative reviews, as well as several thousands of unlabeled examples (4,919 reviews per domain in average: ranging from 3,685 for DVDs to 5,945 for kitchen appliances). As in Blitzer et al. (2007), we randomly split each labelled portion into 1,600 examples for training and 400 examples for testing.

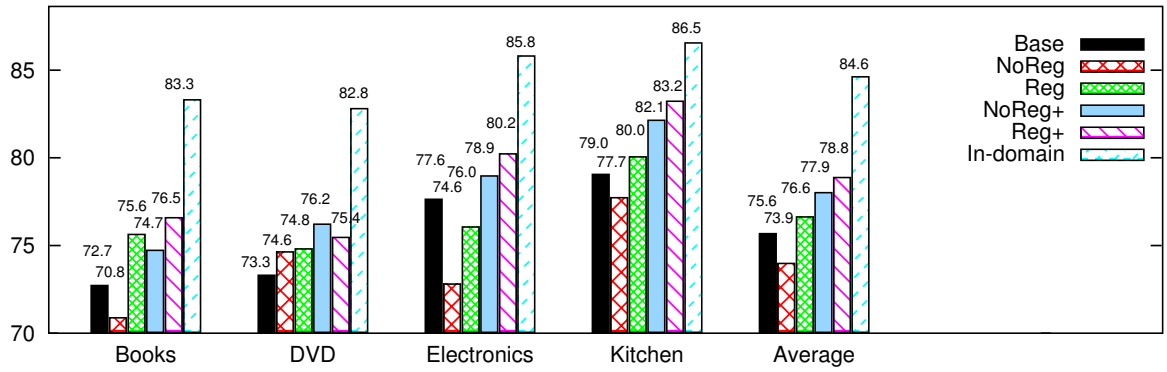

Figure 2: Averages accuracies when transferring to books, DVD, electronics and kitchen appliances domains, and average accuracy over all 12 domain pairs.

We evaluate the performance of our domain-adaptation approach on every ordered pair of domains. For every pair, the semi-supervised methods use labeled data from the source domain and unlabeled data from both domains. We compare them with two supervised methods: a supervised model (*Base*) which is trained on the source domain data only, and another supervised model (*In-domain*) which is learned on the labeled data from the target domain. The Base model can be regarded as a natural baseline model, whereas the In-domain model is essentially an upper-bound for any domain-adaptation method. All the methods, supervised and semi-supervised, are based on the model described in Section 2.

Instead of using the full set of bigram and unigram counts as features (Blitzer et al., 2007), we use a frequency cut-off of 30 to remove infrequent ngrams. This does not seem to have an adverse effect on the accuracy but makes learning very efficient: the average training time for the semi-supervised methods was about 20 minutes on a standard PC.

We coarsely tuned the parameters of the learning methods using a form of cross-validation. Both the parameter of the multi-conditional objective α (see Section 2) and the weighting for the constraint β (see Section 3.2) were set to 5. We used 25 iterations of stochastic gradient descent. The initial learning rate and the weight decay (the inverse squared variance of the Gaussian prior) were set to 0.01, and both parameters were reduced by the factor of 2 every iteration the objective function estimate went down. The size of the latent representation was equal to 10. The stochastic weight updates were amortized with the momentum (γ) of 0.99.

We trained the model both without regularization of the domain variability (*NoReg*, $\beta = 0$), and with the regularizing term (*Reg*). For the SCL method to produce an accurate classifier for the target domain it is necessary to train a classifier using both the induced shared representation and the initial non-transformed representation. In our case, due to joint learning and non-convexity of the learning problem, this approach would be problematic.[4] Instead, we combine predictions of the semi-supervised models *Reg* and *NoReg* with the baseline out-of-domain model (*Base*) using the product-of-experts combination (Hinton, 2002), the corresponding methods are called *Reg+* and *NoReg+*, respectively.

In all our models, we augmented the vector z with an additional component set to 0 for examples in the source domain and to 1 for the target domain examples. In this way, we essentially subtracted a unigram domain-specific model from our latent variable model in the hope that this will further reduce the domain dependence of the rest of the model parameters. In preliminary experiments, this modification was beneficial for all the models including the non-constrained one (*NoReg*).

5.2 Results and Discussion

The results of all the methods are presented in Figure 2. The 4 leftmost groups of results correspond to a single target domain, and therefore each of

[4]The latent variables are not likely to learn any useful mapping in the presence of observable features. Special training regimes may be used to attempt to circumvent this problem.

them is an average over experiments on 3 domain-pairs, for instance, the group Books represents an average over adaptation experiments DVDs→books, electronics→books, kitchen→books. The rightmost group of the results corresponds to the average over all 12 experiments. First, observe that the total drop in the accuracy when moving to the target domain is 8.9%: from 84.6% demonstrated by the In-domain classifier to 75.6% shown by the non-adapted Base classifier. For convenience, we also present the errors due to transfer in a separate Table 1: our best method (*Reg+*) achieves 35% relative reduction of this loss, decreasing the gap to 5.7%.

Now, let us turn to the question of the utility of the constraints. First, observe that the non-regularized version of the model (*NoReg*) often fails to outperform the baseline and achieves the scores considerably worse than the results of the regularized version (2.6% absolute difference). We believe that this happens because the clusters induced when optimizing the non-regularized learning objective are often domain-specific. The regularized model demonstrates substantially better results slightly beating the baseline in most cases. Still, to achieve a larger decrease of the domain-adaptation error, it was necessary to use the combined models, *Reg+* and *NoReg+*. Here, again, the regularized model substantially outperforms the non-regularized one (35% against 26% relative error reduction for *Reg+* and *NoReg+*, respectively).

In Table 1, we also compare the results of our method with the results of the best version of the SCL method (SCL-MI) reported in Blitzer et al. (2007). The average error reductions for our method *Reg+* and for the SCL method are virtually equal. However, formally, these two numbers are not directly comparable. First, the random splits are different, though this is unlikely to result in any significant difference, as the split proportions are the same and the test sets are sufficiently large. Second, the absolute scores achieved in Blitzer et al. (2007) are slightly worse than those demonstrated in our experiments both for supervised and semi-supervised methods. In absolute terms, our *Reg+* method outperforms the SCL method by more than 1%: 75.6% against 74.5%, in average. This is probably due to the difference in the used learning methods: optimization of the Huber loss vs. our latent variable model.[5] This comparison suggests that our domain-adaptation method is a viable alternative to SCL.

D	Base	NoReg	Reg	NoReg+	Reg+	SCL-MI
B	10.6	12.4	7.7	8.6	6.7	**5.8**
D	9.5	8.2	8.0	6.6	7.3	**6.1**
E	8.2	13.0	9.7	6.8	**5.5**	**5.5**
K	7.5	8.8	6.5	4.4	**3.3**	5.6
Av	8.9	10.6	8.0	6.6	**5.7**	5.8

Table 1: Drop in the accuracy score due to the transfer for the 4 domains: (B)ooks, (D)VD, (E)electronics and (K)itchen appliances, and in average over the domains.

Also, it is important to point out that the SCL method uses auxiliary tasks to induce the shared feature representation, these tasks are constructed on the basis of unlabeled data. The auxiliary tasks and the original problem should be closely related, namely they should have the same (or similar) set of predictive features. Defining such tasks can be a challenging engineering problem. On the sentiment classification task in order to construct them two steps need to be performed: (1) a set of words correlated with the sentiment label is selected, and, then (2) prediction of each such word is regarded a distinct auxiliary problem. For many other domains (e.g., parsing (Plank, 2009)) the construction of an effective set of auxiliary tasks is still an open problem.

6 Related Work

There is a growing body of work on domain adaptation. In this paper, we focus on the class of methods which induce a shared feature representation. Another popular class of domain-adaptation techniques assume that the input distributions $P(x)$ for the source and the target domain share support, that is every example x which has a non-zero probability on the target domain must have also a non-zero probability on the source domain, and vice-versa. Such methods tackle domain adaptation by instance re-weighting (Bickel et al., 2007; Jiang and Zhai, 2007), or, similarly, by feature re-weighting (Satpal and Sarawagi, 2007). In NLP, most features

[5]The drop in accuracy for the SCL method in Table 1 is is computed with respect to the less accurate supervised in-domain classifier considered in Blitzer et al. (2007), otherwise, the computed drop would be larger.

are word-based and lexicons are very different for different domains, therefore such assumptions are likely to be overly restrictive.

Various semi-supervised techniques for domain-adaptation have also been considered, one example being self-training (McClosky et al., 2006). However, their behavior in the domain-adaptation setting is not well-understood. Semi-supervised learning with distributed representations and its application to domain adaptation has previously been considered in (Huang and Yates, 2009), but no attempt has been made to address problems specific to the domain-adaptation setting. Similar approaches has also been considered in the context of topic models (Xue et al., 2008), however the preference towards induction of domain-independent topics was not explicitly encoded in the learning objective or model priors.

A closely related method to ours is that of (Druck and McCallum, 2010) which performs semi-supervised learning with posterior regularization (Ganchev et al., 2010). Our approach differs from theirs in many respects. First, they do not focus on the domain-adaptation setting and do not attempt to define constraints to prevent the model from learning domain-specific information. Second, their expectation constraints are estimated from labeled data, whereas we are trying to match expectations computed on unlabeled data for two domains.

This approach bears some similarity to the adaptation methods standard for the setting where labelled data is available for both domains (Chelba and Acero, 2004; Daumé and Marcu, 2006). However, instead of ensuring that the classifier parameters are similar across domains, we favor models resulting in similar marginal distributions of latent variables.

7 Discussion and Conclusions

In this paper we presented a domain-adaptation method based on semi-supervised learning with distributed representations coupled with constraints favoring domain-independence of modeled phenomena. Our approach results in competitive domain-adaptation performance on the sentiment classification task, rivalling that of the state-of-the-art SCL method (Blitzer et al., 2007). Both of these methods induce a shared feature representation but unlike SCL our method does not require construction of any auxiliary tasks in order to induce this representation. The primary area of the future work is to apply our method to structured prediction problems in NLP, such as syntactic parsing or semantic role labeling, where construction of auxiliary tasks proved problematic. Another direction is to favor domain-invariability not only of the expectations of individual variables but rather those of constraint functions involving latent variables, features and labels.

Abstract

We describe an exact decoding algorithm for syntax-based statistical translation. The approach uses Lagrangian relaxation to decompose the decoding problem into tractable subproblems, thereby avoiding exhaustive dynamic programming. The method recovers exact solutions, with certificates of optimality, on over 97% of test examples; it has comparable speed to state-of-the-art decoders.

1 Introduction

Recent work has seen widespread use of synchronous probabilistic grammars in statistical machine translation (SMT). The decoding problem for a broad range of these systems (e.g., (Chiang, 2005; Marcu et al., 2006; Shen et al., 2008)) corresponds to the intersection of a (weighted) hypergraph with an n-gram language model.[1] The hypergraph represents a large set of possible translations, and is created by applying a synchronous grammar to the source language string. The language model is then used to rescore the translations in the hypergraph.

Decoding with these models is challenging, largely because of the cost of integrating an n-gram language model into the search process. Exact dynamic programming algorithms for the problem are well known (Bar-Hillel et al., 1964), but are too expensive to be used in practice.[2] Previous work on decoding for syntax-based SMT has therefore been focused primarily on approximate search methods.

This paper describes an efficient algorithm for exact decoding of synchronous grammar models for translation. We avoid the construction of (Bar-Hillel et al., 1964) by using *Lagrangian relaxation* to decompose the decoding problem into the following sub-problems:

1. Dynamic programming over the weighted hypergraph. This step does not require language model integration, and hence is highly efficient.

2. Application of an all-pairs shortest path algorithm to a directed graph derived from the weighted hypergraph. The size of the derived directed graph is linear in the size of the hypergraph, hence this step is again efficient.

Informally, the first decoding algorithm incorporates the weights and hard constraints on translations from the synchronous grammar, while the second decoding algorithm is used to integrate language model scores. Lagrange multipliers are used to enforce agreement between the structures produced by the two decoding algorithms.

In this paper we first give background on hypergraphs and the decoding problem. We then describe our decoding algorithm. The algorithm uses a subgradient method to minimize a dual function. The dual corresponds to a particular linear programming (LP) relaxation of the original decoding problem. The method will recover an exact solution, with a certificate of optimality, if the underlying LP relaxation has an integral solution. In some cases, however, the underlying LP will have a fractional solution, in which case the method will not be exact. The second technical contribution of this paper is to describe a method that iteratively tightens the underlying LP relaxation until an exact solution is produced. We do this by gradually introducing constraints to step 1 (dynamic programming over the hypergraph), while still maintaining efficiency.

[1] This problem is also relevant to other areas of statistical NLP, for example NL generation (Langkilde, 2000).

[2] E.g., with a trigram language model they run in $O(|E|w^6)$ time, where $|E|$ is the number of edges in the hypergraph, and w is the number of distinct lexical items in the hypergraph.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 72–82,
Portland, Oregon, June 19-24, 2011.

We report experiments using the tree-to-string model of (Huang and Mi, 2010). Our method gives exact solutions on over 97% of test examples. The method is comparable in speed to state-of-the-art decoding algorithms; for example, over 70% of the test examples are decoded in 2 seconds or less. We compare our method to cube pruning (Chiang, 2007), and find that our method gives improved model scores on a significant number of examples. One consequence of our work is that we give accurate estimates of the number of search errors for cube pruning.

2 Related Work

A variety of approximate decoding algorithms have been explored for syntax-based translation systems, including cube-pruning (Chiang, 2007; Huang and Chiang, 2007), left-to-right decoding with beam search (Watanabe et al., 2006; Huang and Mi, 2010), and coarse-to-fine methods (Petrov et al., 2008).

Recent work has developed decoding algorithms based on finite state transducers (FSTs). Iglesias et al. (2009) show that exact FST decoding is feasible for a phrase-based system with limited reordering (the MJ1 model (Kumar and Byrne, 2005)), and de Gispert et al. (2010) show that exact FST decoding is feasible for a specific class of hierarchical grammars (shallow-1 grammars). Approximate search methods are used for more complex reordering models or grammars. The FST algorithms are shown to produce higher scoring solutions than cube-pruning on a large proportion of examples.

Lagrangian relaxation is a classical technique in combinatorial optimization (Korte and Vygen, 2008). Lagrange multipliers are used to add linear constraints to an existing problem that can be solved using a combinatorial algorithm; the resulting dual function is then minimized, for example using subgradient methods. In recent work, *dual decomposition*—a special case of Lagrangian relaxation, where the linear constraints enforce agreement between two or more models—has been applied to inference in Markov random fields (Wainwright et al., 2005; Komodakis et al., 2007; Sontag et al., 2008), and also to inference problems in NLP (Rush et al., 2010; Koo et al., 2010). There are close connections between dual decomposition and work on belief propagation (Smith and Eisner, 2008).

3 Background: Hypergraphs

Translation with many syntax-based systems (e.g., (Chiang, 2005; Marcu et al., 2006; Shen et al., 2008; Huang and Mi, 2010)) can be implemented as a two-step process. The first step is to take an input sentence in the source language, and from this to create a hypergraph (sometimes called a translation forest) that represents the set of possible translations (strings in the target language) and derivations under the grammar. The second step is to integrate an n-gram language model with this hypergraph. For example, in the system of (Chiang, 2005), the hypergraph is created as follows: first, the source side of the synchronous grammar is used to create a parse forest over the source language string. Second, transduction operations derived from synchronous rules in the grammar are used to create the target-language hypergraph. Chiang's method uses a synchronous context-free grammar, but the hypergraph formalism is applicable to a broad range of other grammatical formalisms, for example dependency grammars (e.g., (Shen et al., 2008)).

A hypergraph is a pair (V, E) where $V = \{1, 2, \ldots, |V|\}$ is a set of vertices, and E is a set of hyperedges. A single distinguished vertex is taken as the root of the hypergraph; without loss of generality we take this vertex to be $v = 1$. Each hyperedge $e \in E$ is a tuple $\langle\langle v_1, v_2, \ldots, v_k\rangle, v_0\rangle$ where $v_0 \in V$, and $v_i \in \{2 \ldots |V|\}$ for $i = 1 \ldots k$. The vertex v_0 is referred to as the *head* of the edge. The ordered sequence $\langle v_1, v_2, \ldots, v_k\rangle$ is referred to as the *tail* of the edge; in addition, we sometimes refer to $v_1, v_2, \ldots v_k$ as the *children* in the edge. The number of children k may vary across different edges, but $k \geq 1$ for all edges (i.e., each edge has at least one child). We will use $h(e)$ to refer to the head of an edge e, and $t(e)$ to refer to the tail.

We will assume that the hypergraph is acyclic: intuitively this will mean that no derivation (as defined below) contains the same vertex more than once (see (Martin et al., 1990) for a formal definition).

Each vertex $v \in V$ is either a *non-terminal* in the hypergraph, or a *leaf*. The set of non-terminals is

$$V_N = \{v \in V : \exists e \in E \quad \text{such that} \quad h(e) = v\}$$

Conversely, the set of leaves is defined as

$$V_L = \{v \in V : \nexists e \in E \quad \text{such that} \quad h(e) = v\}$$

Finally, we assume that each $v \in V$ has a label $l(v)$. The labels for leaves will be *words*, and will be important in defining strings and language model scores for those strings. The labels for non-terminal nodes will not be important for results in this paper.[3]

We now turn to derivations. Define an *index set* $\mathcal{I} = V \cup E$. A derivation is represented by a vector $y = \{y_r : r \in \mathcal{I}\}$ where $y_v = 1$ if vertex v is used in the derivation, $y_v = 0$ otherwise (similarly $y_e = 1$ if edge e is used in the derivation, $y_e = 0$ otherwise). Thus y is a vector in $\{0,1\}^{|\mathcal{I}|}$. A valid derivation satisfies the following constraints:

- $y_1 = 1$ (the root must be in the derivation).
- For all $v \in V_N$, $y_v = \sum_{e:h(e)=v} y_e$.
- For all $v \in 2 \ldots |V|$, $y_v = \sum_{e:v \in t(e)} y_e$.

We use $\mathcal{Y}$ to refer to the set of valid derivations. The set $\mathcal{Y}$ is a subset of $\{0,1\}^{|\mathcal{I}|}$ (not all members of $\{0,1\}^{|\mathcal{I}|}$ will correspond to valid derivations).

Each derivation y in the hypergraph will imply an ordered sequence of leaves $v_1 \ldots v_n$. We use $s(y)$ to refer to this sequence. The *sentence* associated with the derivation is then $l(v_1) \ldots l(v_n)$.

In a weighted hypergraph problem, we assume a parameter vector $\theta = \{\theta_r : r \in \mathcal{I}\}$. The score for any derivation is $f(y) = \theta \cdot y = \sum_{r \in \mathcal{I}} \theta_r y_r$. Simple bottom-up dynamic programming—essentially the CKY algorithm—can be used to find $y^* = \arg\max_{y \in \mathcal{Y}} f(y)$ under these definitions.

The focus of this paper will be to solve problems involving the integration of a k'th order language model with a hypergraph. In these problems, the score for a derivation is modified to be

$$f(y) = \sum_{r \in \mathcal{I}} \theta_r y_r + \sum_{i=k}^{n} \theta(v_{i-k+1}, v_{i-k+2}, \ldots, v_i) \quad (1)$$

where $v_1 \ldots v_n = s(y)$. The $\theta(v_{i-k+1}, \ldots, v_i)$ parameters score n-grams of length k. These parameters are typically defined by a language model, for example with $k = 3$ we would have $\theta(v_{i-2}, v_{i-1}, v_i) = \log p(l(v_i)|l(v_{i-2}), l(v_{i-1}))$. The problem is then to find $y^* = \arg\max_{y \in \mathcal{Y}} f(y)$ under this definition.

Throughout this paper we make the following assumption when using a bigram language model:

[3]They might for example be non-terminal symbols from the grammar used to generate the hypergraph.

Assumption 3.1 *(*Bigram start/end assumption.*)* *For any derivation y, with leaves $s(y) = v_1, v_2, \ldots, v_n$, it is the case that: (1) $v_1 = 2$ and $v_n = 3$; (2) the leaves 2 and 3 cannot appear at any other position in the strings $s(y)$ for $y \in \mathcal{Y}$; (3) $l(2) =$ <s> where <s> is the start symbol in the language model; (4) $l(3) =$ </s> where </s> is the end symbol.*

This assumption allows us to incorporate language model terms that depend on the start and end symbols. It also allows a clean solution for boundary conditions (the start/end of strings).[4]

4 A Simple Lagrangian Relaxation Algorithm

We now give a Lagrangian relaxation algorithm for integration of a hypergraph with a bigram language model, in cases where the hypergraph satisfies the following simplifying assumption:

Assumption 4.1 *(*The strict ordering assumption.*)* *For any two leaves v and w, it is either the case that: 1) for all derivations y such that v and w are both in the sequence $l(y)$, v precedes w; or 2) for all derivations y such that v and w are both in $l(y)$, w precedes v.*

Thus under this assumption, the relative ordering of any two leaves is fixed. This assumption is overly restrictive:[5] the next section describes an algorithm that does not require this assumption. However deriving the simple algorithm will be useful in developing intuition, and will lead directly to the algorithm for the unrestricted case.

4.1 A Sketch of the Algorithm

At a high level, the algorithm is as follows. We introduce Lagrange multipliers $u(v)$ for all $v \in V_L$, with initial values set to zero. The algorithm then involves the following steps: (1) For each leaf v, find the previous leaf w that maximizes the score $\theta(w, v) - u(w)$ (call this leaf $\alpha^*(v)$, and define $\alpha_v = \theta(\alpha^*(v), v) - u(\alpha^*(v))$). (2) find the highest scoring derivation using dynamic programming

[4]The assumption generalizes in the obvious way to k'th order language models: e.g., for trigram models we assume that $v_1 = 2$, $v_2 = 3$, $v_n = 4$, $l(2) = l(3) =$ <s>, $l(4) =$ </s>.

[5]It is easy to come up with examples that violate this assumption: for example a hypergraph with edges $\langle\langle 4, 5\rangle, 1\rangle$ and $\langle\langle 5, 4\rangle, 1\rangle$ violates the assumption. The hypergraphs found in translation frequently contain alternative orderings such as this.

over the original (non-intersected) hypergraph, with leaf nodes having weights $\theta_v + \alpha_v + u(v)$. (3) If the output derivation from step 2 has the same set of bigrams as those from step 1, then we have an exact solution to the problem. Otherwise, the Lagrange multipliers $u(v)$ are modified in a way that encourages agreement of the two steps, and we return to step 1.

Steps 1 and 2 can be performed efficiently; in particular, we avoid the classical dynamic programming intersection, instead relying on dynamic programming over the original, simple hypergraph.

4.2 A Formal Description

We now give a formal description of the algorithm. Define $\mathcal{B} \subseteq V_L \times V_L$ to be the set of all ordered pairs $\langle v, w \rangle$ such that there is at least one derivation y with v directly preceding w in $s(y)$. Extend the bit-vector y to include variables $y(v, w)$ for $\langle v, w \rangle \in \mathcal{B}$ where $y(v, w) = 1$ if leaf v is followed by w in $s(y)$, 0 otherwise. We redefine the index set to be $\mathcal{I} = V \cup E \cup \mathcal{B}$, and define $\mathcal{Y} \subseteq \{0, 1\}^{|\mathcal{I}|}$ to be the set of all possible derivations. Under assumptions 3.1 and 4.1 above, $\mathcal{Y} = \{y : y \text{ satisfies constraints } \mathbf{C0}, \mathbf{C1}, \mathbf{C2}\}$ where the constraint definitions are:

- **(C0)** The y_v and y_e variables form a derivation in the hypergraph, as defined in section 3.
- **(C1)** For all $v \in V_L$ such that $v \neq 2$, $y_v = \sum_{w:\langle w,v \rangle \in \mathcal{B}} y(w, v)$.
- **(C2)** For all $v \in V_L$ such that $v \neq 3$, $y_v = \sum_{w:\langle v,w \rangle \in \mathcal{B}} y(v, w)$.

C1 states that each leaf in a derivation has exactly one in-coming bigram, and that each leaf not in the derivation has 0 incoming bigrams; **C2** states that each leaf in a derivation has exactly one out-going bigram, and that each leaf not in the derivation has 0 outgoing bigrams.[6]

The score of a derivation is now $f(y) = \theta \cdot y$, i.e.,

$$f(y) = \sum_v \theta_v y_v + \sum_e \theta_e y_e + \sum_{\langle v,w \rangle \in \mathcal{B}} \theta(v, w) y(v, w)$$

where $\theta(v, w)$ are scores from the language model. Our goal is to compute $y^* = \arg\max_{y \in \mathcal{Y}} f(y)$.

[6] Recall that according to the bigram start/end assumption the leaves 2/3 are reserved for the start/end of the sequence $s(y)$, and hence do not have an incoming/outgoing bigram.

Initialization: Set $u^0(v) = 0$ for all $v \in V_L$
Algorithm: For $t = 1 \ldots T$:

- $y^t = \arg\max_{y \in \mathcal{Y}'} L(u^{t-1}, y)$
- **If** y^t satisfies constraints **C2**, **return** y^t,
  Else $\forall v \in V_L$, $u^t(v) = u^{t-1}(v) - \delta^t \left(y^t(v) - \sum_{w:\langle v,w \rangle \in \mathcal{B}} y^t(v, w) \right)$.

Figure 1: A simple Lagrangian relaxation algorithm. $\delta^t > 0$ is the step size at iteration t.

Next, define $\mathcal{Y}'$ as

$$\mathcal{Y}' = \{y : y \text{ satisfies constraints } \mathbf{C0} \text{ and } \mathbf{C1}\}$$

In this definition we have dropped the **C2** constraints. To incorporate these constraints, we use Lagrangian relaxation, with one Lagrange multiplier $u(v)$ for each constraint in **C2**. The Lagrangian is

$$\begin{aligned} L(u, y) &= f(y) + \sum_v u(v)(y(v) - \sum_{w:\langle v,w \rangle \in \mathcal{B}} y(v, w)) \\ &= \beta \cdot y \end{aligned}$$

where $\beta_v = \theta_v + u(v)$, $\beta_e = \theta_e$, and $\beta(v, w) = \theta(v, w) - u(v)$.

The dual problem is to find $\min_u L(u)$ where

$$L(u) = \max_{y \in \mathcal{Y}'} L(u, y)$$

Figure 1 shows a *subgradient* method for solving this problem. At each point the algorithm finds $y^t = \arg\max_{y \in \mathcal{Y}'} L(u^{t-1}, y)$, where u^{t-1} are the Lagrange multipliers from the previous iteration. If y^t satisfies the **C2** constraints in addition to **C0** and **C1**, then it is returned as the output from the algorithm. Otherwise, the multipliers $u(v)$ are updated. Intuitively, these updates encourage the values of y_v and $\sum_{w:\langle v,w \rangle \in \mathcal{B}} y(v, w)$ to be equal; formally, these updates correspond to subgradient steps.

The main computational step at each iteration is to compute $\arg\max_{y \in \mathcal{Y}'} L(u^{t-1}, y)$ This step is easily solved, as follows (we again use β_v, β_e and $\beta(v_1, v_2)$ to refer to the parameter values that incorporate Lagrange multipliers):

- For all $v \in V_L$, define $\alpha^*(v) = \arg\max_{w:\langle w,v \rangle \in \mathcal{B}} \beta(w, v)$ and $\alpha_v = \beta(\alpha^*(v), v)$. For all $v \in V_N$ define $\alpha_v = 0$.

- Using dynamic programming, find values for the y_v and y_e variables that form a valid derivation, and that maximize $f'(y) = \sum_v (\beta_v + \alpha_v) y_v + \sum_e \beta_e y_e$.
- Set $y(v, w) = 1$ iff $y(w) = 1$ and $\alpha^*(w) = v$.

The critical point here is that through our definition of $\mathcal{Y}'$, which ignores the **C2** constraints, we are able to do efficient search as just described. In the first step we compute the highest scoring incoming bigram for each leaf v. In the second step we use conventional dynamic programming over the hypergraph to find an optimal derivation that incorporates weights from the first step. Finally, we fill in the $y(v, w)$ values. Each iteration of the algorithm runs in $O(|E| + |\mathcal{B}|)$ time.

There are close connections between Lagrangian relaxation and linear programming relaxations. The most important formal results are: 1) for any value of u, $L(u) \geq f(y^*)$ (hence the dual value provides an upper bound on the optimal primal value); 2) under an appropriate choice of the step sizes δ^t, the subgradient algorithm is guaranteed to converge to the minimum of $L(u)$ (i.e., we will minimize the upper bound, making it as tight as possible); 3) if at any point the algorithm in figure 1 finds a y^t that satisfies the **C2** constraints, then this is guaranteed to be the optimal primal solution.

Unfortunately, this algorithm may fail to produce a good solution for hypergraphs where the strict ordering constraint does not hold. In this case it is possible to find derivations y that satisfy constraints **C0**, **C1**, **C2**, but which are invalid. As one example, consider a derivation with $s(y) = 2, 4, 5, 3$ and $y(2, 3) = y(4, 5) = y(5, 4) = 1$. The constraints are all satisfied in this case, but the bigram variables are invalid (e.g., they contain a cycle).

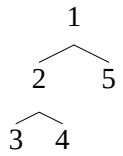
5 The Full Algorithm

We now describe our full algorithm, which does not require the strict ordering constraint. In addition, the full algorithm allows a trigram language model. We first give a sketch, and then give a formal definition.

5.1 A Sketch of the Algorithm

A crucial idea in the new algorithm is that of *paths* between leaves in hypergraph derivations. Previously, for each derivation y, we had defined $s(y) = v_1, v_2, \ldots, v_n$ to be the sequence of leaves in y. In addition, we will define $g(y) = p_0, v_1, p_1, v_2, p_2, v_3, p_3, \ldots, p_{n-1}, v_n, p_n$ where each p_i is a path in the derivation between leaves v_i and v_{i+1}. The path traces through the nonterminals that are between the two leaves in the tree.

As an example, consider the following derivation (with hyperedges $\langle\langle 2, 5\rangle, 1\rangle$ and $\langle\langle 3, 4\rangle, 2\rangle$):



For this example $g(y)$ is $\langle 1\ \downarrow, 2\ \downarrow\rangle\ \langle 2\ \downarrow, 3\ \downarrow\rangle\ \langle 3\ \downarrow\rangle$, 3, $\langle 3\ \uparrow\rangle\ \langle 3\ \uparrow, 4\ \downarrow\rangle\ \langle 4\ \downarrow\rangle$, 4, $\langle 4\ \uparrow\rangle\ \langle 4\ \uparrow, 2\ \uparrow\rangle\ \langle 2\ \uparrow, 5\ \downarrow\rangle\ \langle 5\ \downarrow\rangle$, 5, $\langle 5\ \uparrow\rangle\ \langle 5\ \uparrow, 1\ \uparrow\rangle$. States of the form $\langle a\ \downarrow\rangle$ and $\langle a\ \uparrow\rangle$ where a is a leaf appear in the paths respectively before/after the leaf a. States of the form $\langle a, b\rangle$ correspond to the steps taken in a top-down, left-to-right, traversal of the tree, where down and up arrows indicate whether a node is being visited for the first or second time (the traversal in this case would be $1, 2, 3, 4, 2, 5, 1$).

The mapping from a derivation y to a path $g(y)$ can be performed using the algorithm in figure 2. For a given derivation y, define $E(y) = \{y : y_e = 1\}$, and use $E(y)$ as the set of input edges to this algorithm. The output from the algorithm will be a set of states S, and a set of directed edges T, which together fully define the path $g(y)$.

In the simple algorithm, the first step was to predict the previous leaf for each leaf v, under a score that combined a language model score with a Lagrange multiplier score (i.e., compute $\arg\max_w \beta(w, v)$ where $\beta(w, v) = \theta(w, v) + u(w)$). In this section we describe an algorithm that for each leaf v again predicts the previous leaf, but in addition predicts the full *path* back to that leaf. For example, rather than making a prediction for leaf 5 that it should be preceded by leaf 4, we would also predict the path $\langle 4\ \uparrow\rangle\langle 4\ \uparrow, 2\ \uparrow\rangle\ \langle 2\ \uparrow, 5\ \downarrow\rangle\langle 5\ \downarrow\rangle$ between these two leaves. Lagrange multipliers will be used to enforce consistency between these predictions (both paths and previous words) and a valid derivation.

Input: A set E of hyperedges. **Output:** A directed graph S, T where S is a set of vertices, and T is a set of edges.
Step 1: Creating S: Define $S = \cup_{e \in E} S(e)$ where $S(e)$ is defined as follows. Assume $e = \langle \langle v_1, v_2, \ldots, v_k \rangle, v_0 \rangle$. Include the following states in $S(e)$: (1) $\langle v_0 \downarrow, v_1 \downarrow \rangle$ and $\langle v_k \uparrow, v_0 \uparrow \rangle$. (2) $\langle v_j \uparrow, v_{j+1} \downarrow \rangle$ for $j = 1 \ldots k-1$ (if $k = 1$ then there are no such states). (3) In addition, for any v_j for $j = 1 \ldots k$ such that $v_j \in V_L$, add the states $\langle v_j \downarrow \rangle$ and $\langle v_j \uparrow \rangle$.
Step 2: Creating T**:** T is formed by including the following directed arcs: (1) Add an arc from $\langle a, b \rangle \in S$ to $\langle c, d \rangle \in S$ whenever $b = c$. (2) Add an arc from $\langle a, b \downarrow \rangle \in S$ to $\langle c \downarrow \rangle \in S$ whenever $b = c$. (3) Add an arc from $\langle a \uparrow \rangle \in S$ to $\langle b \uparrow, c \rangle \in S$ whenever $a = b$.

Figure 2: Algorithm for constructing a directed graph (S, T) from a set of hyperedges E.

5.2 A Formal Description

We first use the algorithm in figure 2 with the entire set of hyperedges, E, as its input. The result is a directed graph (S, T) that contains *all possible paths* for valid derivations in V, E (it also contains additional, ill-formed paths). We then introduce the following definition:

Definition 5.1 A trigram path p *is* $p = \langle v_1, p_1, v_2, p_2, v_3 \rangle$ *where: a)* $v_1, v_2, v_3 \in V_L$*; b)* p_1 *is a path (sequence of states) between nodes* $\langle v_1 \uparrow \rangle$ *and* $\langle v_2 \downarrow \rangle$ *in the graph* (S, T)*; c)* p_2 *is a path between nodes* $\langle v_2 \uparrow \rangle$ *and* $\langle v_3 \downarrow \rangle$ *in the graph* (S, T)*. We define* $\mathcal{P}$ *to be the set of all trigram paths in* (S, T)*.*

The set $\mathcal{P}$ of trigram paths plays an analogous role to the set $\mathcal{B}$ of bigrams in our previous algorithm.

We use $v_1(p), p_1(p), v_2(p), p_2(p), v_3(p)$ to refer to the individual components of a path p. In addition, define S_N to be the set of states in S of the form $\langle a, b \rangle$ (as opposed to the form $\langle c \downarrow \rangle$ or $\langle c \uparrow \rangle$ where $c \in V_L$).

We now define a new index set, $\mathcal{I} = V \cup E \cup S_N \cup \mathcal{P}$, adding variables y_s for $s \in S_N$, and y_p for $p \in \mathcal{P}$. If we take $\mathcal{Y} \subset \{0, 1\}^{|\mathcal{I}|}$ to be the set of valid derivations, the optimization problem is to find $y^* = \arg\max_{y \in \mathcal{Y}} f(y)$, where $f(y) = \theta \cdot y$, that is,

$$f(y) = \sum_v \theta_v y_v + \sum_e \theta_e y_e + \sum_s \theta_s y_s + \sum_p \theta_p y_p$$

In particular, we might define $\theta_s = 0$ for all s, and $\theta_p = \log p(l(v_3(p)) | l(v_1(p)), l(v_2(p)))$ where $p(w_3 | w_1, w_2)$ is a trigram probability.

- **D0.** The y_v and y_e variables form a valid derivation in the original hypergraph.
- **D1.** For all $s \in S_N$, $y_s = \sum_{e : s \in S(e)} y_e$ (see figure 2 for the definition of $S(e)$).
- **D2.** For all $v \in V_L$, $y_v = \sum_{p : v_3(p) = v} y_p$
- **D3.** For all $v \in V_L$, $y_v = \sum_{p : v_2(p) = v} y_p$
- **D4.** For all $v \in V_L$, $y_v = \sum_{p : v_1(p) = v} y_p$
- **D5.** For all $s \in S_N$, $y_s = \sum_{p : s \in p_1(p)} y_p$
- **D6.** For all $s \in S_N$, $y_s = \sum_{p : s \in p_2(p)} y_p$
- Lagrangian with Lagrange multipliers for **D3**–**D6**:

$$\begin{aligned} L(y, \lambda, \gamma, u, v) = \theta \cdot y \\ + \textstyle\sum_v \lambda_v \left(y_v - \sum_{p : v_2(p) = v} y_p \right) \\ + \textstyle\sum_v \gamma_v \left(y_v - \sum_{p : v_1(p) = v} y_p \right) \\ + \textstyle\sum_s u_s \left(y_s - \sum_{p : s \in p_1(p)} y_p \right) \\ + \textstyle\sum_s v_s \left(y_s - \sum_{p : s \in p_2(p)} y_p \right). \end{aligned}$$

Figure 3: Constraints **D0**–**D6**, and the Lagrangian.

The set $\mathcal{P}$ is large (typically exponential in size): however, we will see that we do not need to represent the y_p variables explicitly. Instead we will be able to leverage the underlying structure of a path as a sequence of states.

The set of valid derivations is $\mathcal{Y} = \{y : y \text{ satisfies constraints } \mathbf{D0}\text{–}\mathbf{D6}\}$ where the constraints are shown in figure 3. **D1** simply states that $y_s = 1$ iff there is exactly one edge e in the derivation such that $s \in S(e)$. Constraints **D2**–**D4** enforce consistency between leaves in the trigram paths, and the y_v values. Constraints **D5** and **D6** enforce consistency between states seen in the paths, and the y_s values.

The Lagrangian relaxation algorithm is then derived in a similar way to before. Define

$$\mathcal{Y}' = \{y : y \text{ satisfies constraints } \mathbf{D0}\text{–}\mathbf{D2}\}$$

We have dropped the **D3**–**D6** constraints, but these will be introduced using Lagrange multipliers. The resulting Lagrangian is shown in figure 3, and can be written as $L(y, \lambda, \gamma, u, v) = \beta \cdot y$ where $\beta_v = \theta_v + \lambda_v + \gamma_v$, $\beta_s = \theta_s + u_s + v_s$, $\beta_p = \theta_p - \lambda(v_2(p)) - \gamma(v_1(p)) - \sum_{s \in p_1(p)} u(s) - \sum_{s \in p_2(p)} v(s)$.

The dual is $L(\lambda, \gamma, u, v) = \max_{y \in \mathcal{Y}'} L(y, \lambda, \gamma, u, v)$; figure 4 shows a subgradient method that minimizes this dual. The key step in the algorithm at each iteration is to compute

Initialization: Set $\lambda^0 = 0, \gamma^0 = 0, u^0 = 0, v^0 = 0$
Algorithm: For $t = 1 \ldots T$:

- $y^t = \arg\max_{y \in \mathcal{Y}'} L(y, \lambda^{t-1}, \gamma^{t-1}, u^{t-1}, v^{t-1})$
- If y^t satisfies the constraints **D3**–**D6**, return y^t, else:
  - $\forall v \in V_L, \lambda_v^t = \lambda_v^{t-1} - \delta^t(y_v^t - \sum_{p:v_2(p)=v} y_p^t)$
  - $\forall v \in V_L, \gamma_v^t = \gamma_v^{t-1} - \delta^t(y_v^t - \sum_{p:v_1(p)=v} y_p^t)$
  - $\forall s \in S_N, u_s^t = u_s^{t-1} - \delta^t(y_s^t - \sum_{p:s \in p_1(p)} y_p^t)$
  - $\forall s \in S_N, v_s^t = v_s^{t-1} - \delta^t(y_s^t - \sum_{p:s \in p_2(p)} y_p^t)$

Figure 4: The full Lagrangian relaxation algortihm. $\delta^t > 0$ is the step size at iteration t.

$\arg\max_{y \in \mathcal{Y}'} L(y, \lambda, \gamma, u, v) = \arg\max_{y \in \mathcal{Y}'} \beta \cdot y$ where β is defined above. Again, our definition of $\mathcal{Y}'$ allows this maximization to be performed efficiently, as follows:

1. For each $v \in V_L$, define $\alpha_v^* = \arg\max_{p:v_3(p)=v} \beta(p)$, and $\alpha_v = \beta(\alpha_v^*)$. (i.e., for each v, compute the highest scoring trigram path ending in v.)

2. Find values for the y_v, y_e and y_s variables that form a valid derivation, and that maximize $f'(y) = \sum_v (\beta_v + \alpha_v) y_v + \sum_e \beta_e y_e + \sum_s \beta_s y_s$

3. Set $y_p = 1$ iff $y_{v_3(p)} = 1$ and $p = \alpha^*_{v_3(p)}$.

The first step involves finding the highest scoring incoming trigram path for each leaf v. This step can be performed efficiently using the Floyd-Warshall all-pairs shortest path algorithm (Floyd, 1962) over the graph (S, T); the details are given in the appendix. The second step involves simple dynamic programming over the hypergraph (V, E) (it is simple to integrate the β_s terms into this algorithm). In the third step, the path variables y_p are filled in.

5.3 Properties

We now describe some important properties of the algorithm:

Efficiency. The main steps of the algorithm are: 1) construction of the graph (S, T); 2) at each iteration, dynamic programming over the hypergraph (V, E); 3) at each iteration, all-pairs shortest path algorithms over the graph (S, T). Each of these steps is vastly more efficient than computing an exact intersection of the hypergraph with a language model.

Exact solutions. By usual guarantees for Lagrangian relaxation, if at any point the algorithm returns a solution y^t that satisfies constraints **D3**–**D6**, then y^t exactly solves the problem in Eq. 1.

Upper bounds. At each point in the algorithm, $L(\lambda^t, \gamma^t, u^t, v^t)$ is an upper bound on the score of the optimal primal solution, $f(y^*)$. Upper bounds can be useful in evaluating the quality of primal solutions from either our algorithm or other methods such as cube pruning.

Simplicity of implementation. Construction of the (S, T) graph is straightforward. The other steps—hypergraph dynamic programming, and all-pairs shortest path—are widely known algorithms that are simple to implement.

6 Tightening the Relaxation

The algorithm that we have described minimizes the dual function $L(\lambda, \gamma, u, v)$. By usual results for Lagrangian relaxation (e.g., see (Korte and Vygen, 2008)), L is the dual function for a particular LP relaxation arising from the definition of $\mathcal{Y}'$ and the additional constaints **D3**–**D6**. In some cases the LP relaxation has an integral solution, in which case the algorithm will return an optimal solution y^t.[7] In other cases, when the LP relaxation has a fractional solution, the subgradient algorithm will still converge to the minimum of L, but the primal solutions y^t will move between a number of solutions.

We now describe a method that incrementally adds hard constraints to the set $\mathcal{Y}'$, until the method returns an exact solution. For a given $y \in \mathcal{Y}'$, for any v with $y_v = 1$, we can recover the previous two leaves (the trigram ending in v) from either the path variables y_p, or the hypergraph variables y_e. Specifically, define $v_{-1}(v, y)$ to be the leaf preceding v in the trigram path p with y_p = 1 and $v_3(p) = v$, and $v_{-2}(v, y)$ to be the leaf two positions before v in the trigram path p with $y_p = 1$ and $v_3(p) = v$. Similarly, define $v'_{-1}(v, y)$ and $v'_{-2}(v, y)$ to be the preceding two leaves under the y_e variables. If the method has not converged, these two trigram definitions may not be consistent. For a con-

[7] Provided that the algorithm is run for enough iterations for convergence.

sistent solution, we require $v_{-1}(v, y) = v'_{-1}(v, y)$ and $v_{-2}(v, y) = v'_{-2}(v, y)$ for all v with $y_v = 1$. Unfortunately, explicitly enforcing all of these constraints would require exhaustive dynamic programming over the hypergraph using the (Bar-Hillel et al., 1964) method, something we wish to avoid.

Instead, we enforce a weaker set of constraints, which require far less computation. Assume some function $\pi : V_L \rightarrow \{1, 2, \ldots q\}$ that partitions the set of leaves into q different partitions. Then we will add the following constraints to $\mathcal{Y}'$:

$$\begin{aligned} \pi(v_{-1}(v, y)) &= \pi(v'_{-1}(v, y)) \\ \pi(v_{-2}(v, y)) &= \pi(v'_{-2}(v, y)) \end{aligned}$$

for all v such that $y_v = 1$. Finding $\arg\max_{y \in \mathcal{Y}'} \theta \cdot y$ under this new definition of $\mathcal{Y}'$ can be performed using the construction of (Bar-Hillel et al., 1964), with q different lexical items (for brevity we omit the details). This is efficient if q is small.[8]

The remaining question concerns how to choose a partition π that is effective in tightening the relaxation. To do this we implement the following steps: 1) run the subgradient algorithm until L is close to convergence; 2) then run the subgradient algorithm for m further iterations, keeping track of all pairs of leaf nodes that violate the constraints (i.e., pairs $a = v_{-1}(v, y)/b = v'_{-1}(v, y)$ or $a = v_{-2}(v, y)/b = v'_{-2}(v, y)$ such that $a \neq b$); 3) use a graph coloring algorithm to find a small partition that places all pairs $\langle a, b \rangle$ into separate partitions; 4) continue running Lagrangian relaxation, with the new constraints added. We expand π at each iteration to take into account new pairs $\langle a, b \rangle$ that violate the constraints.

In related work, Sontag et al. (2008) describe a method for inference in Markov random fields where additional constraints are chosen to tighten an underlying relaxation. Other relevant work in NLP includes (Tromble and Eisner, 2006; Riedel and Clarke, 2006). Our use of partitions π is related to previous work on coarse-to-fine inference for machine translation (Petrov et al., 2008).

7 Experiments

We report experiments on translation from Chinese to English, using the tree-to-string model described in (Huang and Mi, 2010). We use an identical model, and identical development and test data, to that used by Huang and Mi.[9] The translation model is trained on 1.5M sentence pairs of Chinese-English data; a trigram language model is used. The development data is the newswire portion of the 2006 NIST MT evaluation test set (616 sentences). The test set is the newswire portion of the 2008 NIST MT evaluation test set (691 sentences).

Time	%age (LR)	%age (DP)	%age (ILP)	%age (LP)
0.5s	37.5	10.2	8.8	21.0
1.0s	57.0	11.6	13.9	31.1
2.0s	72.2	15.1	21.1	45.9
4.0s	82.5	20.7	30.7	63.7
8.0s	88.9	25.2	41.8	78.3
16.0s	94.4	33.3	54.6	88.9
32.0s	97.8	42.8	68.5	95.2
Median time	0.79s	77.5s	12.1s	2.4s

Figure 5: Results showing percentage of examples that are decoded in less than t seconds, for $t = 0.5, 1.0, 2.0, \ldots, 32.0$. LR = Lagrangian relaxation; DP = exhaustive dynamic programming; ILP = integer linear programming; LP = linear programming (LP does not recover an exact solution). The (I)LP experiments were carried out using Gurobi, a high-performance commercial-grade solver.

We ran the full algorithm with the tightening method described in section 6. We ran the method for a limit of 200 iterations, hence some examples may not terminate with an exact solution. Our method gives exact solutions on 598/616 development set sentences (97.1%), and 675/691 test set sentences (97.7%).

In cases where the method does not converge within 200 iterations, we can return the best primal solution y^t found by the algorithm during those iterations. We can also get an upper bound on the difference $f(y^*) - f(y^t)$ using $\min_t L(u_t)$ as an upper bound on $f(y^*)$. Of the examples that did not converge, the worst example had a bound that was 1.4% of $f(y^t)$ (more specifically, $f(y^t)$ was -24.74, and the upper bound on $f(y^*) - f(y^t)$ was 0.34).

Figure 5 gives information on decoding time for our method and two other exact decoding methods: integer linear programming (using constraints **D0**–**D6**), and exhaustive dynamic programming using the construction of (Bar-Hillel et al., 1964). Our

[8] In fact in our experiments we use the original hypergraph to compute admissible outside scores for an exact A* search algorithm for this problem. We have found the resulting search algorithm to be very efficient.

[9] We thank Liang Huang and Haitao Mi for providing us with their model and data.

method is clearly the most efficient, and is comparable in speed to state-of-the-art decoding algorithms.

We also compare our method to cube pruning (Chiang, 2007; Huang and Chiang, 2007). We reimplemented cube pruning in C++, to give a fair comparison to our method. Cube pruning has a parameter, b, dictating the maximum number of items stored at each chart entry. With $b = 50$, our decoder finds higher scoring solutions on 50.5% of all examples (349 examples), the cube-pruning method gets a strictly higher score on only 1 example (this was one of the examples that did not converge within 200 iterations). With $b = 500$, our decoder finds better solutions on 18.5% of the examples (128 cases), cube-pruning finds a better solution on 3 examples. The median decoding time for our method is 0.79 seconds; the median times for cube pruning with $b = 50$ and $b = 500$ are 0.06 and 1.2 seconds respectively.

Our results give a very good estimate of the percentage of search errors for cube pruning. A natural question is how large b must be before exact solutions are returned on almost all examples. Even at $b = 1000$, we find that our method gives a better solution on 95 test examples (13.7%).

Figure 5 also gives a speed comparison of our method to a linear programming (LP) solver that solves the LP relaxation defined by constraints **D0**–**D6**. We still see speed-ups, in spite of the fact that our method is solving a harder problem (it provides integral solutions). The Lagrangian relaxation method, when run without the tightening method of section 6, is solving a dual of the problem being solved by the LP solver. Hence we can measure how often the tightening procedure is absolutely necessary, by seeing how often the LP solver provides a fractional solution. We find that this is the case on 54.0% of the test examples: the tightening procedure is clearly important. Inspection of the tightening procedure shows that the number of partitions required (the parameter q) is generally quite small: 59% of examples that require tightening require $q \leq 6$; 97.2% require $q \leq 10$.

8 Conclusion

We have described a Lagrangian relaxation algorithm for exact decoding of syntactic translation models, and shown that it is significantly more efficient than other exact algorithms for decoding tree-to-string models. There are a number of possible ways to extend this work. Our experiments have focused on tree-to-string models, but the method should also apply to Hiero-style syntactic translation models (Chiang, 2007). Additionally, our experiments used a trigram language model, however the constraints in figure 3 generalize to higher-order language models. Finally, our algorithm recovers the 1-best translation for a given input sentence; it should be possible to extend the method to find k-best solutions.

A Computing the Optimal Trigram Paths

For each $v \in V_L$, define $\alpha_v = \max_{p:v_3(p)=v} \beta(p)$, where $\beta(p) = h(v_1(p), v_2(p), v_3(p)) - \lambda_1(v_1(p)) - \lambda_2(v_2(p)) - \sum_{s \in p_1(p)} u(s) - \sum_{s \in p_2(p)} v(s)$. Here h is a function that computes language model scores, and the other terms involve Lagrange mulipliers. Our task is to compute α_v^* for all $v \in V_L$.

It is straightforward to show that the S, T graph is *acyclic*. This will allow us to apply shortest path algorithms to the graph, even though the weights $u(s)$ and $v(s)$ can be positive or negative.

For any pair $v_1, v_2 \in V_L$, define $\mathcal{P}(v_1, v_2)$ to be the set of paths between $\langle v_1 \uparrow \rangle$ and $\langle v_2 \downarrow \rangle$ in the graph S, T. Each path p gets a score $score_u(p) = -\sum_{s \in p} u(s)$. Next, define $p_u^*(v_1, v_2) = \arg\max_{p \in \mathcal{P}(v_1, v_2)} score_u(p)$, and $score_u^*(v_1, v_2) = score_u(p^*)$. We assume similar definitions for $p_v^*(v_1, v_2)$ and $score_v^*(v_1, v_2)$. The p_u^* and $score_u^*$ values can be calculated using an all-pairs shortest path algorithm, with weights $u(s)$ on nodes in the graph. Similarly, p_v^* and $score_v^*$ can be computed using all-pairs shortest path with weights $v(s)$ on the nodes.

Having calculated these values, define $\mathcal{T}(v)$ for any leaf v to be the set of trigrams (x, y, v) such that: 1) $x, y \in V_L$; 2) there is a path from $\langle x \uparrow \rangle$ to $\langle y \downarrow \rangle$ and from $\langle y \uparrow \rangle$ to $\langle v \downarrow \rangle$ in the graph S, T. Then we can calculate

$$\alpha_v = \max_{(x,y,v) \in \mathcal{T}(v)} (h(x, y, v) - \lambda_1(x) - \lambda_2(y) + p_u^*(x, y) + p_v^*(y, v))$$

in $O(|\mathcal{T}(v)|)$ time, by brute force search through the set $\mathcal{T}(v)$.

Abstract

We propose methods for estimating the probability that an entity from an entity database is associated with a web search query. Association is modeled using a query entity click graph, blending general query click logs with vertical query click logs. Smoothing techniques are proposed to address the inherent data sparsity in such graphs, including interpolation using a query synonymy model. A large-scale empirical analysis of the smoothing techniques, over a 2-year click graph collected from a commercial search engine, shows significant reductions in modeling error. The association models are then applied to the task of recommending products to web queries, by annotating queries with products from a large catalog and then mining query-product associations through web search session analysis. Experimental analysis shows that our smoothing techniques improve coverage while keeping precision stable, and overall, that our top-performing model affects 9% of general web queries with 94% precision.

1 Introduction

Commercial search engines use query associations in a variety of ways, including the recommendation of related queries in Bing, 'something different' in Google, and 'also try' and related concepts in Yahoo. Mining techniques to extract such query associations generally fall into four categories: (a) clustering queries by their co-clicked url patterns (Wen et al., 2001; Baeza-Yates et al., 2004); (b) leveraging co-occurrences of sequential queries in web search query sessions (Zhang and Nasraoui, 2006; Boldi et al., 2009); (c) pattern-based extraction over lexico-syntactic structures of individual queries (Paşca and Durme, 2008; Jain and Pantel, 2009); and (d) distributional similarity techniques over news or web corpora (Agirre et al., 2009; Pantel et al., 2009). These techniques operate at the surface level, associating one surface context (e.g., queries) to another.

In this paper, we focus instead on associating surface contexts with entities that refer to a particular entry in a knowledge base such as Freebase, IMDB, Amazon's product catalog, or The Library of Congress. Whereas the former models might associate the string "*Ronaldinho*" with the strings "*AC Milan*" or "*Lionel Messi*", our goal is to associate "*Ronaldinho*" with, for example, the Wikipedia entity page "*wiki/AC_Milan*" or the Freebase entity "*en/lionel_mess*". Or for the query string "*ice fishing*", we aim to recommend products in a commercial catalog, such as jigs or lures.

The benefits and potential applications are large. By knowing the entity identifiers associated with a query (instead of strings), one can greatly improve both the presentation of search results as well as the click-through experience. For example, consider when the associated entity is a product. Not only can we present the product name to the web user, but we can also display the image, price, and reviews associated with the entity identifier. Once the entity is clicked, instead of issuing a simple web search query, we can now directly show a product page for the exact product; or we can even perform actions directly on the entity, such as buying the entity on Amazon.com, retrieving the product's oper-

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 83–92,
Portland, Oregon, June 19-24, 2011.

ating manual, or even polling your social network for friends that own the product. This is a big step towards a richer semantic search experience.

In this paper, we define the association between a query string q and an entity id e as the probability that e is relevant given the query q, $P(e|q)$. Following Baeza-Yates et al. (2004), we model relevance as the likelihood that a user would click on e given q, events which can be observed in large query-click graphs. Due to the extreme sparsity of query click graphs (Baeza-Yates, 2004), we propose several smoothing models that extend the click graph with query synonyms and then use the synonym click probabilities as a background model. We demonstrate the effectiveness of our smoothing models, via a large-scale empirical study over real-world data, which significantly reduce model errors. We further apply our models to the task of query-product recommendation. Queries in session logs are annotated using our association probabilities and recommendations are obtained by modeling session-level query-product co-occurrences in the annotated sessions. Finally, we demonstrate that our models affect 9% of general web queries with 94% recommendation precision.

2 Related Work

We introduce a novel application of significant commercial value: entity recommendations for general Web queries. This is different from the vast body of work on query suggestions (Baeza-Yates et al., 2004; Fuxman et al., 2008; Mei et al., 2008b; Zhang and Nasraoui, 2006; Craswell and Szummer, 2007; Jagabathula et al., 2011), because our suggestions are actual entities (as opposed to queries or documents). There is also a rich literature on recommendation systems (Sarwar et al., 2001), including successful commercial systems such as the Amazon product recommendation system (Linden et al., 2003) and the Netflix movie recommendation system (Bell et al., 2007). However, these are entity-to-entity recommendations systems. For example, Netflix recommends movies based on previously seen movies (i.e., entities). Furthermore, these systems have access to previous transactions (i.e., actual movie rentals or product purchases), whereas our recommendation system leverages a different resource, namely query sessions.

In principle, one could consider vertical search engines (Nie et al., 2007) as a mechanism for associating queries to entities. For example, if we type the query "canon eos digital camera" on a commerce search engine such as Bing Shopping or Google Products, we get a listing of digital camera entities that satisfy our query. However, vertical search engines are essentially rankers that given a query, return a sorted list of (pointers to) entities that are related to the query. That is, they do not expose actual association scores, which is a key contribution of our work, nor do they operate on general search queries.

Our smoothing methods for estimating association probabilities are related to techniques developed by the NLP and speech communities to smooth n-gram probabilities in language modeling. The simplest are discounting methods, such as *additive smoothing* (Lidstone, 1920) and *Good-Turing* (Good, 1953). Other methods leverage lower-order background models for low-frequency events, such as Katz' backoff smoothing (Katz, 1987), Witten-Bell discounting (Witten and Bell, 1991), Jelinek-Mercer interpolation (Jelinek and Mercer, 1980), and Kneser-Ney (Kneser and Ney, 1995).

In the information retrieval community, Ponte and Croft (1998) are credited for accelerating the use of language models. Initial proposals were based on learning *global* smoothing models, where the smoothing of a word would be independent of the document that the word belongs to (Zhai and Lafferty, 2001). More recently, a number of *local* smoothing models have been proposed (Liu and Croft, 2004; Kurland and Lee, 2004; Tao et al., 2006). Unlike global models, local models leverage relationships between documents in a corpus. In particular, they rely on a graph structure that represents document similarity. Intuitively, the smoothing of a word in a document is influenced by the smoothing of the word in similar documents. For a complete survey of these methods and a general optimization framework that encompasses all previous proposals, please see the work of Mei, Zhang et al. (2008a). All the work on local smoothing models has been applied to the prediction of priors for words in documents. To the best of our knowledge, we are the first to establish that query-click graphs can be used to

create accurate models of query-entity associations.

3 Association Model

Task Definition: Consider a collection of entities E. Given a search query q, our task is to compute $P(e|q)$, the probability that an entity e is relevant to q, for all $e \in E$.

We limit our model to sets of entities that can be accessed through urls on the web, such as Amazon.com products, IMDB movies, Wikipedia entities, and Yelp points of interest.

Following Baeza-Yates et al. (2004), we model relevance as the click probability of an entity given a query, which we can observe from click logs of vertical search engines, i.e., domain-specific search engines such as the product search engine at Amazon, the local search engine at Yelp, or the travel search engine at Bing Travel. Clicked results in a vertical search engine are edges between queries and entities e in the vertical's knowledge base. General search query click logs, which capture direct user intent signals, have shown significant improvements when used for web search ranking (Agichtein et al., 2006). Unlike for general search engines, vertical search engines have typically much less traffic resulting in extremely sparse click logs.

In this section, we define a graph structure for recording click information and we propose several models for estimating $P(e|q)$ using the graph.

3.1 Query Entity Click Graph

We define a *query entity click graph*, $QEC(Q \cup U \cup E, C_u \cup C_e)$, as a tripartite graph consisting of a set of query nodes Q, url nodes U, entity nodes E, and weighted edges C_u exclusively between nodes of Q and nodes of U, as well as weighted edges C_e exclusively between nodes of Q and nodes of E. Each edge in C_u and C_e represents the number of clicks observed between query-url pairs and query-entity pairs, respectively. Let $w_u(q, u)$ be the click weight of the edges in C_u, and $w_e(q, e)$ be the click weight of the edges in C_e.

If C_e is very large, then we can model the association probability, $P(e|q)$, as the maximum likelihood estimation (MLE) of observing clicks on e given the query q:

$$\hat{P}_{mle}(e|q) = \frac{w_e(q,e)}{\sum_{e' \in E} w_e(q,e')} \quad (3.1)$$

Figure 1 illustrates an example query entity graph linking general web queries to entities in a large commercial product catalog. Figure 1a illustrates eight queries in Q with their observed clicks (solid lines) with products in E[1]. Some probability estimates, assigned by Equation 3.1, include: $\hat{P}_{mle}(\text{panfish jigs}, e_1) = 0$, $\hat{P}_{mle}(\text{ice jigs}, e_1) = 1$, and $\hat{P}_{mle}(\text{ice auger}, e_4) = \frac{c_e(\text{ice auger},e_4)}{c_e(\text{ice auger},e_3)+c_e(\text{ice auger},e_4)}$.

Even for the largest search engines, query click logs are extremely sparse, and smoothing techniques are necessary (Craswell and Szummer, 2007; Gao et al., 2009). By considering only C_e, those clicked urls that map to our entity collection E, the sparsity situation is even more dire. The sparsity of the graph comes in two forms: a) there are many queries for which an entity is relevant that will never be seen in the click logs (e.g., "panfish jig" in Figure 1a); and b) the query-click distribution is Zipfian and most observed edges will have very low click counts yielding unreliable statistics. In the following subsections, we present a method to expand QEC with unseen queries that are associated with entities in E. Then we propose smoothing methods for leveraging a background model over the expanded click graph.

Throughout our models, we make the simplifying assumption that the knowledge base E is complete.

3.2 Graph Expansion

Following Gao et al. (2009), we address the sparsity of edges in C_e by inferring new edges through traversing the query-url click subgraph, $UC(Q \cup U, C_u)$, *which contains many more edges than* C_e. If two queries q_i and q_j are synonyms or near synonyms[2], then we expect their click patterns to be similar.

We define the synonymy similarity, $s(q_i, q_j)$ as the cosine of the angle between $\mathbf{q_i}$ and $\mathbf{q_j}$, the click pattern vectors of q_i and q_j, respectively:

$$\text{cosine}(\mathbf{q_i}, \mathbf{q_j}) = \frac{\mathbf{q_i} \cdot \mathbf{q_j}}{\sqrt{\mathbf{q_i} \cdot \mathbf{q_i}} \cdot \sqrt{\mathbf{q_j} \cdot \mathbf{q_j}}}$$

where $\mathbf{q}$ is an n_u dimensional vector consisting of the pointwise mutual information between q and each url u in U, $\text{pmi}(q, u)$:

[1] Clicks are collected from a commerce vertical search engine described in Section 5.1.

[2] A query q_i is a near synonym of a query q_j if most relevant results of q_i are also relevant to q_j. Section 5.2.1 describes our adopted metric for near synonymy.

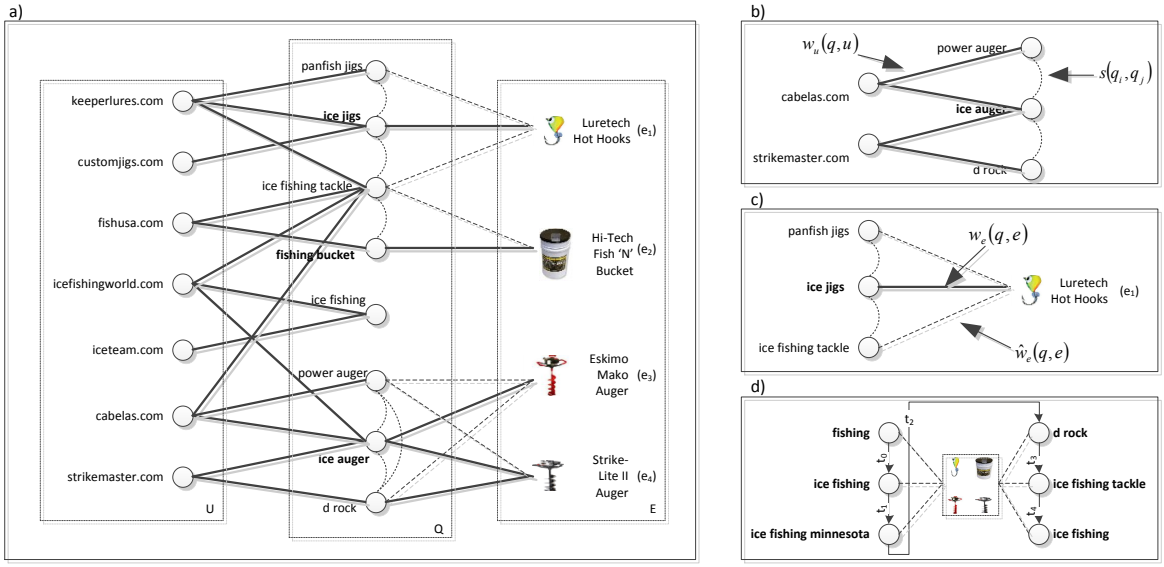

Figure 1: Example QEC graph: (a) Sample queries in Q, clicks connecting queries with urls in U, and clicks to entities in E; (b) Zoom on edges in C_u illustrating clicks observed on urls with weight $w_u(q,u)$ as well as synonymy edges between queries with similarity score $s(q_i,q_j)$ (Section 3.2); (c) Zoom on edges in C_e where solid lines indicate observed clicks with weight $w_e(q,e)$ and dotted lines indicate inferred clicks with smoothed weight $\hat{w}_e(q,e)$ (Section 3.3); and (d) A temporal sequence of queries in a search session illustrating entity associations propagating from the QEC graph to the queries in the session (Section 4).

$$\text{pmi}(q,u) = \log\left(\frac{w_u(q,u)\times\sum_{q'\in Q,u'\in U} w_u(q',u')}{\sum_{u'\in U} w_u(q,u')\sum_{q'\in Q} w_u(q',u)}\right) \tag{3.2}$$

PMI is known to be biased towards infrequent events. We apply the discounting factor, $\delta(q,u)$, proposed in (Pantel and Lin, 2002):

$$\delta(q,u)=\frac{w_u(q,u)}{w_u(q,u)+1}\cdot\frac{\min\left(\sum_{q'\in Q} w_u(q',u),\sum_{u'\in U} w_u(q,u')\right)}{\min\left(\sum_{q'\in Q} w_u(q',u),\sum_{u'\in U} w_u(q,u')\right)+1}$$

Enrichment: We enrich the original QEC graph by creating a new edge $\{q',e\}$, where $q'\in Q$ and $e\in E$, if there exists a query q where $s(q,q')>\rho$ and $w_e(q,e)>0$. ρ is set experimentally, as described in Section 5.2.

Figure 1b illustrates similarity edges created between query "ice auger" and both "power auger" and "d rock". Since "ice auger" was connected to entities e_3 and e_4 in the original QEC, our expansion model creates new edges in C_e between {power auger, e_3}, {power auger, e_4}, and {d rock, e_3}.

For each newly added edge $\{q,e\}$, $\hat{P}_{mle}=0$ according to our model from Equation 3.1 since we have never observed any clicks between q and e. Instead, we define a new model that uses $\hat{P}_{mle}$ when clicks are observed and otherwise assigns uniform probability mass, as:

$$\hat{P}_{hybr}(e|q)=\begin{cases}\hat{P}_{mle}(e|q) & \text{if } \exists e'|w_e(q,e')>0\\ \frac{1}{\sum_{e'\in E}\phi(q,e')} & \text{otherwise}\end{cases} \tag{3.3}$$

where $\phi(q,e)$ is an indicator variable which is 1 if there is an edge between $\{q,e\}$ in C_e.

This model does not leverage the local synonymy graph in order to transfer edge weight to unseen edges. In the next section, we investigate smoothing techniques for achieving this.

3.3 Smoothing

Smoothing techniques can be useful to alleviate data sparsity problems common in statistical models. In practice, methods that leverage a background model (e.g., a lower-order *n*-gram model) have shown most promise (Katz, 1987; Witten and Bell, 1991; Jelinek and Mercer, 1980; Kneser and Ney, 1995). In this section, we present two smoothing methods, derived from Jelinek-Mercer interpolation (Jelinek and Mercer, 1980), for estimating the target association probability $P(e|q)$.

Figure 1c highlights two edges, illustrated with dashed lines, inserted into C_e during the graph expansion phase of Section 3.2. $\hat{w}_e(q,e)$ represents the weight of our background model, which can be viewed as smoothed click counts, and are obtained

Label	Model	Reference
UNIF	$\hat{P}_{unif}(e\|q)$	Eq. 3.8

HYBR	$\hat{P}_{hybr}(e\|q)$	Eq. 3.3
INTU	$\hat{P}_{intu}(e\|q)$	Eq. 3.6
INTP	$\hat{P}_{intp}(e\|q)$	Eq. 3.7

Table 1: Models for estimating the association probability $P(e|q)$.

by propagating clicks to unseen edges using the synonymy model as follows:

$$\hat{w}_e(q,e) = \sum_{q' \in Q} \frac{s(q,q')}{N_{s_q}} \times \hat{P}_{mle}(e|q') \quad (3.4)$$

where $N_{s_q} = \sum_{q' \in Q} s(q,q')$. By normalizing the smoothed weights, we obtain our background model, $\hat{P}_{bsim}$:

$$\hat{P}_{bsim}(e|q) = \frac{\hat{w}_e(q,e)}{\sum_{e' \in E} \hat{w}_e(q,e')} \quad (3.5)$$

Below we propose two models for interpolating our foreground model from Equation 3.1 with the background model from Equation 3.5.

Basic Interpolation: This smoothing model, $\hat{P}_{intu}(e|q)$, linearly combines our foreground and background models using a model parameter α:

$$\hat{P}_{intu}(e|q) = \alpha \hat{P}_{mle}(e|q) + (1-\alpha)\hat{P}_{bsim}(e|q) \quad (3.6)$$

Bucket Interpolation: Intuitively, edges $\{q,e\} \in C_e$ with higher observed clicks, $w_e(q,e)$, should be trusted more than those with low or no clicks. A limitation of $\hat{P}_{intu}(e|q)$ is that it weighs the foreground and background models in the same way irrespective of the observed foreground clicks. Our final model, $\hat{P}_{intp}(e|q)$ parameterizes the interpolation by the number of observed clicks:

$$\begin{aligned}\hat{P}_{intp}(e|q) = &\alpha[w_e(q,e)]\hat{P}_{mle}(e|q) \\ &+ (1 - \alpha[w_e(q,e)])\hat{P}_{bsim}(e|q)\end{aligned} \quad (3.7)$$

In practice, we bucket the observed click parameter, $w_e(q,e)$, into eleven buckets: {1-click, 2-clicks, ..., 10-clicks, more than 10 clicks}.

Section 5.2 outlines our procedure for learning the model parameters for both $\hat{P}_{intu}(e|q)$ and $\hat{P}_{intp}(e|q)$.

3.4 Summary

Table 1 summarizes the association models presented in this section as well as a strawman that assigns uniform probability to all edges in QEC:

$$\hat{P}_{unif}(e|q) = \frac{1}{\sum_{e' \in E} \phi(q,e')} \quad (3.8)$$

In the following section, we apply these models to the task of extracting product recommendations for general web search queries. A large-scale experimental study is presented in Section 5 supporting the effectiveness of our models.

4 Entity Recommendation

Query recommendations are pervasive in commercial search engines. Many systems extract recommendations by mining temporal query chains from search sessions and clickthrough patterns (Zhang and Nasraoui, 2006). We adopt a similar strategy, except instead of mining query-query associations, we propose to mine query-entity associations, where entities come from an entity database as described in Section 1. Our technical challenge lies in annotating sessions with entities that are relevant to the session.

4.1 Product Entity Domain

Although our model generalizes to any entity domain, we focus now on a product domain. Specifically, our universe of entities, E, consists of the entities in a large commercial product catalog, for which we observe query-click-product clicks, C_e, from the vertical search logs. Our QEC graph is completed by extracting query-click-urls from a search engine's general search logs, C_u. These datasets are described in Section 5.1.

4.2 Recommendation Algorithm

We hypothesize that if an entity is relevant to a query, then it is relevant to all other queries co-occurring in the same session. Key to our method are the models from Section 3.

Step 1 – Query Annotation: For each query q in a session s, we annotate it with a set E_q, consisting of every pair $\{e, \hat{P}(e|q)\}$, where $e \in E$ such that there exists an edge $\{q,e\} \in C_e$ with probability $\hat{P}(e|q)$. Note that E_q will be empty for many queries.

Step 2 – Session Analysis: We build a query-entity frequency co-occurrence matrix, $\mathbf{A}$, consisting of $n_{|Q|}$ rows and $n_{|E|}$ columns, where each row corresponds to a query and each column to an entity.

The value of the cell A_{qe} is the sum over each session s, of the maximum edge weight between any query $q' \in s$ and e[3]:

$$A_{qe} = \sum_{s \in \mathbf{S}} \psi(s, e)$$

where $\mathbf{S}$ consists of all observed search sessions and:

$$\psi(s, e) = \arg\max_{\hat{P}(e|q')} (\{e, \hat{P}(e|q')\} \in E_{q'}), \forall q' \in s$$

Step 3 – Ranking: We compute ranking scores between each query q and entity e using pointwise mutual information over the frequencies in $\mathbf{A}$, similarly to Eq. 3.2.

The final recommendations for a query q are obtained by returning the top-k entities e according to Step 3. Filters may be applied on: f the frequency A_{qe}; and p the pointwise mutual information ranking score between q and e.

5 Experimental Results

5.1 Datasets

We instantiate our models from Sections 3 and 4 using search query logs and a large catalog of products from a commercial search engine. We form our QEC graphs by first collecting in C_e aggregate query-click-entity counts observed over two years in a commerce vertical search engine. Similarly, C_u is formed by collecting aggregate query-click-url counts observed over six months in a web search engine, where each query must have frequency at least 10. Three final QEC graphs are sampled by taking various snapshots of the above graph as follows: a) TRAIN consists of 50% of the graph; b) TEST consists of 25% of the graph; c) DEV consists of 25% of the graph.

5.2 Association Models

5.2.1 Model Parameters

We tune the α parameters for $\hat{P}_{intu}$ and $\hat{P}_{intp}$ against the DEV QEC graph. There are twelve parameters to be tuned: α for $\hat{P}_{intu}$ and $\alpha(1)$, $\alpha(2)$, ..., $\alpha(10)$, $\alpha(> 10)$ for $\hat{P}_{intp}$, where $\alpha(x)$ is the observed click bucket as described in Section 3.3. For each, we choose the parameter value that minimizes the mean-squared error (MSE) of the DEV set, where model probabilities are computed using the TRAIN QEC graph. Figure 2 illustrates the MSE ranging over [0, 0.05, 0.1, ..., 1].

[3]Note that this co-occurrence occurs because q' was annotated with entity e in the same session as q occurred.

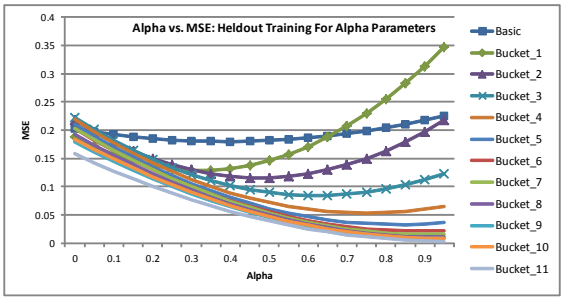

Figure 2: Alpha tuning on held out data.

Model	MSE	Var	Err/MLE	MSE_W	Var	Err/MLE
$\hat{P}_{unif}$	0.0328†	0.0112	-25.7%	0.0663†	0.0211	-71.8%
$\hat{P}_{mle}$	0.0261	0.0111	–	0.0386	0.0141	–
$\hat{P}_{hybr}$	0.0232†	0.0071	11.1%	0.0385	0.0132	0.03%
$\hat{P}_{intu}$	**0.0226**†	**0.0075**	**13.4%**	**0.0369**†	**0.0133**	**4.4%**
$\hat{P}_{intp}$	**0.0213**†	**0.0068**	**18.4%**	**0.0375**†	**0.0131**	**2.8%**

Table 2: Model analysis: MSE and MSE_W with variance and error reduction relative to $\hat{P}_{mle}$. † indicates statistical significance over $\hat{P}_{mle}$ with 95% confidence.

We trained the query synonym model of Section 3.2 on the DEV set and hand-annotated 100 random synonymy pairs according to whether or not the pairs were synonyms [2]. Setting $\rho = 0.4$ results in a precision > 0.9.

5.2.2 Analysis

We evaluate the quality of our models in Table 1 by evaluating their mean-squared error (MSE) against the target $P(e|q)$ computed on the TEST set:

$$MSE(\hat{P}) = \sum_{\{q,e\} \in C_e^T} (P^T(e|q) - \hat{P}(e|q))^2$$

$$MSE_W(\hat{P}) = \sum_{\{q,e\} \in C_e^T} w_e^T(q,e) \cdot (P^T(e|q) - \hat{P}(e|q))^2$$

where C_e^T are the edges in the TEST QEC graph with weight $w_e^T(q, e)$, $P^T(e|q)$ is the target probability computed over the TEST QEC graph, and $\hat{P}$ is one of our models trained on the TRAIN QEC graph. MSE measures against each edge type, which makes it sensitive to the long tail of the click graph. Conversely, MSE_W measures against each edge instance, which makes it a good measure against the head of the click graph. We expect our smoothing models to have much more impact on MSE (i.e., the tail) than on MSE_W since head queries do not suffer from data sparsity.

Table 2 lists the MSE and MSE_W results for each model. We consider $\hat{P}_{unif}$ as a strawman and $\hat{P}_{mle}$ as a strong baseline (i.e., without any graph expansion nor any smoothing against a background

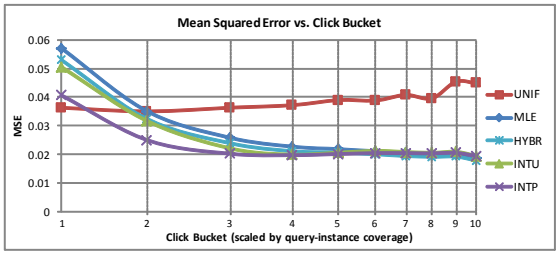

Figure 3: MSE of each model against the number of clicks in the TEST corpus. Buckets scaled by query *instance* coverage of all queries with 10 or fewer clicks.

model). $\hat{P}_{unif}$ performs generally very poorly, however $\hat{P}_{mle}$ is much better, with an expected estimation error of 0.16 accounting for an MSE of 0.0261. As expected, our smoothing models have little improvement on the head-sensitive metric (MSE_W) relative to $\hat{P}_{mle}$. In particular, $\hat{P}_{hybr}$ performs nearly identically to $\hat{P}_{mle}$ on the head. On the tail, all three smoothing models significantly outperform $\hat{P}_{mle}$ with $\hat{P}_{intp}$ reducing the error by 18.4%. Table 3 lists query-product associations for five randomly sampled products along with their model scores from $\hat{P}_{mle}$ with $\hat{P}_{intp}$.

Figure 3 provides an intrinsic view into MSE as a function of the number of observed clicks in the TEST set. As expected, for larger observed click counts (>4), all models perform roughly the same, indicating that smoothing is not necessary. However, for low click counts, which in our dataset accounts for over 20% of the overall click instances, we see a large reduction in MSE with $\hat{P}_{intp}$ outperforming $\hat{P}_{intu}$, which in turn outperforms $\hat{P}_{hybr}$. $\hat{P}_{unif}$ performs very poorly. The reason it does worse as the observed click count rises is that head queries tend to result in more distinct urls with high-variance clicks, which in turn makes a uniform model susceptible to more error.

Figure 3 illustrates that the benefit of the smoothing models is in the tail of the click graph, which supports the larger error reductions seen in MSE in Table 2. For associations only observed once, $\hat{P}_{intp}$ reduces the error by 29% relative to $\hat{P}_{mle}$.

We also performed an editorial evaluation of the query-entity associations obtained with bucket interpolation. We created two samples from the TEST dataset: one randomly sampled by taking click weights into account, and the other sampled uniformly at random. Each set contains results for

Table 3: Example query-product association scores for a random sample of five products. Bold queries resulted from the expansion algorithm in Section 3.2.

100 queries. The former consists of 203 query-product associations, and the latter of 159 associations. The evaluation was done using Amazon Mechanical Turk[4]. We created a Mechanical Turk HIT[5] where we show to the Mechanical Turk workers the query and the actual Web page in a Product search engine. For each query-entity association, we gathered seven labels and considered an association to be correct if five Mechanical Turk workers gave a positive label. An association was considered to be incorrect if at least five workers gave a negative label. Borderline cases where no label got five votes were discarded (14% of items were borderline for the uniform sample; 11% for the weighted sample). To ensure the quality of the results, we introduced 30% of incorrect associations as honeypots. We blocked workers who responded incorrectly on the honeypots so that the precision on honeypots is 1. The result of the evaluation is that the precision of the associations is 0.88 on the weighted sample and 0.90 on the uniform sample.

5.3 Related Product Recommendation

We now present an experimental evaluation of our product recommendation system using the baseline model $\hat{P}_{mle}$ and our best-performing model $\hat{P}_{intp}$. The goals of this evaluation are to (1) determine the quality of our product recommendations; and (2) assess the impact of our association models on the product recommendations.

5.3.1 Experimental Setup

We instantiate our recommendation algorithm from Section 4.2 using session co-occurrence frequencies

[4] `https://www.mturk.com`

[5] HIT stands for Human Intelligence Task

	Query Set Sample				Query Bag Sample			
f	10	25	50	100	10	25	50	100
p	10	10	10	10	10	10	10	10
$\hat{P}_{mle}$ precision	0.89	0.93	0.96	0.96	0.94	0.94	0.93	0.92
$\hat{P}_{intp}$ precision	0.86	0.92	0.96	0.96	0.94	0.94	0.93	0.94
$\hat{P}_{mle}$ coverage	0.007	0.004	0.002	0.001	0.085	0.067	0.052	0.039
$\hat{P}_{intp}$ coverage	0.008	0.005	0.003	0.002	0.094	0.076	0.059	0.045
$R_{intp,mle}$	1.16	1.14	1.13	1.14	1.11	1.13	1.15	1.19

Table 4: Experimental results for product recommendations. All configurations are for $k = 10$.

from a one-month snapshot of user query sessions at a Web search engine, where session boundaries occur when 60 seconds elapse in between user queries. We experiment with the recommendation parameters defined at the end of Section 4.2 as follows: k = 10, f ranging from 10 to 100, and p ranging from 3 to 10.

For each configuration, we report *coverage* as the total number of queries in the output (i.e., the queries for which there is some recommendation) divided by the total number of queries in the log. For our performance metrics, we sampled two sets of queries: (a) `Query Set Sample`: uniform random sample of 100 queries from the *unique* queries in the one-month log; and (b) `Query Bag Sample`: weighted random sample, by query frequency, of 100 queries from the query *instances* in the one-month log. For each sample query, we pooled together and randomly shuffled all recommendations by our algorithm using both $\hat{P}_{mle}$ and $\hat{P}_{intp}$ on each parameter configuration. We then manually annotated each {query, product} pair as *relevant*, *mildly relevant* or *non-relevant*. In total, 1127 pairs were annotated. Interannotator agreement between two judges on this task yielded a Cohen's Kappa (Cohen, 1960) of 0.56. We therefore collapsed the *mildly relevant* and *non-relevant* classes yielding two final classes: *relevant* and *non-relevant*. Cohen's Kappa on this binary classification is 0.71.

Let C_M be the number of relevant (i.e., correct) suggestions recommended by a configuration M and let $|M|$ be the number of recommendations returned by M. Then we define the (micro-) precision of M as: $P_M = \frac{C_M}{C}$. We define relative recall (Pantel et al., 2004) between two configurations M_1 and M_2 as $R_{M_1,M_2} = \frac{P_{M_1} \times |M_1|}{P_{M_2} \times |M_2|}$.

5.3.2 Results

Table 4 summarizes our results for some configurations (others omitted for lack of space). Most remarkable is the $\{f = 10, p = 10\}$ configuration where the $\hat{P}_{intp}$ model *affected 9.4% of all query instances posed by the millions of users of a major search engine*, with a precision of 94%. Although this model covers 0.8% of the unique queries, the fact that it covers many head queries such as *walmart* and *iphone* accounts for the large query instance coverage. Also since there may be many general web queries for which there is no appropriate product in the database, a coverage of 100% is not attainable (nor desirable); in fact the upper bound for the coverage is likely to be much lower.

Table 5: Sample product recommendations.

Turning to the impact of the association models on product recommendations, we note that precision is stable in our $\hat{P}_{intp}$ model relative to our baseline $\hat{P}_{mle}$ model. However, a large lift in relative recall is observed, up to a 19% increase for the $\{f = 100, p = 10\}$ configuration. These results are consistent with those of Section 5.2, which compared the association models independently of the application and showed that $\hat{P}_{intp}$ outperforms $\hat{P}_{mle}$.

Table 5 shows sample product recommendations discovered by our $\hat{P}_{intp}$ model. Manual inspection revealed two main sources of errors. First, *ambiguity* is introduced both by the click model and the graph expansion algorithm of Section 3.2. In many cases, the ambiguity is resolved by user click patterns (i.e., users disambiguate queries through their browsing behavior), but one such error was seen for the query "*shark attack videos*" where several *Shark*-branded vacuum cleaners are recommended. This is because of the ambiguous query "*shark*" that is found in the click logs and in query sessions co-occurring with the query "*shark attack videos*". The second source of errors is caused by *systematic user errors* commonly found in session logs such as a user accidentally submitting a query while typing. An example

session is: {"*speedo*", "*speedometer*"} where the intended session was just the second query and the unintended first query is associated with products such as *Speedo swimsuits*. This ultimately causes our system to recommend various swimsuits for the query "*speedometer*".

6 Conclusion

Learning associations between web queries and entities has many possible applications, including query-entity recommendation, personalization by associating entity vectors to users, and direct advertising. Although many techniques have been developed for associating queries to queries or queries to documents, to the best of our knowledge this is the first that aims to associate queries to entities by leveraging click graphs from both general search logs and vertical search logs.

We developed several models for estimating the probability that an entity is relevant given a user query. The sparsity of *query entity graphs* is addressed by first expanding the graph with query synonyms, and then smoothing query-entity click counts over these unseen queries. Our best performing model, which interpolates between a foreground click model and a smoothed background model, significantly reduces testing error when compared against a strong baseline, by 18%. On associations observed only once in our test collection, the modeling error is reduced by 29% over the baseline.

We applied our best performing model to the task of query-entity recommendation, by analyzing session co-occurrences between queries and annotated entities. Experimental analysis shows that our smoothing techniques improve coverage while keeping precision stable, and overall, that our top-performing model affects 9% of general web queries with 94% precision.

Abstract

Searching documents that are similar to a query document is an important component in modern information retrieval. Some existing hashing methods can be used for efficient document similarity search. However, unsupervised hashing methods cannot incorporate prior knowledge for better hashing. Although some supervised hashing methods can derive effective hash functions from prior knowledge, they are either computationally expensive or poorly discriminative. This paper proposes a novel (semi-)supervised hashing method named Semi-Supervised SimHash (S^3H) for high-dimensional data similarity search. The basic idea of S^3H is to learn the optimal feature weights from prior knowledge to relocate the data such that similar data have similar hash codes. We evaluate our method with several state-of-the-art methods on two large datasets. All the results show that our method gets the best performance.

1 Introduction

Document Similarity Search (DSS) is to find similar documents to a query doc in a text corpus or on the web. It is an important component in modern information retrieval since DSS can improve the traditional search engines and user experience (Wan *et al.*, 2008; Dean *et al.*, 1999). Traditional search engines accept several terms submitted by a user as a query and return a set of docs that are relevant to the query. However, for those users who are not search experts, it is always difficult to accurately specify some query terms to express their search purposes. Unlike short-query based search, DSS queries by a full (long) document, which allows users to directly submit a page or a document to the search engines as the description of their information needs. Meanwhile, the explosion of information has brought great challenges to traditional methods. For example, Inverted List (IL) which is a primary key-term access method would return a very large set of docs for a query document, which leads to the time-consuming post-processing. Therefore, a new effective algorithm is required.

Hashing methods can perform highly efficient but approximate similarity search, and have gained great success in many applications such as Content-Based Image Retrieval (CBIR) (Ke *et al.*, 2004; Kulis *et al.*, 2009b), near-duplicate data detection (Ke *et al.*, 2004; Manku *et al.*, 2007; Costa *et al.*, 2010), etc. Hashing methods project high-dimensional objects to compact binary codes called *fingerprint*s and make similar fingerprints for similar objects. The similarity search in the Hamming space[1] is much more efficient than in the original attribute space (Manku *et al.*, 2007).

Recently, several hashing methods have been proposed. Specifically, SimHash (SH) (Charikar M.S., 2002) uses random projections to hash data. Although it works well with long fingerprints, SH has poor discrimination power for short fingerprints. A kernelized variant of SH, called Kernelized Locality Sensitive Hashing (KLSH) (Kulis *et al.*, 2009a), is proposed to handle non-linearly separable data. These methods are unsupervised thus cannot incorporate prior knowledge for better hashing. Moti-

[1] Hamming space is a set of binary strings of length L.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 93–101,
Portland, Oregon, June 19-24, 2011.

vated by this, some supervised methods are proposed to derive effective hash functions from prior knowledge, i.e., Spectral Hashing (Weiss *et al.*, 2009) and Semi-Supervised Hashing (SSH) (Wang *et al.*, 2010a). Regardless of different objectives, both methods derive hash functions via Principle Component Analysis (PCA) (Jolliffe, 1986). However, PCA is computationally expensive, which limits their usage for high-dimensional data.

This paper proposes a novel (semi-)supervised hashing method, Semi-Supervised SimHash (S^3H), for high-dimensional data similarity search. Unlike SSH that tries to find a sequence of hash functions, S^3H fixes the random projection directions and seeks the optimal feature weights from prior knowledge to relocate the objects such that similar objects have similar fingerprints. This is implemented by maximizing the empirical accuracy on the prior knowledge (labeled data) and the entropy of hash functions (estimated over labeled and unlabeled data). The proposed method avoids using PCA which is computationally expensive especially for high-dimensional data, and leads to an efficient Quasi-Newton based solution. To evaluate our method, we compare with several state-of-the-art hashing methods on two large datasets, i.e., 20 Newsgroups (20K points) and Open Directory Project (ODP) (2.4 million points). All experiments show that S^3H gets the best search performance.

This paper is organized as follows: Section 2 briefly introduces the background and some related works. In Section 3, we describe our proposed Semi-Supervised SimHash (S^3H). Section 4 provides experimental validation on two datasets. The conclusions are given in Section 5.

2 Background and Related Works

Suppose we are given a set of N documents, $\mathcal{X} = \{\mathbf{x}_i \mid \mathbf{x}_i \in \mathbb{R}^M\}_{i=1}^N$. For a given query doc $\mathbf{q}$, DSS tries to find its nearest neighbors in $\mathcal{X}$ or a subset $\mathcal{X}' \subset \mathcal{X}$ in which distance from the documents to the query doc $\mathbf{q}$ is less than a give threshold. However, such two tasks are computationally infeasible for large-scale data. Thus, it turns to the approximate similarity search problem (Indyk *et al.*, 1998). In this section, we briefly review some related approximate similarity search methods.

2.1 SimHash

SimHash (SH) is first proposed by Charikar (Charikar M.S., 2002). SH uses random projections as hash functions, i.e.,

$$h(\mathbf{x}) = \text{sign}(\mathbf{w}^T\mathbf{x}) = \begin{cases} +1, & if\ \mathbf{w}^T\mathbf{x} \geq 0 \\ -1, & otherwise \end{cases} \quad (1)$$

where $\mathbf{w} \in \mathbb{R}^M$ is a vector randomly generated. SH specifies the distribution on a family of hash functions $\mathcal{H} = \{h\}$ such that for two objects $\mathbf{x}_i$ and $\mathbf{x}_j$,

$$\Pr_{h\in\mathcal{H}}\{h(\mathbf{x}_i) = h(\mathbf{x}_j)\} = 1 - \frac{\theta(\mathbf{x}_i, \mathbf{x}_j)}{\pi} \quad (2)$$

where $\theta(\mathbf{x}_i, \mathbf{x}_j)$ is the angle between $\mathbf{x}_i$ and $\mathbf{x}_j$. Obviously, SH is an unsupervised hashing method.

2.2 Kernelized Locality Sensitive Hashing

A kernelized variant of SH, named Kernelized Locality Sensitive Hashing (KLSH) (Kulis *et al.*, 2009a), is proposed for non-linearly separable data. KLSH approximates the underling Gaussian distribution in the implicit embedding space of data based on central limit theory. To calculate the value of hashing fuction $h(\cdot)$, KLSH projects points onto the eigenvectors of the kernel matrix. In short, the complete procedure of KLSH can be summarized as follows: 1) randomly select P (a small value) points from $\mathcal{X}$ and form the kernel matrix, 2) for each hash function $h(\phi(\mathbf{x}))$, calculate its weight $\boldsymbol{\omega} \in \mathbb{R}^P$ just as Kernel PCA (Schölkopf *et al.*, 1997), and 3) the hash function is defined as:

$$h(\phi(\mathbf{x})) = \text{sign}(\sum_{i=1}^{P} \omega_i \cdot \kappa(\mathbf{x}, \mathbf{x}_i)) \quad (3)$$

where $\kappa(\cdot,\cdot)$ can be any kernel function.

KLSH can improve hashing results via the kernel trick. However, KLSH is unsupervised, thus designing a data-specific kernel remains a big challenge.

2.3 Semi-Supervised Hashing

Semi-Supervised Hashing (SSH) (Wang *et al.*, 2010a) is recently proposed to incorporate prior knowledge for better hashing. Besides $\mathcal{X}$, prior knowledge in the form of similar and dissimilar object-pairs is also required in SSH. SSH tries to find L optimal hash functions which have maximum

empirical accuracy on prior knowledge and maximum entropy by finding the top L eigenvectors of an extended covariance matrix[2] via PCA or SVD.

However, despite of the potential problems of numerical stability, SVD requires massive computational space and $O(M^3)$ computational time where M is feature dimension, which limits its usage for high-dimensional data (Trefethen *et al.*, 1997). Furthermore, the variance of directions obtained by PCA decreases with the decrease of the rank (Jolliffe, 1986). Thus, lower hash functions tend to have smaller entropy and larger empirical errors.

2.4 Others

Some other related works should be mentioned. A notable method is Locality Sensitive Hashing (LSH) (Indyk *et al.*, 1998). LSH performs a random linear projection to map similar objects to similar hash codes. However, LSH suffers from the efficiency problem that it tends to generate long codes (Salakhutdinov *et al.*, 2007). LAMP (Mu *et al.*, 2009) considers each hash function as a binary partition problem as in SVMs (Burges, 1998). Spectral Hashing (Weiss *et al.*, 2009) maintains similarity between objects in the reduced Hamming space by minimizing the averaged Hamming distance[3] between similar neighbors in the original Euclidean space. However, spectral hashing takes the assumption that data should be distributed uniformly, which is always violated in real-world applications.

3 Semi-Supervised SimHash

In this section, we present our hashing method, named Semi-Supervised SimHash (S^{3}H). Let $\mathcal{X}_L = \{(\mathbf{x}_1, c_1) \dots (\mathbf{x}_u, c_u)\}$ be the labeled data, $c \in \{1 \dots C\}$, $\mathbf{x} \in \mathbb{R}^M$, and $\mathcal{X}_U = \{\mathbf{x}_{u+1} \dots \mathbf{x}_N\}$ the unlabeled data. Let $\mathcal{X} = \mathcal{X}_L \cup \mathcal{X}_U$. Given the labeled data $\mathcal{X}_L$, we construct two sets, attraction set Θ_a and repulsion set Θ_r. Specifically, any pair $(\mathbf{x}_i, \mathbf{x}_j) \in \Theta_a$, $i, j \le u$, denotes that $\mathbf{x}_i$ and $\mathbf{x}_j$ are in the same class, i.e., $c_i = c_j$, while any pair $(\mathbf{x}_i, \mathbf{x}_j) \in \Theta_r$, $i, j \le u$, denotes that $c_i \neq c_j$. Unlike previews works that attempt to find L optimal hyperplanes, the basic idea of S^{3}H is to fix L random hyperplanes and to find an optimal feature-weight vector to relocate the objects such that similar objects have similar codes.

3.1 Data Representation

Since L random hyperplanes are fixed, we can represent a object $\mathbf{x} \in \mathcal{X}$ as its relative position to these random hyperplanes, i.e.,

$$\mathbf{D} = \mathbf{\Lambda} \cdot \mathbf{V} \tag{4}$$

where the element $\mathrm{V}_{ml} \in \{+1, -1, 0\}$ of $\mathbf{V}$ indicates that the object $\mathbf{x}$ is above, below or just in the l-th hyperplane with respect to the m-th feature, and $\mathbf{\Lambda} = \mathrm{diag}(|x_1|, |x_2|, \dots, |x_M|)$ is a diagonal matrix which, to some extent, reflects the distance from $\mathbf{x}$ to these hyperplanes.

3.2 Formulation

Hashing maps the data set $\mathcal{X}$ to an L-dimensional Hamming space for compact representations. If we represent each object as Equation (4), the l-th hash function is then defined as:

$$h_l(\mathbf{x}) = \hbar_l(\mathbf{D}) = \mathrm{sign}(\mathbf{w}^T \mathbf{d}_l) \tag{5}$$

where $\mathbf{w} \in \mathbb{R}^M$ is the feature weight to be determined and $\mathbf{d}_l$ is the l-th column of the matrix $\mathbf{D}$.

Intuitively, the "contribution" of a specific feature to different classes is different. Therefore, we hope to incorporate this side information in S^{3}H for better hashing. Inspired by (Madani *et al.*, 2009), we can measure this contribution over $\mathcal{X}_L$ as in Algorithm 1. Clearly, if objects are represented as the occurrence numbers of features, the output of Algorithm 1 is just the conditional probability $\Pr(\mathrm{class}|\mathrm{feature})$. Finally, each object $(\mathbf{x}, c) \in \mathcal{X}_L$ can be represented as an $M \times L$ matrix $\mathbf{G}$:

$$\mathbf{G} = \mathrm{diag}(\nu_{1,c}, \nu_{2,c}, \dots, \nu_{M,c}) \cdot \mathbf{D} \tag{6}$$

Note that, one pair $(\mathbf{x}_i, \mathbf{x}_j)$ in Θ_a or Θ_r corresponds to $(\mathbf{G}_i, \mathbf{G}_j)$ while $(\mathbf{D}_i, \mathbf{D}_j)$ if we ignore features' contribution to different classes.

Furthermore, we also hope to maximize the empirical accuracy on the labeled data Θ_a and Θ_r and

[2]The extended covariance matrix is composed of two components, one is an unsupervised covariance term and another is a constraint matrix involving labeled information.

[3]Hamming distance is defined as the number of bits that are different between two binary strings.

Algorithm 1: Feature Contribution Calculation

```
for each (x, c) ∈ X_L do
    for each f ∈ x do
        ν_f ← ν_f + x_f;
        ν_{f,c} ← ν_{f,c} + x_f;
    end
end
for each feature f and class c do
    ν_{f,c} ← ν_{f,c} / ν_f;
end
```

maximize the entropy of hash functions. So, we define the following objective for $\hbar(\cdot)$s:

$$J(\mathbf{w}) = \frac{1}{N_p}\sum_{l=1}^{L}\Big\{\sum_{(\mathbf{x}_i,\mathbf{x}_j)\in\Theta_a}\hbar_l(\mathbf{x}_i)\hbar_l(\mathbf{x}_j) - \sum_{(\mathbf{x}_i,\mathbf{x}_j)\in\Theta_r}\hbar_l(\mathbf{x}_i)\hbar_l(\mathbf{x}_j)\Big\} + \lambda_1\sum_{l=1}^{L}\mathrm{H}(\hbar_l) \tag{7}$$

where $N_p = |\Theta_a| + |\Theta_r|$ is the number of attraction and repulsion pairs and λ_1 is a tradeoff between two terms. Wang *et al.* have proven that hash functions with maximum entropy must maximize the variance of the hash values, and vice-versa (Wang *et al.*, 2010b). Thus, $\mathrm{H}(\hbar(\cdot))$ can be estimated over the labeled and unlabeled data, $\mathcal{X}_L$ and $\mathcal{X}_U$.

Unfortunately, direct solution for above problem is non-trivial since Equation (7) is not differentiable. Thus, we relax the objective and add an additional regularization term which could effectively avoid overfitting. Finally, we obtain the total objective:

$$\begin{aligned}\mathcal{L}(\mathbf{w}) = {} & \frac{1}{N_p}\sum_{l=1}^{L}\{\sum_{(\mathbf{G}_i,\mathbf{G}_j)\in\Theta_a}\psi(\mathbf{w}^T\mathbf{g}_{i,l})\psi(\mathbf{w}^T\mathbf{g}_{j,l}) \\ & - \sum_{(\mathbf{G}_i,\mathbf{G}_j)\in\Theta_r}\psi(\mathbf{w}^T\mathbf{g}_{i,l})\psi(\mathbf{w}^T\mathbf{g}_{j,l})\} \\ & + \frac{\lambda_1}{2N}\sum_{l=1}^{L}\{\sum_{i=1}^{u}\psi^2(\mathbf{w}^T\mathbf{g}_{i,l}) + \sum_{i=u+1}^{N}\psi^2(\mathbf{w}^T\mathbf{d}_{i,l})\} \\ & - \frac{\lambda_2}{2}\|\mathbf{w}\|_2^2\end{aligned} \tag{8}$$

where $\mathbf{g}_{i,l}$ and $\mathbf{d}_{i,l}$ denote the l-th column of $\mathbf{G}_i$ and $\mathbf{D}_i$ respectively, and $\psi(t)$ is a piece-wise linear function defined as:

$$\psi(t) = \begin{cases} T_g & t > T_g \\ t & -T_g \le t \le T_g \\ -T_g & t < -T_g \end{cases} \tag{9}$$

This relaxation has a good intuitive explanation. That is, similar objects are desired to not only have the similar fingerprints but also have sufficient large projection magnitudes, while dissimilar objects are desired to not only differ in their fingerprints but also have large projection margin. However, we do not hope that a small fraction of object-pairs with very large projection magnitude or margin dominate the complete model. Thus, a piece-wise linear function $\psi(\cdot)$ is applied in S^{3}H.

As a result, Equation (8) is a simply unconstrained optimization problem, which can be efficiently solved by a notable Quasi-Newton algorithm, i.e., L-BFGS (Liu *et al.*, 1989). For description simplicity, only attraction set Θ_a is considered and the extension to repulsion set Θ_r is straightforward. Thus, the gradient of $\mathcal{L}(\mathbf{w})$ is as follows:

$$\begin{aligned}\frac{\partial\mathcal{L}(\mathbf{w})}{\partial\mathbf{w}} = {} & \frac{1}{N_p}\sum_{l=1}^{L}\Big\{\sum_{\substack{(\mathbf{G}_i,\mathbf{G}_j)\in\Theta_a,\\ |\mathbf{w}^T\mathbf{g}_{i,l}|\le T_g}}\psi(\mathbf{w}^T\mathbf{g}_{j,l})\cdot\mathbf{g}_{i,l} \\ & + \sum_{\substack{(\mathbf{G}_i,\mathbf{G}_j)\in\Theta_a,\\ |\mathbf{w}^T\mathbf{g}_{j,l}|\le T_g}}\psi(\mathbf{w}^T\mathbf{g}_{i,l})\cdot\mathbf{g}_{j,l}\Big\} \\ & + \frac{\lambda_1}{N}\sum_{l=1}^{L}\Big\{\sum_{\substack{i=1,\\ |\mathbf{w}^T\mathbf{g}_{i,l}|\le T_g}}^{u}\psi(\mathbf{w}^T\mathbf{g}_{i,l})\cdot\mathbf{g}_{i,l} \\ & + \sum_{\substack{i=u+1,\\ |\mathbf{w}^T\mathbf{d}_{i,l}|\le T_g}}^{N}\psi(\mathbf{w}^T\mathbf{d}_{i,l})\cdot\mathbf{d}_{i,l}\Big\} - \lambda_2\mathbf{w}\end{aligned} \tag{10}$$

Note that $\partial\psi(t)/\partial t = 0$ when $|t| > T_g$.

3.3 Fingerprint Generation

When we get the optimal weight $\mathbf{w}^*$, we generate fingerprints for given objects through Equation (5). Then, it tunes to the problem how to efficiently obtain the representation as in Figure 4 for a object. After analysis, we find: 1) hyperplanes are randomly generated and we only need to determine which sides of these hyperplanes the given object lies on, and 2) in real-world applications, objects such as docs are always very sparse. Thus, we can avoid heavy computational demands and efficiently generate fingerprints for objects.

In practice, given an object $\mathbf{x}$, the procedure of generating an L-bit fingerprint is as follows: it maintains an L-dimensional vector initialized to zero. Each feature $f \in \mathbf{x}$ is firstly mapped to an L-bit hash value by *Jenkins Hashing Function*[4]. Then,

[4]http://www.burtleburtle.net/bob/hash/doobs.html

Algorithm 2: Fast Fingerprint Generation

INPUT: $\mathbf{x}$ and $\mathbf{w}^*$;
initialize $\boldsymbol{\alpha} \leftarrow 0, \boldsymbol{\beta} \leftarrow 0, \boldsymbol{\alpha}, \boldsymbol{\beta} \in \mathbb{R}^L$;
for *each* $f \in \mathbf{x}$ **do**
  randomly project f to $\mathbf{h}_f \in \{-1, +1\}^L$;
  $\boldsymbol{\alpha} \leftarrow \boldsymbol{\alpha} + x_f \cdot w_f^* \cdot \mathbf{h}_f$;
end
for $l = 1$ *to* L **do**
  if $\alpha_l > 0$ **then**
    $\beta_l \leftarrow 1$;
  end
end
RETURN $\boldsymbol{\beta}$;

these L bits increment or decrement the L components of the vector by the value $x_f \times w_f^*$. After all features processed, the signs of components determine the corresponding bits of the final fingerprint. The complete algorithm is presented in Algorithm 2.

3.4 Algorithmic Analysis

This section briefly analyzes the relation between S^{3}H and some existing methods. For analysis simplicity, we assume $\psi(t) = t$ and ignore the regularization terms. So, Equation (8) can be rewritten as follows:

$$J(\mathbf{w})_{S^3H} = \frac{1}{2}\mathbf{w}^T[\sum_{l=1}^{L}\boldsymbol{\Gamma}_l(\boldsymbol{\Phi}^+ - \boldsymbol{\Phi}^-)\boldsymbol{\Gamma}_l^T]\mathbf{w} \quad (11)$$

where Φ_{ij}^+ equals to 1 when $(\mathbf{x}_i, \mathbf{x}_j) \in \Theta_a$ otherwise 0, Φ_{ij}^- equals to 1 when $(\mathbf{x}_i, \mathbf{x}_j) \in \Theta_r$ otherwise 0, and $\boldsymbol{\Gamma}_l = [\mathbf{g}_{1,l} \dots \mathbf{g}_{u,l}, \mathbf{d}_{u+1,l} \dots \mathbf{d}_{N,l}]$. We denote $\sum_l \boldsymbol{\Gamma}_l\boldsymbol{\Phi}^+\boldsymbol{\Gamma}_l^T$ and $\sum_l \boldsymbol{\Gamma}_l\boldsymbol{\Phi}^-\boldsymbol{\Gamma}_l^T$ as $\mathbf{S}^+$ and $\mathbf{S}^-$ respectively. Therefore, maximizing above function is equivalent to maximizing the following:

$$\widetilde{J}(\mathbf{w})_{S^3H} = \frac{|\mathbf{w}^T\mathbf{S}^+\mathbf{w}|}{|\mathbf{w}^T\mathbf{S}^-\mathbf{w}|} \quad (12)$$

Clearly, Equation (12) is analogous to Linear Discriminant Analysis (LDA) (Duda *et al.*, 2000) except for the difference: 1) measurement. S^{3}H uses similarity while LDA uses distance. As a result, the objective function of S^{3}H is just the reciprocal of LDA's. 2) embedding space. LDA seeks the best separative direction in the original attribute space. In contrast, S^{3}H firstly maps data from $\mathbb{R}^M$ to $\mathbb{R}^{M\times L}$ through the following projection function

$$\phi(\mathbf{x}) = \mathbf{x} \cdot [\mathrm{diag}(\mathrm{sign}(\mathbf{r}_1)), \dots, \mathrm{diag}(\mathrm{sign}(\mathbf{r}_L))] \quad (13)$$

where $\mathbf{r}_l \in \mathbb{R}^M, l = 1, \dots, L$, are L random hyperplanes. Then, in that space ($\mathbb{R}^{M\times L}$), S^{3}H seeks a direction[5] that can best separate the data.

From this point of view, it is obvious that the basic SH is a special case of S^{3}H when $\mathbf{w}$ is set to $\mathbf{e} = [1, 1, \dots, 1]$. That is, SH firstly maps the data via $\phi(\cdot)$ just as S^{3}H. But then, SH directly separates the data in that feature space at the direction $\mathbf{e}$.

Analogously, we ignore the regularization terms in SSH and rewrite the objective of SSH as:

$$J(\mathbf{W})_{SSH} = \frac{1}{2}\,\mathrm{tr}[\mathbf{W}^T\mathbf{X}(\boldsymbol{\Phi}^+ - \boldsymbol{\Phi}^-)\mathbf{X}^T\mathbf{W}] \quad (14)$$

where $\mathbf{W} = [\mathbf{w}_1, \dots, \mathbf{w}_L] \in \mathbb{R}^{M\times L}$ are L hyperplanes and $\mathbf{X} = [\mathbf{x}_1, \dots, \mathbf{x}_N]$. Maximizing this objective is equivalent to maximizing the following:

$$\widetilde{J}(\mathbf{W})_{SSH} = \frac{|\,\mathrm{tr}[\mathbf{W}^T\mathbf{S}'^+\mathbf{W}]|}{|\,\mathrm{tr}[\mathbf{W}^T\mathbf{S}'^-\mathbf{W}]|} \quad (15)$$

where $\mathbf{S}'^+ = \mathbf{X}\boldsymbol{\Phi}^+\mathbf{X}^T$ and $\mathbf{S}'^- = \mathbf{X}\boldsymbol{\Phi}^-\mathbf{X}^T$. Equation (15) shows that SSH is analogous to Multiple Discriminant Analysis (MDA) (Duda *et al.*, 2000). In fact, SSH uses top L best-separative hyperplanes in the original attribute space found via PCA to hash the data. Furthermore, we rewrite the projection function $\phi(\cdot)$ in S^{3}H as:

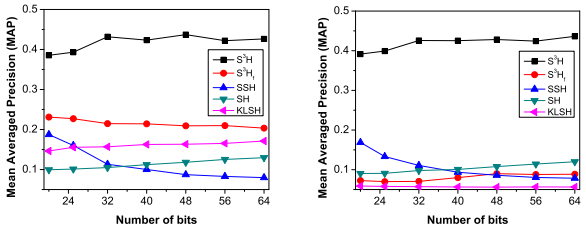
$$\phi(\mathbf{x}) = \mathbf{x} \cdot [\mathbf{R}_1, \dots, \mathbf{R}_L] \quad (16)$$

where $\mathbf{R}_l = \mathrm{diag}(\mathrm{sign}(\mathbf{r}_l))$. Each $\mathbf{R}_l$ is a mapping from $\mathbb{R}^M$ to $\mathbb{R}^M$ and corresponds to one embedding space. From this perspective, unlike SSH, S^{3}H globally seeks a direction that can best separate the data in L different embedding spaces simultaneously.

4 Experiments

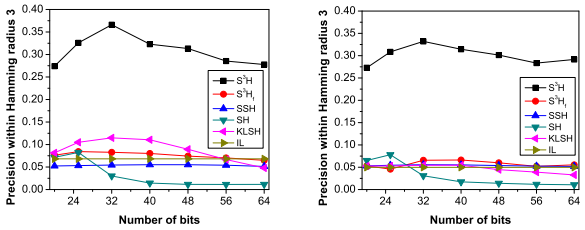
We use two datasets 20 Newsgroups and Open Directory Project (ODP) in our experiments. Each document is represented as a vector of occurrence numbers of the terms within it. The class information of docs is considered as prior knowledge that two docs within a same class should have more similar fingerprints while two docs within different classes should have dissimilar fingerprints. We will demonstrate that our S^{3}H can effectively incorporate this prior knowledge to improve the DSS performance.

[5] The direction is determined by concatenating $\mathbf{w}$ L times.



(a) (b)

Figure 1: Mean Averaged Precision (MAP) for different number of bits for hash ranking on 20 Newsgroups. (a) 10K features. (b) 30K features.



(a) (b)

Figure 2: Precision within Hamming radius 3 for hash lookup on 20 Newsgroups. (a) 10K features. (b) 30K features.

We use Inverted List (IL) (Manning *et al.*, 2002) as the baseline. In fact, given a query doc, IL returns all the docs that contain any term within it. We also compare our method with three state-of-the-art hashing methods, i.e., KLSH, SSH and SH. In KLSH, we adopt the RBF kernel $\kappa(\mathbf{x}_i, \mathbf{x}_j) = \exp(-\frac{\|\mathbf{x}_i - \mathbf{x}_j\|_2^2}{\delta^2})$, where the scaling factor δ^2 takes 0.5 and the other two parameters p and t are set to be 500 and 50 respectively. The parameter λ in SSH is set to 1. For S^{3}H, we simply set the parameters λ_1 and λ_2 in Equation (8) to 4 and 0.5 respectively. To objectively reflect the performance of S^{3}H, we evaluate our S^{3}H with and without Feature Contribution Calculation algorithm (FCC) (Algorithm 1). Specifically, FCC-free S^{3}H (denoted as S^{3}H$_f$) is just a simplification when $\mathbf{G}$s in S^{3}H are simply set to $\mathbf{D}$s.

For quantitative evaluation, as in literature (Wang *et al.*, 2010b; Mu *et al.*, 2009), we calculate the precision under two scenarios: hash lookup and hash ranking. For hash lookup, the proportion of good neighbors (have the same class label as the query) among the searched objects within a given Hamming radius is calculated as precision. Similarly to (Wang *et al.*, 2010b; Weiss *et al.*, 2009), for a query document, if no neighbors within the given Hamming radius can be found, it is considered as zero precision. Note that, the precision of IL is the proportion of good neighbors among the whole searched objects. For hash ranking, all the objects in $\mathcal{X}$ are ranked in terms of their Hamming distance from the query document, and the top K nearest neighbors are returned as the result. Then, Mean Averaged Precision (MAP) (Manning *et al.*, 2002) is calculated. We also calculate the averaged intra- and inter- class Hamming distance for various hashing methods. Intuitively, a good hashing method should have small intra-class distance while large inter-class distance.

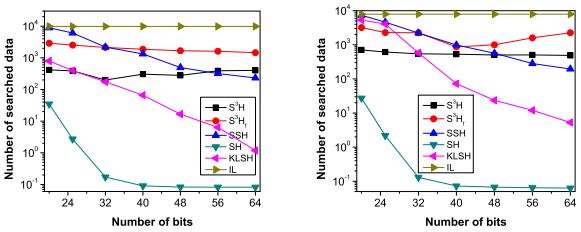
We test all the methods on a PC with a 2.66 GHz processor and 12GB RAM. All experiments repeate 10 times and the averaged results are reported.

4.1 20 Newsgroups

20 Newsgroups[6] contains 20K messages, about 1K messages from each of 20 different newsgroups. The entire vocabulary includes 62,061 words. To evaluate the performance for different feature dimensions, we use Chi-squared feature selection algorithm (Forman, 2003) to select 10K and 30K features. The averaged message length is 54.1 for 10K features and 116.2 for 30K features. We randomly select 4K massages as the test set and the remain 16K as the training set. To train SSH and S^{3}H, from the training set, we randomly generate 40K message-pairs as Θ_a and 80K message-pairs as Θ_r.

For hash ranking, Figure 1 shows MAP for various methods using different number of bits. It shows that performance of SSH decreases with the growing of hash bits. This is mainly because the variance of the directions obtained by PCA decreases with the decrease of their ranks. Thus, lower bits have larger empirical errors. For S^{3}H, FCC (Algorithm 1) can significantly improve the MAP just as discussed in Section 3.2. Moreover, the MAP of FCC-free S^{3}H (S^{3}H$_f$) is affected by feature dimensions while FCC-based (S^{3}H) is relatively stable. This implies FCC can also improve the satiability of S^{3}H. As we see, S^{3}H$_f$ ignores the contribution of features to different classes. However, besides the local description of data locality in the form of object-pairs, such

[6] http://www.cs.cmu.edu/afs/cs/project/theo-3/www/



(a) (b)

Figure 3: Averaged searched sample numbers using 4K query messages for hash lookup. (a) 10K features. (b) 30K features.

(global) information also provides a proper guidance for hashing. So, for S^3H_f, the reason why its results with 30K features are worse than the results with 10K features is probably because S^3H_f learns to hash only according to the local description of data locality and many not too relevant features lead to relatively poor description. In contrast, S^3H can utilize global information to better understand the similarity among objects. In short, S^3H obtains the best MAP for all bits and feature dimensions.

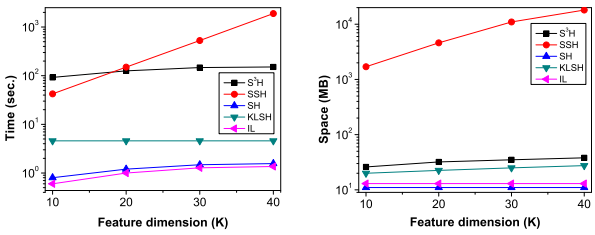
For hash lookup, Figure 2 presents the precision within Hamming radius 3 for different number of bits. It shows that IL even outperforms SH. This is because few objects can be hashed by SH into one hash bucket. Thus, for many queries, SH fails to return any neighbor even in a large Hamming radius of 3. Clearly, S^3H outperforms all the other methods for different number of hash bits and features.

The number of messages searched by different methods are reported in Figure 3. We find that the number of searched data of S^3H (with/without FCC) decreases much more slowly than KLSH, SH and SSH with the growing of the number of hash bits. As discussed in Section 3.4, this mainly benefits from the design of S^3H that S^3H (globally) seeks a direction that can best separate the data in L embedding spaces simultaneously. We also find IL returns a large number of neighbors of each query message which leads to its poor efficiency.

The averaged intra- and inter- class Hamming distance of different methods are reported in Table 1. As it shows, S^3H has relatively larger margin (Δ) between intra- and inter-class Hamming distance. This indicates that S^3H is more effective to make similar points have similar fingerprints while keep the dissimilar points away enough from each other.

	intra-class	inter-class	Δ
S^3H	13.1264	15.6342	**2.5078**
S^3H_f	12.5754	13.3479	0.7725
SSH	6.4134	6.5262	0.1128
SH	15.3908	15.6339	0.2431
KLSH	10.2876	10.8713	0.5841

Table 1: Averaged intra- and inter- class Hamming distance of 20 Newsgroups for 32-bit fingerprint. Δ is the difference between the averaged inter- and intra- class Hamming distance. Large Δ implies good hashing.



(a) (b)

Figure 4: Computational complexity of training for different feature dimensions for 32-bit fingerprint. (a) Training time (sec). (b) Training space cost (MB).

Figure 4 shows the (training) computational complexity of different methods. We find that the time and space cost of SSH grows much faster than SH, KLSH and S^3H with the growing of feature dimension. This is mainly because SSH requires SVD to find the optimal hashing functions which is computational expensive. Instead, S^3H seeks the optimal feature weights via L-BFGS, which is still efficient even for very high-dimensional data.

4.2 Open Directory Project (ODP)

Open Directory Project (ODP)[7] is a multilingual open content directory of web links (docs) organized by a hierarchical ontology scheme. In our experiment, only English docs[8] at level 3 of the category tree are utilized to evaluate the performance. In short, the dataset contains 2,483,388 docs within 6,008 classes. There are totally 862,050 distinct words and each doc contains 14.13 terms on average. Since docs are too short, we do not conduct

[7] http://rdf.dmoz.org/

[8] The title together with the corresponding short description of a page are considered as a document in our experiments.

	intra-class	inter-class	Δ
S^3H	14.0029	15.9508	**1.9479**
S^3H_f	14.3801	15.5260	1.1459
SH	14.7725	15.6432	0.8707
KLSH	9.3382	10.5700	1.2328

Table 2: Averaged intra- and inter- class Hamming distance of ODP for 32-bit fingerprint (860K features). Δ is the difference between averaged intra- and inter- class Hamming distance.

feature selection[9]. An overview of ODP is shown in Figure 5. We randomly sample 10% docs as the test set and the remain as the training set. Furthermore, from training set, we randomly generate 800K doc-pairs as Θ_a, and 1 million doc-pairs as Θ_r. Note that, since there are totally over 800K features, it is extremely inefficient to train SSH. Therefore, we only compare our S^3H with IL, KLSH and SH.

The search performance is given in Figure 6. Figure 6(a) shows the MAP for various methods using different number of bits. It shows KLSH outperforms SH, which mainly contributes to the kernel trick. S^3H and S^3H_f have higher MAP than KLSH and SH. Clearly, FCC algorithm can improve the MAP of S^3H for all bits. Figure 6(b) presents the precision within Hamming radius 2 for hash lookup. We find that IL outperforms SH since SH fails for many queries. It also shows that S^3H (with FCC) can obtain the best precision for all bits.

Table 2 reports the averaged intra- and inter-class Hamming distance for various methods. It shows that S^3H has the largest margin (Δ). This demonstrates S^3H can measure the similarity among the data better than KLSH and SH.

We should emphasize that KLSH needs 0.3ms to return the results for a query document for hash lookup, and S^3H needs <0.1ms. In contrast, IL requires about 75ms to finish searching. This is mainly because IL always returns a large number of objects (dozens or hundreds times more than S^3H and KLSH) and requires much time for post-processing.

All the experiments show S^3H is more effective, efficient and stable than the baseline method and the state-of-the-art hashing methods.

5 Conclusions

We have proposed a novel supervised hashing method named Semi-Supervised Simhash (S^3H) for high-dimensional data similarity search. S^3H learns the optimal feature weights from prior knowledge to relocate the data such that similar objects have similar fingerprints. This is implemented by maximizing the empirical accuracy on labeled data together with the entropy of hash functions. The proposed method leads to a simple Quasi-Newton based solution which is efficient even for very high-dimensional data. Experiments performed on two large datasets have shown that S^3H has better search performance than several state-of-the-art methods.

Abstract

Marking up search queries with linguistic annotations such as part-of-speech tags, capitalization, and segmentation, is an important part of query processing and understanding in information retrieval systems. Due to their brevity and idiosyncratic structure, search queries pose a challenge to existing NLP tools. To address this challenge, we propose a probabilistic approach for performing joint query annotation. First, we derive a robust set of unsupervised independent annotations, using queries and pseudo-relevance feedback. Then, we stack additional classifiers on the independent annotations, and exploit the dependencies between them to further improve the accuracy, even with a very limited amount of available training data. We evaluate our method using a range of queries extracted from a web search log. Experimental results verify the effectiveness of our approach for both short keyword queries, and verbose natural language queries.

1 Introduction

Automatic mark-up of textual documents with linguistic annotations such as part-of-speech tags, sentence constituents, named entities, or semantic roles is a common practice in natural language processing (NLP). It is, however, much less common in information retrieval (IR) applications. Accordingly, in this paper, we focus on annotating search queries submitted by the users to a search engine.

There are several key differences between user queries and the documents used in NLP (e.g., news articles or web pages). As previous research shows, these differences severely limit the applicability of standard NLP techniques for annotating queries and require development of novel annotation approaches for query corpora (Bergsma and Wang, 2007; Barr et al., 2008; Lu et al., 2009; Bendersky et al., 2010; Li, 2010).

The most salient difference between queries and documents is their length. Most search queries are very short, and even longer queries are usually shorter than the average written sentence. Due to their brevity, queries often cannot be divided into sub-parts, and do not provide enough context for accurate annotations to be made using the standard NLP tools such as taggers, parsers or chunkers, which are trained on more syntactically coherent textual units.

A recent analysis of web query logs by Bendersky and Croft (2009) shows, however, that despite their brevity, queries are grammatically diverse. Some queries are keyword concatenations, some are semi-complete verbal phrases and some are wh-questions. It is essential for the search engine to correctly annotate the query structure, and the quality of these query annotations has been shown to be a crucial first step towards the development of reliable and robust query processing, representation and understanding algorithms (Barr et al., 2008; Guo et al., 2008; Guo et al., 2009; Manshadi and Li, 2009; Li, 2010).

However, in current query annotation systems, even sentence-like queries are often hard to parse and annotate, as they are prone to contain misspellings and idiosyncratic grammatical structures.

Figure 1: **E**xamples of a mark-up scheme for annotating capitalization (L – lowercase, C – otherwise), POS tags (N – noun, V – verb, X – otherwise) and segmentation (B/I – beginning of/inside the chunk).

They also tend to lack prepositions, proper punctuation, or capitalization, since users (often correctly) assume that these features are disregarded by the retrieval system.

In this paper, we propose a novel joint query annotation method to improve the effectiveness of existing query annotations, especially for longer, more complex search queries. Most existing research focuses on using a single type of annotation for information retrieval such as subject-verb-object dependencies (Balasubramanian and Allan, 2009), named-entity recognition (Guo et al., 2009), phrase chunking (Guo et al., 2008), or semantic labeling (Li, 2010).

In contrast, the main focus of this work is on developing a unified approach for performing reliable annotations of different types. To this end, we propose a probabilistic method for performing a *joint query annotation*. This method allows us to exploit the dependency between different unsupervised annotations to further improve the accuracy of the entire set of annotations. For instance, our method can leverage the information about estimated parts-of-speech tags and capitalization of query terms to improve the accuracy of query segmentation.

We empirically evaluate the joint query annotation method on a range of query types. Instead of just focusing our attention on keyword queries, as is often done in previous work (Barr et al., 2008; Bergsma and Wang, 2007; Tan and Peng, 2008; Guo et al., 2008), we also explore the performance of our annotations with more complex natural language search queries such as verbal phrases and wh-questions, which often pose a challenge for IR applications (Bendersky et al., 2010; Kumaran and Allan, 2007; Kumaran and Carvalho, 2009; Lease, 2007). We show that even with a very limited amount of training data, our joint annotation method significantly outperforms annotations that were done independently for these queries.

The rest of the paper is organized as follows. In Section 2 we demonstrate several examples of annotated search queries. Then, in Section 3, we introduce our joint query annotation method. In Section 4 we describe two types of independent query annotations that are used as input for the joint query annotation. Section 5 details the related work and Section 6 presents the experimental results. We draw the conclusions from our work in Section 7.

2 Query Annotation Example

To demonstrate a possible implementation of linguistic annotation for search queries, Figure 1 presents a simple mark-up scheme, exemplified using three web search queries (as they appear in a search log): (a) *who won the 2004 kentucky derby*, (b) *kindred where would i be*, and (c) *shih tzu health problems*. In this scheme, each query is marked-up using three annotations: capitalization, POS tags, and segmentation indicators.

Note that all the query terms are non-capitalized, and no punctuation is provided by the user, which complicates the query annotation process. While the simple annotation described in Figure 1 can be done with a very high accuracy for standard document corpora, both previous work (Barr et al., 2008; Bergsma and Wang, 2007; Jones and Fain, 2003) and the experimental results in this paper indicate that it is challenging to perform well on queries.

The queries in Figure 1 illustrate this point. Query (a) in Figure 1 is a wh-question, and it contains

a capitalized concept (*"Kentucky Derby"*), a single verb, and four segments. Query (b) is a combination of an artist name and a song title and should be interpreted as *Kindred — "Where Would I Be"*. Query (c) is a concatenation of two short noun phrases: *"Shih Tzu"* and *"health problems"*.

3 Joint Query Annotation

Given a search query Q, which consists of a sequence of terms $(q_1, \ldots, q_n)$, our goal is to annotate it with an appropriate set of linguistic structures $\mathcal{Z}_Q$. In this work, we assume that the set $\mathcal{Z}_Q$ consists of *shallow* sequence annotations $\mathbf{z}_Q$, each of which takes the form

$$\mathbf{z}_Q = (\zeta_1, \ldots, \zeta_n).$$

In other words, each symbol $\zeta_i \in \mathbf{z}_Q$ annotates a single query term.

Many query annotations that are useful for IR can be represented using this simple form, including capitalization, POS tagging, phrase chunking, named entity recognition, and stopword indicators, to name just a few. For instance, Figure 1 demonstrates an example of a set of annotations $\mathcal{Z}_Q$. In this example,

$$\mathcal{Z}_Q = \{\mathbf{CAP}, \mathbf{TAG}, \mathbf{SEG}\}.$$

Most previous work on query annotation makes the independence assumption — every annotation $\mathbf{z}_Q \in \mathcal{Z}_Q$ is done separately from the others. That is, it is assumed that the optimal linguistic annotation $\mathbf{z}_Q^{*(I)}$ is the annotation that has the highest probability given the query Q, regardless of the other annotations in the set $\mathcal{Z}_Q$. Formally,

$$\mathbf{z}_Q^{*(I)} = \operatorname*{argmax}_{\mathbf{z}_Q} p(\mathbf{z}_Q|Q) \qquad (1)$$

The main shortcoming of this approach is in the assumption that the linguistic annotations in the set $\mathcal{Z}_Q$ are independent. In practice, there are dependencies between the different annotations, and they can be leveraged to derive a better estimate of the entire set of annotations.

For instance, imagine that we need to perform two annotations: capitalization and POS tagging. Knowing that a query term is capitalized, we are more likely to decide that it is a proper noun. Vice versa, knowing that it is a preposition will reduce its probability of being capitalized. We would like to capture this intuition in the annotation process.

To address the problem of joint query annotation, we first assume that we have an initial set of annotations $\mathcal{Z}_Q^{*(I)}$, which were performed for query Q independently of one another (we will show an example of how to derive such a set in Section 4). Given the initial set $\mathcal{Z}_Q^{*(I)}$, we are interested in obtaining an annotation set $\mathcal{Z}_Q^{*(J)}$, which jointly optimizes the probability of *all* the annotations, i.e.

$$\mathcal{Z}_Q^{*(J)} = \operatorname*{argmax}_{\mathcal{Z}_Q} p(\mathcal{Z}_Q|\mathcal{Z}_Q^{*(I)}).$$

If the initial set of estimations is reasonably accurate, we can make the assumption that the annotations in the set $\mathcal{Z}_Q^{*(J)}$ are independent given the initial estimates $\mathcal{Z}_Q^{*(I)}$, allowing us to separately optimize the probability of each annotation $\mathbf{z}_Q^{*(J)} \in \mathcal{Z}_Q^{*(J)}$:

$$\mathbf{z}_Q^{*(J)} = \operatorname*{argmax}_{\mathbf{z}_Q} p(\mathbf{z}_Q|\mathcal{Z}_Q^{*(I)}). \qquad (2)$$

From Eq. 2, it is evident that the joint annotation task becomes that of finding some optimal unobserved sequence (annotation $\mathbf{z}_Q^{*(J)}$), given the observed sequences (independent annotation set $\mathcal{Z}_Q^{*(I)}$).

Accordingly, we can directly use a supervised sequential probabilistic model such as CRF (Lafferty et al., 2001) to find the optimal $\mathbf{z}_Q^{*(J)}$. In this CRF model, the optimal annotation $\mathbf{z}_Q^{*(J)}$ is the *label* we are trying to predict, and the set of independent annotations $\mathcal{Z}_Q^{*(I)}$ is used as the basis for the *features* used for prediction. Figure 2 outlines the algorithm for performing the joint query annotation.

As input, the algorithm receives a training set of queries and their ground truth annotations. It then produces a set of independent annotation estimates, which are jointly used, together with the ground truth annotations, to learn a CRF model for each annotation type. Finally, these CRF models are used to predict annotations on a held-out set of queries, which are the output of the algorithm.

Input:	$\mathbf{Q}_t$ — training set of queries. $\mathcal{Z}_{\mathbf{Q}_t}$ — ground truth annotations for the training set of queries. $\mathbf{Q}_h$ — held-out set of queries.
(1)	Obtain a set of independent annotation estimates $\mathcal{Z}^{*(I)}_{\mathbf{Q}_t}$
(2)	Initialize $\mathcal{Z}^{*(J)}_{\mathbf{Q}_t} \leftarrow \emptyset$
(3)	*for each* $\mathbf{z}^{*(I)}_{\mathbf{Q}_t} \in \mathcal{Z}^{*(I)}_{\mathbf{Q}_t}$:
(4)	$\mathcal{Z}'_{\mathbf{Q}_t} \leftarrow \mathcal{Z}^{*(I)}_{\mathbf{Q}_t} \setminus \mathbf{z}^{*(I)}_{\mathbf{Q}_t}$
(5)	Train a CRF model $\mathcal{CRF}(\mathbf{z}_{\mathbf{Q}_t})$ using $\mathbf{z}_{\mathbf{Q}_t}$ as a *label* and $\mathcal{Z}'_{\mathbf{Q}_t}$ as *features*.
(6)	Predict annotation $\mathbf{z}^{*(J)}_{\mathbf{Q}_h}$, using $\mathcal{CRF}(\mathbf{z}_{\mathbf{Q}_t})$.
(7)	$\mathcal{Z}^{*(J)}_{\mathbf{Q}_h} \leftarrow \mathcal{Z}^{*(J)}_{\mathbf{Q}_h} \cup \mathbf{z}^{*(J)}_{\mathbf{Q}_h}$.
Output:	$\mathcal{Z}^{*(J)}_{\mathbf{Q}_h}$ — predicted annotations for the held-out set of queries.

Figure 2: **A**lgorithm for performing joint query annotation.

Note that this formulation of joint query annotation can be viewed as a *stacked classification*, in which a second, more effective, classifier is trained using the labels inferred by the first classifier as features. Stacked classifiers were recently shown to be an efficient and effective strategy for structured classification in NLP (Nivre and McDonald, 2008; Martins et al., 2008).

4 Independent Query Annotations

While the joint annotation method proposed in Section 3 is general enough to be applied to any set of independent query annotations, in this work we focus on two previously proposed independent annotation methods based on either the query itself, or the top sentences retrieved in response to the query (Bendersky et al., 2010). The main benefits of these two annotation methods are that they can be easily implemented using standard software tools, do not require any labeled data, and provide reasonable annotation accuracy. Next, we briefly describe these two independent annotation methods.

4.1 Query-based estimation

The most straightforward way to estimate the conditional probabilities in Eq. 1 is using the query itself. To make the estimation feasible, Bendersky et al. (2010) take a *bag-of-words* approach, and assume independence between both the query terms and the corresponding annotation symbols. Thus, the indepentent annotations in Eq. 1 are given by

$$\mathbf{z}^{*(QRY)}_{Q} = \underset{(\zeta_1,\ldots,\zeta_n)}{\operatorname{argmax}} \prod_{i\in(1,\ldots,n)} p(\zeta_i|q_i). \qquad (3)$$

Following Bendersky et al. (2010) we use a large n-gram corpus (Brants and Franz, 2006) to estimate $p(\zeta_i|q_i)$ for annotating the query with capitalization and segmentation mark-up, and a standard POS tagger[1] for part-of-speech tagging of the query.

4.2 PRF-based estimation

Given a short, often ungrammatical query, it is hard to accurately estimate the conditional probability in Eq. 1 using the query terms alone. For instance, a keyword query *hawaiian falls*, which refers to a location, is inaccurately interpreted by a standard POS tagger as a *noun-verb* pair. On the other hand, given a sentence from a corpus that is relevant to the query such as *"Hawaiian Falls is a family-friendly waterpark"*, the word "falls" is correctly identified by a standard POS tagger as a proper noun.

Accordingly, the document corpus can be bootstrapped in order to better estimate the query annotation. To this end, Bendersky et al. (2010) employ the *pseudo-relevance feedback* (PRF) — a method that has a long record of success in IR for tasks such as query expansion (Buckley, 1995; Lavrenko and Croft, 2001).

In the most general form, given the set of *all* retrievable sentences r in the corpus $\mathcal{C}$ one can derive

$$p(\mathbf{z}_Q|Q) = \sum_{r\in\mathcal{C}} p(\mathbf{z}_Q|r)p(r|Q).$$

Since for most sentences the conditional probability of relevance to the query $p(r|Q)$ is vanishingly small, the above can be closely approximated

[1] `http://crftagger.sourceforge.net/`

by considering only a set of sentences R, retrieved at top-k positions in response to the query Q. This yields

$$p(\mathbf{z}_Q|Q) \approx \sum_{r \in R} p(\mathbf{z}_Q|r)p(r|Q).$$

Intuitively, the equation above models the query as a mixture of top-k retrieved sentences, where each sentence is weighted by its relevance to the query. Furthermore, to make the estimation of the conditional probability $p(\mathbf{z}_Q|r)$ feasible, it is assumed that the symbols ζ_i in the annotation sequence are independent, given a sentence r. Note that this assumption differs from the independence assumption in Eq. 3, since here the annotation symbols are *not independent* given the query Q.

Accordingly, the PRF-based estimate for independent annotations in Eq. 1 is

$$\mathbf{z}_Q^{*(PRF)} = \underset{(\zeta_1,\ldots,\zeta_n)}{\operatorname{argmax}} \sum_{r \in R} \prod_{i \in (1,\ldots,n)} p(\zeta_i|r)p(r|Q). \quad (4)$$

Following Bendersky et al. (2010), an estimate of $p(\zeta_i|r)$ is a smoothed estimator that combines the information from the retrieved sentence r with the information about unigrams (for capitalization and POS tagging) and bigrams (for segmentation) from a large n-gram corpus (Brants and Franz, 2006).

5 Related Work

In recent years, linguistic annotation of search queries has been receiving increasing attention as an important step toward better query processing and understanding. The literature on query annotation includes query segmentation (Bergsma and Wang, 2007; Jones et al., 2006; Guo et al., 2008; Hagen et al., 2010; Hagen et al., 2011; Tan and Peng, 2008), part-of-speech and semantic tagging (Barr et al., 2008; Manshadi and Li, 2009; Li, 2010), named-entity recognition (Guo et al., 2009; Lu et al., 2009; Shen et al., 2008; Paşca, 2007), abbreviation disambiguation (Wei et al., 2008) and stopword detection (Lo et al., 2005; Jones and Fain, 2003).

Most of the previous work on query annotation focuses on performing a particular annotation task (e.g., segmentation or POS tagging) in isolation. However, these annotations are often related, and thus we take a joint annotation approach, which combines several independent annotations to improve the overall annotation accuracy. A similar approach was recently proposed by Guo et al. (2008). There are several key differences, however, between the work presented here and their work.

First, Guo et al. (2008) focus on *query refinement* (spelling corrections, word splitting, etc.) of short keyword queries. Instead, we are interested in *annotation* of queries of different types, including verbose natural language queries. While there is an overlap between query refinement and annotation, the focus of the latter is on providing linguistic information about existing queries (after initial refinement has been performed). Such information is especially important for more verbose and gramatically complex queries. In addition, while all the methods proposed by Guo et al. (2008) require large amounts of training data (thousands of training examples), our joint annotation method can be effectively trained with a minimal human labeling effort (several hundred training examples).

An additional research area which is relevant to this paper is the work on joint structure modeling (Finkel and Manning, 2009; Toutanova et al., 2008) and stacked classification (Nivre and McDonald, 2008; Martins et al., 2008) in natural language processing. These approaches have been shown to be successful for tasks such as parsing and named entity recognition in newswire data (Finkel and Manning, 2009) or semantic role labeling in the Penn Treebank and Brown corpus (Toutanova et al., 2008). Similarly to this work in NLP, we demonstrate that a joint approach for modeling the linguistic query structure can also be beneficial for IR applications.

6 Experiments

6.1 Experimental Setup

For evaluating the performance of our query annotation methods, we use a random sample of 250 queries[2] from a search log. This sample is manually labeled with three annotations: *capitalization*, *POS tags*, and *segmentation*, according to the description of these annotations in Figure 1. In this set of 250 queries, there are 93 questions, 96 phrases contain-

ing a verb, and 61 short keyword queries (Figure 1 contains a single example of each of these types).

In order to test the effectiveness of the joint query annotation, we compare four methods. In the first two methods, *i-QRY* and *i-PRF* the three annotations are done independently. Method *i-QRY* is based on $\mathbf{z}_Q^{*(QRY)}$ estimator (Eq. 3). Method *i-PRF* is based on the $\mathbf{z}_Q^{*(PRF)}$ estimator (Eq. 4).

The next two methods, *j-QRY* and *j-PRF*, are joint annotation methods, which perform a joint optimization over the entire set of annotations, as described in the algorithm in Figure 2. *j-QRY* and *j-PRF* differ in their choice of the initial independent annotation set $\mathcal{Z}_Q^{*(I)}$ in line (1) of the algorithm (see Figure 2). *j-QRY* uses only the annotations performed by *i-QRY* (3 initial independent annotation estimates), while *j-PRF* combines the annotations performed by *i-QRY* with the annotations performed by *i-PRF* (6 initial annotation estimates). The CRF model training in line (6) of the algorithm is implemented using CRF++ toolkit[3].

[3] `http://crfpp.sourceforge.net/`

The performance of the joint annotation methods is estimated using a 10-fold cross-validation. In order to test the statistical significance of improvements attained by the proposed methods we use a two-sided Fisher's randomization test with 20,000 permutations. Results with p-value < 0.05 are considered statistically significant.

For reporting the performance of our methods we use two measures. The first measure is classification-oriented — treating the annotation decision for each query term as a classification. In case of capitalization and segmentation annotations these decisions are binary and we compute the precision and recall metrics, and report F1 — their harmonic mean. In case of POS tagging, the decisions are ternary, and hence we report the classification accuracy.

We also report an additional, IR-oriented performance measure. As is typical in IR, we propose measuring the performance of the annotation methods on a per-query basis, to verify that the methods have uniform impact across queries. Accordingly, we report the *mean of classification accuracies per query* (MQA). Formally, MQA is computed as

$$\frac{\sum_{i=1}^{N} acc_{Q_i}}{N},$$

where acc_{Q_i} is the classification accuracy for query Q_i, and N is the number of queries.

The empirical evaluation is conducted as follows. In Section 6.2, we discuss the general performance of the four annotation techniques, and compare the effectiveness of independent and joint annotations. In Section 6.3, we analyze the performance of the independent and joint annotation methods by query type. In Section 6.4, we compare the difficulty of performing query annotations for different query types. Finally, in Section 6.5, we compare the effectiveness of the proposed joint annotation for query segmentation with the existing query segmentation methods.

6.2 General Evaluation

Table 1 shows the summary of the performance of the two independent and two joint annotation methods for the entire set of 250 queries. For independent methods, we see that *i-PRF* outperforms *i-QRY* for

Table 2: **D**etailed analysis of the query annotation performance for capitalization (CAP), POS tagging (TAG) and segmentation by query type. Numbers in parentheses indicate % of improvement over the *i-PRF* baseline. Best result per measure and annotation is boldfaced. * denotes statistically significant differences with *i-PRF*.

all annotation types, using both performance measures.

In Table 1, we can also observe that the joint annotation methods are, in all cases, better than the corresponding independent ones. The highest improvements are attained by *j-PRF*, which always demonstrates the best performance both in terms of F1 and MQA. These results attest to both the importance of doing a joint optimization over the entire set of annotations and to the robustness of the initial annotations done by the *i-PRF* method. In all but one case, the *j-PRF* method, which uses these annotations as features, outperforms the *j-QRY* method that only uses the annotation done by *i-QRY*.

The most significant improvements as a result of joint annotation are observed for the segmentation task. In this task, joint annotation achieves close to 20% improvement in MQA over the *i-QRY* method, and more than 10% improvement in MQA over the *i-PRF* method. These improvements indicate that the segmentation decisions are strongly guided by capitalization and POS tagging. We also note that, in case of segmentation, the differences in performance between the two joint annotation methods, *j-QRY* and *j-PRF*, are not significant, indicating that the context of additional annotations in *j-QRY* makes up for the lack of more robust pseudo-relevance feedback based features.

We also note that the *lowest* performance improvement as a result of joint annotation is evidenced for POS tagging. The improvements of joint annotation method *j-PRF* over the *i-PRF* method are less than 1%, and are not statistically significant. This is not surprising, since the standard POS taggers often already use bigrams and capitalization at training time, and do not acquire much additional information from other annotations.

6.3 Evaluation by Query Type

Table 2 presents a detailed analysis of the performance of the best independent (*i-PRF*) and joint (*j-PRF*) annotation methods by the three query types used for evaluation: verbal phrases, questions and keyword queries. From the analysis in Table 2, we note that the contribution of joint annotation varies significantly across query types. For instance, using *j-PRF* always leads to statistically significant improvements over the *i-PRF* baseline for questions. On the other hand, it is either statistically indistinguishable, or even significantly worse (in the case of capitalization) than the *i-PRF* baseline for the verbal phrases.

Table 2 also demonstrates that joint annotation has a different impact on various annotations for the *same* query type. For instance, *j-PRF* has a significant positive effect on capitalization and segmentation for keyword queries, but only marginally improves the POS tagging. Similarly, for the verbal phrases, *j-PRF* has a significant positive effect only for the segmentation annotation.

These variances in the performance of the *j-PRF* method point to the differences in the structure be-

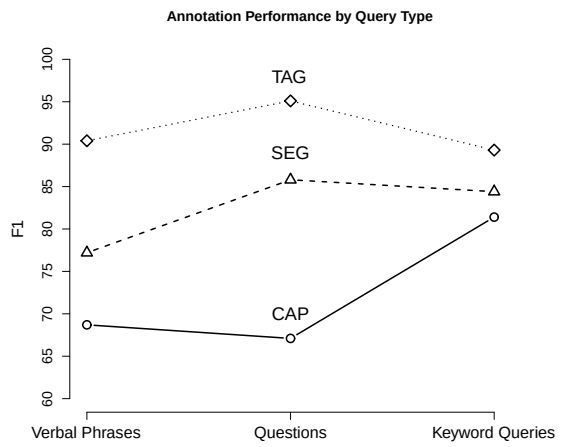

Figure 3: **C**omparative performance (in terms of F1 for capitalization and segmentation and accuracy for POS tagging) of the *j-PRF* method on the three query types.

tween the query types. While dependence between the annotations plays an important role for question and keyword queries, which often share a common grammatical structure, this dependence is less useful for verbal phrases, which have a more diverse linguistic structure. Accordingly, a more in-depth investigation of the linguistic structure of the verbal phrase queries is an interesting direction for future work.

6.4 Annotation Difficulty

Recall that in our experiments, out of the overall 250 annotated queries, there are 96 verbal phrases, 93 questions and 61 keyword queries. Figure 3 shows a plot that contrasts the relative performance for these three query types of our best-performing joint annotation method, *j-PRF*, on capitalization, POS tagging and segmentation annotation tasks. Next, we analyze the performance profiles for the annotation tasks shown in Figure 3.

For the capitalization task, the performance of *j-PRF* on verbal phrases and questions is similar, with the difference below 3%. The performance for keyword queries is much higher — with improvement over 20% compared to either of the other two types. We attribute this increase to both a larger number of positive examples in the short keyword queries (a higher percentage of terms in keyword queries is capitalized) and their simpler syntactic structure (adjacent terms in these queries are likely to have the same case).

SEG	F1	MQA
SEG-1	0.768	0.754
SEG-2	**0.824***	0.787*
j-PRF	0.819* *(+6.7%/-0.6%)*	**0.803*** *(+6.5%/+2.1%)*

Table 3: **C**omparison of the segmentation performance of the *j-PRF* method to two state-of-the-art segmentation methods. Numbers in parentheses indicate % of improvement over the *SEG-1* and *SEG-2* baselines respectively. Best result per measure and annotation is boldfaced. * denotes statistically significant differences with *SEG-1*.

For the segmentation task, the performance is at its best for the question and keyword queries, and at its worst (with a drop of 11%) for the verbal phrases. We hypothesize that this is due to the fact that question queries and keyword queries tend to have repetitive structures, while the grammatical structure for verbose queries is much more diverse.

For the tagging task, the performance profile is reversed, compared to the other two tasks — the performance is at its worst for keyword queries, since their grammatical structure significantly differs from the grammatical structure of sentences in news articles, on which the POS tagger is trained. For question queries the performance is the best (6% increase over the keyword queries), since they resemble sentences encountered in traditional corpora.

It is important to note that the results reported in Figure 3 are based on training the joint annotation model on *all* available queries with 10-fold cross-validation. We might get different profiles if a separate annotation model was trained for each query type. In our case, however, the number of queries from each type is not sufficient to train a reliable model. We leave the investigation of separate training of joint annotation models by query type to future work.

6.5 Additional Comparisons

In order to further evaluate the proposed joint annotation method, *j-PRF*, in this section we compare its performance to other query annotation methods previously reported in the literature. Unfortunately, there is not much published work on query capitalization and query POS tagging that goes beyond the simple query-based methods described in Sec-

tion 4.1. The published work on the more advanced methods usually requires access to large amounts of proprietary user data such as query logs and clicks (Barr et al., 2008; Guo et al., 2008; Guo et al., 2009).

Therefore, in this section we focus on recent work on query segmentation (Bergsma and Wang, 2007; Hagen et al., 2010). We compare the segmentation effectiveness of our best performing method, *j-PRF*, to that of these query segmentation methods.

The first method, *SEG-1*, was first proposed by Hagen et al. (2010). It is currently the most effective publicly disclosed *unsupervised* query segmentation method. *SEG-1* method requires an access to a large web n-gram corpus (Brants and Franz, 2006). The optimal segmentation for query Q, S^*_Q, is then obtained using

$$S^*_Q = \underset{S \in \mathcal{S}_Q}{\operatorname{argmax}} \sum_{s \in S, |s|>1} |s|^{|s|} count(s),$$

where $\mathcal{S}_Q$ is the set of all possible query segmentations, S is a possible segmentation, s is a segment in S, and $count(s)$ is the frequency of s in the web n-gram corpus.

The second method, *SEG-2*, is based on a successful supervised segmentation method, which was first proposed by Bergsma and Wang (2007). *SEG-2* employs a large set of features, and is pre-trained on the query collection described by Bergsma and Wang (2007). The features used by the *SEG-2* method are described by Bendersky et al. (2009), and include, among others, n-gram frequencies in a sample of a query log, web corpus and Wikipedia titles.

Table 3 demonstrates the comparison between the *j-PRF*, *SEG-1* and *SEG-2* methods. When compared to the *SEG-1* baseline, *j-PRF* is significantly more effective, even though it only employs bigram counts (see Eq. 4), instead of the high-order n-grams used by *SEG-1*, for computing the score of a segmentation. This results underscores the benefit of joint annotation, which leverages capitalization and POS tagging to improve the quality of the segmentation.

When compared to the *SEG-2* baseline, *j-PRF* and *SEG-2* are statistically indistinguishable. *SEG-2* posits a slightly better F1, while *j-PRF* has a better MQA. This result demonstrates that the segmentation produced by the *j-PRF* method is as effective as the segmentation produced by the current supervised state-of-the-art segmentation methods, which employ external data sources and high-order n-grams. The benefit of the *j-PRF* method compared to the *SEG-2* method, is that, simultaneously with the segmentation, it produces several additional query annotations (in this case, capitalization and POS tagging), eliminating the need to construct separate sequence classifiers for each annotation.

7 Conclusions

In this paper, we have investigated a joint approach for annotating search queries with linguistic structures, including capitalization, POS tags and segmentation. To this end, we proposed a probabilistic approach for performing joint query annotation that takes into account the dependencies that exist between the different annotation types.

Our experimental findings over a range of queries from a web search log unequivocally point to the superiority of the joint annotation methods over both query-based and pseudo-relevance feedback based independent annotation methods. These findings indicate that the different annotations are mutually-dependent.

We are encouraged by the success of our joint query annotation technique, and intend to pursue the investigation of its utility for IR applications. In the future, we intend to research the use of joint query annotations for additional IR tasks, e.g., for constructing better query formulations for ranking algorithms.

Abstract

We propose to directly measure the importance of queries in the source domain to the target domain where no rank labels of documents are available, which is referred to as query weighting. Query weighting is a key step in ranking model adaptation. As the learning object of ranking algorithms is divided by query instances, we argue that it's more reasonable to conduct importance weighting at query level than document level. We present two query weighting schemes. The first compresses the query into a *query feature vector*, which aggregates all document instances in the same query, and then conducts query weighting based on the query feature vector. This method can efficiently estimate query importance by compressing query data, but the potential risk is information loss resulted from the compression. The second measures the similarity between the source query and each target query, and then combines these *fine-grained* similarity values for its importance estimation. Adaptation experiments on LETOR3.0 data set demonstrate that query weighting significantly outperforms document instance weighting methods.

1 Introduction

Learning to rank, which aims at ranking documents in terms of their relevance to user's query, has been widely studied in machine learning and information retrieval communities (Herbrich et al., 2000; Freund et al., 2004; Burges et al., 2005; Yue et al., 2007; Cao et al., 2007; Liu, 2009). In general, large amount of training data need to be annotated by domain experts for achieving better ranking performance. In real applications, however, it is time consuming and expensive to annotate training data for each search domain. To alleviate the lack of training data in the target domain, many researchers have proposed to transfer ranking knowledge from the source domain with plenty of labeled data to the target domain where only a few or no labeled data is available, which is known as ranking model adaptation (Chen et al., 2008a; Chen et al., 2010; Chen et al., 2008b; Geng et al., 2009; Gao et al., 2009).

Intuitively, the more similar an source instance is to the target instances, it is expected to be more useful for cross-domain knowledge transfer. This motivated the popular domain adaptation solution based on instance weighting, which assigns larger weights to those transferable instances so that the model trained on the source domain can adapt more effectively to the target domain (Jiang and Zhai, 2007). Existing instance weighting schemes mainly focus on the adaptation problem for classification (Zadrozny, 2004; Huang et al., 2007; Jiang and Zhai, 2007; Sugiyama et al., 2008).

Although instance weighting scheme may be applied to documents for ranking model adaptation, the difference between classification and learning to rank should be highlighted to take careful consideration. Compared to classification, the learning object for ranking is essentially a query, which contains a list of document instances each with a relevance judgement. Recently, researchers proposed listwise ranking algorithms (Yue et al., 2007; Cao et al., 2007) to take the whole query as a learning object. The benchmark evaluation showed that list-

(a) Instance based weighting (b) Query based weighting

Figure 1: The information about which document instances belong to the same query is lost in document instance weighting scheme. To avoid losing this information, query weighting takes the query as a whole and directly measures its importance.

wise approach significantly outperformed pointwise approach, which takes each document instance as independent learning object, as well as pairwise approach, which concentrates learning on the order of a pair of documents (Liu, 2009). Inspired by the principle of listwise approach, we hypothesize that the importance weighting for ranking model adaptation could be done better at query level rather than document level.

Figure 1 demonstrates the difference between instance weighting and query weighting, where there are two queries q_{s1} and q_{s2} in the source domain and q_{t1} and q_{t2} in the target domain, respectively, and each query has three retrieved documents. In Figure 1(a), source and target domains are represented as a bag of document instances. It is worth noting that the information about which document instances belong to the same query is lost. To avoid this information loss, query weighting scheme shown as Figure 1(b) directly measures importance weight at query level.

Instance weighting makes the importance estimation of document instances inaccurate when documents of the same source query are similar to the documents from different target queries. Take Figure 2 as a toy example, where the document instance is represented as a feature vector with four features. No matter what weighting schemes are used, it makes sense to assign high weights to source queries q_{s1} and q_{s2} because they are similar to target queries q_{t1} and q_{t2}, respectively. Meanwhile, the source query q_{s3} should be weighted lower because

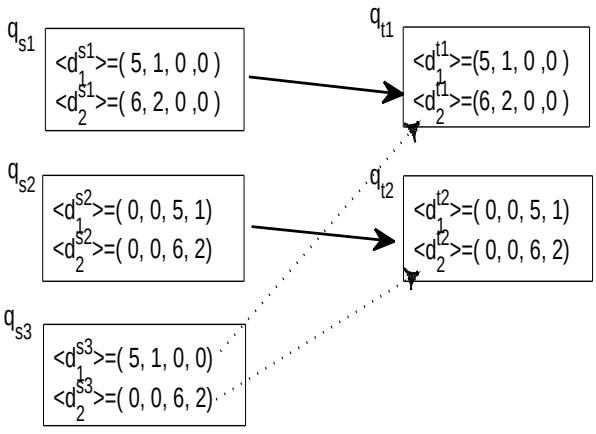

Figure 2: A toy example showing the problem of document instance weighting scheme.

it's not quite similar to any of q_{t1} and q_{t2} at query level, meaning that the ranking knowledge from q_{s3} is different from that of q_{t1} and q_{t2} and thus less useful for the transfer to the target domain. Unfortunately, the three source queries q_{s1}, q_{s2} and q_{s3} would be weighted equally by document instance weighting scheme. The reason is that all of their documents are similar to the two document instances in target domain despite the fact that the documents of q_{s3} correspond to their counterparts from *different* target queries.

Therefore, we should consider the source query as a whole and directly measure the query importance. However, it's not trivial to directly estimate

a query's weight because a query is essentially provided as a matrix where each row represents a vector of document features. In this work, we present two simple but very effective approaches attempting to resolve the problem from distinct perspectives: (1) we compress each query into a *query feature vector* by aggregating all of its document instances, and then conduct query weighting on these query feature vectors; (2) we measure the similarity between the source query and each target query one by one, and then combine these *fine-grained* similarity values to calculate its importance to the target domain.

2 Instance Weighting Scheme Review

The basic idea of instance weighting is to put larger weights on source instances which are more similar to target domain. As a result, the key problem is how to accurately estimate the instance's weight indicating its importance to target domain. (Jiang and Zhai, 2007) used a small number of *labeled* data from target domain to weight source instances. Recently, some researchers proposed to weight source instance only using *unlabeled* target instances (Shimodaira, 2000; Sugiyama et al., 2008; Huang et al., 2007; Zadrozny, 2004; Gao et al., 2010). In this work, we also focus on weighting source queries only using *unlabeled* target queries.

(Gao et al., 2010; Ben-David et al., 2010) proposed to use a classification hyperplane to separate source instances from target instances. With the domain separator, the probability that a source instance is classified to target domain can be used as the importance weight. Other instance weighting methods were proposed for the sample selection bias or covariate shift in the more general setting of classifier learning (Shimodaira, 2000; Sugiyama et al., 2008; Huang et al., 2007; Zadrozny, 2004). (Sugiyama et al., 2008) used a natural model selection procedure, referred to as Kullback-Leibler divergence Importance Estimation Procedure (KLIEP), for automatically tuning parameters, and showed that its importance estimation was more accurate. The main idea is to directly estimate the density function ratio of target distribution $p_t(x)$ to source distribution $p_s(x)$, i.e. $w(x) = \frac{p_t(x)}{p_s(x)}$. Then model $w(x)$ can be used to estimate the importance of source instances. Model parameters were computed with a linear model by minimizing the KL-divergence from $p_t(x)$ to its estimator $\hat{p}_t(x)$. Since $\hat{p}_t(x) = \hat{w}(x)p_s(x)$, the ultimate objective only contains model $\hat{w}(x)$.

For using instance weighting in pairwise ranking algorithms, the weights of document instances should be transformed into those of document pairs (Gao et al., 2010). Given a pair of documents $\langle x_i, x_j \rangle$ and their weights w_i and w_j, the pairwise weight w_{ij} could be estimated probabilistically as $w_i * w_j$. To consider query factor, query weight was further estimated as the average value of the weights over all the pairs, i.e., $w_q = \frac{1}{M} \sum_{i,j} w_{ij}$, where M is the number of pairs in query q. Additionally, to take the advantage of both query and document information, a probabilistic weighting for $\langle x_i, x_j \rangle$ was modeled by $w_q * w_{ij}$. Through the transformation, instance weighting schemes for classification can be applied to ranking model adaptation.

3 Query Weighting

In this section, we extend instance weighting to directly estimate query importance for more effective ranking model adaptation. We present two query weighting methods from different perspectives. Note that although our methods are based on domain separator scheme, other instance weighting schemes such as KLIEP (Sugiyama et al., 2008) can also be extended similarly.

3.1 Query Weighting by Document Feature Aggregation

Our first query weighting method is inspired by the recent work on local learning for ranking (Geng et al., 2008; Banerjee et al., 2009). The query can be compressed into a query feature vector, where each feature value is obtained by the aggregate of its corresponding features of all documents in the query. We concatenate two types of aggregates to construct the query feature vector: the mean $\vec{\mu} = \frac{1}{|q|} \sum_{i=1}^{|q|} \vec{f_i}$ and the variance $\vec{\sigma} = \frac{1}{|q|} \sum_{i=1}^{|q|} (\vec{f_i} - \vec{\mu})^2$, where $\vec{f_i}$ is the feature vector of document i and $|q|$ denotes the number of documents in q . Based on the aggregation of documents within each query, we can use a domain separator to directly weight the source queries with the set of queries from both domains.

Given query data sets $D_s = \{q_s^i\}_{i=1}^m$ and $D_t = \{q_t^j\}_{j=1}^n$ respectively from the source and target do-

Algorithm 1 Query Weighting Based on Document Feature Aggregation in the Query

Input:

Queries in the source domain, $D_s = \{q_s^i\}_{i=1}^m$;

Queries in the target domain, $D_t = \{q_t^j\}_{j=1}^n$;

Output:

Importance weights of queries in the source domain, $IW_s = \{W_i\}_{i=1}^m$;

1: $y_s = -1, y_t = +1$;
2: **for** $i = 1; i \leq m; i++$ **do**
3: Calculate the mean vector $\vec{\mu}_i$ and variance vector $\vec{\sigma}_i$ for q_s^i;
4: Add query feature vector $\vec{q}_s^i = (\vec{\mu}_i, \vec{\sigma}_i, y_s)$ to D'_s ;
5: **end for**
6: **for** $j = 1; j \leq n; j++$ **do**
7: Calculate the mean vector $\vec{\mu}_j$ and variance vector $\vec{\sigma}_j$ for q_t^j;
8: Add query feature vector $\vec{q}_t^j = (\vec{\mu}_j, \vec{\sigma}_j, y_t)$ to D'_t;
9: **end for**
10: Find classification hyperplane H_{st} which separates D'_s from D'_t;
11: **for** $i = 1; i \leq m; i++$ **do**
12: Calculate the distance of $\vec{q}_s^i$ to H_{st}, denoted as $\mathcal{L}(\vec{q}_s^i)$;
13: $W_i = P(q_s^i \in D_t) = \frac{1}{1+exp(\alpha * \mathcal{L}(\vec{q}_s^i)+\beta)}$
14: Add W_i to IW_s;
15: **end for**
16: **return** IW_s;

mains, we use algorithm 1 to estimate the probability that the query q_s^i can be classified to D_t, i.e. $P(q_s^i \in D_t)$, which can be used as the importance of q_s^i relative to the target domain. From step 1 to 9, D'_s and D'_t are constructed using query feature vectors from source and target domains. Then, a classification hyperplane H_{st} is used to separate D'_s from D'_t in step 10. The distance of the query feature vector $\vec{q}_s^i$ from H_{st} are transformed to the probability $P(q_s^i \in D_t)$ using a sigmoid function (Platt and Platt, 1999).

3.2 Query Weighting by Comparing Queries across Domains

Although the query feature vector in algorithm 1 can approximate a query by aggregating its documents' features, it potentially fails to capture important feature information due to the averaging effect during the aggregation. For example, the merit of features in some influential documents may be canceled out in the mean-variance calculation, resulting in many distorted feature values in the query feature vector that hurts the accuracy of query classification hyperplane. This urges us to propose another query weighting method from a different perspective of query similarity.

Intuitively, the importance of a source query to the target domain is determined by its overall similarity to every target query. Based on this intuition, we leverage domain separator to measure the similarity between a source query and each one of the target queries, where an individual domain separator is created for each pair of queries. We estimate the weight of a source query using algorithm 2. Note that we assume document instances in the same query are conditionally independent and all queries are independent of each other. In step 3, $D'_{q_s^i}$ is constructed by all the document instances $\{\vec{x}_k\}$ in query q_s^i with the domain label y_s. For each target query q_t^j, we use the classification hyperplane H_{ij} to estimate $P(\vec{x}_k \in D'_{q_t^j})$, i.e. the probability that each document $\vec{x}_k$ of q_s^i is classified into the document set of q_t^j (step 8). Then the similarity between q_s^i and q_t^j is measured by the probability $P(q_s^i \sim q_t^j)$ at step 9. Finally, the probability of q_s^i belonging to the target domain $P(q_s^i \in D_t)$ is calculated at step 11.

It can be expected that algorithm 2 will generate

Algorithm 2 Query Weighting by Comparing Source and Target Queries

Input:

Queries in source domain, $D_s = \{q_s^i\}_{i=1}^m$;

Queries in target domain, $D_t = \{q_t^j\}_{j=1}^n$;

Output:

  for $j = 1; j \leq n; j++$ **do**
    Set $D'_{q_t^j}$=$\{\vec{x}_{k'}, y_t)\}_{k'=1}^{|q_t^j|}$;
    Find a classification hyperplane H_{ij} which separates $D'_{q_s^i}$ from $D'_{q_t^j}$;
    For each k, calculate the distance of $\vec{x}_k$ to H_{ij}, denoted as $\mathcal{L}(\vec{x}_k)$;
    For each k, calculate $P(\vec{x}_k \in D'_{q_t^j}) = \frac{1}{1+exp(\alpha * \mathcal{L}(\vec{x}_k)+\beta)}$;
    Calculate $P(q_s^i \sim q_t^j) = \frac{1}{|q_s^i|} \sum_{k=1}^{|q_s^i|} P(\vec{x}_k \in D'_{q_t^j})$;
  end for
  Add $W_i = P(q_s^i \in D_t) = \frac{1}{n} \sum_{j=1}^n P(q_s^i \sim q_t^j)$ to IW_s;
end for
return IW_s;

more precise measures of query similarity by utilizing the more fine-grained classification hyperplane for separating the queries of two domains.

4 Ranking Model Adaptation via Query Weighting

To adapt the source ranking model to the target domain, we need to incorporate query weights into existing ranking algorithms. Note that query weights can be integrated with either pairwise or listwise algorithms. For pairwise algorithms, a straightforward way is to assign the query weight to all the document pairs associated with this query. However, document instance weighting cannot be appropriately utilized in listwise approach. In order to compare query weighting with document instance weighting, we need to fairly apply them for the same approach of ranking. Therefore, we choose pairwise approach to incorporate query weighting. In this section, we extend Ranking SVM (RSVM) (Herbrich et al., 2000; Joachims, 2002) — one of the typical pairwise algorithms for this.

Let's assume there are m queries in the data set of source domain, and for each query q_i there are $\ell(q_i)$ number of meaningful document pairs that can be constructed based on the ground truth rank labels. Given ranking function f, the objective of RSVM is presented as follows:

$$\min \frac{1}{2}||\vec{w}||^2 + C \sum_{i=1}^{m} \sum_{j=1}^{\ell(q_i)} \xi_{ij} \quad (1)$$
$$\text{subject to } z_{ij} * f(\vec{w}, \vec{x}_{q_i}^{j(1)} - \vec{x}_{q_i}^{j(2)}) \geq 1 - \xi_{ij}$$
$$\xi_{ij} \geq 0, i = 1, \ldots, m; j = 1, \ldots, \ell(q_i)$$

where $\vec{x}_{q_i}^{j(1)}$ and $\vec{x}_{q_i}^{j(2)}$ are two documents with different rank label, and $z_{ij} = +1$ if $\vec{x}_{q_i}^{j(1)}$ is labeled more relevant than $\vec{x}_{q_i}^{j(2)}$; or $z_{ij} = -1$ otherwise.

Let $\lambda = \frac{1}{2C}$ and replace ξ_{ij} with Hinge Loss function $(.)^+$, Equation 1 can be turned to the following form:

$$\min \lambda||\vec{w}||^2 + \sum_{i=1}^{m} \sum_{j=1}^{\ell(q_i)} \left(1 - z_{ij} * f(\vec{w}, \vec{x}_{q_i}^{j(1)} - \vec{x}_{q_i}^{j(2)})\right)^+ \quad (2)$$

Let $IW(q_i)$ represent the importance weight of source query q_i. Equation 2 is extended for integrating the query weight into the loss function in a

straightforward way:

$$\min \lambda||\vec{w}||^2 + \sum_{i=1}^{m} IW(q_i) * \sum_{j=1}^{\ell(q_i)} \left(1 - z_{ij} * f(\vec{w}, \vec{x}_{q_i}^{j(1)} - \vec{x}_{q_i}^{j(2)})\right)^+$$

where $IW(.)$ takes any one of the weighting schemes given by algorithm 1 and algorithm 2.

5 Evaluation

We evaluated the proposed two query weighting methods on TREC-2003 and TREC-2004 web track datasets, which were released through LETOR3.0 as a benchmark collection for learning to rank by (Qin et al., 2010). Originally, different query tasks were defined on different parts of data in the collection, which can be considered as different domains for us. Adaptation takes place when ranking tasks are performed by using the models trained on the domains in which they were originally defined to rank the documents in other domains. Our goal is to demonstrate that query weighting can be more effective than the state-of-the-art document instance weighting.

5.1 Datasets and Setup

Three query tasks were defined in TREC-2003 and TREC-2004 web track, which are home page finding (HP), named page finding (NP) and topic distillation (TD) (Voorhees, 2003; Voorhees, 2004). In this dataset, each document instance is represented by 64 features, including low-level features such as term frequency, inverse document frequency and document length, and high-level features such as BM25, language-modeling, PageRank and HITS. The number of queries of each task is given in Table 1.

The *baseline* ranking model is an RSVM directly trained on the source domain without using any weighting methods, denoted as *no-weight*. We implemented two weighting measures based on domain separator and Kullback-Leibler divergence, referred to *DS* and *KL*, respectively. In *DS* measure, three document instance weighting methods based on probability principle (Gao et al., 2010) were implemented for comparison, denoted as *doc-pair*, *doc-avg* and *doc-comb* (see Section 2). In *KL* measure, there is no probabilistic meaning for KL weight and the *doc-comb* based on KL is not interpretable, and we only present the results of *doc-pair* and *doc-avg* for KL measure. Our proposed query weighting methods are denoted by *query-aggr* and *query-comp*, corresponding to document feature aggregation in query and query comparison across domains, respectively. All ranking models above were trained only on source domain training data and the labeled data of target domain was just used for testing.

Query Task	TREC 2003	TREC 2004
Topic Distillation	50	75
Home Page finding	150	75
Named Page finding	150	75

Table 1: The number of queries in TREC-2003 and TREC-2004 web track

For training the models efficiently, we implemented RSVM with Stochastic Gradient Descent (SGD) optimizer (Shalev-Shwartz et al., 2007). The reported performance is obtained by five-fold cross validation.

5.2 Experimental Results

The task of HP and NP are more similar to each other whereas HP/NP is rather different from TD (Voorhees, 2003; Voorhees, 2004). Thus, we carried out HP/NP to TD and TD to HP/NP ranking adaptation tasks. Mean Average Precision (MAP) (Baeza-Yates and Ribeiro-Neto, 1999) is used as the ranking performance measure.

5.2.1 Adaptation from HP/NP to TD

The first set of experiments performed adaptation from HP to TD and NP to TD. The results of MAP are shown in Table 2.

For the DS-based measure, as shown in the table, *query-aggr* works mostly better than *no-weight*,*doc-pair*, *doc-avg* and *doc-comb*, and *query-comp* performs the best among the five weighting methods. T-test on MAP indicates that the improvement of *query-aggr* over *no-weight* is statistically significant on two adaptation tasks while the improvement of document instance weighting over *no-weight* is statistically significant only on one task. All of the improvement of *query-comp* over *no-weight*, *doc-pair*,*doc-avg* and *doc-comb* are statistically significant. This demonstrates the effectiveness of query

Model	Weighting method	HP03 to TD03	HP04 to TD04	NP03 to TD03	NP04 to TD04
	no-weight	0.2508	0.2086	0.1936	0.1756
DS	*doc-pair*	0.2505	0.2042	$0.1982^{\dagger}$	0.1708
	doc-avg	0.2514	0.2019	$0.2122^{\dagger\ddagger}$	0.1716
	doc-comb	0.2562	0.2051	$0.2224^{\dagger\ddagger\sharp}$	0.1793
	query-aggr	0.2573	$\mathbf{0.2106}^{\dagger\ddagger\sharp}$	0.2088	$\mathbf{0.1808}^{\dagger\ddagger\sharp}$
	query-comp	$\mathbf{0.2816}^{\dagger\ddagger\sharp}$	$\mathbf{0.2147}^{\dagger\ddagger\sharp}$	$\mathbf{0.2392}^{\dagger\ddagger\sharp}$	$\mathbf{0.1861}^{\dagger\ddagger\sharp}$
KL	*doc-pair*	0.2521	0.2048	0.1901	0.1761
	doc-avg	0.2534	$0.2127^{\dagger}$	0.1904	0.1777

weighting compared to document instance weighting.

Furthermore, *query-comp* can perform better than *query-aggr*. The reason is that although document feature aggregation might be a reasonable representation for a set of document instances, it is possible that some information could be lost or distorted in the process of compression. By contrast, more accurate query weights can be achieved by the more fine-grained similarity measure between the source query and all target queries in algorithm 2.

For the KL-based measure, similar observation can be obtained. However, it's obvious that DS-based models can work better than the KL-based. The reason is that KL conducts weighting by density function ratio which is sensitive to the data scale. Specifically, after document feature aggregation, the number of query feature vectors in all adaptation tasks is no more than 150 in source and target domains. It renders the density estimation in *query-aggr* is very inaccurate since the set of samples is too small. As each query contains 1000 documents, they seemed to provide *query-comp* enough samples for achieving reasonable estimation of the density functions in both domains.

5.2.2 Adaptation from TD to HP/NP

To further validate the effectiveness of query weighting, we also conducted adaptation from TD to HP and TD to NP . MAP results with significant test are shown in Table 3.

We can see that document instance weighting schemes including *doc-pair*, *doc-avg* and *doc-comb* can not outperform *no-weight* based on MAP measure. The reason is that each query in TD has 1000 retrieved documents in which 10-15 documents are relevant whereas each query in HP or NP only consists 1-2 relevant documents. Thus, when TD serves as the source domain, it leads to the problem that too many document pairs were generated for training the RSVM model. In this case, a small number of documents that were weighted inaccurately can make significant impact on many number of document pairs. Since query weighting method directly estimates the query importance instead of document instance importance, both *query-aggr* and *query-comp* can avoid such kind of negative influence that is inevitable in the three document instance weighting methods.

5.2.3 The Analysis on Source Query Weights

An interesting problem is which queries in the source domain are assigned high weights and why it's the case. Query weighting assigns each source query with a weight value. Note that it's not meaningful to directly compare absolute weight values between *query-aggr* and *query-comp* because source query weights from distinct weighting methods have different range and scale. However, it is feasible to compare the weights with the same weighting method. Intuitively, if the ranking model learned from a source query can work well in target domain, it should get high weight. According to this intuition, if ranking models $f_{q_s^1}$ and $f_{q_s^2}$ are learned

model	weighting scheme	TD03 to HP03	TD04 to HP04	TD03 to NP03	TD04 to NP04
	no-weight	0.6986	0.6158	0.5053	0.5427
DS	*doc-pair*	0.6588	$0.6235^{\dagger}$	0.4878	0.5212
	doc-avg	0.6654	0.6200	0.4736	0.5035
	doc-comb	0.6932	$0.6214^{\dagger}$	0.4974	0.5077
	query-aggr	$\mathbf{0.7179}^{\dagger\ddagger\sharp}$	$0.6292^{\dagger\ddagger\sharp}$	$\mathbf{0.5198}^{\dagger\ddagger\sharp}$	$\mathbf{0.5551}^{\dagger\ddagger\sharp}$
	query-comp	$\mathbf{0.7297}^{\dagger\ddagger\sharp}$	$\mathbf{0.6499}^{\dagger\ddagger\sharp}$	$\mathbf{0.5203}^{\dagger\ddagger\sharp}$	$\mathbf{0.6541}^{\dagger\ddagger\sharp}$
KL	*doc-pair*	0.6480	0.6107	0.4633	0.5413
	doc-avg	0.6472	0.6132	0.4626	0.5406
	doc-comb	–	–	–	–
	query-aggr	0.6263	0.5929	0.4597	0.4673
	query-comp	$0.6530^{\ddagger\sharp}$	$0.6358^{\dagger\ddagger\sharp}$	0.4726	$0.5559^{\dagger\ddagger\sharp}$

Table 3: Results of MAP for TD to HP/NP adaptation. †, ‡, ♯ and boldface indicate significantly better than *no-weight*, *doc-pair*, *doc-avg* and *doc-comb*, respectively. Confidence level is set as 95%.

from queries q_s^1 and q_s^2 respectively, and $f_{q_s^1}$ performs better than $f_{q_s^2}$, then the source query weight of q_s^1 should be higher than that of q_s^2.

For further analysis, we compare the weight values between each source query pair, for which we trained RSVM on each source query and evaluated the learned model on test data from target domain. Then, the source queries are ranked according to the MAP values obtained by their corresponding ranking models. The order is denoted as R_{map}. Meanwhile, the source queries are also ranked with respect to their weights estimated by DS-based measure, and the order is denoted as R_{weight}. We hope R_{weight} is correlated as positively as possible with R_{map}. For comparison, we also ranked these queries according to randomly generated query weights, which is denoted as *query-rand* in addition to *query-aggr* and *query-comp*. The Kendall's $\tau = \frac{P-Q}{P+Q}$ is used to measure the correlation (Kendall, 1970), where P is the number of concordant query pairs and Q is the number of discordant pairs. It's noted that τ's range is from -1 to 1, and the larger value means the two ranking is better correlated. The Kendall's τ by different weighting methods are given in Table 4 and 5.

We find that R_{weight} produced by *query-aggr* and *query-comp* are all positively correlated with R_{map} and clearly the orders generated by *query-comp* are more positive than those by *query-aggr*. This is another explanation why *query-comp* outperforms *query-aggr*. Furthermore, both are far better than *query-rand* because the R_{weight} by *query-rand* is actually independent of R_{map}.

weighting	TD03 to HP03	TD04 to HP04
doc-pair	28,835 secs	21,640 secs
query-aggr	182 secs	123 secs
query-comp	15,056 secs	10,081 secs

Table 6: The efficiency of weighting in seconds.

5.2.4 Efficiency

In the situation where there are large scale data in source and target domains, how to efficiently weight a source query is another interesting problem. Without the loss of generality, we reported the weighting time of *doc-pair*, *query-aggr* and *query-comp* from adaptation from TD to HP using DS measure. As *doc-avg* and *doc-comb* are derived from *doc-pair*, their efficiency is equivalent to *doc-pair*.

As shown in table 6, *query-aggr* can efficiently weight query using query feature vector. The reason is two-fold: one is the operation of query document aggregation can be done very fast, and the other is there are 1000 documents in each query of TD or HP, which means that the compression ratio is 1000:1. Thus, the domain separator can be found quickly. In addition, *query-comp* is more efficient than *doc-pair* because *doc-pair* needs too much time to find the separator using all instances from source and target domain. And *query-comp* uses a divide-and-conquer method to measure the similarity of source query to each target query, and then efficiently combine these

Weighting method	HP03 to TD03	HP04 to TD04	NP03 to TD03	NP04 to TD04

fine-grained similarity values.

6 Related Work

Cross-domain knowledge transfer has became an important topic in machine learning and natural language processing (Ben-David et al., 2010; Jiang and Zhai, 2007; Blitzer et al., 2006; Daumé III and Marcu, 2006). (Blitzer et al., 2006) proposed model adaptation using pivot features to build structural feature correspondence in two domains. (Pan et al., 2009) proposed to seek a common features space to reduce the distribution difference between the source and target domain. (Daumé III and Marcu, 2006) assumed training instances were generated from source domain, target domain and cross-domain distributions, and estimated the parameter for the mixture distribution.

Recently, domain adaptation in learning to rank received more and more attentions due to the lack of training data in new search domains. Existing ranking adaptation approaches can be grouped into feature-based (Geng et al., 2009; Chen et al., 2008b; Wang et al., 2009; Gao et al., 2009) and instance-based (Chen et al., 2010; Chen et al., 2008a; Gao et al., 2010) approaches. In (Geng et al., 2009; Chen et al., 2008b), the parameters of ranking model trained on the source domain was adjusted with the small set of labeled data in the target domain. (Wang et al., 2009) aimed at ranking adaptation in heterogeneous domains. (Gao et al., 2009) learned ranking models on the source and target domains independently, and then constructed a stronger model by interpolating the two models. (Chen et al., 2010; Chen et al., 2008a) weighted source instances by using small amount of labeled data in the target domain. (Gao et al., 2010) studied instance weighting based on domain separator for learning to rank by only using training data from source domain. In this work, we propose to directly measure the query importance instead of document instance importance by considering information at both levels.

7 Conclusion

We introduced two simple yet effective query weighting methods for ranking model adaptation. The first represents a set of document instances within the same query as a query feature vector, and then directly measure the source query importance to the target domain. The second measures the similarity between a source query and each target query, and then combine the fine-grained similarity values to estimate its importance to target domain. We evaluated our approaches on LETOR3.0 dataset for ranking adaptation and found that: (1) the first method efficiently estimate query weights, and can outperform the document instance weighting but some information is lost during the aggregation; (2) the second method consistently and significantly outperforms document instance weighting.

Abstract

Joint sentiment-topic (JST) model was previously proposed to detect sentiment and topic simultaneously from text. The only supervision required by JST model learning is domain-independent polarity word priors. In this paper, we modify the JST model by incorporating word polarity priors through modifying the topic-word Dirichlet priors. We study the polarity-bearing topics extracted by JST and show that by augmenting the original feature space with polarity-bearing topics, the in-domain supervised classifiers learned from augmented feature representation achieve the state-of-the-art performance of 95% on the movie review data and an average of 90% on the multi-domain sentiment dataset. Furthermore, using feature augmentation and selection according to the information gain criteria for cross-domain sentiment classification, our proposed approach performs either better or comparably compared to previous approaches. Nevertheless, our approach is much simpler and does not require difficult parameter tuning.

1 Introduction

Given a piece of text, sentiment classification aims to determine whether the semantic orientation of the text is positive, negative or neutral. Machine learning approaches to this problem (**?**; **?**; **?**; **?**; **?**; **?**) typically assume that classification models are trained and tested using data drawn from some fixed distribution. However, in many practical cases, we may have plentiful labeled examples in the *source* domain, but very few or no labeled examples in the *target* domain with a different distribution. For example, we may have many labeled books reviews, but we are interested in detecting the polarity of electronics reviews. Reviews for different produces might have widely different vocabularies, thus classifiers trained on one domain often fail to produce satisfactory results when shifting to another domain. This has motivated much research on sentiment transfer learning which transfers knowledge from a source task or domain to a different but related task or domain (**?**; **?**; **?**; **?**).

Joint sentiment-topic (JST) model (**?**; **?**) was extended from the latent Dirichlet allocation (LDA) model (**?**) to detect sentiment and topic simultaneously from text. The only supervision required by JST learning is domain-independent polarity word prior information. With prior polarity words extracted from both the MPQA subjectivity lexicon[1] and the appraisal lexicon[2], the JST model achieves a sentiment classification accuracy of 74% on the movie review data[3] and 71% on the multi-domain sentiment dataset[4]. Moreover, it is also able to extract coherent and informative topics grouped under different sentiment. The fact that the JST model does not required any labeled documents for training makes it desirable for domain adaptation in sentiment classification. Many existing approaches solve the sentiment transfer problem by associating words

from different domains which indicate the same sentiment (**?**; **?**). Such an association mapping problem can be naturally solved by the posterior inference in the JST model. Indeed, the polarity-bearing topics extracted by JST essentially capture sentiment associations among words from different domains which effectively overcome the data distribution difference between source and target domains.

The previously proposed JST model uses the sentiment prior information in the Gibbs sampling inference step that a sentiment label will only be sampled if the current word token has no prior sentiment as defined in a sentiment lexicon. This in fact implies a different generative process where many of the word prior sentiment labels are observed. The model is no longer "latent". We propose an alternative approach by incorporating word prior polarity information through modifying the topic-word Dirichlet priors. This essentially creates an informed prior distribution for the sentiment labels and would allow the model to actually be latent and would be consistent with the generative story.

We study the polarity-bearing topics extracted by the JST model and show that by augmenting the original feature space with polarity-bearing topics, the performance of in-domain supervised classifiers learned from augmented feature representation improves substantially, reaching the state-of-the-art results of 95% on the movie review data and an average of 90% on the multi-domain sentiment dataset. Furthermore, using simple feature augmentation, our proposed approach outperforms the structural correspondence learning (SCL) (**?**) algorithm and achieves comparable results to the recently proposed spectral feature alignment (SFA) method (**?**). Nevertheless, our approach is much simpler and does not require difficult parameter tuning.

We proceed with a review of related work on sentiment domain adaptation. We then briefly describe the JST model and present another approach to incorporate word prior polarity information into JST learning. We subsequently show that words from different domains can indeed be grouped under the same polarity-bearing topic through an illustration of example topic words extracted by JST before proposing a domain adaptation approach based on JST. We verify our proposed approach by conducting experiments on both the movie review data and the multi-domain sentiment dataset. Finally, we conclude our work and outline future directions.

2 Related Work

There has been significant amount of work on algorithms for domain adaptation in NLP. Earlier work treats the source domain data as "prior knowledge" and uses maximum a posterior (MAP) estimation to learn a model for the target domain data under this prior distribution (**?**). Chelba and Acero (**?**) also uses the source domain data to estimate prior distribution but in the context of a maximum entropy (ME) model. The ME model has later been studied in (**?**) for domain adaptation where a mixture model is defined to learn differences between domains.

Other approaches rely on unlabeled data in the target domain to overcome feature distribution differences between domains. Motivated by the alternating structural optimization (ASO) algorithm (**?**) for multi-task learning, Blitzer et al. (**?**) proposed structural correspondence learning (SCL) for domain adaptation in sentiment classification. Given labeled data from a source domain and unlabeled data from target domain, SCL selects a set of pivot features to link the source and target domains where pivots are selected based on their common frequency in both domains and also their mutual information with the source labels.

There has also been research in exploring careful structuring of features for domain adaptation. Daumé (**?**) proposed a kernel-mapping function which maps both source and target domains data to a high-dimensional feature space so that data points from the same domain are twice as similar as those from different domains. Dai et al.(**?**) proposed translated learning which uses a language model to link the class labels to the features in the source spaces, which in turn is translated to the features in the target spaces. Dai et al. (**?**) further proposed using spectral learning theory to learn an eigen feature representation from a task graph representing features, instances and class labels. In a similar vein, Pan et al. (**?**) proposed the spectral feature alignment (SFA) algorithm where some domain-independent words are used as a bridge to construct a bipartite graph to model the co-occurrence relationship between domain-specific words and domain-independent words. Feature clusters are

generated by co-align domain-specific and domain-independent words.

Graph-based approach has also been studied in (**?**) where a graph is built with nodes denoting documents and edges denoting content similarity between documents. The sentiment score of each unlabeled documents is recursively calculated until convergence from its neighbors the actual labels of source domain documents and pseudo-labels of target document documents. This approach was later extended by simultaneously considering relations between documents and words from both source and target domains (**?**).

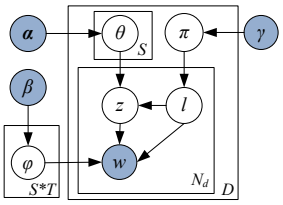
More recently, Seah et al. (**?**) addressed the issue when the predictive distribution of class label given input data of the domains differs and proposed Predictive Distribution Matching SVM learn a robust classifier in the target domain by leveraging the labeled data from only the relevant regions of multiple sources.

3 Joint Sentiment-Topic (JST) Model

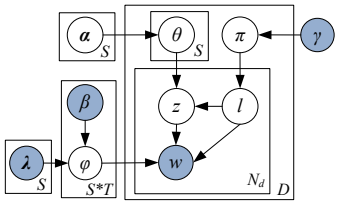
Assume that we have a corpus with a collection of D documents denoted by $C = \{d_1, d_2, ..., d_D\}$; each document in the corpus is a sequence of N_d words denoted by $d = (w_1, w_2, ..., w_{N_d})$, and each word in the document is an item from a vocabulary index with V distinct terms denoted by $\{1, 2, ..., V\}$. Also, let S be the number of distinct sentiment labels, and T be the total number of topics. The generative process in JST which corresponds to the graphical model shown in Figure **??**(a) is as follows:

- For each document d, choose a distribution $\pi_d \sim \text{Dir}(\gamma)$.
- For each sentiment label l under document d, choose a distribution $\theta_{d,l} \sim \text{Dir}(\alpha)$.
- For each word w_i in document d
  - choose a sentiment label $l_i \sim \text{Mult}(\pi_d)$,
  - choose a topic $z_i \sim \text{Mult}(\theta_{d,l_i})$,
  - choose a word w_i from $\varphi^{l_i}_{z_i}$, a Multinomial distribution over words conditioned on topic z_i and sentiment label l_i.

Gibbs sampling was used to estimate the posterior distribution by sequentially sampling each variable of interest, z_t and l_t here, from the distribution over



(a) JST model.



(b) Modified JST model.

Figure 1: JST model and its modified version.

that variable given the current values of all other variables and data. Letting the superscript $-t$ denote a quantity that excludes data from t^{th} position, the conditional posterior for z_t and l_t by marginalizing out the random variables φ, θ, and π is

$$P(z_t = j, l_t = k | \mathbf{w}, \mathbf{z^{-t}}, \mathbf{l^{-t}}, \alpha, \beta, \gamma) \propto \frac{N^{-t}_{w_t,j,k} + \beta}{N^{-t}_{j,k} + V\beta} \cdot \frac{N^{-t}_{j,k,d} + \alpha_{j,k}}{N^{-t}_{k,d} + \sum_j \alpha_{j,k}} \cdot \frac{N^{-t}_{k,d} + \gamma}{N^{-t}_{d} + S\gamma}. \quad (1)$$

where $N_{w_t,j,k}$ is the number of times word w_t appeared in topic j and with sentiment label k, $N_{j,k}$ is the number of times words assigned to topic j and sentiment label k, $N_{j,k,d}$ is the number of times a word from document d has been associated with topic j and sentiment label k, $N_{k,d}$ is the number of times sentiment label k has been assigned to some word tokens in document d, and N_d is the total number of words in the document collection.

In the modified JST model as shown in Figure **??**(b), we add an additional dependency link of $\boldsymbol{\varphi}$ on the matrix $\boldsymbol{\lambda}$ of size $S \times V$ which we use to encode word prior sentiment information into the JST model. For each word $w \in \{1, ..., V\}$, if w is found in the sentiment lexicon, for each $l \in \{1, ..., S\}$, the element λ_{lw} is updated as follows

$$\lambda_{lw} = \begin{cases} 1 & \text{if } S(w) = l \\ 0 & \text{otherwise} \end{cases}, \quad (2)$$

where the function $S(w)$ returns the prior sentiment label of w in a sentiment lexicon, i.e. neutral, posi-

Table 1: Extracted polarity words by JST on the combined data sets.

tive or negative.

The matrix $\boldsymbol{\lambda}$ can be considered as a transformation matrix which modifies the Dirichlet priors $\boldsymbol{\beta}$ of size $S \times T \times V$, so that the word prior polarity can be captured. For example, the word "*excellent*" with index i in the vocabulary has a positive polarity. The corresponding row vector in $\boldsymbol{\lambda}$ is $[0, 1, 0]$ with its elements representing neutral, positive, and negative. For each topic j, multiplying λ_{li} with β_{lji}, only the value of $\beta_{l_{pos}ji}$ is retained, and $\beta_{l_{neu}ji}$ and $\beta_{l_{neg}ji}$ are set to 0. Thus, the word "*excellent*" can only be drawn from the positive topic word distributions generated from a Dirichlet distribution with parameter $\boldsymbol{\beta}_{l_{pos}}$.

4 Polarity Words Extracted by JST

The JST model allows clustering different terms which share similar sentiment. In this section, we study the polarity-bearing topics extracted by JST. We combined reviews from the source and target domains and discarded document labels in both domains. There are a total of six different combinations. We then run JST on the combined data sets and listed some of the topic words extracted as shown in Table **??**. Words in each cell are grouped under one topic and the upper half of the table shows topic words under the positive sentiment label while the lower half shows topic words under the negative sentiment label.

We can see that JST appears to better capture sentiment association distribution in the source and target domains. For example, in the DVD+Elec. set, words from the DVD domain describe a rock concert DVD while words from the Electronics domain are likely relevant to stereo amplifiers and receivers, and yet they are grouped under the same topic by the JST model. Checking the word coverage in each domain reveals that for example "bass" seldom appears in the DVD domain, but appears more often in the Electronics domain. Likewise, in the Book+Kitch. set, "stainless" rarely appears in the Book domain and "interest" does not occur often in the Kitchen domain and they are grouped under the same topic. These observations motivate us to explore polarity-bearing topics extracted by JST for cross-domain sentiment classification since grouping words from different domains but bearing similar sentiment has the effect of overcoming the data distribution difference of two domains.

5 Domain Adaptation using JST

Given input data x and a class label y, labeled patterns of one domain can be drawn from the joint distribution $P(x, y) = P(y|x)P(x)$. Domain adaptation usually assume that data distribution are different in source and target domains, i.e., $P_s(x) \neq P_t(x)$. The task of domain adaptation is to predict the label y_i^t corresponding to x_i^t in the target domain.

We assume that we are given two sets of training data, $\mathcal{D}^s$ and $\mathcal{D}^t$, the *source domain* and *target domain* data sets, respectively. In the multiclass classification problem, the source domain data consist of labeled instances, $\mathcal{D}^s = \{(x_n^s; y_n^s) \in \mathcal{X} \times \mathcal{Y} : 1 \leq n \leq N^s\}$, where $\mathcal{X}$ is the input space and $\mathcal{Y}$ is a finite set of class labels. No class label is given in the target domain, $\mathcal{D}^t = \{x_n^t \in \mathcal{X} : 1 \leq n \leq N^t, N^t \gg N^s\}$. Algorithm **??** shows how to perform domain adaptation using the JST model. The source and target domain data are first merged with document labels discarded. A JST model is then

learned from the merged corpus to generate polarity-bearing topics for each document. The original documents in the source domain are augmented with those polarity-bearing topics as shown in Step 4 of Algorithm **??**, where $l_i\_z_i$ denotes a combination of sentiment label l_i and topic z_i for word w_i. Finally, feature selection is performed according to the information gain criteria and a classifier is then trained from the source domain using the new document representations. The target domain documents are also encoded in a similar way with polarity-bearing topics added into their feature representations.

Algorithm 1 Domain adaptation using JST.

Input: The source domain data $\mathcal{D}^s = \{(x_n^s; y_n^s) \in \mathcal{X} \times \mathcal{Y} : 1 \leq n \leq N^s\}$, the target domain data, $\mathcal{D}^t = \{x_n^t \in \mathcal{X} : 1 \leq n \leq N^t, N^t \gg N^s\}$

Output: A sentiment classifier for the target domain $\mathcal{D}^t$

1: Merge $\mathcal{D}^s$ and $\mathcal{D}^t$ with document labels discarded, $\mathcal{D} = \{(x_n^s, 1 \leq n \leq N^s; x_n^t, 1 \leq n \leq N^t\}$
2: Train a JST model on $\mathcal{D}$
3: **for** each document $x_n^s = (w_1, w_2, ..., w_m) \in \mathcal{D}^s$ **do**
4: Augment document with polarity-bearing topics generated from JST, $x_n^{s'} = (w_1, w_2, ..., w_m, l_1\_z_1, l_2\_z_2, ..., l_m\_z_m)$
5: Add $\{x_n^{s'}; y_n^s\}$ into a document pool $\mathcal{B}$
6: **end for**
7: Perform feature selection using IG on $\mathcal{B}$
8: Return a classifier, trained on $\mathcal{B}$

As discussed in Section **??** that the JST model directly models $P(\mathbf{l}|d)$, the probability of sentiment label given document, and hence document polarity can be classified accordingly. Since JST model learning does not require the availability of document labels, it is possible to augment the source domain data by adding most confident pseudo-labeled documents from the target domain by the JST model as shown in Algorithm **??**.

6 Experiments

We evaluate our proposed approach on the two datasets, the movie review (MR) data and the multi-domain sentiment (MDS) dataset. The movie review data consist of 1000 positive and 1000 negative movie reviews drawn from the IMDB movie archive while the multi-domain sentiment dataset contains four different types of product reviews extracted from Amazon.com including Book, DVD, Electronics and Kitchen appliances. Each category

Algorithm 2 Adding pseudo-labeled documents.

Input: The target domain data, $\mathcal{D}^t = \{x_n^t \in \mathcal{X} : 1 \leq n \leq N^t, N^t \gg N^s\}$, document sentiment classification threshold τ

Output: A labeled document pool $\mathcal{B}$

1: Train a JST model parameterized by Λ on $\mathcal{D}^t$
2: **for** each document $x_n^t \in \mathcal{D}^t$ **do**
3: Infer its sentiment class label from JST as $l_n = \arg\max_s P(l|x_n^t; \Lambda)$
4: **if** $P(l_n|x_n^t; \Lambda) > \tau$ **then**
5: Add labeled sample (x_n^t, l_n) into a document pool $\mathcal{B}$
6: **end if**
7: **end for**

of product reviews comprises of 1000 positive and 1000 negative reviews and is considered as a domain. Preprocessing was performed on both of the datasets by removing punctuation, numbers, non-alphabet characters and stopwords. The MPQA subjectivity lexicon is used as a sentiment lexicon in our experiments.

6.1 Experimental Setup

While the original JST model can produce reasonable results with a simple symmetric Dirichlet prior, here we use asymmetric prior $\boldsymbol{\alpha}$ over the topic proportions which is learned directly from data using a fixed-point iteration method (**?**).

In our experiment, $\boldsymbol{\alpha}$ was updated every 25 iterations during the Gibbs sampling procedure. In terms of other priors, we set symmetric prior $\beta = 0.01$ and $\gamma = (0.05 \times L)/S$, where L is the average document length, and the value of 0.05 on average allocates 5% of probability mass for mixing.

6.2 Supervised Sentiment Classification

We performed 5-fold cross validation for the performance evaluation of supervised sentiment classification. Results reported in this section are averaged over 10 such runs. We have tested several classifiers including Naïve Bayes (NB) and support vector machines (SVMs) from WEKA[5], and maximum entropy (ME) from MALLET[6]. All parameters are set to their default values except the Gaussian

[5] http://www.cs.waikato.ac.nz/ml/weka/
[6] http://mallet.cs.umass.edu/

prior variance is set to 0.1 for the ME model training. The results show that ME consistently outperforms NB and SVM on average. Thus, we only report results from ME trained on document vectors with each term weighted according to its frequency.

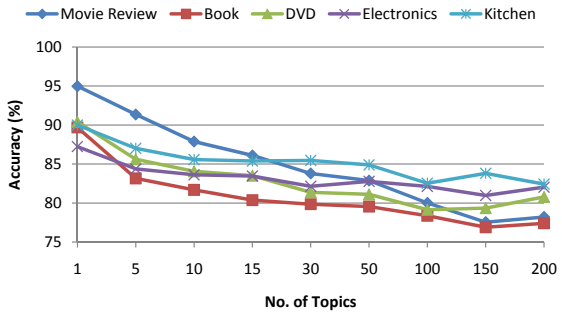

Figure 2: Classification accuracy vs. no. of topics.

The only parameter we need to set is the number of topics T. It has to be noted that the actual number of feature clusters is $3 \times T$. For example, when T is set to 5, there are 5 topic groups under each of the positive, negative, or neutral sentiment labels and hence there are altogether 15 feature clusters. The generated topics for each document from the JST model were simply added into its bag-of-words (BOW) feature representation prior to model training. Figure **??** shows the classification results on the five different domains by varying the number of topics from 1 to 200. It can be observed that the best classification accuracy is obtained when the number of topics is set to 1 (or 3 feature clusters). Increasing the number of topics results in the decrease of accuracy though it stabilizes after 15 topics. Nevertheless, when the number of topics is set to 15, using JST feature augmentation still outperforms ME without feature augmentation (the baseline model) in all of the domains. It is worth pointing out that the JST model with single topic becomes the standard LDA model with only three sentiment topics. Nevertheless, we have proposed an effective way to incorporate domain-independent word polarity prior information into model learning. As will be shown later in Table **??** that the JST model with word polarity priors incorporated performs significantly better than the LDA model without incorporating such prior information.

For comparison purpose, we also run the LDA model and augmented the BOW features with the generated topics in a similar way. The best accuracy was obtained when the number of topics is set to 15 in the LDA model. Table **??** shows the classification accuracy results with or without feature augmentation. We have performed significance test and found that LDA performs statistically significant better than Baseline according to a paired t-test with $p < 0.005$ for the Kitchen domain and with $p < 0.001$ for all the other domains. JST performs statistically significant better than both Baseline and LDA with $p < 0.001$.

Method	*MR*	*MDS*			
		Book	*DVD*	*Elec.*	*Kitch.*
Baseline	82.53	79.96	81.32	83.61	85.82
LDA	83.76	84.32	85.62	85.4	87.68
JST	**94.98**	**89.95**	**91.7**	**88.25**	**89.85**
[YE10]	91.78	82.75	82.85	84.55	87.9
[LI10]	-	79.49	81.65	83.64	85.65

Table 2: Supervised sentiment classification accuracy.

We also compare our method with other recently proposed approaches. Yessenalina et al. (**?**) explored different methods to automatically generate annotator rationales to improve sentiment classification accuracy. Our method using JST feature augmentation consistently performs better than their approach (denoted as [YE10] in Table **??**). They further proposed a two-level structured model (**?**) for document-level sentiment classification. The best accuracy obtained on the MR data is 93.22% with the model being initialized with sentence-level human annotations, which is still worse than ours. Li et al. (**?**) adopted a two-stage process by first classifying sentences as personal views and impersonal views and then using an ensemble method to perform sentiment classification. Their method (denoted as [LI10] in Table **??**) performs worse than either LDA or JST feature augmentation. To the best of our knowledge, the results achieved using JST feature augmentation are the state-of-the-art for both the MR and the MDS datasets.

6.3 Domain Adaptation

We conducted domain adaptation experiments on the MDS dataset comprising of four different domains, Book (B), DVD (D), Electronics (E), and Kitchen appliances (K). We randomly split each do-

main data into a training set of 1,600 instances and a test set of 400 instances. A classifier trained on the training set of one domain is tested on the test set of a different domain. We preformed 5 random splits and report the results averaged over 5 such runs.

Comparison with Baseline Models

We compare our proposed approaches with two baseline models. The first one (denoted as "Base" in Table **??**) is an ME classifier trained without adaptation. LDA results were generated from an ME classifier trained on document vectors augmented with topics generated from the LDA model. The number of topics was set to 15. JST results were obtained in a similar way except that we used the polarity-bearing topics generated from the JST model. We also tested with adding pseudo-labeled examples from the JST model into the source domain for ME classifier training (following Algorithm **??**), denoted as "JST-PL" in Table **??**. The document sentiment classification probability threshold τ was set to 0.8. Finally, we performed feature selection by selecting the top 2000 features according to the information gain criteria ("JST-IG")[7].

There are altogether 12 cross-domain sentiment classification tasks. We showed the adaptation loss results in Table **??** where the result for each domain and for each method is averaged over all three possible adaptation tasks by varying the source domain. The adaptation loss is calculated with respect to the in-domain gold standard classification result. For example, the in-domain goal standard for the Book domain is 79.96%. For adapting from DVD to Book, baseline achieves 72.25% and JST gives 76.45%. The adaptation loss is 7.71 for baseline and 3.51 for JST.

It can be observed from Table **??** that LDA only improves slightly compared to the baseline with an error reduction of 11%. JST further reduces the error due to transfer by 27%. Adding pseudo-labeled examples gives a slightly better performance compared to JST with an error reduction of 36%. With feature selection, JST-IG outperforms all the other approaches with a relative error reduction of 53%.

[7] Both values of 0.8 and 2000 were set arbitrarily after an initial run on some held-out data; they were not tuned to optimize test performance.

Domain	Base	LDA	JST	JST-PL	JST-IG
Book	10.8	9.4	7.2	6.3	**5.2**
DVD	8.3	6.1	4.8	4.4	**2.9**
Electr.	7.9	7.7	6.3	5.4	**3.9**
Kitch.	7.6	7.6	6.9	6.1	**4.4**
Average	8.6	7.7	6.3	5.5	**4.1**

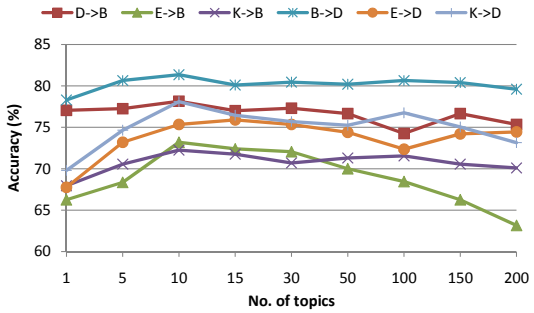
Table 3: Adaptation loss with respect to the in-domain gold standard. The last row shows the average loss over all the four domains.

Parameter Sensitivity

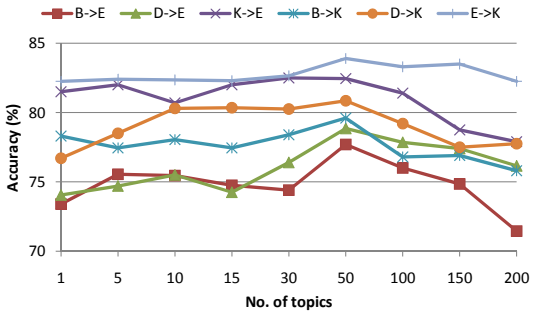
There is only one parameters to be set in the JST-IG approach, the number of topics. We plot the classification accuracy versus different topic numbers in Figure **??** with the number of topics varying between 1 and 200, corresponding to feature clusters varying between 3 and 600. It can be observed that for the relatively larger Book and DVD data sets, the accuracies peaked at topic number 10, whereas for the relatively smaller Electronics and Kitchen data sets, the best performance was obtained at topic number 50. Increasing topic numbers results in the decrease of classification accuracy. Manually examining the extracted polarity topics from JST reveals that when the topic number is small, each topic cluster contains well-mixed words from different domains. However, when the topic number is large, words under each topic cluster tend to be dominated by a single domain.

Comparison with Existing Approaches

We compare in Figure **??** our proposed approach with two other domain adaptation algorithms for sentiment classification, SCL and SFA. Each set of bars represent a cross-domain sentiment classification task. The thick horizontal lines are in-domain sentiment classification accuracies. It is worth noting that our in-domain results are slightly different from those reported in (**?**; **?**) due to different random splits. Our proposed JST-IG approach outperforms SCL in average and achieves comparable results to SFA. While SCL requires the construction of a reasonable number of auxiliary tasks that are useful to model "pivots" and "non-pivots", SFA relies on a good selection of domain-independent features for the construction of bipartite feature graph before running spectral clustering to derive feature clusters.

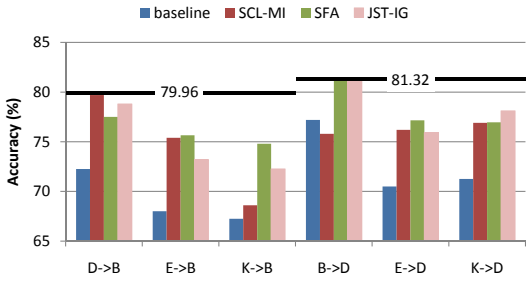


(a) Adapted to Book and DVD data sets.

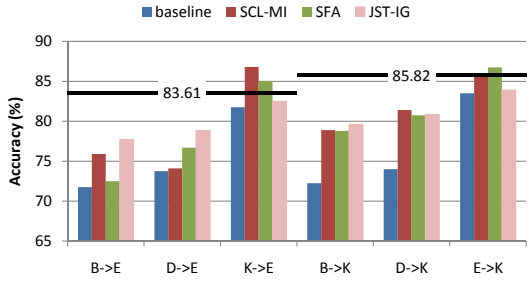


(b) Adapted to Electronics and Kitchen data sets.

Figure 3: Classification accuracy vs. no. of topics.



(a) Adapted to Book and DVD data sets.



(b) Adapted to Electronics and Kitchen data sets.

Figure 4: Comparison with existing approaches.

On the contrary, our proposed approach based on the JST model is much simpler and yet still achieves comparable results.

7 Conclusions

In this paper, we have studied polarity-bearing topics generated from the JST model and shown that by augmenting the original feature space with polarity-bearing topics, the in-domain supervised classifiers learned from augmented feature representation achieve the state-of-the-art performance on both the movie review data and the multi-domain sentiment dataset. Furthermore, using feature augmentation and selection according to the information gain criteria for cross-domain sentiment classification, our proposed approach outperforms SCL and gives similar results as SFA. Nevertheless, our approach is much simpler and does not require difficult parameter tuning.

There are several directions we would like to explore in the future. First, polarity-bearing topics generated by the JST model were simply added into the original feature space of documents, it is worth investigating attaching different weight to each topic maybe in proportional to the posterior probability of sentiment label and topic given a word estimated by the JST model. Second, it might be interesting to study the effect of introducing a tradeoff parameter to balance the effect of original and new features. Finally, our experimental results show that adding pseudo-labeled examples by the JST model does not appear to be effective. We could possibly explore instance weight strategies (**?**) on both pseudo-labeled examples and source domain training examples in order to improve the adaptation performance.

Abstract

We describe a sentiment classification method that is applicable when we do not have any labeled data for a *target* domain but have some labeled data for multiple other domains, designated as the *source* domains. We automatically create a *sentiment sensitive* thesaurus using both labeled and unlabeled data from multiple source domains to find the association between words that express similar sentiments in different domains. The created thesaurus is then used to expand feature vectors to train a binary classifier. Unlike previous cross-domain sentiment classification methods, our method can efficiently learn from *multiple source* domains. Our method significantly outperforms numerous baselines and returns results that are better than or comparable to previous cross-domain sentiment classification methods on a benchmark dataset containing Amazon user reviews for different types of products.

1 Introduction

Users express opinions about products or services they consume in blog posts, shopping sites, or review sites. It is useful for both consumers as well as for producers to know what general public think about a particular product or service. Automatic document level sentiment classification (Pang et al., 2002; Turney, 2002) is the task of classifying a given review with respect to the sentiment expressed by the author of the review. For example, a sentiment classifier might classify a user review about a movie as *positive* or *negative* depending on the sentiment expressed in the review. Sentiment classification has been applied in numerous tasks such as opinion mining (Pang and Lee, 2008), opinion summarization (Lu et al., 2009), contextual advertising (Fan and Chang, 2010), and market analysis (Hu and Liu, 2004).

Supervised learning algorithms that require labeled data have been successfully used to build sentiment classifiers for a specific domain (Pang et al., 2002). However, sentiment is expressed differently in different domains, and it is costly to annotate data for each new domain in which we would like to apply a sentiment classifier. For example, in the domain of reviews about *electronics* products, the words "durable" and "light" are used to express positive sentiment, whereas "expensive" and "short battery life" often indicate negative sentiment. On the other hand, if we consider the *books* domain the words "exciting" and "thriller" express positive sentiment, whereas the words "boring" and "lengthy" usually express negative sentiment. A classifier trained on one domain might not perform well on a different domain because it would fail to learn the sentiment of the unseen words.

Work in *cross-domain sentiment classification* (Blitzer et al., 2007) focuses on the challenge of training a classifier from one or more domains (source domains) and applying the trained classifier in a different domain (target domain). A cross-domain sentiment classification system must overcome two main challenges. First, it must identify which source domain features are related to which target domain features. Second, it requires a learning framework to incorporate the information re-

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 132–141,
Portland, Oregon, June 19-24, 2011.

garding the relatedness of source and target domain features. Following previous work, we define cross-domain sentiment classification as the problem of learning a binary classifier (i.e. positive or negative sentiment) given a small set of labeled data for the source domain, and unlabeled data for both source and target domains. In particular, no labeled data is provided for the target domain.

In this paper, we describe a cross-domain sentiment classification method using an automatically created sentiment sensitive thesaurus. We use labeled data from multiple source domains and unlabeled data from source and target domains to represent the distribution of features. We represent a *lexical element* (i.e. a unigram or a bigram of word lemma) in a review using a feature vector. Next, for each lexical element we measure its relatedness to other lexical elements and group related lexical elements to create a thesaurus. The thesaurus captures the relatedness among lexical elements that appear in source and target domains based on the contexts in which the lexical elements appear (their distributional context). A distinctive aspect of our approach is that, in addition to the usual co-occurrence features typically used in characterizing a word's distributional context, we make use, where possible, of the sentiment label of a document: i.e. sentiment labels form part of our context features. This is what makes the distributional thesaurus sensitive to sentiment. Unlabeled data is cheaper to collect compared to labeled data and is often available in large quantities. The use of unlabeled data enables us to accurately estimate the distribution of words in source and target domains. Our method can learn from a large amount of unlabeled data to leverage a robust cross-domain sentiment classifier.

We model the cross-domain sentiment classification problem as one of *feature expansion*, where we append additional related features to feature vectors that represent source and target domain reviews in order to reduce the mismatch of features between the two domains. Methods that use related features have been successfully used in numerous tasks such as query expansion (Fang, 2008), and document classification (Shen et al., 2009). However, feature expansion techniques have not previously been applied to the task of cross-domain sentiment classification.

In our method, we use the automatically created thesaurus to *expand* feature vectors in a binary classifier at train and test times by introducing related lexical elements from the thesaurus. We use L1 regularized logistic regression as the classification algorithm. (However, the method is agnostic to the properties of the classifier and can be used to expand feature vectors for any binary classifier). L1 regularization enables us to select a small subset of features for the classifier. Unlike previous work which attempts to learn a cross-domain classifier using a single source domain, we leverage data from multiple source domains to learn a robust classifier that generalizes across multiple domains. Our contributions can be summarized as follows.

- We describe a fully automatic method to create a thesaurus that is sensitive to the sentiment of words expressed in different domains.
- We describe a method to use the created thesaurus to expand feature vectors at train and test times in a binary classifier.

2 A Motivating Example

To explain the problem of cross-domain sentiment classification, consider the reviews shown in Table 1 for the domains *books* and *kitchen appliances*. Table 1 shows two positive and one negative review from each domain. We have emphasized in boldface the words that express the sentiment of the authors of the reviews. We see that the words **excellent**, **broad**, **high quality**, **interesting**, and **well researched** are used to express positive sentiment in the books domain, whereas the word **disappointed** indicates negative sentiment. On the other hand, in the kitchen appliances domain the words **thrilled**, **high quality**, **professional**, **energy saving**, **lean**, and **delicious** express positive sentiment, whereas the words **rust** and **disappointed** express negative sentiment. Although **high quality** would express positive sentiment in both domains, and **disappointed** negative sentiment, it is unlikely that we would encounter **well researched** in kitchen appliances reviews, or **rust** or **delicious** in book reviews. Therefore, a model that is trained only using book reviews might not have any weights learnt for **delicious** or **rust**, which would make it difficult for this model to accurately classify reviews of kitchen appliances.

	books	*kitchen appliances*
+	**Excellent** and **broad** survey of the development of civilization with all the punch of **high quality** fiction.	I was so **thrilled** when I unpack my processor. It is so **high quality** and **professional** in both looks and performance.
+	This is an **interesting** and **well researched** book.	**Energy saving** grill. My husband loves the burgers that I make from this grill. They are **lean** and **delicious**.
-	Whenever a new book by Philippa Gregory comes out, I buy it hoping to have the same experience, and lately have been sorely **disappointed**.	These knives are already showing spots of **rust** despite washing by hand and drying. Very **disappointed**.

Table 1: Positive (+) and negative (-) sentiment reviews in two different domains.

sentence	Excellent and broad survey of the development of civilization.
POS tags	Excellent/JJ and/CC broad/JJ survey/NN1 of/IO the/AT development/NN1 of/IO civilization/NN1
lexical elements (unigrams)	excellent, broad, survey, development, civilization
lexical elements (bigrams)	excellent+broad, broad+survey, survey+development, development+civilization
sentiment features (lemma)	excellent*P, broad*P, survey*P, excellent+broad*P, broad+survey*P
sentiment features (POS)	JJ*P, NN1*P, JJ+NN1*P

Table 2: Generating lexical elements and sentiment features from a positive review sentence.

3 Sentiment Sensitive Thesaurus

One solution to the feature mismatch problem outlined above is to use a thesaurus that groups different words that express the same sentiment. For example, if we know that both *excellent* and *delicious* are positive sentiment words, then we can use this knowledge to *expand* a feature vector that contains the word *delicious* using the word *excellent*, thereby reducing the mismatch between features in a test instance and a trained model. Below we describe a method to construct a sentiment sensitive thesaurus for feature expansion.

Given a labeled or an unlabeled review, we first split the review into individual sentences. We carry out part-of-speech (POS) tagging and lemmatization on each review sentence using the RASP system (Briscoe et al., 2006). Lemmatization reduces the data sparseness and has been shown to be effective in text classification tasks (Joachims, 1998). We then apply a simple word filter based on POS tags to select content words (nouns, verbs, adjectives, and adverbs). In particular, previous work has identified adjectives as good indicators of sentiment (Hatzivassiloglou and McKeown, 1997; Wiebe, 2000). Following previous work in cross-domain sentiment classification, we model a review as a bag of words. We select unigrams and bigrams from each sentence. For the remainder of this paper, we will refer to unigrams and bigrams collectively as *lexical elements*. Previous work on sentiment classification has shown that both unigrams and bigrams are useful for training a sentiment classifier (Blitzer et al., 2007). We note that it is possible to create lexical elements both from source domain labeled reviews as well as from unlabeled reviews in source and target domains.

Next, we represent each lexical element u using a set of features as follows. First, we select other lexical elements that co-occur with u in a review sentence as features. Second, from each source domain labeled review sentence in which u occurs, we create *sentiment features* by appending the label of the review to each lexical element we generate from that review. For example, consider the sentence selected from a positive review of a book shown in Table 2. In Table 2, we use the notation "*P" to indicate positive sentiment features and "*N" to indicate negative sentiment features. The example sentence shown in Table 2 is selected from a positively labeled review, and generates positive sentiment features as shown in Table 2. In addition to word-level sentiment features, we replace words with their POS tags to create

POS-level sentiment features. POS tags generalize the word-level sentiment features, thereby reducing feature sparseness.

Let us denote the value of a feature w in the feature vector $\boldsymbol{u}$ representing a lexical element u by $f(\boldsymbol{u}, w)$. The vector $\boldsymbol{u}$ can be seen as a compact representation of the distribution of a lexical element u over the set of features that co-occur with u in the reviews. From the construction of the feature vector $\boldsymbol{u}$ described in the previous paragraph, it follows that w can be either a sentiment feature or another lexical element that co-occurs with u in some review sentence. The distributional hypothesis (Harris, 1954) states that words that have similar distributions are semantically similar. We compute $f(\boldsymbol{u}, w)$ as the pointwise mutual information between a lexical element u and a feature w as follows:

$$f(\boldsymbol{u}, w) = \log\left(\frac{\frac{c(u,w)}{N}}{\frac{\sum_{i=1}^{n} c(i,w)}{N} \times \frac{\sum_{j=1}^{m} c(u,j)}{N}}\right) \quad (1)$$

Here, $c(u, w)$ denotes the number of review sentences in which a lexical element u and a feature w co-occur, n and m respectively denote the total number of lexical elements and the total number of features, and $N = \sum_{i=1}^{n}\sum_{j=1}^{m} c(i, j)$. Pointwise mutual information is known to be biased towards infrequent elements and features. We follow the discounting approach of Pantel & Ravichandran (2004) to overcome this bias.

Next, for two lexical elements u and v (represented by feature vectors $\boldsymbol{u}$ and $\boldsymbol{v}$, respectively), we compute the relatedness $\tau(v, u)$ of the feature v to the feature u as follows,

$$\tau(v, u) = \frac{\sum_{w \in \{x | f(\boldsymbol{v}, x) > 0\}} f(\boldsymbol{u}, w)}{\sum_{w \in \{x | f(\boldsymbol{u}, x) > 0\}} f(\boldsymbol{u}, w)}. \quad (2)$$

Here, we use the set notation $\{x | f(\boldsymbol{v}, x) > 0\}$ to denote the set of features that co-occur with v. Relatedness of a lexical element u to another lexical element v is the fraction of feature weights in the feature vector for the element u that also co-occur with the features in the feature vector for the element v. If there are no features that co-occur with both u and v, then the relatedness reaches its minimum value of 0. On the other hand if all features that co-occur with u also co-occur with v, then the relatedness , $\tau(v, u)$, reaches its maximum value of 1. Note that relatedness is an asymmetric measure by the definition given in Equation 2, and the relatedness $\tau(v, u)$ of an element v to another element u is not necessarily equal to $\tau(u, v)$, the relatedness of u to v.

We use the relatedness measure defined in Equation 2 to construct a *sentiment sensitive* thesaurus in which, for each lexical element u we list lexical elements v that co-occur with u (i.e. $f(\boldsymbol{u}, v) > 0$) in descending order of relatedness values $\tau(v, u)$. In the remainder of the paper, we use the term *base entry* to refer to a lexical element u for which its related lexical elements v (referred to as the *neighbors* of u) are listed in the thesaurus. Note that relatedness values computed according to Equation 2 are sensitive to sentiment labels assigned to reviews in the source domain, because co-occurrences are computed over both lexical and sentiment elements extracted from reviews. In other words, the relatedness of an element u to another element v depends upon the sentiment labels assigned to the reviews that generate u and v. This is an important fact that differentiates our sentiment-sensitive thesaurus from other distributional thesauri which do not consider sentiment information.

Moreover, we only need to retain lexical elements in the sentiment sensitive thesaurus because when predicting the sentiment label for target reviews (at test time) we cannot generate sentiment elements from those (unlabeled) reviews, therefore we are not required to find expansion candidates for sentiment elements. However, we emphasize the fact that the relatedness values between the lexical elements listed in the sentiment-sensitive thesaurus are computed using co-occurrences with both lexical and sentiment features, and therefore the expansion candidates selected for the lexical elements in the target domain reviews are sensitive to sentiment labels assigned to reviews in the source domain. Using a sparse matrix format and approximate similarity matching techniques (Sarawagi and Kirpal, 2004), we can efficiently create a thesaurus from a large set of reviews.

4 Feature Expansion

Our *feature expansion* phase augments a feature vector with additional related features selected from the

sentiment-sensitive thesaurus created in Section 3 to overcome the feature mismatch problem. First, following the bag-of-words model, we model a review d using the set $\{w_1, \ldots, w_N\}$, where the elements w_i are either unigrams or bigrams that appear in the review d. We then represent a review d by a real-valued term-frequency vector $\boldsymbol{d} \in \mathbb{R}^N$, where the value of the j-th element d_j is set to the total number of occurrences of the unigram or bigram w_j in the review d. To find the suitable candidates to expand a vector $\boldsymbol{d}$ for the review d, we define a ranking score $\text{score}(u_i, \boldsymbol{d})$ for each base entry in the thesaurus as follows:

$$\text{score}(u_i, \boldsymbol{d}) = \frac{\sum_{j=1}^{N} d_j \tau(w_j, u_i)}{\sum_{l=1}^{N} d_l} \quad (3)$$

According to this definition, given a review d, a base entry u_i will have a high ranking score if there are many words w_j in the review d that are also listed as neighbors for the base entry u_i in the sentiment-sensitive thesaurus. Moreover, we weight the relatedness scores for each word w_j by its normalized term-frequency to emphasize the salient unigrams and bigrams in a review. Recall that relatedness is defined as an asymmetric measure in Equation 2, and we use $\tau(w_j, u_i)$ in the computation of $\text{score}(u_i, \boldsymbol{d})$ in Equation 3. This is particularly important because we would like to score base entries u_i considering *all* the unigrams and bigrams that appear in a review d, instead of considering each unigram or bigram individually.

To expand a vector, $\boldsymbol{d}$, for a review d, we first rank the base entries, u_i using the ranking score in Equation 3 and select the top k ranked base entries. Let us denote the r-th ranked ($1 \leq r \leq k$) base entry for a review d by v_d^r. We then extend the original set of unigrams and bigrams $\{w_1, \ldots, w_N\}$ by the base entries $v_d^1, \ldots, v_d^k$ to create a new vector $\boldsymbol{d'} \in \mathbb{R}^{(N+k)}$ with dimensions corresponding to $w_1, \ldots, w_N, v_d^1, \ldots, v_d^k$ for a review d. The values of the extended vector $\boldsymbol{d'}$ are set as follows. The values of the first N dimensions that correspond to unigrams and bigrams w_i that occur in the review d are set to d_i, their frequency in d. The subsequent k dimensions that correspond to the top ranked based entries for the review d are weighted according to their ranking score. Specifically, we set the value of the r-th ranked base entry v_d^r to $1/r$. Alternatively, one could use the ranking score, $\text{score}(v_d^r, d)$, itself as the value of the appended base entries. However, both relatedness scores as well as normalized term-frequencies can be small in practice, which leads to very small absolute ranking scores. By using the inverse rank, we only take into account the relative ranking of base entries and ignore their absolute scores.

Note that the score of a base entry depends on a review d. Therefore, we select different base entries as additional features for expanding different reviews. Furthermore, we do *not* expand each w_i individually when expanding a vector $\boldsymbol{d}$ for a review. Instead, we consider *all* unigrams and bigrams in d when selecting the base entries for expansion. One can think of the feature expansion process as a lower dimensional latent mapping of features onto the space spanned by the base entries in the sentiment-sensitive thesaurus. The asymmetric property of the relatedness (Equation 2) implicitly prefers common words that co-occur with numerous other words as expansion candidates. Such words act as domain independent pivots and enable us to transfer the information regarding sentiment from one domain to another.

Using the extended vectors $\boldsymbol{d'}$ to represent reviews, we train a binary classifier from the source domain labeled reviews to predict positive and negative sentiment in reviews. We differentiate the appended base entries v_d^r from w_i that existed in the original vector $\boldsymbol{d}$ (prior to expansion) by assigning different feature identifiers to the appended base entries. For example, a unigram *excellent* in a feature vector is differentiated from the base entry *excellent* by assigning the feature id, "BASE=*excellent*" to the latter. This enables us to learn different weights for base entries depending on whether they are useful for expanding a feature vector. We use L1 regularized logistic regression as the classification algorithm (Ng, 2004), which produces a sparse model in which most irrelevant features are assigned a zero weight. This enables us to select useful features for classification in a systematic way without having to preselect features using heuristic approaches. The regularization parameter is set to its default value of 1 for all the experiments described in this paper.

5 Experiments

5.1 Dataset

To evaluate our method we use the cross-domain sentiment classification dataset prepared by Blitzer et al. (2007). This dataset consists of Amazon product reviews for four different product types: books (**B**), DVDs (**D**), electronics (**E**) and kitchen appliances (**K**). There are 1000 positive and 1000 negative labeled reviews for each domain. Moreover, the dataset contains some unlabeled reviews (on average $17,547$) for each domain. This benchmark dataset has been used in much previous work on cross-domain sentiment classification and by evaluating on it we can directly compare our method against existing approaches.

Following previous work, we randomly select 800 positive and 800 negative labeled reviews from each domain as training instances (i.e. $1600 \times 4 = 6400$); the remainder is used for testing (i.e. $400 \times 4 = 1600$). In our experiments, we select each domain in turn as the target domain, with one or more other domains as sources. Note that when we combine more than one source domain we limit the total number of source domain labeled reviews to 1600, balanced between the domains. For example, if we combine two source domains, then we select 400 positive and 400 negative labeled reviews from each domain giving $(400 + 400) \times 2 = 1600$. This enables us to perform a fair evaluation when combining multiple source domains. The evaluation metric is classification accuracy on a target domain, computed as the percentage of correctly classified target domain reviews out of the total number of reviews in the target domain.

5.2 Effect of Feature Expansion

To study the effect of feature expansion at train time compared to test time, we used Amazon reviews for two further domains, *music* and *video*, which were also collected by Blitzer et al. (2007) but are not part of the benchmark dataset. Each validation domain has 1000 positive and 1000 negative labeled reviews, and 15000 unlabeled reviews. Using the validation domains as targets, we vary the number of top k ranked base entries (Equation 3) used for feature expansion during training (Train_k) and testing (Test_k), and measure the average classification accuracy. Figure 1 illustrates the results using a *heat map*, where dark colors indicate low accuracy values and light colors indicate high accuracy values. We see that expanding features only at test time (the left-most column) does not work well because we have not learned proper weights for the additional features. Similarly, expanding features only at train time (the bottom-most row) also does not perform well because the expanded features are not used during testing. The maximum classification accuracy is obtained when $\text{Test}_k = 400$ and $\text{Train}_k = 800$, and we use these values for the remainder of the experiments described in the paper.

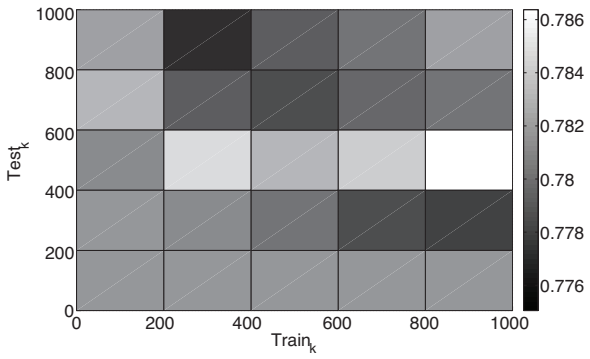

Figure 1: Feature expansion at train vs. test times.

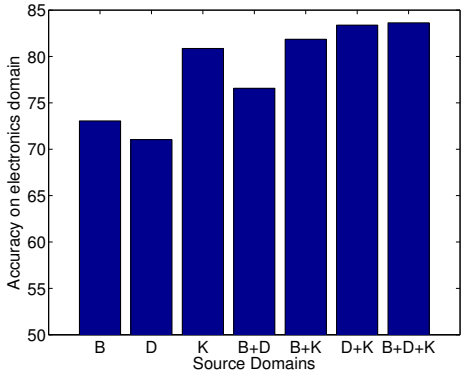

Figure 2: Effect of using multiple source domains.

5.3 Combining Multiple Sources

Figure 2 shows the effect of combining multiple source domains to build a sentiment classifier for the electronics domain. We see that the kitchen domain is the single best source domain when adapting to the electronics target domain. This behavior

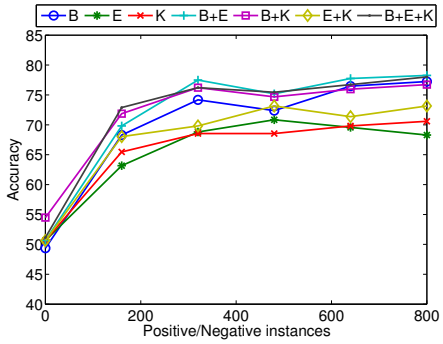

Figure 3: Effect of source domain labeled data.

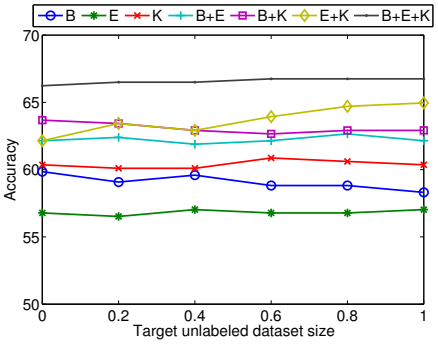

Figure 5: Effect of target domain unlabeled data.

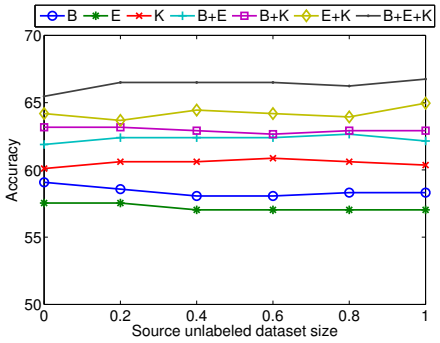

Figure 4: Effect of source domain unlabeled data.

is explained by the fact that in general kitchen appliances and electronic items have similar aspects. But a more interesting observation is that the accuracy that we obtain when we use two source domains is always greater than the accuracy if we use those domains individually. The highest accuracy is achieved when we use all three source domains. Although not shown here for space limitations, we observed similar trends with other domains in the benchmark dataset.

To investigate the impact of the quantity of source domain labeled data on our method, we vary the amount of data from zero to 800 reviews, with equal amounts of positive and negative labeled data. Figure 3 shows the accuracy with the DVD domain as the target. Note that source domain labeled data is used both to create the sentiment sensitive thesaurus as well as to train the sentiment classifier. When there are multiple source domains we limit and balance the number of labeled instances as outlined in Section 5.1. The amount of unlabeled data is held constant, so that any change in classification accuracy is directly attributable to the source domain labeled instances. Because this is a binary classification task (i.e. positive vs. negative sentiment), a random classifier that does not utilize any labeled data would report a 50% classification accuracy. From Figure 3, we see that when we increase the amount of source domain labeled data the accuracy increases quickly. In fact, by selecting only 400 (i.e. 50% of the total 800) labeled instances per class, we achieve the maximum performance in most of the cases.

To study the effect of source and target domain unlabeled data on the performance of our method, we create sentiment sensitive thesauri using different proportions of unlabeled data. The amount of labeled data is held constant and is balanced across multiple domains as outlined in Section 5.1, so any changes in classification accuracy can be directly attributed to the contribution of unlabeled data. Figure 4 shows classification accuracy on the DVD target domain when we vary the proportion of source domain unlabeled data (target domain's unlabeled data is fixed).

Likewise, Figure 5 shows the classification accuracy on the DVD target domain when we vary the proportion of the target domain's unlabeled data (source domains' unlabeled data is fixed). From Figures 4 and 5, we see that irrespective of the amount being used, there is a clear performance gain when we use unlabeled data from multiple source domains compared to using a single source domain. However, we could not observe a clear gain in performance when we increase the amount of the unlabeled data used to create the sentiment sensitive thesaurus.

Method	K	D	E	B
No Thesaurus	72.61	68.97	70.53	62.72
SCL	80.83	74.56	78.43	72.76

NSS	77.50	73.50	75.50	71.46
Proposed	**85.18**	**78.77**	**83.63**	76.32
Within-Domain	*87.70*	*82.40*	*84.40*	*80.40*

Table 3: Cross-domain sentiment classification accuracy.

5.4 Cross-Domain Sentiment Classification

Table 3 compares our method against a number of baselines and previous cross-domain sentiment classification techniques using the benchmark dataset. For all previous techniques we give the results reported in the original papers. The **No Thesaurus** baseline simulates the effect of not performing any feature expansion. We simply train a binary classifier using unigrams and bigrams as features from the labeled reviews in the source domains and apply the trained classifier on the target domain. This can be considered to be a lower bound that does not perform domain adaptation. **SCL** is the structural correspondence learning technique of Blitzer et al. (2006). In **SCL-MI**, features are selected using the mutual information between a feature (unigram or bigram) and a domain label. After selecting salient features, the SCL algorithm is used to train a binary classifier. **SFA** is the spectral feature alignment technique of Pan et al. (2010). Both the **LSA** and **FALSA** techniques are based on latent semantic analysis (Pan et al., 2010). For the **Within-Domain** baseline, we train a binary classifier using the labeled data from the target domain. This upper baseline represents the classification accuracy we could hope to obtain if we were to have labeled data for the target domain. Note that this is not a cross-domain classification setting. To evaluate the benefit of using sentiment features on our method, we give a **NSS** (non-sentiment sensitive) baseline in which we create a thesaurus without using any sentiment features. **Proposed** is our method.

From Table 3, we see that our **proposed** method returns the best cross-domain sentiment classification accuracy (shown in boldface) for the three domains kitchen appliances, DVDs, and electronics. For the books domain, the best results are returned by **SFA**. The books domain has the lowest number of unlabeled reviews (around 5000) in the dataset. Because our method relies upon the availability of unlabeled data for the construction of a sentiment sensitive thesaurus, we believe that this accounts for our lack of performance on the books domain. However, given that it is much cheaper to obtain unlabeled than labeled data for a target domain, there is strong potential for improving the performance of our method in this domain. The analysis of variance (ANOVA) and Tukey's honestly significant differences (HSD) tests on the classification accuracies for the four domains show that our method is statistically significantly better than both the **No Thesaurus** and **NSS** baselines, at confidence level 0.05. We therefore conclude that using the sentiment sensitive thesaurus for feature expansion is useful for cross-domain sentiment classification. The results returned by our method are comparable to state-of-the-art techniques such as **SCL-MI** and **SFA**. In particular, the differences between those techniques and our method are not statistically significant.

6 Related Work

Compared to single-domain sentiment classification, which has been studied extensively in previous work (Pang and Lee, 2008; Turney, 2002), cross-domain sentiment classification has only recently received attention in response to advances in the area of domain adaptation. Aue and Gammon (2005) report a number of empirical tests into domain adaptation of sentiment classifiers using an ensemble of classifiers. However, most of these tests were unable to outperform a simple baseline classifier that is trained using all labeled data for all domains.

Blitzer et al. (2007) apply the structural correspondence learning (SCL) algorithm to train a cross-domain sentiment classifier. They first chooses a set of *pivot features* using pointwise mutual information between a feature and a domain label. Next, linear predictors are learnt to predict the occurrences of those pivots. Finally, they use singular value decomposition (SVD) to construct a lower-dimensional feature space in which a binary classi-

fier is trained. The selection of pivots is vital to the performance of SCL and heuristically selected pivot features might not guarantee the best performance on target domains. In contrast, our method uses all features when creating the thesaurus and selects a subset of features during training using L1 regularization. Moreover, we do not require SVD, which has cubic time complexity so can be computationally expensive for large datasets.

Pan et al. (2010) use structural feature alignment (SFA) to find an alignment between domain specific and domain independent features. The mutual information of a feature with domain labels is used to classify domain specific and domain independent features. Next, spectral clustering is performed on a bipartite graph that represents the relationship between the two sets of features. Finally, the top eigenvectors are selected to construct a lower-dimensional projection. However, not all words can be cleanly classified into domain specific or domain independent, and this process is conducted prior to training a classifier. In contrast, our method lets a particular lexical entry to be listed as a neighour for multiple base entries. Moreover, we expand each feature vector individually and do not require any clustering. Furthermore, unlike SCL and SFA, which consider a single source domain, our method can efficiently adapt from multiple source domains.

7 Conclusions

We have described and evaluated a method to construct a sentiment-sensitive thesaurus to bridge the gap between source and target domains in cross-domain sentiment classification using multiple source domains. Experimental results using a benchmark dataset for cross-domain sentiment classification show that our proposed method can improve classification accuracy in a sentiment classifier. In future, we intend to apply the proposed method to other domain adaptation tasks.

Abstract

Unsupervised vector-based approaches to semantics can model rich lexical meanings, but they largely fail to capture sentiment information that is central to many word meanings and important for a wide range of NLP tasks. We present a model that uses a mix of unsupervised and supervised techniques to learn word vectors capturing semantic term–document information as well as rich sentiment content. The proposed model can leverage both continuous and multi-dimensional sentiment information as well as non-sentiment annotations. We instantiate the model to utilize the document-level sentiment polarity annotations present in many online documents (e.g. star ratings). We evaluate the model using small, widely used sentiment and subjectivity corpora and find it out-performs several previously introduced methods for sentiment classification. We also introduce a large dataset of movie reviews to serve as a more robust benchmark for work in this area.

1 Introduction

Word representations are a critical component of many natural language processing systems. It is common to represent words as indices in a vocabulary, but this fails to capture the rich relational structure of the lexicon. Vector-based models do much better in this regard. They encode continuous similarities between words as distance or angle between word vectors in a high-dimensional space. The general approach has proven useful in tasks such as word sense disambiguation, named entity recognition, part of speech tagging, and document retrieval (Turney and Pantel, 2010; Collobert and Weston, 2008; Turian et al., 2010).

In this paper, we present a model to capture both semantic and sentiment similarities among words. The semantic component of our model learns word vectors via an unsupervised probabilistic model of documents. However, in keeping with linguistic and cognitive research arguing that expressive content and descriptive semantic content are distinct (Kaplan, 1999; Jay, 2000; Potts, 2007), we find that this basic model misses crucial sentiment information. For example, while it learns that *wonderful* and *amazing* are semantically close, it doesn't capture the fact that these are both very strong positive sentiment words, at the opposite end of the spectrum from *terrible* and *awful*.

Thus, we extend the model with a supervised sentiment component that is capable of embracing many social and attitudinal aspects of meaning (Wilson et al., 2004; Alm et al., 2005; Andreevskaia and Bergler, 2006; Pang and Lee, 2005; Goldberg and Zhu, 2006; Snyder and Barzilay, 2007). This component of the model uses the vector representation of words to predict the sentiment annotations on contexts in which the words appear. This causes words expressing similar sentiment to have similar vector representations. The full objective function of the model thus learns semantic vectors that are imbued with nuanced sentiment information. In our experiments, we show how the model can leverage document-level sentiment annotations of a sort that are abundant online in the form of consumer reviews for movies, products, etc. The technique is suffi-

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 142–150,
Portland, Oregon, June 19-24, 2011.

ciently general to work also with continuous and multi-dimensional notions of sentiment as well as non-sentiment annotations (e.g., political affiliation, speaker commitment).

After presenting the model in detail, we provide illustrative examples of the vectors it learns, and then we systematically evaluate the approach on document-level and sentence-level classification tasks. Our experiments involve the small, widely used sentiment and subjectivity corpora of Pang and Lee (2004), which permits us to make comparisons with a number of related approaches and published results. We also show that this dataset contains many correlations between examples in the training and testing sets. This leads us to evaluate on, and make publicly available, a large dataset of informal movie reviews from the Internet Movie Database (IMDB).

2 Related work

The model we present in the next section draws inspiration from prior work on both probabilistic topic modeling and vector-spaced models for word meanings.

Latent Dirichlet Allocation (LDA; (Blei et al., 2003)) is a probabilistic document model that assumes each document is a mixture of latent topics. For each latent topic T, the model learns a conditional distribution $p(w|T)$ for the probability that word w occurs in T. One can obtain a k-dimensional vector representation of words by first training a k-topic model and then filling the matrix with the $p(w|T)$ values (normalized to unit length). The result is a word–topic matrix in which the rows are taken to represent word meanings. However, because the emphasis in LDA is on modeling topics, not word meanings, there is no guarantee that the row (word) vectors are sensible as points in a k-dimensional space. Indeed, we show in section 4 that using LDA in this way does not deliver robust word vectors. The semantic component of our model shares its probabilistic foundation with LDA, but is factored in a manner designed to discover word vectors rather than latent topics. Some recent work introduces extensions of LDA to capture sentiment in addition to topical information (Li et al., 2010; Lin and He, 2009; Boyd-Graber and Resnik, 2010). Like LDA, these methods focus on modeling sentiment-imbued topics rather than embedding words in a vector space.

Vector space models (VSMs) seek to model words directly (Turney and Pantel, 2010). Latent Semantic Analysis (LSA), perhaps the best known VSM, explicitly learns semantic word vectors by applying singular value decomposition (SVD) to factor a term–document co-occurrence matrix. It is typical to weight and normalize the matrix values prior to SVD. To obtain a k-dimensional representation for a given word, only the entries corresponding to the k largest singular values are taken from the word's basis in the factored matrix. Such matrix factorization-based approaches are extremely successful in practice, but they force the researcher to make a number of design choices (weighting, normalization, dimensionality reduction algorithm) with little theoretical guidance to suggest which to prefer.

Using term frequency (tf) and inverse document frequency (idf) weighting to transform the values in a VSM often increases the performance of retrieval and categorization systems. Delta idf weighting (Martineau and Finin, 2009) is a supervised variant of idf weighting in which the idf calculation is done for each document class and then one value is subtracted from the other. Martineau and Finin present evidence that this weighting helps with sentiment classification, and Paltoglou and Thelwall (2010) systematically explore a number of weighting schemes in the context of sentiment analysis. The success of delta idf weighting in previous work suggests that incorporating sentiment information into VSM values via supervised methods is helpful for sentiment analysis. We adopt this insight, but we are able to incorporate it directly into our model's objective function. (Section 4 compares our approach with a representative sample of such weighting schemes.)

3 Our Model

To capture semantic similarities among words, we derive a probabilistic model of documents which learns word representations. This component does not require labeled data, and shares its foundation with probabilistic topic models such as LDA. The sentiment component of our model uses sentiment annotations to constrain words expressing similar

sentiment to have similar representations. We can efficiently learn parameters for the joint objective function using alternating maximization.

3.1 Capturing Semantic Similarities

We build a probabilistic model of a document using a continuous mixture distribution over words indexed by a multi-dimensional random variable θ. We assume words in a document are conditionally independent given the mixture variable θ. We assign a probability to a document d using a joint distribution over the document and θ. The model assumes each word $w_i \in d$ is conditionally independent of the other words given θ. The probability of a document is thus

$$p(d) = \int p(d, \theta) d\theta = \int p(\theta) \prod_{i=1}^{N} p(w_i|\theta) d\theta. \quad (1)$$

Where N is the number of words in d and w_i is the i^{th} word in d. We use a Gaussian prior on θ.

We define the conditional distribution $p(w_i|\theta)$ using a log-linear model with parameters R and b. The energy function uses a word representation matrix $R \in \mathbb{R}^{(\beta \times |V|)}$ where each word w (represented as a one-on vector) in the vocabulary V has a β-dimensional vector representation $\phi_w = Rw$ corresponding to that word's column in R. The random variable θ is also a β-dimensional vector, $\theta \in \mathbb{R}^{\beta}$ which weights each of the β dimensions of words' representation vectors. We additionally introduce a bias b_w for each word to capture differences in overall word frequencies. The energy assigned to a word w given these model parameters is

$$E(w; \theta, \phi_w, b_w) = -\theta^T \phi_w - b_w. \quad (2)$$

To obtain the distribution $p(w|\theta)$ we use a softmax,

$$p(w|\theta; R, b) = \frac{\exp(-E(w; \theta, \phi_w, b_w))}{\sum_{w' \in V} \exp(-E(w'; \theta, \phi_{w'}, b_{w'}))} \quad (3)$$

$$= \frac{\exp(\theta^T \phi_w + b_w)}{\sum_{w' \in V} \exp(\theta^T \phi_{w'} + b_{w'})}. \quad (4)$$

The number of terms in the denominator's summation grows linearly in $|V|$, making exact computation of the distribution possible. For a given θ, a word w's occurrence probability is related to how closely its representation vector ϕ_w matches the scaling direction of θ. This idea is similar to the word vector inner product used in the log-bilinear language model of Mnih and Hinton (2007).

Equation 1 resembles the probabilistic model of LDA (Blei et al., 2003), which models documents as mixtures of latent topics. One could view the entries of a word vector ϕ as that word's association strength with respect to each latent topic dimension. The random variable θ then defines a weighting over topics. However, our model does not attempt to model individual topics, but instead directly models word probabilities conditioned on the topic mixture variable θ. Because of the log-linear formulation of the conditional distribution, θ is a vector in $\mathbb{R}^{\beta}$ and not restricted to the unit simplex as it is in LDA.

We now derive maximum likelihood learning for this model when given a set of unlabeled documents D. In maximum likelihood learning we maximize the probability of the observed data given the model parameters. We assume documents $d_k \in D$ are i.i.d. samples. Thus the learning problem becomes

$$\max_{R,b} p(D; R, b) = \prod_{d_k \in D} \int p(\theta) \prod_{i=1}^{N_k} p(w_i|\theta; R, b) d\theta. \quad (5)$$

Using *maximum a posteriori* (MAP) estimates for θ, we approximate this learning problem as

$$\max_{R,b} \prod_{d_k \in D} p(\hat{\theta}_k) \prod_{i=1}^{N_k} p(w_i|\hat{\theta}_k; R, b), \quad (6)$$

where $\hat{\theta}_k$ denotes the MAP estimate of θ for d_k. We introduce a Frobenious norm regularization term for the word representation matrix R. The word biases b are not regularized reflecting the fact that we want the biases to capture whatever overall word frequency statistics are present in the data. By taking the logarithm and simplifying we obtain the final objective,

$$\nu ||R||_F^2 + \sum_{d_k \in D} \lambda ||\hat{\theta}_k||_2^2 + \sum_{i=1}^{N_k} \log p(w_i|\hat{\theta}_k; R, b), \quad (7)$$

which is maximized with respect to R and b. The hyper-parameters in the model are the regularization

weights (λ and ν), and the word vector dimensionality β.

3.2 Capturing Word Sentiment

The model presented so far does not explicitly capture sentiment information. Applying this algorithm to documents will produce representations where words that occur together in documents have similar representations. However, this unsupervised approach has no explicit way of capturing which words are predictive of sentiment as opposed to content-related. Much previous work in natural language processing achieves better representations by learning from multiple tasks (Collobert and Weston, 2008; Finkel and Manning, 2009). Following this theme we introduce a second task to utilize labeled documents to improve our model's word representations.

Sentiment is a complex, multi-dimensional concept. Depending on which aspects of sentiment we wish to capture, we can give some body of text a sentiment label s which can be categorical, continuous, or multi-dimensional. To leverage such labels, we introduce an objective that the word vectors of our model should predict the sentiment label using some appropriate predictor,

$$\hat{s} = f(\phi_w). \tag{8}$$

Using an appropriate predictor function $f(x)$ we map a word vector ϕ_w to a predicted sentiment label $\hat{s}$. We can then improve our word vector ϕ_w to better predict the sentiment labels of contexts in which that word occurs.

For simplicity we consider the case where the sentiment label s is a scalar continuous value representing sentiment polarity of a document. This captures the case of many online reviews where documents are associated with a label on a star rating scale. We linearly map such star values to the interval $s \in [0, 1]$ and treat them as a probability of positive sentiment polarity. Using this formulation, we employ a logistic regression as our predictor $f(x)$. We use w's vector representation ϕ_w and regression weights ψ to express this as

$$p(s = 1|w; R, \psi) = \sigma(\psi^T \phi_w + b_c), \tag{9}$$

where $\sigma(x)$ is the logistic function and $\psi \in \mathbb{R}^\beta$ is the logistic regression weight vector. We additionally introduce a scalar bias b_c for the classifier.

The logistic regression weights ψ and b_c define a linear hyperplane in the word vector space where a word vector's positive sentiment probability depends on where it lies with respect to this hyperplane. Learning over a collection of documents results in words residing different distances from this hyperplane based on the average polarity of documents in which the words occur.

Given a set of labeled documents D where s_k is the sentiment label for document d_k, we wish to maximize the probability of document labels given the documents. We assume documents in the collection and words within a document are i.i.d. samples. By maximizing the log-objective we obtain,

$$\max_{R,\psi,b_c} \sum_{k=1}^{|D|} \sum_{i=1}^{N_k} \log p(s_k|w_i; R, \psi, b_c). \tag{10}$$

The conditional probability $p(s_k|w_i; R, \psi, b_c)$ is easily obtained from equation 9.

3.3 Learning

The full learning objective maximizes a sum of the two objectives presented. This produces a final objective function of,

$$\nu||R||_F^2 + \sum_{k=1}^{|D|} \lambda||\hat{\theta}_k||_2^2 + \sum_{i=1}^{N_k} \log p(w_i|\hat{\theta}_k; R, b) + \sum_{k=1}^{|D|} \frac{1}{|S_k|} \sum_{i=1}^{N_k} \log p(s_k|w_i; R, \psi, b_c). \tag{11}$$

$|S_k|$ denotes the number of documents in the dataset with the same rounded value of s_k (i.e. $s_k < 0.5$ and $s_k \geq 0.5$). We introduce the weighting $\frac{1}{|S_k|}$ to combat the well-known imbalance in ratings present in review collections. This weighting prevents the overall distribution of document ratings from affecting the estimate of document ratings in which a particular word occurs. The hyper-parameters of the model are the regularization weights (λ and ν), and the word vector dimensionality β.

Maximizing the objective function with respect to R, b, ψ, and b_c is a non-convex problem. We use alternating maximization, which first optimizes the

word representations (R, b, ψ, and b_c) while leaving the MAP estimates ($\hat{\theta}$) fixed. Then we find the new MAP estimate for each document while leaving the word representations fixed, and continue this process until convergence. The optimization algorithm quickly finds a global solution for each $\hat{\theta}_k$ because we have a low-dimensional, convex problem in each $\hat{\theta}_k$. Because the MAP estimation problems for different documents are independent, we can solve them on separate machines in parallel. This facilitates scaling the model to document collections with hundreds of thousands of documents.

4 Experiments

We evaluate our model with document-level and sentence-level categorization tasks in the domain of online movie reviews. For document categorization, we compare our method to previously published results on a standard dataset, and introduce a new dataset for the task. In both tasks we compare our model's word representations with several bag of words weighting methods, and alternative approaches to word vector induction.

4.1 Word Representation Learning

We induce word representations with our model using 25,000 movie reviews from IMDB. Because some movies receive substantially more reviews than others, we limited ourselves to including at most 30 reviews from any movie in the collection. We build a fixed dictionary of the 5,000 most frequent tokens, but ignore the 50 most frequent terms from the original full vocabulary. Traditional stop word removal was not used because certain stop words (e.g. negating words) are indicative of sentiment. Stemming was not applied because the model learns similar representations for words of the same stem when the data suggests it. Additionally, because certain non-word tokens (e.g. "!" and ":-)") are indicative of sentiment, we allow them in our vocabulary. Ratings on IMDB are given as star values ($\in \{1, 2, ..., 10\}$), which we linearly map to $[0, 1]$ to use as document labels when training our model.

The semantic component of our model does not require document labels. We train a variant of our model which uses 50,000 unlabeled reviews in addition to the labeled set of 25,000 reviews. The unlabeled set of reviews contains neutral reviews as well as those which are polarized as found in the labeled set. Training the model with additional unlabeled data captures a common scenario where the amount of labeled data is small relative to the amount of unlabeled data available. For all word vector models, we use 50-dimensional vectors.

As a qualitative assessment of word representations, we visualize the words most similar to a query word using vector similarity of the learned representations. Given a query word w and another word w' we obtain their vector representations ϕ_w and $\phi_{w'}$, and evaluate their cosine similarity as $S(\phi_w, \phi_{w'}) = \frac{\phi_w^T \phi_{w'}}{||\phi_w|| \cdot ||\phi_{w'}||}$. By assessing the similarity of w with all other words w', we can find the words deemed most similar by the model.

Table 1 shows the most similar words to given query words using our model's word representations as well as those of LSA. All of these vectors capture broad semantic similarities. However, both versions of our model seem to do better than LSA in avoiding accidental distributional similarities (e.g., *screwball* and *grant* as similar to *romantic*) A comparison of the two versions of our model also begins to highlight the importance of adding sentiment information. In general, words indicative of sentiment tend to have high similarity with words of the same sentiment polarity, so even the purely unsupervised model's results look promising. However, they also show more genre and content effects. For example, the sentiment enriched vectors for *ghastly* are truly semantic alternatives to that word, whereas the vectors without sentiment also contain some content words that tend to have *ghastly* predicated of them. Of course, this is only an impressionistic analysis of a few cases, but it is helpful in understanding why the sentiment-enriched model proves superior at the sentiment classification results we report next.

4.2 Other Word Representations

For comparison, we implemented several alternative vector space models that are conceptually similar to our own, as discussed in section 2:

Latent Semantic Analysis (LSA; Deerwester et al., 1990) We apply truncated SVD to a tf.idf weighted, cosine normalized count matrix, which is a standard weighting and smoothing scheme for

	Our model Sentiment + Semantic	Our model Semantic only	LSA
melancholy	bittersweet	thoughtful	poetic
	heartbreaking	warmth	lyrical
	happiness	layer	poetry
	tenderness	gentle	profound
	compassionate	loneliness	vivid
ghastly	embarrassingly	predators	hideous
	trite	hideous	inept
	laughably	tube	severely
	atrocious	baffled	grotesque
	appalling	smack	unsuspecting
lackluster	lame	passable	uninspired
	laughable	unconvincing	flat
	unimaginative	amateurish	bland
	uninspired	clichéd	forgettable
	awful	insipid	mediocre
romantic	romance	romance	romance
	love	charming	screwball
	sweet	delightful	grant
	beautiful	sweet	comedies
	relationship	chemistry	comedy

Table 1: Similarity of learned word vectors. Each target word is given with its five most similar words using cosine similarity of the vectors determined by each model. The full version of our model (left) captures both lexical similarity as well as similarity of sentiment strength and orientation. Our unsupervised semantic component (center) and LSA (right) capture semantic relations.

VSM induction (Turney and Pantel, 2010).

Latent Dirichlet Allocation (LDA; Blei et al., 2003) We use the method described in section 2 for inducing word representations from the topic matrix. To train the 50-topic LDA model we use code released by Blei et al. (2003). We use the same 5,000 term vocabulary for LDA as is used for training word vector models. We leave the LDA hyperparameters at their default values, though some work suggests optimizing over priors for LDA is important (Wallach et al., 2009).

Weighting Variants We evaluate both binary (b) term frequency weighting with smoothed delta idf (Δt') and no idf (n) because these variants worked well in previous experiments in sentiment (Martineau and Finin, 2009; Pang et al., 2002). In all cases, we use cosine normalization (c). Paltoglou and Thelwall (2010) perform an extensive analysis of such weighting variants for sentiment tasks.

4.3 Document Polarity Classification

Our first evaluation task is document-level sentiment polarity classification. A classifier must predict whether a given review is positive or negative given the review text.

Given a document's bag of words vector v, we obtain features from our model using a matrix-vector product Rv, where v can have arbitrary tf.idf weighting. We do not cosine normalize v, instead applying cosine normalization to the final feature vector Rv. This procedure is also used to obtain features from the LDA and LSA word vectors. In preliminary experiments, we found 'bnn' weighting to work best for v when generating document features via the product Rv. In all experiments, we use this weighting to get multi-word representations

Features	PL04	Our Dataset	Subjectivity
Bag of Words (bnc)	85.45	87.80	87.77

Table 2: Classification accuracy on three tasks. From left to right the datasets are: A collection of 2,000 movie reviews often used as a benchmark of sentiment classification (Pang and Lee, 2004), 50,000 reviews we gathered from IMDB, and the sentence subjectivity dataset also released by (Pang and Lee, 2004). All tasks are balanced two-class problems.

from word vectors.

4.3.1 Pang and Lee Movie Review Dataset

The polarity dataset version 2.0 introduced by Pang and Lee (2004) [1] consists of 2,000 movie reviews, where each is associated with a binary sentiment polarity label. We report 10-fold cross validation results using the authors' published folds to make our results comparable with others in the literature. We use a linear support vector machine (SVM) classifier trained with LIBLINEAR (Fan et al., 2008), and set the SVM regularization parameter to the same value used by Pang and Lee (2004).

Table 2 shows the classification performance of our method, other VSMs we implemented, and previously reported results from the literature. Bag of words vectors are denoted by their weighting notation. Features from word vector learner are denoted by the learner name. As a control, we trained versions of our model with only the unsupervised semantic component, and the full model (semantic and sentiment). We also include results for a version of our full model trained with 50,000 additional unlabeled examples. Finally, to test whether our models' representations complement a standard bag of words, we evaluate performance of the two feature representations concatenated.

Our method's features clearly outperform those of other VSMs, and perform best when combined with the original bag of words representation. The variant of our model trained with additional unlabeled data performed best, suggesting the model can effectively utilize large amounts of unlabeled data along with labeled examples. Our method performs competitively with previously reported results in spite of our restriction to a vocabulary of only 5,000 words.

We extracted the movie title associated with each review and found that 1,299 of the 2,000 reviews in the dataset have at least one other review of the same movie in the dataset. Of 406 movies with multiple reviews, 249 have the same polarity label for all of their reviews. Overall, these facts suggest that, relative to the size of the dataset, there are highly correlated examples with correlated labels. This is a natural and expected property of this kind of document collection, but it can have a substantial impact on performance in datasets of this scale. In the random folds distributed by the authors, approximately 50% of reviews in each validation fold's test set have a review of the same movie with the same label in the training set. Because the dataset is small, a learner may perform well by memorizing the association between label and words unique to a particular movie (e.g., character names or plot terms).

We introduce a substantially larger dataset, which

[1] http://www.cs.cornell.edu/people/pabo/movie-review-data

uses disjoint sets of movies for training and testing. These steps minimize the ability of a learner to rely on idiosyncratic word–class associations, thereby focusing attention on genuine sentiment features.

4.3.2 IMDB Review Dataset

We constructed a collection of 50,000 reviews from IMDB, allowing no more than 30 reviews per movie. The constructed dataset contains an even number of positive and negative reviews, so randomly guessing yields 50% accuracy. Following previous work on polarity classification, we consider only highly polarized reviews. A negative review has a score ≤ 4 out of 10, and a positive review has a score ≥ 7 out of 10. Neutral reviews are not included in the dataset. In the interest of providing a benchmark for future work in this area, we release this dataset to the public.[2]

We evenly divided the dataset into training and test sets. The training set is the same 25,000 labeled reviews used to induce word vectors with our model. We evaluate classifier performance after cross-validating classifier parameters on the training set, again using a linear SVM in all cases. Table 2 shows classification performance on our subset of IMDB reviews. Our model showed superior performance to other approaches, and performed best when concatenated with bag of words representation. Again the variant of our model which utilized extra unlabeled data during training performed best.

Differences in accuracy are small, but, because our test set contains 25,000 examples, the variance of the performance estimate is quite low. For example, an accuracy increase of 0.1% corresponds to correctly classifying an additional 25 reviews.

4.4 Subjectivity Detection

As a second evaluation task, we performed sentence-level subjectivity classification. In this task, a classifier is trained to decide whether a given sentence is subjective, expressing the writer's opinions, or objective, expressing purely facts. We used the dataset of Pang and Lee (2004), which contains subjective sentences from movie review summaries and objective sentences from movie plot summaries. This task is substantially different from the review classification task because it uses sentences as opposed to entire documents and the target concept is subjectivity instead of opinion polarity. We randomly split the 10,000 examples into 10 folds and report 10-fold cross validation accuracy using the SVM training protocol of Pang and Lee (2004).

Table 2 shows classification accuracies from the sentence subjectivity experiment. Our model again provided superior features when compared against other VSMs. Improvement over the bag-of-words baseline is obtained by concatenating the two feature vectors.

5 Discussion

We presented a vector space model that learns word representations captuing semantic and sentiment information. The model's probabilistic foundation gives a theoretically justified technique for word vector induction as an alternative to the overwhelming number of matrix factorization-based techniques commonly used. Our model is parametrized as a log-bilinear model following recent success in using similar techniques for language models (Bengio et al., 2003; Collobert and Weston, 2008; Mnih and Hinton, 2007), and it is related to probabilistic latent topic models (Blei et al., 2003; Steyvers and Griffiths, 2006). We parametrize the topical component of our model in a manner that aims to capture word representations instead of latent topics. In our experiments, our method performed better than LDA, which models latent topics directly.

We extended the unsupervised model to incorporate sentiment information and showed how this extended model can leverage the abundance of sentiment-labeled texts available online to yield word representations that capture both sentiment and semantic relations. We demonstrated the utility of such representations on two tasks of sentiment classification, using existing datasets as well as a larger one that we release for future research. These tasks involve relatively simple sentiment information, but the model is highly flexible in this regard; it can be used to characterize a wide variety of annotations, and thus is broadly applicable in the growing areas of sentiment analysis and retrieval.

Abstract

Sentiment analysis on Twitter data has attracted much attention recently. In this paper, we focus on target-dependent Twitter sentiment classification; namely, given a query, we classify the sentiments of the tweets as positive, negative or neutral according to whether they contain positive, negative or neutral sentiments about that query. Here the query serves as the target of the sentiments. The state-of-the-art approaches for solving this problem always adopt the target-independent strategy, which may assign irrelevant sentiments to the given target. Moreover, the state-of-the-art approaches only take the tweet to be classified into consideration when classifying the sentiment; they ignore its context (i.e., related tweets). However, because tweets are usually short and more ambiguous, sometimes it is not enough to consider only the current tweet for sentiment classification. In this paper, we propose to improve target-dependent Twitter sentiment classification by 1) incorporating target-dependent features; and 2) taking related tweets into consideration. According to the experimental results, our approach greatly improves the performance of target-dependent sentiment classification.

1 Introduction

Twitter, as a micro-blogging system, allows users to publish tweets of up to 140 characters in length to tell others what they are doing, what they are thinking, or what is happening around them. Over the past few years, Twitter has become very popular. According to the latest Twitter entry in Wikipedia, the number of Twitter users has climbed to 190 million and the number of tweets published on Twitter every day is over 65 million[1].

As a result of the rapidly increasing number of tweets, mining people's sentiments expressed in tweets has attracted more and more attention. In fact, there are already many web sites built on the Internet providing a Twitter sentiment search service, such as Tweetfeel[2], Twendz[3], and Twitter Sentiment[4]. In those web sites, the user can input a sentiment target as a query, and search for tweets containing positive or negative sentiments towards the target. The problem needing to be addressed can be formally named as Target-dependent Sentiment Classification of Tweets; namely, given a query, classifying the sentiments of the tweets as positive, negative or neutral according to whether they contain positive, negative or neutral sentiments about that query. Here the query serves as the target of the sentiments.

The state-of-the-art approaches for solving this problem, such as (Go et al., 2009[5]; Barbosa and Feng, 2010), basically follow (Pang et al., 2002), who utilize machine learning based classifiers for the sentiment classification of texts. However, their classifiers actually work in a target-independent way: all the features used in the classifiers are independent of the target, so the sentiment is decided no matter what the target is. Since (Pang et al., 2002) (or later research on sentiment classification

of product reviews) aim to classify the polarities of movie (or product) reviews and each movie (or product) review is assumed to express sentiments only about the target movie (or product), it is reasonable for them to adopt the target-independent approach. However, for target-dependent sentiment classification of tweets, it is not suitable to exactly adopt that approach. Because people may mention multiple targets in one tweet or comment on a target in a tweet while saying many other unrelated things in the same tweet, target-independent approaches are likely to yield unsatisfactory results:

1. Tweets that do not express any sentiments to the given target but express sentiments to other things will be considered as being opinionated about the target. For example, the following tweet expresses no sentiment to *Bill Gates* but is very likely to be classified as positive about *Bill Gates* by target-independent approaches.

   "People everywhere love Windows & vista. Bill Gates"

2. The polarities of some tweets towards the given target are misclassified because of the interference from sentiments towards other targets in the tweets. For example, the following tweet expresses a positive sentiment to *Windows 7* and a negative sentiment to *Vista*. However, with target-independent sentiment classification, both of the targets would get positive polarity.

   "Windows 7 is much better than Vista!"

In fact, it is easy to find many such cases by looking at the output of Twitter Sentiment or other Twitter sentiment analysis web sites. Based on our manual evaluation of Twitter Sentiment output, about 40% of errors are because of this (see Section 6.1 for more details).

In addition, tweets are usually shorter and more ambiguous than other sentiment data commonly used for sentiment analysis, such as reviews and blogs. Consequently, it is more difficult to classify the sentiment of a tweet only based on its content. For instance, for the following tweet, which contains only three words, it is difficult for any existing approaches to classify its sentiment correctly.

"First game: Lakers!"

However, relations between individual tweets are more common than those in other sentiment data. We can easily find many related tweets of a given tweet, such as the tweets published by the same person, the tweets replying to or replied by the given tweet, and retweets of the given tweet. These related tweets provide rich information about what the given tweet expresses and should definitely be taken into consideration for classifying the sentiment of the given tweet.

In this paper, we propose to improve target-dependent sentiment classification of tweets by using both target-dependent and context-aware approaches. Specifically, the target-dependent approach refers to incorporating syntactic features generated using words syntactically connected with the given target in the tweet to decide whether or not the sentiment is about the given target. For instance, in the second example, using syntactic parsing, we know that "*Windows 7*" is connected to "*better*" by a copula, while "*Vista*" is connected to "*better*" by a preposition. By learning from training data, we can probably predict that "*Windows 7*" should get a positive sentiment and "*Vista*" should get a negative sentiment.

In addition, we also propose to incorporate the contexts of tweets into classification, which we call a context-aware approach. By considering the sentiment labels of the related tweets, we can further boost the performance of the sentiment classification, especially for very short and ambiguous tweets. For example, in the third example we mentioned above, if we find that the previous and following tweets published by the same person are both positive about the *Lakers*, we can confidently classify this tweet as positive.

The remainder of this paper is structured as follows. In Section 2, we briefly summarize related work. Section 3 gives an overview of our approach. We explain the target-dependent and context-aware approaches in detail in Sections 4 and 5 respectively. Experimental results are reported in Section 6 and Section 7 concludes our work.

2 Related Work

In recent years, sentiment analysis (SA) has become a hot topic in the NLP research community. A lot of papers have been published on this topic.

2.1 Target-independent SA

Specifically, Turney (2002) proposes an unsupervised method for classifying product or movie reviews as positive or negative. In this method, sentimental phrases are first selected from the reviews according to predefined part-of-speech patterns. Then the semantic orientation score of each phrase is calculated according to the mutual information values between the phrase and two predefined seed words. Finally, a review is classified based on the average semantic orientation of the sentimental phrases in the review.

In contrast, (Pang et al., 2002) treat the sentiment classification of movie reviews simply as a special case of a topic-based text categorization problem and investigate three classification algorithms: Naive Bayes, Maximum Entropy, and Support Vector Machines. According to the experimental results, machine learning based classifiers outperform the unsupervised approach, where the best performance is achieved by the SVM classifier with unigram presences as features.

2.2 Target-dependent SA

Besides the above mentioned work for target-independent sentiment classification, there are also several approaches proposed for target-dependent classification, such as (Nasukawa and Yi, 2003; Hu and Liu, 2004; Ding and Liu, 2007). (Nasukawa and Yi, 2003) adopt a rule based approach, where rules are created by humans for adjectives, verbs, nouns, and so on. Given a sentiment target and its context, part-of-speech tagging and dependency parsing are first performed on the context. Then predefined rules are matched in the context to determine the sentiment about the target. In (Hu and Liu, 2004), opinions are extracted from product reviews, where the features of the product are considered opinion targets. The sentiment about each target in each sentence of the review is determined based on the dominant orientation of the opinion words appearing in the sentence.

As mentioned in Section 1, target-dependent sentiment classification of review sentences is quite different from that of tweets. In reviews, if any sentiment is expressed in a sentence containing a feature, it is very likely that the sentiment is about the feature. However, the assumption does not hold in tweets.

2.3 SA of Tweets

As Twitter becomes more popular, sentiment analysis on Twitter data becomes more attractive. (Go et al., 2009; Parikh and Movassate, 2009; Barbosa and Feng, 2010; Davidiv et al., 2010) all follow the machine learning based approach for sentiment classification of tweets. Specifically, (Davidiv et al., 2010) propose to classify tweets into multiple sentiment types using hashtags and smileys as labels. In their approach, a supervised KNN-like classifier is used. In contrast, (Barbosa and Feng, 2010) propose a two-step approach to classify the sentiments of tweets using SVM classifiers with abstract features. The training data is collected from the outputs of three existing Twitter sentiment classification web sites. As mentioned above, these approaches work in a target-independent way, and so need to be adapted for target-dependent sentiment classification.

3 Approach Overview

The problem we address in this paper is target-dependent sentiment classification of tweets. So the input of our task is a collection of tweets containing the target and the output is labels assigned to each of the tweets. Inspired by (Barbosa and Feng, 2010; Pang and Lee, 2004), we design a three-step approach in this paper:

1. Subjectivity classification as the first step to decide if the tweet is subjective or neutral about the target;
2. Polarity classification as the second step to decide if the tweet is positive or negative about the target if it is classified as subjective in Step 1;
3. Graph-based optimization as the third step to further boost the performance by taking the related tweets into consideration.

In each of the first two steps, a binary SVM classifier is built to perform the classification. To train the classifiers, we use SVM-Light[6] with a linear kernel; the default setting is adopted in all experiments.

[6] http://svmlight.joachims.org/

3.1 Preprocessing

In our approach, rich feature representations are used to distinguish between sentiments expressed towards different targets. In order to generate such features, much NLP work has to be done beforehand, such as tweet normalization, POS tagging, word stemming, and syntactic parsing.

In our experiments, POS tagging is performed by the OpenNLP POS tagger[7]. Word stemming is performed by using a word stem mapping table consisting of about 20,000 entries. We also built a simple rule-based model for tweet normalization which can correct simple spelling errors and variations into normal form, such as "gooood" to "good" and "luve" to "love". For syntactic parsing we use a Maximum Spanning Tree dependency parser (McDonald et al., 2005).

3.2 Target-independent Features

Previous work (Barbosa and Feng, 2010; Davidiv et al., 2010) has discovered many effective features for sentiment analysis of tweets, such as emoticons, punctuation, prior subjectivity and polarity of a word. In our classifiers, most of these features are also used. Since these features are all generated without considering the target, we call them target-independent features. In both the subjectivity classifier and polarity classifier, the same target-independent feature set is used. Specifically, we use two kinds of target-independent features:

1. Content features, including words, punctuation, emoticons, and hashtags (hashtags are provided by the author to indicate the topic of the tweet).
2. Sentiment lexicon features, indicating how many positive or negative words are included in the tweet according to a predefined lexicon. In our experiments, we use the lexicon downloaded from General Inquirer[8].

4 Target-dependent Sentiment Classification

Besides target-independent features, we also incorporate target-dependent features in both the subjectivity classifier and polarity classifier. We will explain them in detail below.

4.1 Extended Targets

It is quite common that people express their sentiments about a target by commenting not on the target itself but on some related things of the target. For example, one may express a sentiment about a company by commenting on its products or technologies. To express a sentiment about a product, one may choose to comment on the features or functionalities of the product. It is assumed that readers or audiences can clearly infer the sentiment about the target based on those sentiments about the related things. As shown in the tweet below, the author expresses a positive sentiment about "Microsoft" by expressing a positive sentiment directly about "Microsoft technologies".

"I am passionate about Microsoft technologies especially Silverlight."

In this paper, we define those aforementioned related things as Extended Targets. Tweets expressing positive or negative sentiments towards the extended targets are also regarded as positive or negative about the target. Therefore, for target-dependent sentiment classification of tweets, the first thing is identifying all extended targets in the input tweet collection.

In this paper, we first regard all noun phrases, including the target, as extended targets for simplicity. However, it would be interesting to know under what circumstances the sentiment towards the target is truly consistent with that towards its extended targets. For example, a sentiment about someone's behavior usually means a sentiment about the person, while a sentiment about someone's colleague usually has nothing to do with the person. This could be a future work direction for target-dependent sentiment classification.

In addition to the noun phrases including the target, we further expand the extended target set with the following three methods:

1. Adding mentions co-referring to the target as new extended targets. It is common that people use definite or demonstrative noun phrases or pronouns referring to the target in a tweet and express sentiments directly on them. For instance, in "Oh, Jon Stewart. How I love you so.", the author expresses

[7] http://opennlp.sourceforge.net/projects.html
[8] http://www.wjh.harvard.edu/~inquirer/

a positive sentiment to "you" which actually refers to "Jon Stewart". By using a simple co-reference resolution tool adapted from (Soon et al., 2001), we add all the mentions referring to the target into the extended target set.

2. Identifying the top K nouns and noun phrases which have the strongest association with the target. Here, we use Pointwise Mutual Information (PMI) to measure the association.

$$PMI(w,t) = \log \frac{p(w,t)}{p(w)p(t)}$$

Where *p(w,t)*, *p(w)*, and *p(t)* are probabilities of *w* and *t* co-occurring, *w* appearing, and *t* appearing in a tweet respectively. In the experiments, we estimate them on a tweet corpus containing 20 million tweets. We set $K = 20$ in the experiments based on empirical observations.

3. Extracting head nouns of all extended targets, whose PMI values with the target are above some predefined threshold, as new extended targets. For instance, suppose we have found *"Microsoft Technologies"* as the extended target, we will further add *"technologies"* into the extended target set if the PMI value for *"technologies"* and *"Microsoft"* is above the threshold. Similarly, we can find *"price"* as the extended targets for *"iPhone"* from *"the price of iPhone"* and *"LoveGame"* for *"Lady Gaga"* from *"LoveGame by Lady Gaga"*.

4.2 Target-dependent Features

Target-dependent sentiment classification needs to distinguish the expressions describing the target from other expressions. In this paper, we rely on the syntactic parse tree to satisfy this need. Specifically, for any word stem w_i in a tweet which has one of the following relations with the given target *T* or any from the extended target set, we generate corresponding target-dependent features with the following rules:

- w_i is a transitive verb and *T* (or any of the extended target) is its object; we generate a feature w_i *_arg2*. "arg" is short for "argument". For example, for the target iPhone in *"I love iPhone"*, we generate *"love_arg2"* as a feature.
- w_i is a transitive verb and *T* (or any of the extended target) is its subject; we generate a feature w_i*_arg1* similar to Rule 1.
- w_i is a intransitive verb and *T* (or any of the extended target) is its subject; we generate a feature w_i*_it_arg1*.
- w_i is an adjective or noun and *T* (or any of the extended target) is its head; we generate a feature w_i*_arg1*.
- w_i is an adjective or noun and it (or its head) is connected by a copula with *T* (or any of the extended target); we generate a feature w_i*_cp_arg1*.
- w_i is an adjective or intransitive verb appearing alone as a sentence and *T* (or any of the extended target) appears in the previous sentence; we generate a feature w_i*_arg*. For example, in "*John did that. Great!*", "*Great*" appears alone as a sentence, so we generate "*great_arg*" for the target "*John*".
- w_i is an adverb, and the verb it modifies has *T* (or any of the extended target) as its subject; we generate a feature *arg1_v_*w_i. For example, for the target *iPhone* in the tweet "*iPhone works better with the CellBand",* we will generate the feature "*arg1_v_well*".

Moreover, if any word included in the generated target-dependent features is modified by a negation[9], then we will add a prefix "*neg-*" to it in the generated features. For example, for the target iPhone in the tweet "*iPhone does not work better with the CellBand*", we will generate the features "*arg1_v_neg-well*" and "*neg-work_it_arg1*".

To overcome the sparsity of target-dependent features mentioned above, we design a special binary feature indicating whether or not the tweet contains at least one of the above target-dependent features. Target-dependent features are binary features, each of which corresponds to the presence of the feature in the tweet. If the feature is present, the entry will be 1; otherwise it will be 0.

[9] Seven negations are used in the experiments: *not, no, never, n't, neither, seldom, hardly*.

5 Graph-based Sentiment Optimization

As we mentioned in Section 1, since tweets are usually shorter and more ambiguous, it would be useful to take their contexts into consideration when classifying the sentiments. In this paper, we regard the following three kinds of related tweets as context for a tweet.

1. Retweets. Retweeting in Twitter is essentially the forwarding of a previous message. People usually do not change the content of the original tweet when retweeting. So retweets usually have the same sentiment as the original tweets.
2. Tweets containing the target and published by the same person. Intuitively, the tweets published by the same person within a short timeframe should have a consistent sentiment about the same target.
3. Tweets replying to or replied by the tweet to be classified.

Based on these three kinds of relations, we can construct a graph using the input tweet collection of a given target. As illustrated in Figure 1, each circle in the graph indicates a tweet. The three kinds of edges indicate being published by the same person (solid line), retweeting (dash line), and replying relations (round dotted line) respectively.

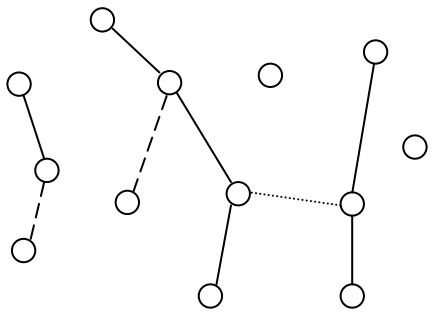

Figure 1. An example graph of tweets about a target

If we consider that the sentiment of a tweet only depends on its content and immediate neighbors, we can leverage a graph-based method for sentiment classification of tweets. Specifically, the probability of a tweet belonging to a specific sentiment class can be computed with the following formula:

$$p(c \mid \tau, G) = p(c \mid \tau) \sum_{N(d)} p(c \mid N(d)) p(N(d))$$

Where c is the sentiment label of a tweet which belongs to {positive, negative, neutral}, G is the tweet graph, $N(d)$ is a specific assignment of sentiment labels to all immediate neighbors of the tweet, and τ is the content of the tweet.

We can convert the output scores of a tweet by the subjectivity and polarity classifiers into probabilistic form and use them to approximate $p(c \mid \tau)$. Then a relaxation labeling algorithm described in (Angelova and Weikum, 2006) can be used on the graph to iteratively estimate $p(c \mid \tau, G)$ for all tweets. After the iteration ends, for any tweet in the graph, the sentiment label that has the maximum $p(c \mid \tau, G)$ is considered the final label.

6 Experiments

Because there is no annotated tweet corpus publicly available for evaluation of target-dependent Twitter sentiment classification, we have to create our own. Since people are most interested in sentiments towards celebrities, companies and products, we selected 5 popular queries of these kinds: {*Obama*, *Google*, *iPad*, *Lakers*, *Lady Gaga*}. For each of those queries, we downloaded 400 English tweets[10] containing the query using the Twitter API.

We manually classify each tweet as positive, negative or neutral towards the query with which it is downloaded. After removing duplicate tweets, we finally obtain 459 positive, 268 negative and 1,212 neutral tweets.

Among the tweets, 100 are labeled by two human annotators for inter-annotator study. The results show that for 86% of them, both annotators gave identical labels. Among the 14 tweets which the two annotators disagree on, only 1 case is a positive-negative disagreement (one annotator considers it positive while the other negative), and the other 13 are all neutral-subjective disagreement. This probably indicates that it is harder for humans to decide if a tweet is neutral or subjective than to decide if it is positive or negative.

[10] In this paper, we use sentiment classification of English tweets as a case study; however, our approach is applicable to other languages as well.

6.1 Error Analysis of Twitter Sentiment Output

We first analyze the output of Twitter Sentiment (TS) using the five test queries. For each query, we randomly select 20 tweets labeled as positive or negative by TS. We also manually classify each tweet as positive, negative or neutral about the corresponding query. Then, we analyze those tweets that get different labels from TS and humans. Finally we find two major types of error: 1) Tweets which are totally neutral (for any target) are classified as subjective by TS; 2) sentiments in some tweets are classified correctly but the sentiments are not truly about the query. The two types take up about 35% and 40% of the total errors, respectively.

The second type is actually what we want to resolve in this paper. After further checking those tweets of the second type, we found that most of them are actually neutral for the target, which means that the dominant error in Twitter Sentiment is classifying neutral tweets as subjective. Below are several examples of the second type where the bolded words are the targets.

*"No debate needed, heat can't beat **lakers** or celtics"* (negative by TS but positive by human)

*"why am i getting spams from weird people asking me if i want to chat with **lady gaga**"* (positive by TS but neutral by human)

*"Bringing iPhone and **iPad** apps into cars? http://www.speakwithme.com/ will be out soon and alpha is awesome in my car."* (positive by TS but neutral by human)

*"Here's a great article about Monte Veronese cheese. It's in Italian so just put the url into **Google** translate and enjoy http://ow.ly/3oQ77"* (positive by TS but neutral by human)

6.2 Evaluation of Subjectivity Classification

We conduct several experiments to evaluate subjectivity classifiers using different features. In the experiments, we consider the positive and negative tweets annotated by humans as subjective tweets (i.e., positive instances in the SVM classifiers), which amount to 727 tweets. Following (Pang et al., 2002), we balance the evaluation data set by randomly selecting 727 tweets from all neutral tweets annotated by humans and consider them as objective tweets (i.e., negative instances in the classifiers). We perform 10-fold cross-validations on the selected data. Following (Go et al., 2009; Pang et al., 2002), we use accuracy as a metric in our experiments. The results are listed below.

Features	Accuracy (%)
Content features	61.1
+ Sentiment lexicon features	63.8
+ Target-dependent features	**68.2**
Re-implementation of (Barbosa and Feng, 2010)	60.3

Table 1. Evaluation of subjectivity classifiers.

As shown in Table 1, the classifier using only the content features achieves an accuracy of 61.1%. Adding sentiment lexicon features improves the accuracy to 63.8%. Finally, the best performance (68.2%) is achieved by combining target-dependent features and other features (t-test: $p < 0.005$). This clearly shows that target-dependent features do help remove many sentiments not truly about the target. We also re-implemented the method proposed in (Barbosa and Feng, 2010) for comparison. From Table 1, we can see that all our systems perform better than (Barbosa and Feng, 2010) on our data set. One possible reason is that (Barbosa and Feng, 2010) use only abstract features while our systems use more lexical features.

To further evaluate the contribution of target extension, we compare the system using the exact target and all extended targets with that using only the exact target. We also eliminate the extended targets generated by each of the three target extension methods and reevaluate the performances.

Target	Accuracy (%)
Exact target	65.6
+ all extended targets	**68.2**
- co-references	68.0
- targets found by PMI	67.8
- head nouns	67.3

Table 2. Evaluation of target extension methods.

As shown in Table 2, without extended targets, the accuracy is 65.6%, which is still higher than those using only target-independent features. After adding all extended targets, the accuracy is improved significantly to 68.2% ($p < 0.005$), which suggests that target extension does help find indi-

rectly expressed sentiments about the target. In addition, all of the three methods contribute to the overall improvement, with the head noun method contributing most. However, the other two methods do not contribute significantly.

6.3 Evaluation of Polarity Classification

Similarly, we conduct several experiments on positive and negative tweets to compare the polarity classifiers with different features, where we use 268 negative and 268 randomly selected positive tweets. The results are listed below.

Features	Accuracy (%)
Content features	78.8
+ Sentiment lexicon features	84.2
+ Target-dependent features	**85.6**
Re-implementation of (Barbosa and Feng, 2010)	83.9

Table 3. Evaluation of polarity classifiers.

From Table 3, we can see that the classifier using only the content features achieves the worst accuracy (78.8%). Sentiment lexicon features are shown to be very helpful for improving the performance. Similarly, we re-implemented the method proposed by (Barbosa and Feng, 2010) in this experiment. The results show that our system using both content features and sentiment lexicon features performs slightly better than (Barbosa and Feng, 2010). The reason may be same as that we explained above.

Again, the classifier using all features achieves the best performance. Both the classifiers with all features and with the combination of content and sentiment lexicon features are significantly better than that with only the content features ($p < 0.01$). However, the classifier with all features does not significantly outperform that using the combination of content and sentiment lexicon features. We also note that the improvement by target-dependent features here is not as large as that in subjectivity classification. Both of these indicate that target-dependent features are more useful for improving subjectivity classification than for polarity classification. This is consistent with our observation in Subsection 6.2 that most errors caused by incorrect target association are made in subjectivity classification. We also note that all numbers in Table 3 are much bigger than those in Table 1, which suggests that subjectivity classification of tweets is more difficult than polarity classification.

Similarly, we evaluated the contribution of target extension for polarity classification. According to the results, adding all extended targets improves the accuracy by about 1 point. However, the contributions from the three individual methods are not statistically significant.

6.4 Evaluation of Graph-based Optimization

As seen in Figure 1, there are several tweets which are not connected with any other tweets. For these tweets, our graph-based optimization approach will have no effect. The following table shows the percentages of the tweets in our evaluation data set which have at least one related tweet according to various relation types.

Relation type	Percentage
Published by the same person[11]	41.6
Retweet	23.0
Reply	21.0
All	**66.2**

Table 4. Percentages of tweets having at least one related tweet according to various relation types.

According to Table 4, for 66.2% of the tweets concerning the test queries, we can find at least one related tweet. That means our context-aware approach is potentially useful for most of the tweets.

To evaluate the effectiveness of our context-aware approach, we compared the systems with and without considering the context.

System	Accuracy	F1-score (%)		
		pos	neu	neg
Target-dependent sentiment classifier	66.0	57.5	70.1	66.1
+Graph-based optimization	**68.3**	**63.5**	**71.0**	**68.5**

Table 5. Effectiveness of the context-aware approach.

As shown in Table 5, the overall accuracy of the target-dependent classifiers over three classes is 66.0%. The graph-based optimization improves the performance by over 2 points ($p < 0.005$), which clearly shows that the context information is very

[11] We limit the time frame from one week before to one week after the post time of the current tweet.

useful for classifying the sentiments of tweets. From the detailed improvement for each sentiment class, we find that the context-aware approach is especially helpful for positive and negative classes.

Relation type	Accuracy (%)
Published by the same person	**67.8**
Retweet	66.0
Reply	67.0

Table 6. Contribution comparison between relations.

We further compared the three types of relations for context-aware sentiment classification; the results are reported in Table 6. Clearly, being published by the same person is the most useful relation for sentiment classification, which is consistent with the percentage distribution of the tweets over relation types; using retweet only does not help. One possible reason for this is that the retweets and their original tweets are nearly the same, so it is very likely that they have already got the same labels in previous classifications.

7 Conclusions and Future Work

Twitter sentiment analysis has attracted much attention recently. In this paper, we address target-dependent sentiment classification of tweets. Different from previous work using target-independent classification, we propose to incorporate syntactic features to distinguish texts used for expressing sentiments towards different targets in a tweet. According to the experimental results, the classifiers incorporating target-dependent features significantly outperform the previous target-independent classifiers.

In addition, different from previous work using only information on the current tweet for sentiment classification, we propose to take the related tweets of the current tweet into consideration by utilizing graph-based optimization. According to the experimental results, the graph-based optimization significantly improves the performance.

As mentioned in Section 4.1, in future we would like to explore the relations between a target and any of its extended targets. We are also interested in exploring relations between Twitter accounts for classifying the sentiments of the tweets published by them.

Acknowledgments

We would like to thank Matt Callcut for refining the language of this paper, and thank Yuki Arase and the anonymous reviewers for many valuable comments and helpful suggestions. We would also thank Furu Wei and Xiaolong Wang for their help with some of the experiments and the preparation of the camera-ready version of the paper.

Abstract

It has been widely recognized that one of the most difficult and intriguing problems in natural language processing (NLP) is how to cope with idiosyncratic multiword expressions. This paper presents an overview of the comprehensive dictionary (JDMWE) of Japanese multiword expressions. The JDMWE is characterized by a large notational, syntactic, and semantic diversity of contained expressions as well as a detailed description of their syntactic functions, structures, and flexibilities. The dictionary contains about 104,000 expressions, potentially 750,000 expressions. This paper shows that the JDMWE's validity can be supported by comparing the dictionary with a large-scale Japanese N-gram frequency dataset, namely the LDC2009T08, generated by Google Inc. (Kudo et al. 2009).

1 Introduction

Linguistically idiosyncratic multiword expressions occur in authentic sentences with an unexpectedly high frequency. Since (Sag et al. 2002), we have become aware that a proper solution of idiosyncratic multiword expressions (MWEs) is one of the most difficult and intriguing problems in NLP. In principle, the nature of the idiosyncrasy of MWEs is twofold: one is idiomaticity, i.e., non-compositionality of meaning; the other is the strong probabilistic affinity between component words. Many attempts have been made to extract these expressions from corpora, mainly using automated methods that exploit statistical means. However, to our knowledge, no reliable, extensive solution has yet been made available, presumably because of the difficulty of extracting correctly without any human insight. Recognizing the crucial importance of such expressions, one of the authors of the current paper began in the 1970s to construct a Japanese electronic dictionary with comprehensive inclusion of idioms, idiom-like expressions, and probabilistically idiosyncratic expressions for general use. In this paper, we begin with an overview of the JDMWE (Japanese Dictionary of Multi-Word Expressions). It has approximately 104,000 dictionary entries and covers potentially at least 750,000 expressions. The most important features of the JDMWE are:

1. A large notational, syntactic, and semantic diversity of contained expressions
2. A detailed description of syntactic function and structure for each entry expression
3. An indication of the syntactic flexibility of entry expressions (i.e., possibility of internal modification of constituent words) of entry expressions.

In section 2, we outline the main features of the present study, first presenting a brief summary of significant previous work on this topic. In section 3, we propose and describe the criteria for selecting MWEs and introduce a number of classes of multiword expressions. In section 4, we outline the format and contents of the JDMWE, discussing the information on notational variants, syntactic functions, syntactic structures, and the syntactic flexibility of MWEs. In section 5, we describe and explain the contextual conditions stipulated in the JDMWE. In section 6, we illustrate some important statistical properties of the JDMWE by comparing the dictionary with a large-scale Japanese N-gram frequency dataset, the LDC2009T08, generated by Google Inc. (Kudo et al. 2009). The paper ends with concluding remarks in section 7.

2 Related Work

Gross (1986) analyzed French compound adverbs and compound verbs. According to his estimate, the lexical stock of such words in French would be respectively 3.3 and 1.7 times greater than that of single-word adverbs and single-word verbs. Jackendoff (1997) notes that an English speaker's lexicon would contain as many MWEs as single words. Sag et al. (2002) pointed out that 41% of the entries of WordNet 1.7 (Fellbaum 1999) are multiword; and Uchiyama et al. (2003) reported that 44% of Japanese verbs are VV-type compounds. These and other similar observations underscore the great need for a well-designed, extensive MWE lexicon for practical natural language processing.

In the past, attempts have been made to produce an MWE dictionary. Examples include the following: Gross (1986) reported on a dictionary of French verbal MWEs with description of 22 syntactic structures; Kuiper et al. (2003) constructed a database of 13,000 English idioms tagged with syntactic structures; Villavicencio (2004) attempted to compile lexicons of English idioms and verb-particle constructions (VPCs) by augmenting existing single-word dictionaries with specific tables; Baptista et al. (2004) reported on a dictionary of 3,500 Portuguese verbal MWEs with ten syntactic structures; Fellbaum et al. (2006) reported corpus-based studies in developing German verb phrase idiom resources; and recently, Laporte et al. (2008) have reported on a dictionary of 6,800 French adverbial MWEs annotated with 15 syntactic structures.

Our JDMWE approach differs from these studies in that it can treat more comprehensive types of MWEs. Our system can handle almost all types of MWEs except compositional compounds, named entities, acronyms, blends, politeness expressions, and functional expressions; in contrast, the types of MWEs that most of the other studies can deal with are limited to verb-object idioms, VPCs, verbal MWEs, support-verb constructions (SVCs) and so forth.

Many attempts have been made to extract MWEs automatically using statistical corpus-based methods. For example, Pantel et al. (2001) sought to extract Chinese compounds using mutual information and the log-likelihood measure. Fazly et al. (2006) attempted to extract English verb-object type idioms by recognizing their structural fixedness in terms of mutual information and relative entropy. Bannard (2007) tried to extract English syntactically fixed verb-noun combinations using pointwise mutual information, and so on.

In spite of these and many similar efforts, it is still difficult to adequately extract MWEs from corpora using a statistical approach, because regarding the types of multiword expressions, realistically speaking, the corpus-wide distribution can be far from exhaustive. Paradoxically, to compile an MWE lexicon we need a reliable standard MWE lexicon, as it is impossible to evaluate the automatic extraction by recall rate without such a reference. The conventional idiom dictionaries published for human readers have been occasionally used for the evaluation of automatic extraction methods in some past studies. However, no conventional Japanese dictionary of idioms would suffice for an MWE lexicon for the practical NLP because they lack entries related to the diverse MWE objects we frequently encounter in common textual materials, such as quasi-idioms, quasi-clichés, metaphoric fixed or partly fixed expressions. In addition, they provide no systematic information on the notational variants, syntactic functions, or syntactic structures of the entry expressions. The JDMWE is intended to circumvent these problems.

In past Japanese MWE studies, Shudo et al. (1980) compiled a lexicon of 3,500 functional multiword expressions and used the lexicon for a morphological analysis of Japanese. Koyama et al. (1998) made a seven-point increase in the precision rate of kana-to-kanji conversion for a commercial Japanese word processor by using a prototype of the JDMWE with 65,000 MWEs. Baldwin et al. (2003) discussed the treatment of Japanese MWEs in the framework of Sag et al. (2002). Shudo et al. (2004) pointed out the importance of the auxiliary-verbal MWEs and their non-propositional meanings (i.e., modality in a generalized sense). Hashimoto et al. (2009) studied a disambiguation method of semantically ambiguous idioms using 146 basic idioms.

3 MWEs Selected for the JDMWE

The human deliberate judgment is indispensable for the correct, extensive extraction of MWEs. In

view of this, we have manually extracted multiword expressions that have definite syntactic, semantic, or communicative functions and are linguistically idiosyncratic from a variety of publications, such as newspaper articles, journals, magazines, novels, and dictionaries. In principle, the idiosyncrasy of MWEs is twofold: first, the semantic non-compositionality (i.e., idiomaticity); second, the strong probabilistic affinity between component words. Here we have treated them differently.

The number of words included in a MWE ranges from two to eighteen. The length distribution is shown in Figure 1.

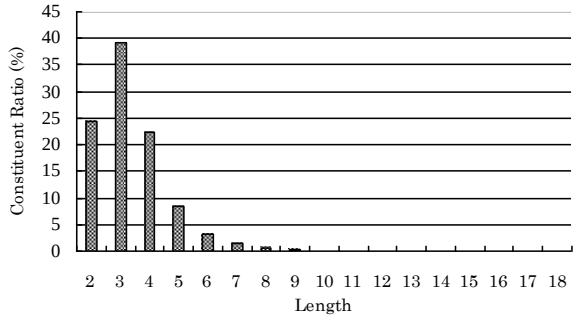

Figure 1: Length distribution of MWEs

type	example
Idiom: Semantically Non-Compositional Expression	赤−の−他人 *aka-no-tanin* (lit. red stranger) “complete stranger”
Morphologically or Syntactically Non-Compositional Expression, Cranberry-Type Expression	と−は−いえ *to-ha-ie* “however”
SVC: Support-Verb Construction	批判−を−加える *hihan-wo-kuwaeru* (lit. add criticism) “criticize”
Compound Noun; Compound Verb; Compound Adjective; Compound Adjective-Verb	打ち−拉がれる *uti-hisigareru* (lit. be hit and smashed) “become depressed”
Four-Character-Idiom	支離−滅裂 *siri-meturetu* “incoherence”
Metaphorical Expression	命−の−限り *inoti-no-kagiri* (lit. limit of life) “at the risk of life”
Quasi-Idiom	辞書−を−引く *jisho-wo-hiku* (lit. pull dictionary) “look up in a dictionary”

Table 1: Non-Compositional Expressions

3.1 Non-Compositional MWEs

In our approach, we use non-substitutability criterion to define a word string as an MWE, the logic being that an MWE expression is usually fixed in its form and the substitution of one of its constituent words would yield a meaningless expression or an expression with a meaning that is completely different from that of the original MWE expression. Formally, a word string $w_1w_2\cdots w_i\cdots w_n$ ($2\leq n\leq 18$) is an MWE if it has a definite syntactic, semantic, or communicative function of its own, and if $w_1w_2 \cdots w_i' \cdots w_n$ is either meaningless or has a meaning completely different from that of $w_1w_2\cdots w_i\cdots w_n$ for some i, where w_i' is any synonym or synonymous phrase of w_i. For example, 赤(w_1)-の-他人 *aka-no-tanin* (lit. “red stranger”) is selected because it has a definite nominal meaning of “complete stranger” and neither 真紅(w_1')-の-他人 *sinku-no-tanin* nor レッド(w_1')-の-他人 *reddo-no-tanin* means “complete stranger”. The evaluation of semantic relevance of MWEs was carried out by human judges entirely. It is just too difficult to judge the semantic relevance automatically and correctly. Table 1 shows a number of MWEs of this type.[1]

3.2 Probabilistically Idiosyncratic MWEs

An MWE must form a linguistic unit of its own. This and the following transition probability condition constitute another criterion that we adopt to define what an MWE is. Formally, a word string $w_1w_2\cdots w_i\cdots w_n$ ($2\leq n\leq 18$) is an MWE if it has a definite syntactic, semantic, or communicative function of its own, and if its forward or backward transition probability $\boldsymbol{p}_f(w_{i+1}|w_1\cdots w_i)$ or $\boldsymbol{p}_b(w_i|w_{i+1}\cdots w_n)$, respectively is judged to be in the relatively high range for some i. With this definition, for example, 手-を-拱く *te-wo-komaneku* “fold arms” is selected as an MWE because it is a well-formed verb phrase and $\boldsymbol{p}_b$(手|を-拱く) is judged empirically to be very high. No general probabilistic threshold value can be fixed a priori because the value is expression-dependent. Although the probabilistic judgment was performed, for each expression in turn, on the basis of the developer’s empirical language model, the resulting dataset is consistent with this criterion on

[1] These classes are not necessarily disjoint.

the whole as shown in section 6.1. Table 2 lists some MWEs of this type.[2]

type	example
Cliché, Stereotyped, Hackneyed, or Set Expression	風前−の−灯 *fuuzen-no-tomosibi* (lit. light in front of the wind) "candle flickering in the wind"
Proverb, Old-Saying	急が−ば−回れ *isoga-ba-maware* (lit. make a detour when in a hurry) "more haste, less speed"
Onomatopoeic or Mimetic Expression	ノロノロ−と−歩く *noronoro-to-aruku* (lit. slouchingly walk) "walk slowly"
Quasi-Cliché, Institutionalized Phrase	肩−の−荷−を−下ろす *kata-no-ni-wo-orosu* (lit. lower lord from the shoulder) "take a big load off one's mind"

Table 2: Probabilistically Idiosyncratic Expressions

With entries like these, an NLP system can use the JDMWE as a reliable reference while effectively disambiguating the structures in the syntactic analysis process.

Of the MWEs in the JDMWE, approximately 38% and 92% of them were judged to meet criterion 3.1 and criterion 3.2, respectively. These are illustrated in Figure 2.

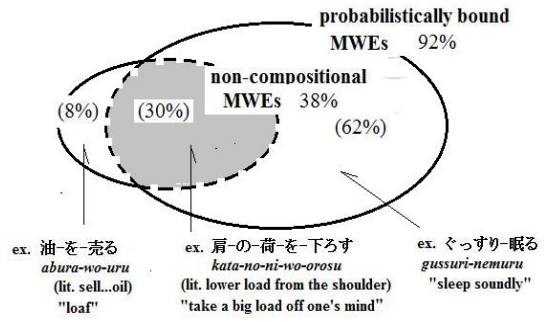

Figure 2: Approximate constituent ratio of non-compositional MWEs and probabilistically bound MWEs

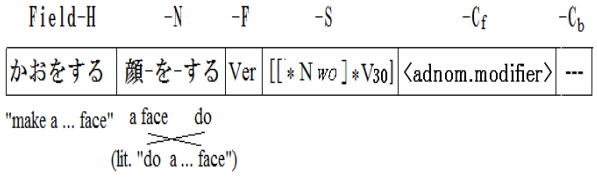

Figure 3: Example JDMWE entry

[2] These classes are not necessarily disjoint.

4 Contents of the JDMWE

The JDMWE has approximately 104,000 entries, one for each MWE, composed of six fields, namely, Field-H, -N, -F, -S, -C_f, and -C_b. The dictionary entry form of an MWE is stated in Field-H in the form of a non-segmented hira-kana (phonetic character) string. An example is given in Figure 3.

4.1 Notational Information (Field-N)

Japanese has three notational options: hira-kana, kata-kana, and kanji. The two kanas are phonological syllabaries. Kanji are originally Chinese idiographic characters. As we have many kanji characters that are both homophonic and synonymous, sentences can contain kanji replaceable by others. In addition, the inflectional suffix of some verbs can be absent in some contexts. The JDMWE has flexible conventions to cope with these characteristics. It uses brackets to indicate an optional word (or a series of interchangeable words marked off by the slash "/") in the Field-N description. Therefore, the entry whose Field-H (the first field) is きのいいやつ *ki-no-ii-yatu* (lit. "a guy who has a good spirit") "good-natured guy", can have (き/気)-の-(い/良/好/善)い-(やつ/奴/ヤツ) in its Field-N. The dash "-" is used as a word boundary indicator. This example can stand for twenty-four combinatorial variants, i.e., きのいいやつ,…, 気の良い奴,…, 気の善いヤツ.

If fully expanded with this information, the JDMWE's total number of MWEs can exceed 750,000.

4.2 Functional Information (Field-F)

Linguistic functions of MWEs can be simply classified by means of codes, as shown in Tables 3 and 4. Field-F is filled with one of those codes which corresponds to a root node label in the syntactic tree representation of a MWE.

code	function	size	example
Cdis	Discourse-Connective	1,000	言い−換えれ−ば *ii-kaere-ba* (lit. if (I) paraphrase) "in other words"
Adv	Adverbial	6,000	不思議−と *fusigi-to* "strangely enough"
Pren	Prenominal-Adjectival	13,700	確−たる *kaku-taru* "definite"

Nom	Nominal	12,000	灰汁−の−強さ *aku-no-tuyosa* (lit. strong taste of lye) “strong harshness”
Nd	Nominal/ Dynamic	4,700	一目−惚れ *hitome-bore* “love at first sight”
Nk	Nominal/State-describing	5,400	二−枚−舌 *ni-mai-jita* “being double-tongued”
Ver	Verbal	49,000	油−を−売る *abura-wo-uru* (lit. sell oil) “idle away”
Adj	Adjectival	4,600	眼−に−入れ−ても−痛く−ない *me-ni-ire-temo-itaku-nai* (lit. have no pain even if put into eyes) “an apple in ones eye”
K	Adjective-Verbal	3,500	経験−豊か *keiken-yutaka* “abundant in experience”
Ono	Onomatopoeic or Mimetic Expression	1,300	スラスラ−と *surasura-to* “smoothly”, “easily”, “fluently”

Table 3: Syntactic Functions and Examples

code	function	size	example
_P	Proverb, Old-Saying	2,300	百聞−は−一見−に−如か−ず *hyakubun-ha-ikken-ni-sika-zu* (lit. hearing about something a hundred times is not as good as seeing it once) “a picture is worth a thousand words”
_Self	Soliloquy, Monologue	200	困っ−た−なあ *komat-ta-naa* “Oh boy, we’re in trouble!”
_Call	Call, Yell	150	済み−ませ−ん−が *sumi-mase-n-ga* “Excuse me.”
_Grt	Greeting	200	いらっしゃい−ませ *irasshai-mase* “Welcome!”
_Res	Response	350	どう−いたし−まし−て *dou-itasi-masi-te* “You’re welcome.”

Table 4: Communicative Functions and Examples

4.3 Structural Information (Field-S)

4.3.1 Dependency Structure

The dependency structure of an MWE is given in Field-S by a phrase marker bracketing the modifier-head pairs, using POS symbols for conceptual words.[3] For example, an idiom 真っ赤-な - 嘘 *makka-na-uso* (lit. “crimson lie”) “downright lie” is given a marker [[K_{00} *na*] N]. This description represents the structure shown in Figure 4, where K_{00} and N are POS symbols denoting an adjective-verb stem and a noun, respectively.

[3] The intra-sentential dependency relation in Japanese is unilateral, i.e., the left modifier depends on the right head.

The JDMWE contains 49,000 verbal entries, making this the largest functional class in the JDMWE. For these verbal entries, more than 90 patterns are actually used as structural descriptors in Field-S. This fact can indicate the broadness of the structural spectrum of Japanese verbal MWEs. Some examples are shown in Table 5.

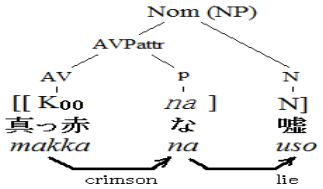

Figure 4: Example of dependency structure given in Field-S

example of structural pattern of verbal MWE	example of MWE
[[N *wo*] V_{30}]	異−を−唱える *i-wo-tonaeru* (lit. chant the difference) “raise an objection”
[[N *ga*] V_{30}]	撚り-が-戻る *yori-ga-modoru* (lit. the twist comes undone) “get reconciled”
[[N *ni*] V_{30}]	手−に−入れる *te-ni-ireru* (lit. put...into hands) “get”, “obtain”
[[[[N *no*] N] *ga*] V_{30}]	化け−の−皮−が−剥げる *bake-no-kawa-ga-hageru* (lit. peel off disguise) “expose the true colors”
[[[[N *no*] N] *ni*] V_{30}]	玉−の−輿−に−乗る *tama-no-kosi-ni-noru* (lit. ride on a palanquin for the nobility) “marry into wealth”
[[N *de*][[N *wo*] V_{30}]]	顎−で−人−を−使う *ago-de-hito-wo-tukau* (lit. use person by a chin) “order a person around”
[[N *ni*][[N *ga*] V_{30}]]	尻−に−火−が−付く *siri-ni-higa-tuku* (lit. buttocks catch fire) “get in great haste”
[[V_{23} *te*] V_{30}]	切っ−て−落とす *ki-te-otosu* (lit. cut and drop) “cut off”
[[V_{23} *ba*] V_{30}]	打て−ば−響く *ute-ba-hibiku* (lit. reverberate if hit) “respond quickly”
[[[[N *ni*] V_{23}] *te*] V_{30}]	束−に−なっ−て−掛かる *taba-ni-nat-te-kakaru* (lit. attack someone by becoming a bunch) “attack all at once”
[Adv [[N *ga*] V_{30}]]	どっと−疲れ−が−出る *dotto-tukare-ga-deru* (lit. fatigue bursts out) “being suddenly overcome with fatigue”

Table 5: Examples of structural types of verbal MWEs (N: noun, V_{23}: verb (adverbial form), V_{30}: verb (end form), Adv: adverb, *wo*, *ga*, *ni*, *no*, *de*, *te*, and *ba*: particle)

4.3.2 Coordinate Structure

Approximately 2,500 MWEs in the JDMWE contain internal coordinate structures. This information is described in Field-S by bracketing with "<" and ">", and the coordinated parts by "(" and ")". The coordinative phrase specification usually requires that the conjuncts must be parallel with respect to the syntactic function of the constituents appearing in the bracketed description. For example, an expression 後-は-野-と-なれ-山-と-なれ *ato-ha-no-to-nare-yama-to-nare* (lit. "the rest might become either a field or a mountain") "what will be, will be", has an internal coordinate structure. Thus, its Field-S is [[N *ha*]<([[N *to*] V_{60}])([[N *to*] V_{60}])>]. This description represents the structure shown in Figure 5, where V_{60} denotes an imperative form of the verb.

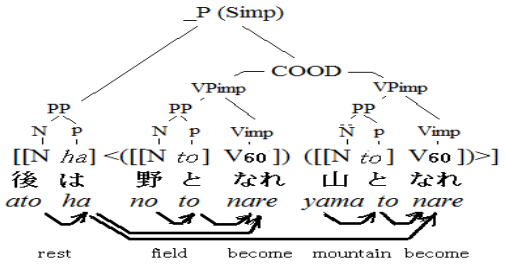

Figure 5: Example of the coordinate structure shown by "<" and ">" in Field-S

4.3.3 Non-phrasal Structure

Approximately 250 MWEs in the JDMWE are syntactically ill-formed in the sense of context-free grammar but still form a syntactic unit on their own. For example, 揺り籠-から-墓場-まで *yurikago-kara-hakaba-made* "from the cradle to the grave" is an adjunct of two postpositional phrases but is often used as a state-describing noun as in 揺り籠-から-墓場-まで-の-保証 *yurikago-kara-hakaba-made-no-hoshou* (lit. security of from cradle to grave) "security from the cradle to the grave". Thus Field-F and Field-S have a functional code N_k and a description [[N *kara*][N *made*] $]], respectively. The symbol "$" denotes a null constituent occupying the position of the governor on which this MWE depends. This structure is shown in Figure 6.

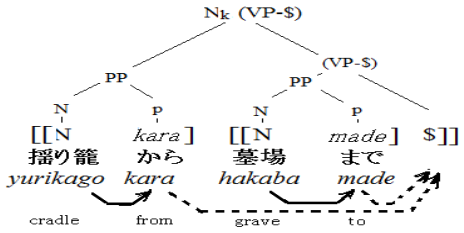

Figure 6: Example of a non-phrasal expression with a null constituent marked with "$" in Field-S

The total number of structural types specified in Field-S is nearly 6,000. This indicates that Japanese MWEs present a wide structural variety.

4.3.4 Internal Modifiability

Some MWEs are not fixed-length word strings, but allow the occurrence of phrasal modifiers internally. In our system, this aspect is captured by prefixing a modifiable element of the structural description stated in the Field-S with an asterisk "*". An adverbial MWE 上-に-述べ-た-様-に *ue-ni-nobe-ta-you-ni* "as I explained above" is one such MWE and thus has a description [[[[[N *ni*] *V_{23}] *ta*] N] *ni*] in Field-S, meaning that the third element V_{23} is a verb that can be modified internally by adverb phrases. Since the asterisk designates such optional phrasal modification, our system allows a derivative expression like 理由 -を-上-に-詳しく-述べ-た-様-に *riyuu-wo-ue-ni-kuwasiku-nobe-ta-you-ni* "as I explained in detail the reason above", which contains two additional, internal modifiers. The structure is shown in Figure 7.[4]

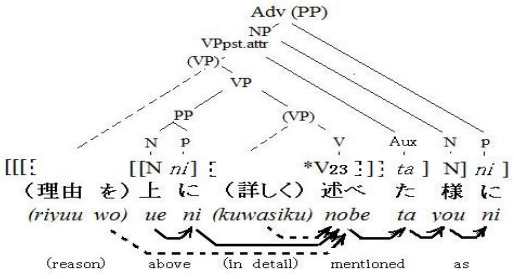

Figure 7: Example of internal modifiability marked by "*" in Field-S

[4] The positions to be taken by an internal modifier can be easily decided by the structural description given in Field-S along with the nest structure requirement.

Roughly speaking, 30,000 MWEs in the JDMWE have no asterisk in their Field-S. Our rigid examination reveals that internal modification is not allowed for them.

5 Contextual Condition (Field-C_f , C_b)

Approximately 6,700 MWEs need to be classified differently because they require particular forward contexts, i.e., they require co-occurrence of a particular syntactic phrase in the context that immediately precedes them. For example, 顔-を-する *kao-wo-suru* (lit. "do face") which is a support-verb construction, cannot occur without an immediately preceding adnominal modifier, e.g., the adjective 悲しい *kanasii* "sad", yielding 悲しい-顔-を-する *kanasii-kao-wo-suru* (lit. "do sad face") "make a sad face". This adnominal modifier co-occurrence requirement is stipulated in Field-C_f by a code <adnom. modifier>. There are about 30 of these forward contextual requirements. Similarly, backward contextual requirements, of which there are about 70, are stated in Field-C_b. Approximately 300 MWEs require particular backward contexts.

6 Statistical Properties

Without a rule system of semantic composition, it is difficult to evaluate the validity of the JDMWE concerning idiomaticity. However, we can confirm that 3,600 Japanese standard idioms that Sato (2007) listed from five Japanese idiom dictionaries published for human readers are included in the JDMWE as a proper subset. In addition, the JDMWE contains the information about their syntactic functions, structures, and flexibilities.

6.1 Comparison with Web N-gram Frequency Data

We examined the statistical properties of the JDMWE using the Japanese Web N-gram, version 1: LDC2009T08, which is a word N-gram ($1 \leq N \leq 7$) frequency dataset generated from 2×10^{10} sentences in a Japanese Web corpus, supplied by Google Inc. (Kudo et al. 2009). We will refer to this (or the Web corpus examined) subsequently as GND. We will refer to trigram $w_1w_2w_3$ as an NpV-trigram only when w_1 and w_3 are restricted to a noun and a verb (end form), respectively, and w_2 is one of the following case-particles: accusative を *wo*, subjective が *ga*, or dative に *ni*.[5] We write the number of occurrences of an expression x, counted in the GND, as C(x).

First, we obtain from the GND sets G, T, D, B, and R_i's defined below, using a Japanese word dictionary IPADIC (Asahara et al. 2003):

G={$w_1w_2w_3$| $w_1w_2w_3 \in$ GND, $w_1w_2w_3$ is an NpV-trigram.}
T={$w_1w_2w_3$| $w_1w_2w_3 \in$ JDMWE, $w_1w_2w_3$ is an NpV-trigram.}
D={w_1w_2|$\exists w_3$, $w_1w_2w_3 \in G$}
B={w_1w_2|$\exists w_3$, $w_1w_2w_3 \in T$}
R_i={$w_1w_2w_3$| $w_1w_2w_3 \in T$, C($w_1w_2w_3$) is the i-th largest among C(w_1w_2v)'s for all $w_1w_2v \in G$}.

We then found the following data:
・$|B|$=10,548
・$|D|$=110,822
・$|R_1|$=4,983, $|R_2|$=1,495, $|R_3|$=786, $|R_4|$=433, …
From these, we realize, for example, that 47.2% =($|R_1|/|B|$)×100 of trigrams in T have verbs that occur most frequently in the GND, succeeding the individual bigrams. An example of such a trigram is アクション-を-起こす *akushon-wo-okosu* (lit. "raise action") "take action". Similarly, 14.0%= ($|R_2|/|B|$)×100 have the second most frequent verbs, 7.5% have the third most frequent verbs, and so on. Figure 8(a) illustrates the results. From this, we can assume that the higher probability $\boldsymbol{p}_f(w_3|w_1w_2)$ a trigram $w_1w_2w_3$ has, the more likely w_3 is chosen for each w_1w_2 in the JDMWE. This is consistent with what we wrote in section 3.2. Figure 8(b) is the accumulative substitute of Figure 8(a). Extrapolating Figure 8(b) suggests that 10% of NpV-trigrams in the JDMWE do not occur in the GND. This implies that the size, i.e., 2×10^{10} sentences of the Web corpus used by the GND is not sufficiently large to allow MWE extraction.[6]

[5] The NpV-trigrams represent the typical forms of shortest Japanese sentences, corresponding roughly to subject-verb, verb-object/direct, and verb-object/indirect constructions in English.
[6] Otherwise, the frequency cut-off point of 20 adopted in GND is too high.

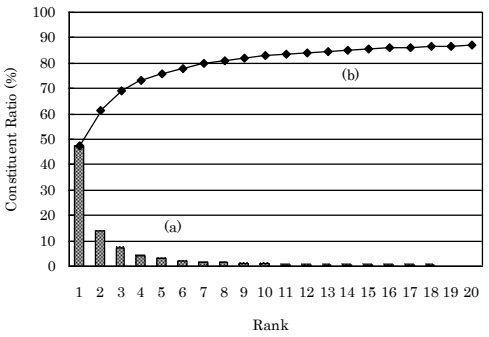

Figure 8 (a): Constituent ratio ($|R_i|/|B|$)×100 for rank i of probability $\boldsymbol{p}_f(w_3|w_1w_2)$; (b): Accumulative variant of (a) for rank i of probability $\boldsymbol{p}_f(w_3|w_1w_2)$

Second, we calculate the (normalized) entropy $H_f(w_3|w_1w_2)$ for each $w_1w_2 \in D$ defined below, where the probability $\boldsymbol{p}_f(w_3|w_1w_2)$ is estimated by $C(w_1w_2w_3)/C(w_1w_2)$. This provides a measure of the flatness of the $\boldsymbol{p}_f(w_3|w_1w_2)$ distribution canceling out the influence of the number N of verb types w_3's.

$$H_f(w_3|w_1w_2) = -\Big(\sum_{w_3} \boldsymbol{p}_f(w_3|w_1w_2) \log \boldsymbol{p}_f(w_3|w_1w_2)\Big) / \log N$$

After arranging 110,822 bigrams in *D* in ascending order of $H_f(w_3|w_1w_2)$, we divided them into 20 intervals $A_1, A_2, \ldots, A_{20}$ each with an equal number of bigrams (5,542). We then examined how many bigrams in *B* were included in each interval. Figures 9(a) and (b) plot the resulting constituent ratio of the bigrams in *B* and the mean value of $H_f(w_3|w_1w_2)$'s in each interval, respectively. We found, for example, that 1,262 out of 5,542 bigrams are in *B* for the first interval, i.e., the constituent ratio is 22.8%=(1,262/5,542) × 100. Similarly, we obtain 22.5%=(1,248/5,542) × 100 for the second interval, 20.5%=(1,136/5,542)×100 for the third, and so on. From this, we realize the macroscopic tendency that the larger the entropy $H_f(w_3|w_1w_2)$, or equivalently the perplexity of the succeeding verb w_3, a bigram w_1w_2 has, the less likely it is adopted as a prefix of a trigram in *T*.

Taking the results in Figure 8 and Figure 9 together, we can presume that not only frequently but also exclusively occurring verbs would be the preferred choice in *T*.

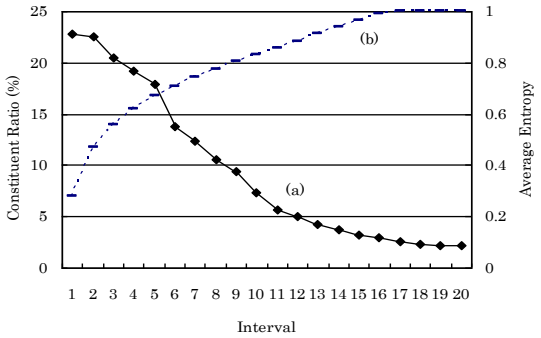

Figure 9 (a): Constituent ratio of the bigrams in *B* among bigrams in *D* in interval k ($1 \le k \le 20$); (b): Mean value of entropies $H_f(w_3|w_1w_2)$'s in the interval k ($1 \le k \le 20$)

This suggests the general feasibility of the JDMWE, for its relative compactness, in effectively disambiguating the syntactic structures of input word strings.

The above investigations were carried out on the forward conditional probabilities for restricted types of MWEs. However, the results imply a general validity of the JDMWE since the same criteria for selection were applied to all kinds of multiword expressions.

6.2 Occurrences in Newspapers

We examined 2,500 randomly selected sentences in Nikkei newspaper articles (published in 2009) to determine how many MWE tokens of the JDMWE occur in them. We found that in 100 sentences an average of 74 tokens of our MWEs were used. This suggests a large lexical coverage of the JDMWE.

7 Concluding Remarks

The JDMWE is a slotted tree bank for idiosyncratic multiword expressions, annotated with detailed notational, syntactic information.

The idea underlying the JDMWE is that the volume and meticulousness of the lexical resource crucially affects the outcome of the rule-oriented, large-scale NLP. In view of this, the JDMWE was designed to encompass the wide range of linguistic objects related to Japanese MWEs, by placing importance on the recall rate in the selection of the

candidate expressions.[7] The statistical properties clarified in this paper imply the general feasibility of the JDMWE at least in the probabilistic respect.

Possible fields of application of the JDMWE include, for example:

- Phrase-based machine translation
- Phrase-based speech recognition
- Phrase-based kana-to-kanji conversion
- Search engine for Japanese corpus
- Paraphrasing system
- Japanese dialoguer
- Japanese language education system

Another aspect of the JDMWE is that it would provide linguists with lexicological data. For example, the usage of Japanese onomatopoeic adverbs, which are mostly bound probabilistically to specific verbs or adjectives, is extensively catalogued in the JDMWE.

The first version of the JDMWE will be released after proofreading.[8] If possible, we would like to add further information to each MWE on morphological variants, passivization, relativization, decomposability, paraphrasing, and semantic disambiguation for future versions.

Acknowledgments

We would like to thank the late Professors Toshihiko Kurihara and Sho Yoshida, who inspired our current research in the 1970s. Similar thanks go to Makoto Nagao. We are also grateful to everyone who assisted in the development of the JDMWE. Further special thanks go to Akira Shimazu, Takano Ogino, and Kenji Yoshimura for their encouragement and useful discussions, to those who worked on the LDC2009T08 and IPADIC, to the three anonymous reviewers for their valuable comments and advice, and to Stephan Howe for advice on matters of English style in the current paper.

Abstract

We describe an annotation tool developed to assist in the creation of multimodal action-communication corpora from on-line massively multi-player games, or MMGs. MMGs typically involve groups of players (5-30) who control their avatars[1], perform various activities (questing, competing, fighting, etc.) and communicate via chat or speech using assumed screen names. We collected a corpus of 48 group quests in Second Life that jointly involved 206 players who generated over 30,000 messages in quasi-synchronous chat during approximately 140 hours of recorded action. Multiple levels of co-ordinated annotation of this corpus (dialogue, movements, touch, gaze, wear, etc) are required in order to support development of automated predictors of selected real-life social and demographic characteristics of the players. The annotation tool presented in this paper was developed to enable efficient and accurate annotation of all dimensions simultaneously.

1 Introduction

The aim of our project is to predict the real world characteristics of players of massively-multiplayer online games, such as Second Life (SL). We sought to predict actual player attributes like age or education levels, and personality traits including leadership or conformity. Our task was to do so using only the behaviors, communication, and interaction among the players produced during game play. To do so, we logged all players' avatar movements, "touch events" (putting on or taking off clothing items, for example), and their public chat messages (i.e., messages that can be seen by all players in the group). Given the complex nature of interpreting chat in an online game environment, we required a tool that would allow annotators to have a synchronized view of both the event action as well as the chat utterances. This would allow our annotators to correlate the events and the chat by marking them simultaneously. More importantly, being able to view game events enables more accurate chat annotation; and conversely, viewing chat utterances helps to interpret the significance of certain events in the game, e.g., one avatar following another. For example, an exclamation of: "I can't do it!" could be simply a response (rejection) to a request from another player; however, when the game action is viewed and the speaker is seen attempting to enter a building without success, another interpretation may arise (an assertion, a call for help, etc.).

The Real World (RW) characteristics of SL players (and other on-line games) may be inferred to varying degrees from the appearance of their avatars, the behaviors they engage in, as well as from their on-line chat communications. For example, the avatar gender generally matches the gender of the owner; on the other hand, vocabulary choices in chat are rather poor predictors of a player's age, even though such correlation is generally seen in real life conversation.

Second Life[2] was the chosen platform because of the ease of creating objects, controlling the play environment, and collecting players' movement, chat, and other behaviors. We generated a corpus of chat and movement data from 48 quests comprised of 206 participants who generated over 30,000

[1] All avatar names seen in this paper have been changed to protect players' identities.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 171–179,
Portland, Oregon, June 19-24, 2011.

messages and approximately 140 hours of recorded action. We required an annotation tool to help us efficiently annotate dialogue acts and communication links in chat utterances as well as avatar movements from such a large corpus. Moreover, we required correlation between these two dimensions of chat and movement since movement and other actions may be both causes and effects of verbal communication. We developed a multimodal event and chat annotation tool (called RAT, the Relational Annotation Tool), which will simultaneously display a 2D rendering of all movement activity recorded during our Second Life studies, synchronized with the chat utterances. In this way both chat and movements can be annotated simultaneously: the avatar movement actions can be reviewed while making dialogue act annotations. This has the added advantage of allowing the annotator to see the relationships between chat, behavior, and location/movement. This paper will describe our annotation process and the RAT tool.

2 Related Work

Annotation tools have been built for a variety of purposes. The CSLU Toolkit (Sutton et al., 1998) is a suite of tools used for annotating spoken language. Similarly, the EMU System (Cassidy and Harrington, 2001) is a speech database management system that supports multi-level annotations. Systems have been created that allow users to readily build their own tools such as AGTK (Bird et al., 2001). The multi-modal tool DAT (Core and Allen, 1997) was developed to assist testing of the DAMSL annotation scheme. With DAT, annotators were able to listen to the actual dialogues as well as view the transcripts. While these tools are all highly effective for their respective tasks, ours is unique in its synchronized view of both event action and chat utterances.

Although researchers studying online communication use either off-the shelf qualitative data analysis programs like Atlas.ti or NVivo, a few studies have annotated chat using custom-built tools. One approach uses computer-mediated discourse analysis approaches and the Dynamic Topic Analysis tool (Herring, 2003; Herring & Nix; 1997; Stromer-Galley & Martison, 2009), which allows annotators to track a specific phenomenon of online interaction in chat: topic shifts during an interaction. The Virtual Math Teams project (Stahl, 2009) created a tool that allowed for the simultaneous playback of messages posted to a quasi-synchronous discussion forum with whiteboard drawings that student math team members used to illustrate their ideas or visualize the math problem they were trying to solve (Çakir, 2009).

A different approach to data capture of complex human interaction is found in the AMI Meeting Corpus (Carletta, 2007). It captures participants' head movement information from individual head-mounted cameras, which allows for annotation of nodding (consent, agreement) or shaking (disagreement), as well as participants' locations within the room; however, no complex events involving series of movements or participant proximity are considered. We are unaware of any other tools that facilitate the simultaneous playback of multi-modes of communication and behavior.

3 Second Life Experiments

To generate player data, we rented an island in Second Life and developed an approximately two hour quest, the Case of the Missing Moonstone. In this quest, small groups of 4 to 5 players, who were previously unacquainted, work their way together through the clues and puzzles to solve a murder mystery. We recruited Second Life players in-game through advertising and setting up a shop that interested players could browse. We also used Facebook ads, which were remarkably effective.

The process of the quest experience for players started after they arrived in a starting area of the island (the quest was open only to players who were made temporary members of our island) where they met other players, browsed quest-appropriate clothing to adorn their avatars, and received information from one of the researchers. Once all players arrived, the main quest began, progressing through five geographic areas in the island. Players were accompanied by a "training sergeant", a researcher using a robot avatar, that followed players through the quest and provided hints when groups became stymied along their investigation but otherwise had little interaction with the group.

The quest was designed for players to encounter obstacles that required coordinated action, such as all players standing on special buttons to activate a door, or the sharing of information between players, such as solutions to a word puzzle, in order to advance to the next area of the quest (Figure 1).

Slimy Roastbeef*: "who's got the square gear?"*

Kenny Superstar: *"I do, but I'm stuck"*

Slimy Roastbeef: *"can you hand it to me?"*

Kenny Superstar*: "i don't know how"*

Slimy Roastbeef: *"open your inventory, click and drag it onto me"*

Figure 1: Excerpt of dialogue during a coordination activity

Quest activities requiring coordination among the players were common and also necessary to ensure a sufficient degree of movement and message traffic to provide enough material to test our predictions, and to allow us to observe particular social characteristics of players. Players answered a survey before and then again after the quest, providing demographic and trait information and evaluating other members of their group on the characteristics of interest.

3.1 Data Collection

We recorded all players' avatar movements as they purposefully moved avatars through the virtual spaces of the game environment, their public chat, and their "touch events", which are the actions that bring objects out of player inventories, pick up objects to put in their inventories, or to put objects, such as hats or clothes, onto the avatars, and the like. We followed Yee and Bailenson's (2008) technical approach for logging player behavior. To get a sense of the volume of data generated, 206 players generated over 30,000 messages into the group's public chat from the 48 sessions. We compiled approximately 140 hours of recorded action. The avatar logger was implemented to record each avatar's location through their (x,y,z) coordinates, recorded at two second intervals. This information was later used to render the avatar's position on our 2D representation of the action (section 4.1).

4 RAT

The Relational Annotation Tool (RAT) was built to assist in annotating the massive collection of data collected during the Second Life experiments. A tool was needed that would allow annotators to see the textual transcripts of the chat while at the same time view a 2D representation of the action. Additionally, we had a textual transcript for a select set of events: touch an object, stand on an object, attach an object, etc., that we needed to make available to the annotator for review.

These tool characteristics were needed for several reasons. First, in order to fully understand the communication and interaction occurring between players in the game environment and accurately annotate those messages, we needed annotators to have as much information about the context as possible. The 2D map coupled with the events information made it easier to understand. For example, in the quest, players in a specific zone, encounter a dead, maimed body. As annotators assigned codes to the chat, they would sometimes encounter exclamations, such as "ew" or "gross". Annotators would use the 2D map and the location of the exclaiming avatar to determine if the exclamation was a result of their location (in the zone with the dead body) or because of something said or done by another player. Location of avatars on the 2D map synchronized with chat was also helpful for annotators when attempting to disambiguate communicative links. For example, in one subzone, mad scribblings are written on a wall. If player A says "You see that scribbling on the wall?" the annotator needs to use the 2D map to see who the player is speaking to. If player A and player C are both standing in that subzone, then the annotator can make a reasonable assumption that player A is directing the question to player C, and not player B who is located in a different subzone. Second, we annotated coordinated avatar movement actions (such as following each other into a building or into a room), and the only way to readily identify such complex events was through the 2D map of avatar movements.

The overall RAT interface, Figure 2, allows the annotator to simultaneously view all modes of representation. There are three distinct panels in this interface. The left hand panel is the 2D representation of the action (section 4.1). The upper right hand panel displays the chat and event transcripts (section 4.2), while the lower right hand portion is reserved for the three annotator sub-panels (section 4.3).

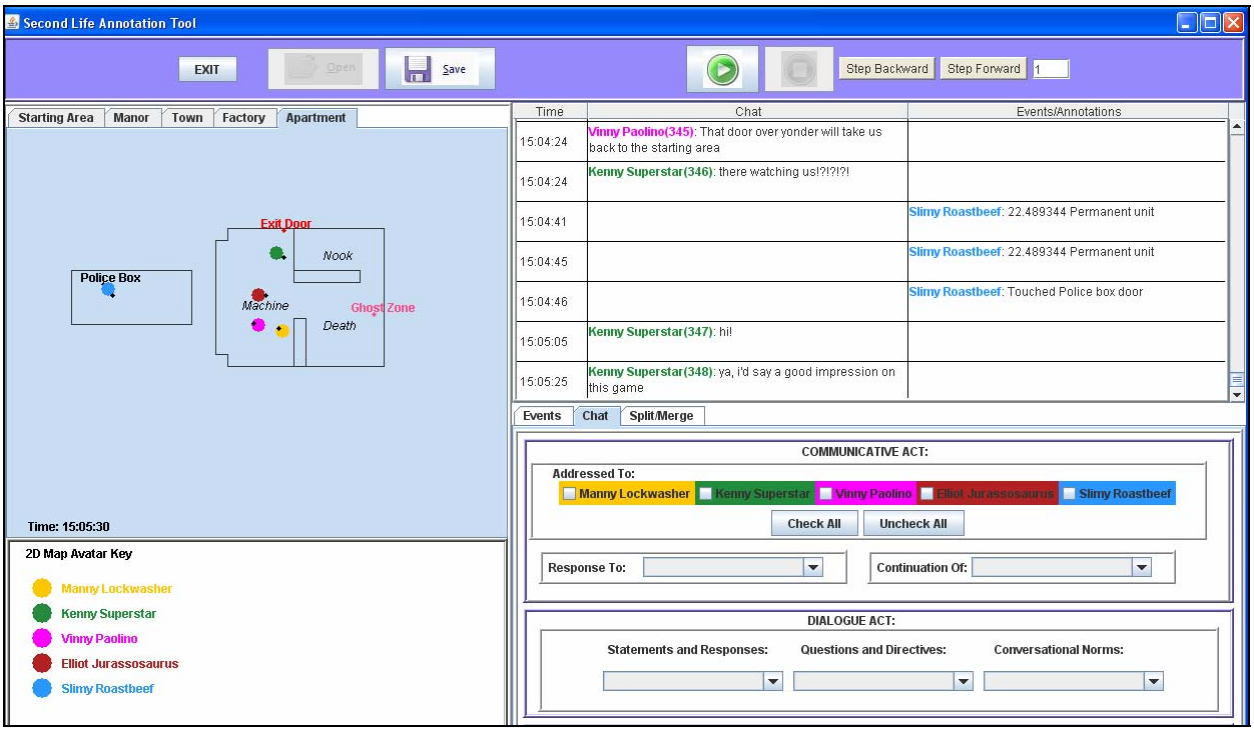

Figure 2: RAT interface

4.1 The 2D Game Representation

The 2D representation was the most challenging of the panels to implement. We needed to find the proper level of abstraction for the action, while maintaining its usefulness for the annotator. Too complex a representation would cause cognitive overload for the annotator, thus potentially deteriorating the speed and quality of the annotations. Conversely, an overly abstract representation would not be of significant value in the annotation process.

There were five distinct geographic areas on our Second Life Island: *Starting Area, Mansion, Town Center, Factory and Apartments*. An overview of the area in Second Life is displayed in Figure 3. We decided to represent each area separately as each group moves between the areas together, and it was therefore never necessary to display more than one area at a time. The 2D representation of the Mansion Area is displayed in Figure 4 below. Figure 5 is an exterior view of the actual Mansion in Second Life. Each area's fixed representation was rendered using Java Graphics, reading in the Second Life (x,y,z) coordinates from an XML data file. We represented the walls of the buildings as connected solid black lines with openings left for doorways. Key item locations were marked and labeled, e.g. *Kitten, maid, the Idol*, etc. Even though annotators visited the island to familiarize themselves with the layout, many mansion rooms were labeled to help the annotator recall the layout of the building, and minimize error of annotation based on flawed recall. Finally, the exact time of the action that is currently being represented is displayed in the lower left hand corner.

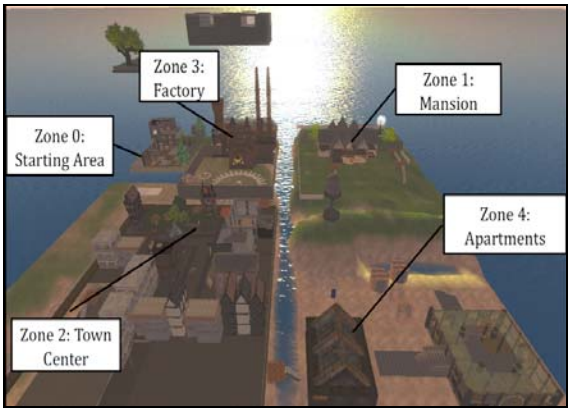

Figure 3: Second Life overview map

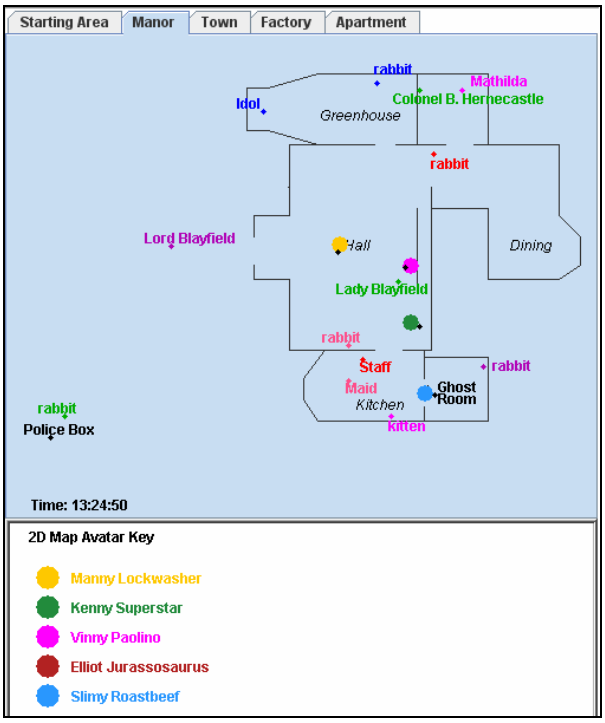

Figure 4: 2D representation of Second Life action inside the Mansion/Manor

Figure 5: Second Life view of Mansion exterior

Avatar location was recorded in our log files as an (x,y,z) coordinate at a two second interval. Avatars were represented in our 2D panel as moving solid color circles, using the x and y coordinates. A color coded avatar key was displayed below the 2D representation. This key related the full name of every avatar to its colored circle representation. The z coordinate was used to determine if the avatar was on the second floor of a building. If the z value indicated an avatar was on a second floor, their icon was modified to include the number "2" for the duration of their time on the second floor. Also logged was the avatar's degree of rotation. Using this we were able to represent which direction the avatar was looking by a small black dot on their colored circle.

As the annotators stepped through the chat and event annotation, the action would move forward, in synchronized step in the 2D map. In this way at any given time the annotator could see the avatar action corresponding to the chat and event transcripts appearing in the right panels. The annotator had the option to step forward or backward through the data at any step interval, where each step corresponded to a two second increment or decrement, to provide maximum flexibility to the annotator in viewing and reviewing the actions and communications to be annotated. Additionally, "Play" and "Stop" buttons were added to the tool so the annotator may simply watch the action play forward rather than manually stepping through.

4.2 The Chat & Event Panel

Avatar utterances along with logged Second Life events were displayed in the Chat and Event Panel (Figure 6). Utterances and events were each displayed in their own column. Time was recorded for every utterance and event, and this was displayed in the first column of the Chat and Event Panel. All avatar names in the utterances and events were color coded, where the colors corresponded to the avatar color used in the 2D panel. This panel was synchronized with the 2D Representation panel and as the annotator stepped through the game action on the 2D display, the associated utterances and events populated the Chat and Event panel.

Time	Chat	Events/Annotations
13:47:40		Kenny Superstar: Touched Square gear
13:47:46		Slimy Roastbeef: Touched Round gear
13:48:01	Kenny Superstar(142): we have to put all the gears in place	
13:48:06	Slimy Roastbeef(143): put the triangle gear on there or something	
13:48:10		Elliot Jurassosaurus: Touched Sharp gear
13:48:25	Manny Lockwasher(144): how	
13:48:26	Slimy Roastbeef(145): probably have to detach from your hand first	

Figure 6: Chat & Event Panel

4.3 The Annotator Panels

The Annotator Panels (Figures 7 and 10) contains all features needed for the annotator to quickly annotate the events and dialogue. Annotators could choose from a number of categories to label each dialogue utterance. Coding categories included communicative links, dialogue acts, and selected multi-avatar actions. In the following we briefly outline each of these. A more detailed description of the chat annotation scheme is available in (Shaikh et al., 2010).

4.3.1 Communicative Links

One of the challenges in multi-party dialogue is to establish which user an utterance is directed towards. Users do not typically add addressing information in their utterances, which leads to ambiguity while creating a communication link between users. With this annotation level, we asked the annotators to determine whether each utterance was addressed to some user, in which case they were asked to mark which specific user it was addressed to; was in response to another prior utterance by a different user, which required marking the specific utterance responded to; or a continuation of the user's own prior utterance.

Communicative link annotation allows for accurate mapping of dialogue dynamics in the multi-party setting, and is a critical component of tracking such social phenomena as disagreements and leadership.

4.3.2 Dialogue Acts

We developed a hierarchy of 19 dialogue acts for annotating the functional aspect of the utterance in the discussion. The tagset we adopted is loosely based on DAMSL (Allen & Core, 1997) and SWBD (Jurafsky et al., 1997), but greatly reduced and also tuned significantly towards dialogue pragmatics and away from more surface characteristics of utterances. In particular, we ask our annotators what is the pragmatic function of each utterance within the dialogue, a decision that often depends upon how earlier utterances were classified. Thus augmented, DA tags become an important source of evidence for detecting language uses and such social phenomena as conformity. Examples of dialogue act tags include Assertion-Opinion, Acknowledge, Information-Request, and Confirmation-Request.

Using the augmented DA tagset also presents a fairly challenging task to our annotators, who need to be trained for many hours before an acceptable rate of inter-annotator agreement is achieved. For this reason, we consider our current DA tagging as a work in progress.

4.3.3 Zone coding

Each of the five main areas had a corresponding set of subzones. A subzone is a building, a room within a building, or any other identifiable area within the playable spaces of the quest, e.g. the *Mansion* has the subzones: *Hall*, *Dining Room*, *Kitchen*, *Outside*, *Ghost Room*, etc. The subzone was determined based on the avatar(s) (x,y,z) coordinates and the known subzone boundaries. This additional piece of data allowed for statistical analysis at different levels: avatar, dialogue unit, and subzone.

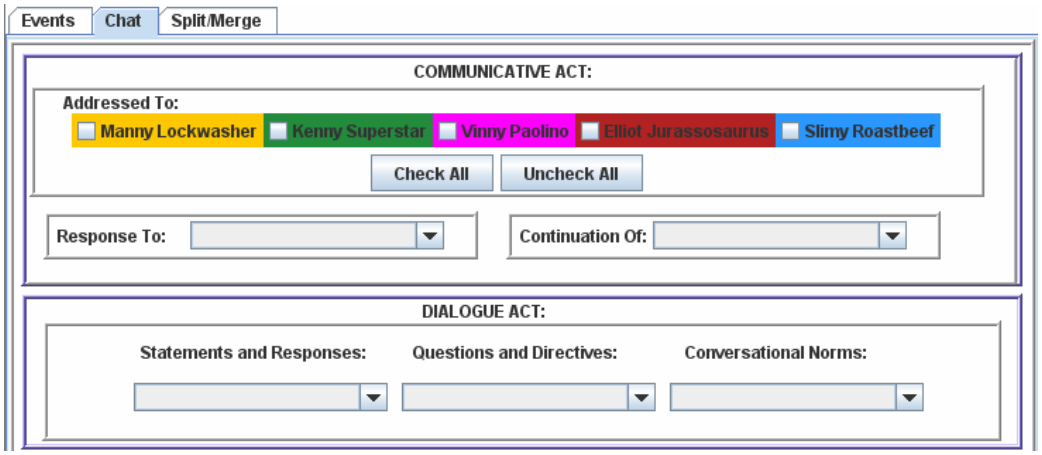

Figure 7: Chat Annotation Sub-Panel

4.3.4 Multi-avatar events

As mentioned, in addition to chat we also were interested in having the annotators record composite events involving multiple avatars over a span of time and space. While the design of the RAT tool will support annotation of any event of interest with only slight modifications, for our purposes, we were interested in annotating two types of events that we considered significant for our research hypotheses. The first type of event was the multi-avatar entry (or exit) into a sub-zone, including the order in which the avatars moved.

Figure 8 shows an example of a "Moves into Subzone" annotation as displayed in the Chat & Event Panel. Figure 9 shows the corresponding series of progressive moments in time portraying entry into the Bank subzone as represented in RAT. In the annotation, each avatar name is recorded in order of its entry into the subzone (here, the Bank). Additionally, we record the subzone name and the time the event is completed[3].

The second type of event we annotated was the "follow X" event, i.e., when one or more avatars appeared to be following one another within a subzone. These two types of events were of particular interest because we hypothesized that players who are leaders are likely to enter first into a subzone and be followed around once inside.

In addition, support for annotation of other types of composite events can be added as needed; for example, group forming and splitting, or certain joint activities involving objects, etc. were fairly common in quests and may be significant for some analyses (although not for our hypotheses).

For each type of event, an annotation subpanel is created to facilitate speedy markup while minimizing opportunities for error (Figure 10). A "Moves Into Subzone" event is annotated by recording the ordinal (1, 2, 3, etc.) for each avatar. Similarly, a "Follows" event is coded as avatar group "A" follows group "B', where each group will contain one or more avatars.

Figure 8: The corresponding annotation for Figure 9 event, as displayed in the Chat & Event Panel

5 The Annotation Process

To annotate the large volume of data generated from the Second Life quests, we developed an annotation guide that defined and described the annotation categories and decision rules annotators were to follow in categorizing the data units (following previous projects (Shaikh et al., 2010). Two students were hired and trained for approximately 60 hours, during which time they learned how to use the annotation tool and the categories and rules for the annotation process. After establishing a satisfactory level of interrater reliability (average Krippendorff's alpha of all measures was <0.8. Krippendorff's alpha accounts for the probability of

[3] We are also able to record the start time of any event but for our purposes we were only concerned with the end time.

chance agreement and is therefore a conservative measure of agreement), the two students then annotated the 48 groups over a four-month period. It took approximately 230 hours to annotate the sessions, and they assigned over 39,000 dialogue act tags. Annotators spent roughly 7 hours marking up the movements and chat messages per 2.5 hour quest session.

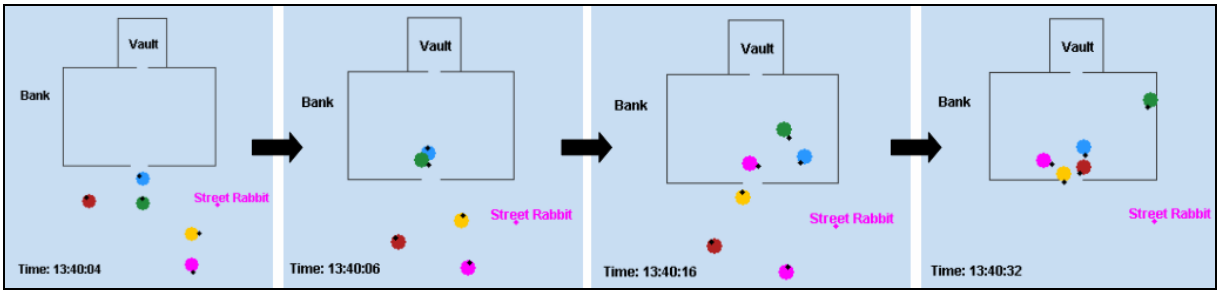

Figure 9: A series of progressive moments in time portraying avatar entry into the Bank subzone

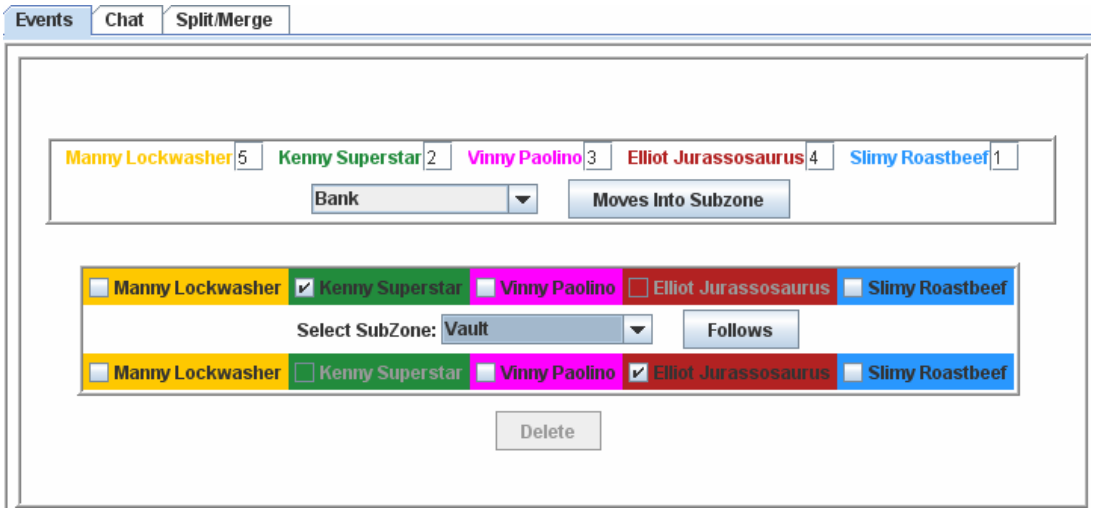

Figure 10: Event Annotation Sub-Panel, currently showing the "Moves Into Subzone" event from figure 9, as well as: "*Kenny follows Elliot in Vault*"

5.1 The Annotated Corpus

The current version of the annotated corpus consists of thousands of tagged messages including: 4,294 action-directives, 17,129 assertion-opinions, 4,116 information requests, 471 confirmation requests, 394 offer-commits, 3,075 responses to information requests, 1,317 agree-accepts, 215 disagree-rejects, and 2,502 acknowledgements, from 30,535 pre-split utterances (31,801 post-split). We also assigned 4,546 following events.

6 Conclusion

In this paper we described the successful implementation and use of our multi-modal annotation tool, RAT. Our tool was used to accurately and simultaneously annotate over 30,000 messages and approximately 140 hours of action. For each hour spent annotating, our annotators were able to tag approximately 170 utterances as well as 36 minutes of action.

The annotators reported finding the tool highly functional and very efficient at helping them easily assign categories to the relevant data units, and that they could assign those categories without producing too many errors, such as accidentally assigning the wrong category or selecting the wrong avatar. The function allowing for the synchronized playback of the chat and movement data coupled with the 2D map increased comprehension of utterances

and behavior of the players during the quest, improving validity and reliability of the results.

Abstract

We demonstrate how supervised discriminative machine learning techniques can be used to automate the assessment of 'English as a Second or Other Language' (ESOL) examination scripts. In particular, we use rank preference learning to explicitly model the grade relationships between scripts. A number of different features are extracted and ablation tests are used to investigate their contribution to overall performance. A comparison between regression and rank preference models further supports our method. Experimental results on the first publically available dataset show that our system can achieve levels of performance close to the upper bound for the task, as defined by the agreement between human examiners on the same corpus. Finally, using a set of 'outlier' texts, we test the validity of our model and identify cases where the model's scores diverge from that of a human examiner.

1 Introduction

The task of automated assessment of free text focuses on automatically analysing and assessing the quality of writing competence. Automated assessment systems exploit textual features in order to measure the overall quality and assign a score to a text. The earliest systems used superficial features, such as word and sentence length, as proxies for understanding the text. More recent systems have used more sophisticated automated text processing techniques to measure grammaticality, textual coherence, prespecified errors, and so forth.

Deployment of automated assessment systems gives a number of advantages, such as the reduced workload in marking texts, especially when applied to large-scale assessments. Additionally, automated systems guarantee the application of the same marking criteria, thus reducing inconsistency, which may arise when more than one human examiner is employed. Often, implementations include feedback with respect to the writers' writing abilities, thus facilitating self-assessment and self-tutoring.

Implicitly or explicitly, previous work has mostly treated automated assessment as a supervised text classification task, where training texts are labelled with a grade and unlabelled test texts are fitted to the same grade point scale via a regression step applied to the classifier output (see Section 6 for more details). Different techniques have been used, including cosine similarity of vectors representing text in various ways (Attali and Burstein, 2006), often combined with dimensionality reduction techniques such as Latent Semantic Analysis (LSA) (Landauer et al., 2003), generative machine learning models (Rudner and Liang, 2002), domain-specific feature extraction (Attali and Burstein, 2006), and/or modified syntactic parsers (Lonsdale and Strong-Krause, 2003).

A recent review identifies twelve different automated free-text scoring systems (Williamson, 2009). Examples include e-Rater (Attali and Burstein, 2006), Intelligent Essay Assessor (IEA) (Landauer et al., 2003), IntelliMetric (Elliot, 2003; Rudner et al., 2006) and Project Essay Grade (PEG) (Page, 2003). Several of these are now deployed in high-stakes assessment of examination scripts. Although there are many published analyses of the perfor-

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 180–189,
Portland, Oregon, June 19-24, 2011.

mance of individual systems, as yet there is no publically available shared dataset for training and testing such systems and comparing their performance. As it is likely that the deployment of such systems will increase, standardised and independent evaluation methods are important. We make such a dataset of ESOL examination scripts available[1] (see Section 2 for more details), describe our novel approach to the task, and provide results for our system on this dataset.

We address automated assessment as a supervised discriminative machine learning problem and particularly as a rank preference problem (Joachims, 2002). Our reasons are twofold:

Discriminative classification techniques often outperform non-discriminative ones in the context of text classification (Joachims, 1998). Additionally, rank preference techniques (Joachims, 2002) allow us to explicitly learn an optimal ranking model of text quality. Learning a ranking directly, rather than fitting a classifier score to a grade point scale after training, is both a more generic approach to the task and one which exploits the labelling information in the training data efficiently and directly.

Techniques such as LSA (Landauer and Foltz, 1998) measure, in addition to writing competence, the semantic relevance of a text written in response to a given prompt. However, although our corpus of manually-marked texts was produced by learners of English in response to prompts eliciting free-text answers, the marking criteria are primarily based on the accurate use of a range of different linguistic constructions. For this reason, we believe that an approach which directly measures linguistic competence will be better suited to ESOL text assessment, and will have the additional advantage that it may not require retraining for new prompts or tasks.

As far as we know, this is the first application of a rank preference model to automated assessment (hereafter AA). In this paper, we report experiments on rank preference Support Vector Machines (SVMs) trained on a relatively small amount of data, on identification of appropriate feature types derived automatically from generic text processing tools, on comparison with a regression SVM model, and on the robustness of the best model to 'outlier' texts. We report a consistent, comparable and replicable set of results based entirely on the new dataset and on public-domain tools and data, whilst also experimentally motivating some novel feature types for the AA task, thus extending the work described in (Briscoe et al., 2010).

In the following sections we describe in more detail the dataset used for training and testing, the system developed, the evaluation methodology, as well as ablation experiments aimed at studying the contribution of different feature types to the AA task. We show experimentally that discriminative models with appropriate feature types can achieve performance close to the upper bound, as defined by the agreement between human examiners on the same test corpus.

2 Cambridge Learner Corpus

The Cambridge Learner Corpus[2] (CLC), developed as a collaborative project between Cambridge University Press and Cambridge Assessment, is a large collection of texts produced by English language learners from around the world, sitting Cambridge Assessment's English as a Second or Other Language (ESOL) examinations[3].

For the purpose of this work, we extracted scripts produced by learners taking the First Certificate in English (FCE) exam, which assesses English at an upper-intermediate level. The scripts, which are anonymised, are annotated using XML and linked to meta-data about the question prompts, the candidate's grades, native language and age. The FCE writing component consists of two tasks asking learners to write either a letter, a report, an article, a composition or a short story, between 200 and 400 words. Answers to each of these tasks are annotated with marks (in the range 1–40), which have been fitted to a RASCH model (Fischer and Molenaar, 1995) to correct for inter-examiner inconsistency and comparability. In addition, an overall mark is assigned to both tasks, which is the one we use in our experiments.

Each script has been also manually tagged with information about the linguistic errors committed,

[3] http://www.cambridgeesol.org/

using a taxonomy of approximately 80 error types (Nicholls, 2003). The following is an example error-coded sentence:

> *In the morning, you are* <NS type = "TV"> *waken|woken*</NS> *up by a singing puppy.*

In this sentence, TV denotes an incorrect tense of verb error, where *waken* can be corrected to *woken*.

Our data consists of 1141 scripts from the year 2000 for training written by 1141 distinct learners, and 97 scripts from the year 2001 for testing written by 97 distinct learners. The learners' ages follow a bimodal distribution with peaks at approximately 16–20 and 26–30 years of age.

The prompts eliciting the free text are provided with the dataset. However, in this paper we make no use of prompt information and do not make any attempt to check that the text answer is appropriate to the prompt. Our focus is on developing an accurate AA system for ESOL text that does not require prompt-specific or topic-specific training. There is no overlap between the prompts used in 2000 and in 2001. A typical prompt taken from the 2000 training dataset is shown below:

Your teacher has asked you to write a story for the school's English language magazine. The story must begin with the following words: "Unfortunately, Pat wasn't very good at keeping secrets".

3 Approach

We treat automated assessment of ESOL text (see Section 2) as a rank preference learning problem (see Section 1). In the experiments reported here we use Support Vector Machines (SVMs) (Vapnik, 1995) through the SVM$^{\text{light}}$ package (Joachims, 1999). Using the dataset described in Section 2, a number of linguistic features are automatically extracted and their contribution to overall performance is investigated.

3.1 Rank preference model

SVMs have been extensively used for learning classification, regression and ranking functions. In its basic form, a binary SVM classifier learns a linear threshold function that discriminates data points of two categories. By using a different loss function, the ε-insensitive loss function (Smola, 1996), SVMs can also perform regression. SVMs in regression mode estimate a function that outputs a real number based on the training data. In both cases, the model generalises by computing a hyperplane that has the largest (soft-)margin.

In rank preference SVMs, the goal is to learn a ranking function which outputs a score for each data point, from which a global ordering of the data is constructed. This procedure requires a set R consisting of training samples $\vec{x}_n$ and their target rankings r_n:

$$R = \{(\vec{x}_1, r_1), (\vec{x}_2, r_2), ..., (\vec{x}_n, r_n)\} \quad (1)$$

such that $\vec{x}_i \succ_R \vec{x}_j$ when $r_i < r_j$, where $1 \leq i, j \leq n$ and $i \neq j$.

A rank preference model is not trained directly on this set of data objects and their labels; rather a set of pair-wise difference vectors is created. The goal of a linear ranking model is to compute a weight vector $\vec{w}$ that maximises the number of correctly ranked pairs:

$$\forall(\vec{x}_i \succ_R \vec{x}_j) : \vec{w}(\vec{x_i} - \vec{x_j}) > 0 \quad (2)$$

This is equivalent to solving the following optimisation problem:

Minimise:

$$\frac{1}{2}\|\vec{w}\|^2 + C\sum \xi_{ij} \quad (3)$$

Subject to the constraints:

$$\forall(\vec{x}_i \succ_R \vec{x}_j) : \vec{w}(\vec{x_i} - \vec{x_j}) \geq 1 - \xi_{ij} \quad (4)$$

$$\xi_{ij} \geq 0 \quad (5)$$

The factor C allows a trade-off between the training error and the margin size, while ξ_{ij} are non-negative slack variables that measure the degree of misclassification.

The optimisation problem is equivalent to that for the classification model on pair-wise difference vectors. In this case, generalisation is achieved by maximising the differences between closely-ranked data pairs.

The principal advantage of applying rank preference learning to the AA task is that we explicitly

model the grade relationships between scripts and do not need to apply a further regression step to fit the classifier output to the scoring scheme. The results reported in this paper are obtained by learning a linear classification function.

3.2 Feature set

We parsed the training and test data (see Section 2) using the Robust Accurate Statistical Parsing (RASP) system with the standard tokenisation and sentence boundary detection modules (Briscoe et al., 2006) in order to broaden the space of candidate features suitable for the task. The features used in our experiments are mainly motivated by the fact that lexical and grammatical features should be highly discriminative for the AA task. Our full feature set is as follows:

i. Lexical ngrams
   (a) Word unigrams
   (b) Word bigrams

ii. Part-of-speech (PoS) ngrams
   (a) PoS unigrams
   (b) PoS bigrams
   (c) PoS trigrams

iii. Features representing syntax
   (a) Phrase structure (PS) rules
   (b) Grammatical relation (GR) distance measures

iv. Other features
   (a) Script length
   (b) Error-rate

Word unigrams and bigrams are lower-cased and used in their inflected forms. PoS unigrams, bigrams and trigrams are extracted using the RASP tagger, which uses the CLAWS[4] tagset. The most probable posterior tag per word is used to construct PoS ngram features, but we use the RASP parser's option to analyse words assigned multiple tags when the posterior probability of the highest ranked tag is less than 0.9, and the next n tags have probability greater than $\frac{1}{50}$ of it.

[4]http://ucrel.lancs.ac.uk/claws/

Based on the most likely parse for each identified sentence, we extract the rule names from the phrase structure (PS) tree. RASP's rule names are semi-automatically generated and encode detailed information about the grammatical constructions found (e.g. V1/modal_bse/+-, 'a VP consisting of a modal auxiliary head followed by an (optional) adverbial phrase, followed by a VP headed by a verb with base inflection'). Moreover, rule names explicitly represent information about peripheral or rare constructions (e.g. S/pp-ap_s-r, 'a S with preposed PP with adjectival complement, e.g. *for better or worse, he left*'), as well as about fragmentary and likely extra-grammatical sequences (e.g. T/txt-frag, 'a text unit consisting of 2 or more subanalyses that cannot be combined using any rule in the grammar'). Therefore, we believe that many (longer-distance) grammatical constructions and errors found in texts can be (implicitly) captured by this feature type.

In developing our AA system, a number of different grammatical complexity measures were extracted from parses, and their impact on the accuracy of the system was explored. For the experiments reported here, we use complexity measures representing the sum of the longest distance in word tokens between a head and dependent in a grammatical relation (GR) from the RASP GR output, calculated for each GR graph from the top 10 parses per sentence. In particular, we extract the mean and median values of these distances per sentence and use the maximum values per script. Intuitively, this feature captures information about the grammatical sophistication of the writer. However, it may also be confounded in cases where sentence boundaries are not identified through, for example, poor punctuation.

Although the CLC contains information about the linguistic errors committed (see Section 2), we try to extract an error-rate in a way that doesn't require manually tagged data. However, we also use an error-rate calculated from the CLC error tags to obtain an upper bound for the performance of an automated error estimator (true CLC error-rate).

In order to estimate the error-rate, we build a trigram language model (LM) using ukWaC (ukWaC LM) (Ferraresi et al., 2008), a large corpus of English containing more than 2 billion tokens. Next, we extend our language model with trigrams extracted from a subset of the texts contained in the

CLC (CLC LM). As the CLC contains texts produced by second language learners, we only extract frequently occurring trigrams from highly ranked scripts to avoid introducing erroneous ones to our language model. A word trigram in test data is counted as an error if it is not found in the language model. We compute presence/absence efficiently using a Bloom filter encoding of the language models (Bloom, 1970).

Feature instances of types i and ii are weighted using the *tf*idf* scheme and normalised by the L2 norm. Feature type iii is weighted using frequency counts, while iii and iv are scaled so that their final value has approximately the same order of magnitude as i and ii.

The script length is based on the number of words and is mainly added to balance the effect the length of a script has on other features. Finally, features whose overall frequency is lower than four are discarded from the model.

4 Evaluation

In order to evaluate our AA system, we use two correlation measures, Pearson's product-moment correlation coefficient and Spearman's rank correlation coefficient (hereafter Pearson's and Spearman's correlation respectively). Pearson's correlation determines the degree to which two linearly dependent variables are related. As Pearson's correlation is sensitive to the distribution of data and, due to outliers, its value can be misleading, we also report Spearman's correlation. The latter is a non-parametric robust measure of association which is sensitive only to the ordinal arrangement of values. As our data contains some tied values, we calculate Spearman's correlation by using Pearson's correlation on the ranks.

Table 1 presents the Pearson's and Spearman's correlation between the CLC scores and the AA system predicted values, when incrementally adding to the model the feature types described in Section 3.2. Each feature type improves the model's performance. Extending our language model with frequent trigrams extracted from the CLC improves Pearson's and Spearman's correlation by 0.006 and 0.015 respectively. The addition of the error-rate obtained from the manually annotated CLC error tags on top of all the features further improves performance by 0.01 and 0.016. An evaluation of our best error detection method shows a Pearson correlation of 0.611 between the estimated and the true CLC error counts. This suggests that there is room for improvement in the language models we developed to estimate the error-rate. In the experiments reported hereafter, we use the ukWaC+CLC LM to calculate the error-rate.

In order to assess the independent as opposed to the order-dependent additive contribution of each feature type to the overall performance of the system, we run a number of ablation tests. An ablation test consists of removing one feature of the system at a time and re-evaluating the model on the test set. Table 2 presents Pearson's and Spearman's correlation between the CLC and our system, when removing one feature at a time. All features have a positive effect on performance, while the error-rate has a big impact, as its absence is responsible for a 0.061 decrease of Spearman's correlation. In addition, the

Model	Pearson's correlation	Spearman's correlation
Regression	0.697	0.706
Rank preference	0.741	0.773

Table 3: Comparison between regression and rank preference model.

removal of either the word ngrams, the PS rules, or the error-rate estimate contributes to a large decrease in Pearson's correlation.

In order to test the significance of the improved correlations, we ran one-tailed t-tests with $a = 0.05$ for the difference between dependent correlations (Williams, 1959; Steiger, 1980). The results showed that PoS ngrams, PS rules, the complexity measures, and the estimated error-rate contribute significantly to the improvement of Spearman's correlation, while PS rules also contribute significantly to the improvement of Pearson's correlation.

One of the main approaches adopted by previous systems involves the identification of features that measure writing skill, and then the application of linear or stepwise regression to find optimal feature weights so that the correlation with manually assigned scores is maximised. We trained a SVM regression model with our full set of feature types and compared it to the SVM rank preference model. The results are given in Table 3. The rank preference model improves Pearson's and Spearman's correlation by 0.044 and 0.067 respectively, and these differences are significant, suggesting that rank preference is a more appropriate model for the AA task.

Four senior and experienced ESOL examiners remarked the 97 FCE test scripts drawn from 2001 exams, using the marking scheme from that year (see Section 2). In order to obtain a ceiling for the performance of our system, we calculate the average correlation between the CLC and the examiners' scores, and find an upper bound of **0.796** and **0.792** Pearson's and Spearman's correlation respectively.

In order to evaluate the overall performance of our system, we calculate its correlation with the four senior examiners in addition to the RASCH-adjusted CLC scores. Tables 4 and 5 present the results obtained.

The average correlation of the AA system with the CLC and the examiner scores shows that it is close

	CLC	E1	E2	E3	E4	AA
CLC	-	0.820	0.787	0.767	0.810	0.741

E4	0.782	0.850	0.787	0.794	-	0.697
AA	0.773	0.675	0.724	0.738	0.697	-
Avg	0.788	0.788	0.772	0.774	0.782	0.721

Table 5: Spearman's correlation of the AA system predicted values with the CLC and the examiners' scores, where E1 refers to the first examiner, E2 to the second etc.

to the upper bound for the task. Human–machine agreement is comparable to that of human–human agreement, with the exception of Pearson's correlation with examiner E4 and Spearman's correlation with examiners E1 and E4, where the discrepancies are higher. It is likely that a larger training set and/or more consistent grading of the existing training data would help to close this gap. However, our system is not measuring some properties of the scripts, such as discourse cohesion or relevance to the prompt eliciting the text, that examiners will take into account.

5 Validity tests

The practical utility of an AA system will depend strongly on its robustness to subversion by writers who understand something of its workings and attempt to exploit this to maximise their scores (independently of their underlying ability). Surprisingly, there is very little published data on the robustness of existing systems. However, Powers et al. (2002) invited writing experts to trick the scoring

capabilities of an earlier version of e-Rater (Burstein et al., 1998). e-Rater (see Section 6 for more details) assigns a score to a text based on linguistic feature types extracted using relatively domain-specific techniques. Participants were given a description of these techniques as well as of the cue words that the system uses. The results showed that it was easier to fool the system into assigning higher than lower scores.

Our goal here is to determine the extent to which knowledge of the feature types deployed poses a threat to the validity of our system, where certain text generation strategies may give rise to large positive discrepancies. As mentioned in Section 2, the marking criteria for FCE scripts are primarily based on the accurate use of a range of different grammatical constructions relevant to specific communicative goals, but our system assesses this indirectly.

We extracted 6 high-scoring FCE scripts from the CLC that do not overlap with our training and test data. Based on the features used by our system and without bias towards any modification, we modified each script in one of the following ways:

i. Randomly order:
   (a) word unigrams within a sentence
   (b) word bigrams within a sentence
   (c) word trigrams within a sentence
   (d) sentences within a script

ii. Swap words that have the same PoS within a sentence

Although the above modifications do not exhaust the potential challenges a deployed AA system might face, they represent a threat to the validity of our system since we are using a highly related feature set. In total, we create 30 such 'outlier' texts, which were given to an ESOL examiner for marking. Using the 'outlier' scripts as well as their original/unmodified versions, we ran our system on each modification separately and calculated the correlation between the predicted values and the examiner's scores. Table 6 presents the results.

The predicted values of the system have a high correlation with the examiner's scores when tested on 'outlier' texts of modification types i(a), i(b) and i(c). However, as i(c) has a lower correlation compared to i(a) and i(b), it is likely that a random ordering of ngrams with $N > 3$ will further decrease performance. A modification of type ii, where words with the same PoS within a sentence are swapped, results in a Pearson and Spearman correlation of 0.634 and 0.761 respectively.

Modification	**Pearson's correlation**	**Spearman's correlation**
i(a)	0.960	0.912
i(b)	0.938	0.914
i(c)	0.801	0.867
i(d)	0.08	0.163
ii	0.634	0.761

Table 6: Correlation between the predicted values and the examiner's scores on 'outlier' texts.

Analysis of the results showed that our system predicted higher scores than the ones assigned by the examiner. This can be explained by the fact that texts produced using modification type ii contain a small portion of correct sentences. However, the marking criteria are based on the overall writing quality. The final case, where correct sentences are randomly ordered, receives the lowest correlation. As our system is not measuring discourse cohesion, discrepancies are much higher; the system's predicted scores are high whilst the ones assigned by the examiner are very low. However, for a writer to be able to generate text of this type already requires significant linguistic competence, whilst a number of generic methods for assessing text and/or discourse cohesion have been developed and could be deployed in an extended version of our system.

It is also likely that highly creative 'outlier' essays may give rise to large negative discrepancies. Recent comments in the British media have focussed on this issue, reporting that, for example, one deployed essay marking system assigned Winston Churchill's speech 'We Shall Fight on the Beaches' a low score because of excessive repetition[5]. Our model predicted a high passing mark for this text, but not the highest one possible, that some journalists clearly feel it deserves.

6 Previous work

In this section we briefly discuss a number of the more influential and/or better described approaches. Pérez-Marín et al. (2009), Williamson (2009), Dikli (2006) and Valenti et al. (2003) provide a more detailed overview of existing AA systems.

Project Essay Grade (PEG) (Page, 2003), one of the earliest systems, uses a number of manually-identified mostly shallow textual features, which are considered to be proxies for intrinsic qualities of writing competence. Linear regression is used to assign optimal feature weights that maximise the correlation with the examiner's scores. The main issue with this system is that features such as word length and script length are easy to manipulate independently of genuine writing ability, potentially undermining the validity of the system.

In e-Rater (Attali and Burstein, 2006), texts are represented using vectors of weighted features. Each feature corresponds to a different property of texts, such as an aspect of grammar, style, discourse and topic similarity. Additional features, representing stereotypical grammatical errors for example, are extracted using manually-coded task-specific detectors based, in part, on typical marking criteria. An unmarked text is scored based on the cosine similarity between its weighted vector and the ones in the training set. Feature weights and/or scores can be fitted to a marking scheme by stepwise or linear regression. Unlike our approach, e-Rater models discourse structure, semantic coherence and relevance to the prompt. However, the system contains manually developed task-specific components and requires retraining or tuning for each new prompt and assessment task.

Intelligent Essay Assessor (IEA) (Landauer et al., 2003) uses Latent Semantic Analysis (LSA) (Landauer and Foltz, 1998) to compute the semantic similarity between texts, at a specific grade point, and a test text. In LSA, text is represented by a matrix, where rows correspond to words and columns to context (texts). Singular Value Decomposition (SVD) is used to obtain a reduced dimension matrix clustering words and contexts. The system is trained on topic and/or prompt specific texts while test texts are assigned a score based on the ones in the training set that are most similar. The overall score, which is calculated using regression techniques, is based on the content score as well as on other properties of texts, such as style, grammar, and so forth, though the methods used to assess these are not described in any detail in published work. Again, the system requires retraining or tuning for new prompts and assessment tasks.

Lonsdale and Strong-Krause (2003) use a modified syntactic parser to analyse and score texts. Their method is based on a modified version of the Link Grammar parser (Sleator and Templerley, 1995) where the overall score of a text is calculated as the average of the scores assigned to each sentence. Sentences are scored on a five-point scale based on the parser's cost vector, which roughly measures the complexity and deviation of a sentence from the parser's grammatical model. This approach bears some similarities to our use of grammatical complexity and extragrammaticality features, but grammatical features represent only one component of our overall system, and of the task.

The Bayesian Essay Test Scoring sYstem (BETSY) (Rudner and Liang, 2002) uses multinomial or Bernoulli Naive Bayes models to classify texts into different classes (e.g. pass/fail, grades A–F) based on content and style features such as word unigrams and bigrams, sentence length, number of verbs, noun–verb pairs etc. Classification is based on the conditional probability of a class given a set of features, which is calculated using the assumption that each feature is independent of the other. This system shows that treating AA as a text classification problem is viable, but the feature types are all fairly shallow, and the approach doesn't make efficient use of the training data as a separate classifier is trained for each grade point.

Recently, Chen et al. (2010) has proposed an unsupervised approach to AA of texts addressing the same topic, based on a voting algorithm. Texts are clustered according to their grade and given an initial Z-score. A model is trained where the initial score of a text changes iteratively based on its similarity with the rest of the texts as well as their Z-scores. The approach might be better described as weakly supervised as the distribution of text grades in the training data is used to fit the final Z-scores to grades. The system uses a bag-of-words representation of text, so would be easy to subvert. Never-

theless, exploration of the trade-offs between degree of supervision required in training and grading accuracy is an important area for future research.

7 Conclusions and future work

Though many of the systems described in Section 6 have been shown to correlate well with examiners' marks on test data in many experimental contexts, no cross-system comparisons are available because of the lack of a shared training and test dataset. Furthermore, none of the published work of which we are aware has systematically compared the contribution of different feature types to the AA task, and only one (Powers et al., 2002) assesses the ease with which the system can be subverted given some knowledge of the features deployed.

We have shown experimentally how rank preference models can be effectively deployed for automated assessment of ESOL free-text answers. Based on a range of feature types automatically extracted using generic text processing techniques, our system achieves performance close to the upper bound for the task. Ablation tests highlight the contribution of each feature type to the overall performance, while significance of the resulting improvements in correlation with human scores has been calculated. A comparison between regression and rank preference models further supports our approach. Preliminary experiments based on a set of 'outlier' texts have shown the types of texts for which the system's scoring capability can be undermined.

We plan to experiment with better error detection techniques, since the overall error-rate of a script is one of the most discriminant features. Briscoe et al. (2010) describe an approach to automatic off-prompt detection which does not require retraining for each new question prompt and which we plan to integrate with our system. It is clear from the 'outlier' experiments reported here that our system would benefit from features assessing discourse coherence, and to a lesser extent from features assessing semantic (selectional) coherence over longer bounds than those captured by ngrams. The addition of an incoherence metric to the feature set of an AA system has been shown to improve performance significantly (Miltsakaki and Kukich, 2000; Miltsakaki and Kukich, 2004).

Finally, we hope that the release of the training and test dataset described here will facilitate further research on the AA task for ESOL free text and, in particular, precise comparison of different systems, feature types, and grade fitting methods.

Acknowledgements

We would like to thank Cambridge ESOL, a division of Cambridge Assessment, for permission to use and distribute the examination scripts. We are also grateful to Cambridge Assessment for arranging for the test scripts to be remarked by four of their senior examiners. Finally, we would like to thank Marek Rei, Øistein Andersen and the anonymous reviewers for their useful comments.

Abstract

A lack of standard datasets and evaluation metrics has prevented the field of *paraphrasing* from making the kind of rapid progress enjoyed by the machine translation community over the last 15 years. We address both problems by presenting a novel data collection framework that produces highly parallel text data relatively inexpensively and on a large scale. The highly parallel nature of this data allows us to use simple n-gram comparisons to measure both the semantic adequacy and lexical dissimilarity of paraphrase candidates. In addition to being simple and efficient to compute, experiments show that these metrics correlate highly with human judgments.

1 Introduction

Machine paraphrasing has many applications for natural language processing tasks, including machine translation (MT), MT evaluation, summary evaluation, question answering, and natural language generation. However, a lack of standard datasets and automatic evaluation metrics has impeded progress in the field. Without these resources, researchers have resorted to developing their own small, ad hoc datasets (Barzilay and McKeown, 2001; Shinyama et al., 2002; Barzilay and Lee, 2003; Quirk et al., 2004; Dolan et al., 2004), and have often relied on human judgments to evaluate their results (Barzilay and McKeown, 2001; Ibrahim et al., 2003; Bannard and Callison-Burch, 2005). Consequently, it is difficult to compare different systems and assess the progress of the field as a whole.

Despite the similarities between paraphrasing and translation, several major differences have prevented researchers from simply following standards that have been established for machine translation. Professional translators produce large volumes of bilingual data according to a more or less consistent specification, indirectly fueling work on machine translation algorithms. In contrast, there are no "professional paraphrasers", with the result that there are no readily available large corpora and no consistent standards for what constitutes a high-quality paraphrase. In addition to the lack of standard datasets for training and testing, there are also no standard metrics like BLEU (Papineni et al., 2002) for evaluating paraphrase systems. Paraphrase evaluation is inherently difficult because the range of potential paraphrases for a given input is both large and unpredictable; in addition to being meaning-preserving, an ideal paraphrase must also diverge as sharply as possible in form from the original while still sounding natural and fluent.

Our work introduces two novel contributions which combine to address the challenges posed by paraphrase evaluation. First, we describe a framework for easily and inexpensively crowdsourcing arbitrarily large training and test sets of independent, redundant linguistic descriptions of the same semantic content. Second, we define a new evaluation metric, PINC (Paraphrase In N-gram Changes), that relies on simple BLEU-like n-gram comparisons to measure the degree of novelty of automatically generated paraphrases. We believe that this metric, along with the sentence-level paraphrases provided by our data collection approach, will make it possi-

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 190–200,
Portland, Oregon, June 19-24, 2011.

ble for researchers working on paraphrasing to compare system performance and exploit the kind of automated, rapid training-test cycle that has driven work on Statistical Machine Translation.

In addition to describing a mechanism for collecting large-scale sentence-level paraphrases, we are also making available to the research community 85K parallel English sentences as part of the Microsoft Research Video Description Corpus [1].

The rest of the paper is organized as follows. We first review relevant work in Section 2. Section 3 then describes our data collection framework and the resulting data. Section 4 discusses automatic evaluations of paraphrases and introduces the novel metric PINC. Section 5 presents experimental results establishing a correlation between our automatic metric and human judgments. Sections 6 and 7 discuss possible directions for future research and conclude.

2 Related Work

Since paraphrase data are not readily available, various methods have been used to extract parallel text from other sources. One popular approach exploits multiple translations of the same data (Barzilay and McKeown, 2001; Pang et al., 2003). Examples of this kind of data include the Multiple-Translation Chinese (MTC) Corpus [2] which consists of Chinese news stories translated into English by 11 translation agencies, and literary works with multiple translations into English (e.g. Flaubert's *Madame Bovary*.) Another method for collecting monolingual paraphrase data involves aligning semantically parallel sentences from different news articles describing the same event (Shinyama et al., 2002; Barzilay and Lee, 2003; Dolan et al., 2004).

While utilizing multiple translations of literary work or multiple news stories of the same event can yield significant numbers of parallel sentences, this data tend to be noisy, and reliably identifying good paraphrases among all possible sentence pairs remains an open problem. On the other hand, multiple translations on the sentence level such as the MTC Corpus provide good, natural paraphrases, but relatively little data of this type exists. Finally, some approaches avoid the need for monolingual paraphrase data altogether by using a second language as the pivot language (Bannard and Callison-Burch, 2005; Callison-Burch, 2008; Kok and Brockett, 2010). Phrases that are aligned to the same phrase in the pivot language are treated as potential paraphrases. One limitation of this approach is that only words and phrases are identified, not whole sentences.

While most work on evaluating paraphrase systems has relied on human judges (Barzilay and McKeown, 2001; Ibrahim et al., 2003; Bannard and Callison-Burch, 2005) or indirect, task-based methods (Lin and Pantel, 2001; Callison-Burch et al., 2006), there have also been a few attempts at creating automatic metrics that can be more easily replicated and used to compare different systems. ParaMetric (Callison-Burch et al., 2008) compares the paraphrases discovered by an automatic system with ones annotated by humans, measuring precision and recall. This approach requires additional human annotations to identify the paraphrases within parallel texts (Cohn et al., 2008) and does not evaluate the systems at the sentence level. The more recently proposed metric PEM (Paraphrase Evaluation Metric) (Liu et al., 2010) produces a single score that captures the semantic adequacy, fluency, and lexical dissimilarity of candidate paraphrases, relying on bilingual data to learn semantic equivalences without using n-gram similarity between candidate and reference sentences. In addition, the metric was shown to correlate well with human judgments. However, a significant drawback of this approach is that PEM requires substantial in-domain bilingual data to train the semantic adequacy evaluator, as well as sample human judgments to train the overall metric.

We designed our data collection framework for use on crowdsourcing platforms such as Amazon's Mechanical Turk. Crowdsourcing can allow inexpensive and rapid data collection for various NLP tasks (Ambati and Vogel, 2010; Bloodgood and Callison-Burch, 2010a; Bloodgood and Callison-Burch, 2010b; Irvine and Klementiev, 2010), including human evaluations of NLP systems (Callison-Burch, 2009; Denkowski and Lavie, 2010; Zaidan and Callison-Burch, 2009). Of particular relevance are the paraphrasing work by Buzek et al. (2010)

[1] Available for download at `http://research.microsoft.com/en-us/downloads/38cf15fd-b8df-477e-a4e4-a4680caa75af/`

and Denkowski et al. (2010). Buzek et al. automatically identified problem regions in a translation task and had workers attempt to paraphrase them, while Denkowski et al. asked workers to assess the validity of automatically extracted paraphrases. Our work is distinct from these earlier efforts both in terms of the task – attempting to collect linguistic descriptions using a visual stimulus – and the dramatically larger scale of the data collected.

3 Data Collection

Since our goal was to collect large numbers of paraphrases quickly and inexpensively using a crowd, our framework was designed to make the tasks short, simple, easy, accessible and somewhat fun. For each task, we asked the annotators to watch a very short video clip (usually less than 10 seconds long) and describe in one sentence the main action or event that occurred in the video clip

We deployed the task on Amazon's Mechanical Turk, with video segments selected from YouTube. A screenshot of our annotation task is shown in Figure 1. On average, annotators completed each task within 80 seconds, including the time required to watch the video. Experienced annotators were even faster, completing the task in only 20 to 25 seconds.

One interesting aspect of this framework is that each annotator approaches the task from a linguistically independent perspective, unbiased by the lexical or word order choices in a pre-existing description. The data thus has some similarities to parallel news descriptions of the same event, while avoiding much of the noise inherent in news. It is also similar in spirit to the 'Pear Stories' film used by Chafe (1997). Crucially, our approach allows us to gather arbitrarily many of these independent descriptions for each video, capturing nearly-exhaustive coverage of how native speakers are likely to summarize a small action. It might be possible to achieve similar effects using images or panels of images as the stimulus (von Ahn and Dabbish, 2004; Fei-Fei et al., 2007; Rashtchian et al., 2010), but we believed that videos would be more engaging and less ambiguous in their focus. In addition, videos have been shown to be more effective in prompting descriptions of motion and contact verbs, as well as verbs that are generally not imageable (Ma and Cook, 2009).

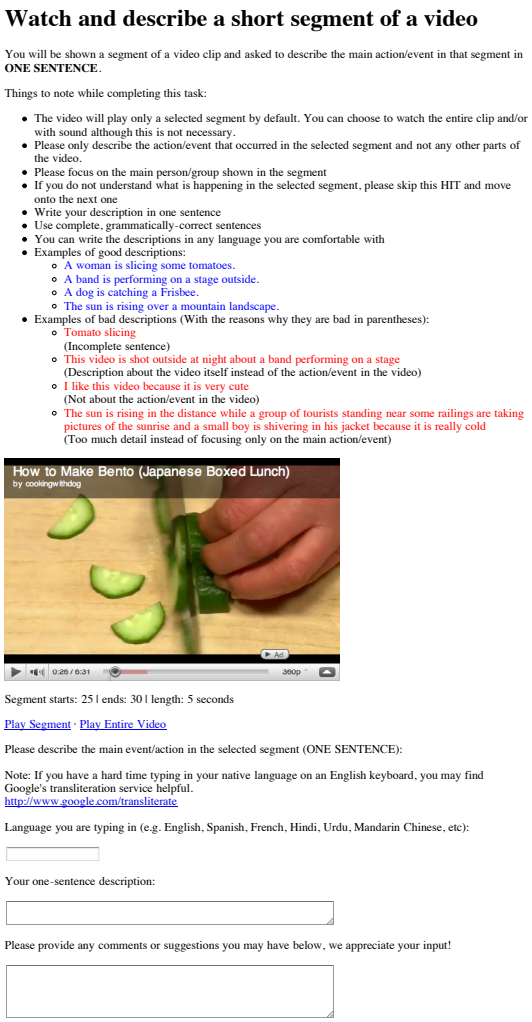

Figure 1: A screenshot of our annotation task as it was deployed on Mechanical Turk.

3.1 Quality Control

One of the main problems with collecting data using a crowd is quality control. While the cost is very low compared to traditional annotation methods, workers recruited over the Internet are often unqualified for the tasks or are incentivized to cheat in order to maximize their rewards.

To encourage native and fluent contributions, we asked annotators to write the descriptions in the language of their choice. The result was a significant amount of translation data, unique in its multilingual parallelism. While included in our data release, we leave aside a full discussion of this multilingual data for future work.

To ensure the quality of the annotations being produced, we used a two-tiered payment system. The idea was to reward workers who had shown the ability to write quality descriptions and the willingness to work on our tasks consistently. While everyone had access to the Tier-1 tasks, only workers who had been manually qualified could work on the Tier-2 tasks. The tasks were identical in the two tiers but each Tier-1 task only paid 1 cent while each Tier-2 task paid 5 cents, giving the workers a strong incentive to earn the qualification.

The qualification process was done manually by the authors. We periodically evaluated the workers who had submitted the most Tier-1 tasks (usually on the order of few hundred submissions) and granted them access to the Tier-2 tasks if they had performed well. We assessed their work mainly on the grammaticality and spelling accuracy of the submitted descriptions. Since we had hundreds of submissions to base our decisions on, it was fairly easy to identify the cheaters and people with poor English skills [3]. Workers who were rejected during this process were still allowed to work on the Tier-1 tasks.

While this approach requires significantly more manual effort initially than other approaches such as using a qualification test or automatic post-annotation filtering, it creates a much higher quality workforce. Moreover, the initial effort is amortized over time as these quality workers are retained over the entire duration of the data collection. Many of them annotated all the available videos we had.

3.2 Video Collection

To find suitable videos to annotate, we deployed a separate task. Workers were asked to submit short (generally 4-10 seconds) video segments depicting single, unambiguous events by specifying links to YouTube videos, along with the start and end times. We again used a tiered payment system to reward and retain workers who performed well.

Since the scope of this data collection effort extended beyond gathering English data alone, we tried to collect videos that could be understood regardless of the annotator's linguistic or cultural background. In order to avoid biasing lexical choices in the descriptions, we muted the audio and excluded videos that contained either subtitles or overlaid text. Finally, we manually filtered the submitted videos to ensure that each met our criteria and was free of inappropriate content.

- Someone is coating a pork chop in a glass bowl of flour.
- A person breads a pork chop.
- Someone is breading a piece of meat with a white powdery substance.
- A chef seasons a slice of meat.
- Someone is putting flour on a piece of meat.
- A woman is adding flour to meat.
- A woman is coating a piece of pork with breadcrumbs.
- A man dredges meat in bread crumbs.
- A person breads a piece of meat.
- A woman is breading some meat.
- Someone is breading meat.
- A woman coats a meat cutlet in a dish.
- A woman is coating a pork loin in bread crumbs.
- The laldy coated the meat in bread crumbs.
- The woman is breading pork chop.
- A woman adds a mixture to some meat.
- The lady put the batter on the meat.

Figure 2: Examples of English descriptions collected for a particular video segment.

3.3 Data

We deployed our data collection framework on Mechanical Turk over a two-month period from July to September in 2010, collecting 2,089 video segments and 85,550 English descriptions. The rate of data collection accelerated as we built up our workforce, topping 10K descriptions a day when we ended our data collection. Of the descriptions, 33,855 were from Tier-2 tasks, meaning they were provided by workers who had been manually identified as good performers. Examples of some of the descriptions collected are shown in Figure 2.

Overall, 688 workers submitted at least one English description. Of these workers, 113 submitted at least 100 descriptions and 51 submitted at least 500. The largest number of descriptions submitted by a single worker was 3496 [4]. Out of the 688 workers, 50 were granted access to the Tier-2 tasks. The

[3] Everyone who submitted descriptions in a foreign language was granted access to the Tier-2 tasks. This was done to encourage more submissions in different languages and also because we could not verify the quality of those descriptions other than using online translation services (and some of the languages were not available to be translated).

[4] This number exceeds the total number of videos because the worker completed both Tier-1 and Tier-2 tasks for the same videos

	Tier 1	Tier 2
pay	$0.01	$0.05
# workers (English)	683	50
# workers (total)	835	94
# submitted (English)	51510	33829
# submitted (total)	68578	55682
# accepted (English)	51052	33825
# accepted (total)	67968	55658

Table 1: Statistics for the two video description tasks

success of our data collection effort was in part due to our ability to retain these good workers, building a reliable and efficient workforce. Table 1 shows some statistics for the Tier-1 and Tier-2 tasks [5]. Overall, we spent under $5,000 including Amazon's service fees, some pilot experiments and surveys.

On average, 41 descriptions were produced for each video, with at least 27 for over 95% of the videos. Even limiting the set to descriptions produced from the Tier-2 tasks, there are still 16 descriptions on average for each video, with at least 12 descriptions for over 95% of the videos. For most clusters, then, we have a dozen or more high-quality parallel descriptions that can be paired with one another to create monolingual parallel training data.

4 Paraphrase Evaluation Metrics

One of the limitations to the development of machine paraphrasing is the lack of standard metrics like BLEU, which has played a crucial role in driving progress in MT. Part of the issue is that a good paraphrase has the additional constraint that it should be lexically dissimilar to the source sentence while preserving the meaning. These can become competing goals when using n-gram overlaps to establish semantic equivalence. Thus, researchers have been unable to rely on BLEU or some derivative: the optimal paraphrasing engine under these terms would be one that simply returns the input.

To combat such problems, Liu et al. (2010) have proposed PEM, which uses a second language as pivot to establish semantic equivalence. Thus, no n-gram overlaps are required to determine the semantic adequacy of the paraphrase candidates. PEM also separately measures lexical dissimilarity and fluency. Finally, all three scores are combined using a support vector machine (SVM) trained on human ratings of paraphrase pairs. While PEM was shown to correlate well with human judgments, it has some limitations. It only models paraphrasing at the phrase level and not at the sentence level. Further, while it does not need reference sentences for the evaluation dataset, PEM does require suitable bilingual data to train the metric. The result is that training a successful PEM becomes almost as challenging as the original paraphrasing problem, since paraphrases need to be learned from bilingual data.

The highly parallel nature of our data suggests a simpler solution to this problem. To measure semantic equivalence, we simply use BLEU with multiple references. The large number of reference paraphrases capture a wide space of sentences with equivalent meanings. While the set of reference sentences can of course never be exhaustive, our data collection method provides a natural distribution of common phrases that might be used to describe an action or event. A tight cluster with many similar parallel descriptions suggests there are only few common ways to express that concept.

In addition to measuring semantic adequacy and fluency using BLEU, we also need to measure lexical dissimilarity with the source sentence. We introduce a new scoring metric PINC that measures how many n-grams differ between the two sentences. In essence, it is the inverse of BLEU since we want to minimize the number of n-gram overlaps between the two sentences. Specifically, for source sentence s and candidate sentence c:

$$PINC(s,c) = \frac{1}{N}\sum_{n=1}^{N} 1 - \frac{|\text{ n-gram}_s \cap \text{n-gram}_c|}{|\text{ n-gram}_c|}$$

where N is the maximum n-gram considered and n-gram$_s$ and n-gram$_c$ are the lists of n-grams in the source and candidate sentences, respectively. We use $N = 4$ in our evaluations.

The PINC score computes the percentage of n-grams that appear in the candidate sentence but not in the source sentence. This score is similar to the Jaccard distance, except that it excludes n-grams that only appear in the source sentence and not in the candidate sentence. In other words, it rewards candi-

[5] The numbers for the English data are slightly underestimated since the workers sometimes incorrectly filled out the form when reporting what language they were using.

dates for introducing new n-grams but not for omitting n-grams from the original sentence. The results for each n are averaged arithmetically. PINC evaluates single sentences instead of entire documents because we can reliably measure lexical dissimilarity at the sentence level. Also notice that we do not put additional constraints on sentence length: while extremely short and extremely long sentences are likely to score high on PINC, they still must maintain semantic adequacy as measured by BLEU.

We use BLEU and PINC together as a 2-dimensional scoring metric. A good paraphrase, according to our evaluation metric, has few n-gram overlaps with the source sentence but many n-gram overlaps with the reference sentences. This is consistent with our requirement that a good paraphrase should be lexically dissimilar from the source sentence while preserving its semantics.

Unlike Liu et al. (2010), we treat these two criteria separately, since different applications might have different preferences for each. For example, a paraphrase suggestion tool for a word processing software might be more concerned with semantic adequacy, since presenting a paraphrase that does not preserve the meaning would likely result in a negative user experience. On the other hand, a query expansion algorithm might be less concerned with preserving the precise meaning so long as additional relevant terms are added to improve search recall.

5 Experiments

To verify the usefulness of our paraphrase corpus and the BLEU/PINC metric, we built and evaluated several paraphrase systems and compared the automatic scores to human ratings of the generated paraphrases. We also investigated the pros and cons of collecting paraphrases using video annotation rather than directly eliciting them.

5.1 Building paraphrase models

We built 4 paraphrase systems by training English to English translation models using Moses (Koehn et al., 2007) with the default settings. Using our paraphrase corpus to train and to test, we divided the sentence clusters associated with each video into 90% for training and 10% for testing. We restricted our attention to sentences produced from the Tier-2 tasks

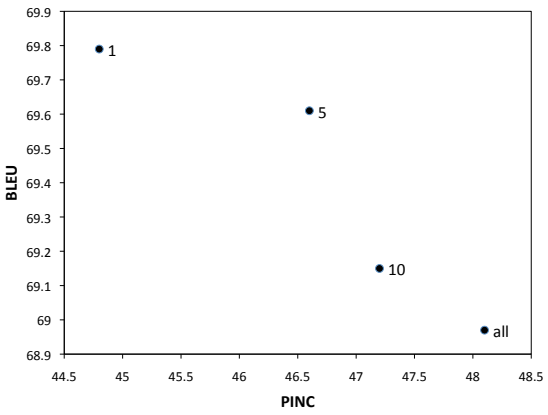

Figure 3: Evaluation of paraphrase systems trained on different numbers of parallel sentences. As more training pairs are used, the model produces more varied sentences (PINC) but preserves the meaning less well (BLEU)

in order to avoid excessive noise in the datasets, resulting in 28,785 training sentences and 3,367 test sentences. To construct the training examples, we randomly paired each sentence with 1, 5, 10, or all parallel descriptions of the same video segment. This corresponds to 28K, 143K, 287K, and 449K training pairs respectively. For the test set, we used each sentence once as the source sentence with all parallel descriptions as references (there were 16 references on average, with a minimum of 10 and a maximum of 31.) We also included the source sentence as a reference for itself.

Overall, all the trained models produce reasonable paraphrase systems, even the model trained on just 28K single parallel sentences. Examples of the outputs produced by the models trained on single parallel sentences and on all parallel sentences are shown in Table 2. Some of the changes are simple word substitutions, e.g. *rabbit* for *bunny* or *gun* for *revolver*, while others are phrasal, e.g. *frying meat* for *browning pork* or *made a basket* for *scores in a basketball game*. One interesting result of using videos as the stimulus to collect training data is that sometimes the learned paraphrases are not based on linguistic closeness, but rather on visual similarity, e.g. substituting *cricket* for *baseball*.

To evaluate the results quantitatively, we used the BLEU/PINC metric. The performance of all the trained models is shown in Figure 3. Unsurprisingly, there is a tradeoff between preserving the meaning

Original sentence	Trained on 1 parallel sentence	Trained on all parallel sentences
a bunny is cleaning its paw	a rabbit is licking its paw	a rabbit is cleaning itself
a man fires a revolver	a man is shooting targets	a man is shooting a gun
a big turtle is walking	a huge turtle is walking	a large tortoise is walking
a guy is doing a flip over a park bench	a man does a flip over a bench	a man is doing stunts on a bench
milk is being poured into a mixer	a man is pouring milk into a mixer	a man is pouring milk into a bowl
children are practicing baseball	children are doing a cricket	children are playing cricket
a boy is doing karate	a man is doing karate	a boy is doing martial arts
a woman is browning pork in a pan	a woman is browning pork in a pan	a woman is frying meat in a pan
a player scores in a basketball game	a player made a basketball game	a player made a basket

Table 2: Examples of paraphrases generated by the trained models.

and producing more varied paraphrases. Systems trained on fewer parallel sentences are more conservative and make fewer mistakes. On the other hand, systems trained on more parallel sentences often produce very good paraphrases but are also more likely to diverge from the original meaning. As a comparison, evaluating each human description as a paraphrase for the other descriptions in the same cluster resulted in a BLEU score of 52.9 and a PINC score of 77.2. Thus, all the systems performed very well in terms of retaining semantic content, although not as well in producing novel sentences.

To validate the results suggested by the automatic metrics, we asked two fluent English speakers to rate the generated paraphrases on the following categories: semantic, dissimilarity, and overall. Semantic measures how well the paraphrase preserves the original meaning while dissimilarity measures how much the paraphrase differs from the source sentence. Each category is rated from 1 to 4, with 4 being the best. A paraphrase identical to the source sentence would receive a score of 4 for meaning and 1 for dissimilarity and overall. We randomly selected 200 source sentences and generated 2 paraphrases for each, representing the two extremes: one paraphrase produced by the model trained with single parallel sentences, and the other by the model trained with all parallel sentences. The average scores of the two human judges are shown in Table 3. The results confirm our finding that the system trained with single parallel sentences preserves the meaning better but is also more conservative.

	Semantic	Dissimilarity	Overall
1	3.09	2.65	2.51
All	2.91	2.89	2.43

Table 3: Average human ratings of the systems trained on single parallel sentences and on all parallel sentences.

5.2 Correlation with human judgments

Having established rough correspondences between BLEU/PINC scores and human judgments of semantic equivalence and lexical dissimilarity, we quantified the correlation between these automatic metrics and human ratings using Pearson's correlation coefficient, a measure of linear dependence between two random variables. We computed the inter-annotator agreement as well as the correlation between BLEU, PINC, PEM (Liu et al., 2010) and the average human ratings on the sentence level. Results are shown in Table 4.

In order to measure correlation, we need to score each paraphrase individually. Thus, we recomputed BLEU on the sentence level and left the PINC scores unchanged. While BLEU is typically not reliable at the single sentence level, our large number of reference sentences makes BLEU more stable even at this granularity. Empirically, BLEU correlates fairly well with human judgments of semantic equivalence, although still not as well as the inter-annotator agreement. On the other hand, PINC correlates as well as humans agree with each other in assessing lexical dissimilarity. We also computed each metric's correlation with the overall ratings, although neither should be used alone to assess the overall quality of paraphrases.

PEM had the worst correlation with human judgments of all the metrics. Since PEM was trained on newswire data, its poor adaptation to this domain is expected. However, given the large amount of training data needed (PEM was trained on 250K Chinese-

	Semantic	Dissimilarity	Overall
Judge A vs. B	0.7135	0.6319	0.4920
BLEU vs. Human	0.5095	N/A	0.2127
PINC vs. Human	N/A	0.6672	0.0775
PEM vs. Human	N/A	N/A	0.0654
PINC vs. Human (BLEU $>$ threshold)			
threshold $= 0$	N/A	0.6541	0.1817
threshold $= 30$	N/A	0.6493	0.1984
threshold $= 60$	N/A	0.6815	0.3986
threshold $= 90$	N/A	0.7922	0.4350
Combined BLEU and PINC vs. Human			
Arithmetic Mean	N/A	N/A	0.3173
Geometric Mean	N/A	N/A	0.3003
Harmonic Mean	N/A	N/A	0.3036
PINC $\times$ Sigmoid(BLEU)	N/A	N/A	0.3532

Table 4: Correlation between the human judges as well as between the automatic metrics and the human judges.

English sentence pairs and 2400 human ratings of paraphrase pairs), it is difficult to use PEM as a general metric. Adapting PEM to a new domain would require sufficient in-domain bilingual data to support paraphrase extraction. In contrast, our approach only requires monolingual data, and evaluation can be performed using arbitrarily small, highly-parallel datasets. Moreover, PEM requires sample human ratings in training, thereby lessening the advantage of having automatic metrics.

Since lexical dissimilarity is only desirable when the semantics of the original sentence is unchanged, we also computed correlation between PINC and the human ratings when BLEU is above certain thresholds. As we restrict our attention to the set of paraphrases with higher BLEU scores, we see an increase in correlation between PINC and the human assessments. This confirms our intuition that PINC is a more useful measure when semantic content has been preserved.

Finally, while we do not believe any single score could adequately describe the quality of a paraphrase outside of a specific application, we experimented with different ways of combining BLEU and PINC into a single score. Almost any simple combination, such as taking the average of the two, yielded decent correlation with the human ratings. The best correlation was achieved by taking the product of PINC and a sigmoid function of BLEU. This follows the intuition that semantic preservation is closer to a

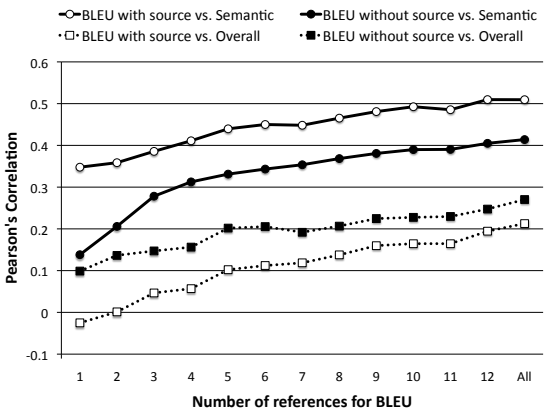

Figure 4: Correlation between BLEU and human judgments as we vary the number of reference sentences.

binary decision (i.e. a paraphrase either preserves the meaning or it does not, in which case PINC does not matter at all) than a linear function. We used an oracle to pick the best logistic function in our experiment. In practice, some sample human ratings would be required to tune this function. Other more complicated methods for combining BLEU and PINC are also possible with sample human ratings, such as using a SVM as was done in PEM.

We quantified the utility of our highly parallel data by computing the correlation between BLEU and human ratings when different numbers of references were available. The results are shown in Figure 4. As the number of references increases, the correlation with human ratings also increases. The graph also shows the effect of adding the source sentence as a reference. If our goal is to assess semantic equivalence only, then it is better to include the source sentence. If we are trying to assess the overall quality of the paraphrase, it is better to exclude the source sentence, since otherwise the metric will tend to favor paraphrases that introduce fewer changes.

5.3 Direct paraphrasing versus video annotation

In addition to collecting paraphrases through video annotations, we also experimented with the more traditional task of presenting a sentence to an annotator and explicitly asking for a paraphrase. We randomly selected a thousand sentences from our data and collected two paraphrases of each using Mechanical Turk. We conducted a post-annotation sur-

vey of workers who had completed both the video description and the direct paraphrasing tasks, and found that paraphrasing was considered more difficult and less enjoyable than describing videos. Of those surveyed, 92% found video annotations more enjoyable, and 75% found them easier. Based on the comments, the only drawback of the video annotation task is the time required to load and watch the videos. Overall, half of the workers preferred the video annotation task while only 16% of the workers preferred the paraphrasing task.

The data produced by the direct paraphrasing task also diverged less, since the annotators were inevitably biased by lexical choices and word order in the original sentences. On average, a direct paraphrase had a PINC score of 70.08, while a parallel description of the same video had a score of 78.75.

6 Discussions and Future Work

While our data collection framework yields useful parallel data, it also has some limitations. Finding appropriate videos is time-consuming and remains a bottleneck in the process. Also, more abstract actions such as *reducing the deficit* or *fighting for justice* cannot be easily captured by our method. One possible solution is to use longer video snippets or other visual stimuli such as graphs, schemas, or illustrated storybooks to convey more complicated information. However, the increased complexity is also likely to reduce the semantic closeness of the parallel descriptions.

Another limitation is that sentences produced by our framework tend to be short and follow similar syntactic structures. Asking annotators to write multiple descriptions or longer descriptions would result in more varied data but at the cost of more noise in the alignments. Other than descriptions, we could also ask the annotators for more complicated responses such as "fill in the blanks" in a dialogue (e.g. "If you were this person in the video, what would you say at this point?"), their opinion of the event shown, or the moral of the story. However, as with the difficulty of aligning news stories, finding paraphrases within these more complex responses could require additional annotation efforts.

In our experiments, we only used a subset of our corpus to avoid dealing with excessive noise. However, a significant portion of the remaining data is useful. Thus, an automatic method for filtering those sentences could allow us to utilize even more of the data. For example, sentences from the Tier-2 tasks could be used as positive examples to train a string classifier to determine whether a noisy sentence belongs in the same cluster or not.

We have so far used BLEU to measure semantic adequacy since it is the most common MT metric. However, other more advanced MT metrics that have shown higher correlation with human judgments could also be used.

In addition to paraphrasing, our data collection framework could also be used to produces useful data for machine translation and computer vision. By pairing up descriptions of the same video in different languages, we obtain parallel data without requiring any bilingual skills. Another application for our data is to apply it to computer vision tasks such as video retrieval. The dataset can be readily used to train and evaluate systems that can automatically generate full descriptions of unseen videos. As far as we know, there are currently no datasets that contain whole-sentence descriptions of open-domain video segments.

7 Conclusion

We introduced a data collection framework that produces highly parallel data by asking different annotators to describe the same video segments. Deploying the framework on Mechanical Turk over a two-month period yielded 85K English descriptions for 2K videos, one of the largest paraphrase data resources publicly available. In addition, the highly parallel nature of the data allows us to use standard MT metrics such as BLEU to evaluate semantic adequacy reliably. Finally, we also introduced a new metric, PINC, to measure the lexical dissimilarity between the source sentence and the paraphrase.

Abstract

This paper presents an attempt at building a large scale distributed composite language model that simultaneously accounts for local word lexical information, mid-range sentence syntactic structure, and long-span document semantic content under a directed Markov random field paradigm. The composite language model has been trained by performing a convergent N-best list approximate EM algorithm that has linear time complexity and a follow-up EM algorithm to improve word prediction power on corpora with up to a billion tokens and stored on a supercomputer. The large scale distributed composite language model gives drastic perplexity reduction over n-grams and achieves significantly better translation quality measured by the BLEU score and "readability" when applied to the task of re-ranking the N-best list from a state-of-the-art parsing-based machine translation system.

1 Introduction

The Markov chain (n-gram) source models, which predict each word on the basis of previous n-1 words, have been the workhorses of state-of-the-art speech recognizers and machine translators that help to resolve acoustic or foreign language ambiguities by placing higher probability on more likely original underlying word strings. Research groups (Brants et al., 2007; Zhang, 2008) have shown that using an immense distributed computing paradigm, up to 6-grams can be trained on up to billions and trillions of words, yielding consistent system improvements, but Zhang (2008) did not observe much improvement beyond 6-grams. Although the Markov chains are efficient at encoding local word interactions, the n-gram model clearly ignores the rich syntactic and semantic structures that constrain natural languages. As the machine translation (MT) working groups stated on page 3 of their final report (Lavie et al., 2006), "These approaches have resulted in small improvements in MT quality, but have not fundamentally solved the problem. There is a dire need for developing novel approaches to language modeling."

Wang et al. (2006) integrated n-gram, structured language model (SLM) (Chelba and Jelinek, 2000) and probabilistic latent semantic analysis (PLSA) (Hofmann, 2001) under the directed MRF framework (Wang et al., 2005) and studied the stochastic properties for the composite language model. They derived a *generalized inside-outside* algorithm to train the composite language model from a general EM (Dempster et al., 1977) by following Jelinek's ingenious definition of the inside and outside probabilities for SLM (Jelinek, 2004) with 6th order of sentence length time complexity. Unfortunately, there are no experimental results reported.

In this paper, we study the same composite language model. Instead of using the 6th order generalized inside-outside algorithm proposed in (Wang et al., 2006), we train this composite model by a convergent N-best list approximate EM algorithm that has linear time complexity and a follow-up EM algorithm to improve word prediction power. We conduct comprehensive experiments on corpora with 44 million tokens, 230 million tokens, and 1.3 billion tokens and compare perplexity results with n-grams (n=3,4,5 respectively) on these three corpora, we obtain drastic perplexity reductions. Finally, we ap-

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 201–210,
Portland, Oregon, June 19-24, 2011.

ply our language models to the task of re-ranking the N-best list from Hiero (Chiang, 2005; Chiang, 2007), a state-of-the-art parsing-based MT system, we achieve significantly better translation quality measured by the BLEU score and "readability".

2 Composite language model

The n-gram language model is essentially a word predictor that given its entire document history it predicts next word w_{k+1} based on the last n-1 words with probability $p(w_{k+1}|w_{k-n+2}^{k})$ where $w_{k-n+2}^{k} = w_{k-n+2}, \cdots, w_k$.

The SLM (Chelba and Jelinek, 1998; Chelba and Jelinek, 2000) uses syntactic information beyond the regular n-gram models to capture sentence level long range dependencies. The SLM is based on statistical parsing techniques that allow syntactic analysis of sentences; it assigns a probability $p(W, T)$ to every sentence W and every possible binary parse T. The terminals of T are the words of W with POS tags, and the nodes of T are annotated with phrase headwords and non-terminal labels. Let W be a sentence of length n words to which we have prepended the sentence beginning marker $<s>$ and appended the sentence end marker $</s>$ so that $w_0 =<s>$ and $w_{n+1} =</s>$. Let $W_k = w_0, \cdots, w_k$ be the word k-prefix of the sentence – the words from the beginning of the sentence up to the current position k and $W_k T_k$ the word-parse k-prefix. A word-parse k-prefix has a set of exposed heads $h_{-m}, \cdots, h_{-1}$, with each head being a pair (headword, non-terminal label), or in the case of a root-only tree (word, POS tag). An *m-th order SLM* (m-SLM) has three operators to generate a sentence: WORD-PREDICTOR predicts the next word w_{k+1} based on the m left-most exposed headwords $h_{-m}^{-1} = h_{-m}, \cdots, h_{-1}$ in the word-parse k-prefix with probability $p(w_{k+1}|h_{-m}^{-1})$, and then passes control to the TAGGER; the TAGGER predicts the POS tag t_{k+1} to the next word w_{k+1} based on the next word w_{k+1} and the POS tags of the m left-most exposed headwords h_{-m}^{-1} in the word-parse k-prefix with probability $p(t_{k+1}|w_{k+1}, h_{-m}.\text{tag}, \cdots, h_{-1}.\text{tag})$; the CONSTRUCTOR builds the partial parse T_k from T_{k-1}, w_k, and t_k in a series of moves ending with NULL, where a parse move a is made with probability $p(a|h_{-m}^{-1})$; $a \in \mathcal{A}$={(unary, NTlabel), (adjoin-left, NTlabel), (adjoin-right, NTlabel), null}. Once the CONSTRUCTOR hits NULL, it passes control to the WORD-PREDICTOR. See detailed description in (Chelba and Jelinek, 2000).

A PLSA model (Hofmann, 2001) is a generative probabilistic model of word-document co-occurrences using the bag-of-words assumption described as follows: (i) choose a document d with probability $p(d)$; (ii) SEMANTIZER: select a semantic class g with probability $p(g|d)$; and (iii) WORD-PREDICTOR: pick a word w with probability $p(w|g)$. Since only one pair of (d, w) is being observed, as a result, the joint probability model is a mixture of log-linear model with the expression $p(d, w) = p(d) \sum_g p(w|g)p(g|d)$. Typically, the number of documents and vocabulary size are much larger than the size of latent semantic class variables. Thus, latent semantic class variables function as bottleneck variables to constrain word occurrences in documents.

When combining n-gram, m order SLM and PLSA models together to build a composite generative language model under the directed MRF paradigm (Wang et al., 2005; Wang et al., 2006), the TAGGER and CONSTRUCTOR in SLM and SEMANTIZER in PLSA remain unchanged; however the WORD-PREDICTORs in n-gram, m-SLM and PLSA are combined to form a stronger WORD-PREDICTOR that generates the next word, w_{k+1}, not only depending on the m left-most exposed headwords h_{-m}^{-1} in the word-parse k-prefix but also its n-gram history w_{k-n+2}^{k} and its semantic content g_{k+1}. The parameter for WORD-PREDICTOR in the composite n-gram/m-SLM/PLSA language model becomes $p(w_{k+1}|w_{k-n+2}^{k} h_{-m}^{-1} g_{k+1})$. The resulting composite language model has an even more complex dependency structure but with more expressive power than the original SLM. Figure 1 illustrates the structure of a composite n-gram/m-SLM/PLSA language model.

The composite n-gram/m-SLM/PLSA language model can be formulated as a directed MRF model (Wang et al., 2006) with local normalization constraints for the parameters of each model component, WORD-PREDICTOR, TAGGER, CONSTRUCTOR, SEMANTIZER, i.e., $\sum_{w \in \mathcal{V}} p(w|w_{-n+1}^{-1} h_{-m}^{-1} g) = 1, \sum_{t \in \mathcal{O}} p(t|w h_{-m}^{-1}.\text{tag}) = 1, \sum_{a \in \mathcal{A}} p(a|h_{-m}^{-1}) = 1, \sum_{g \in \mathcal{G}} p(g|d) = 1$.

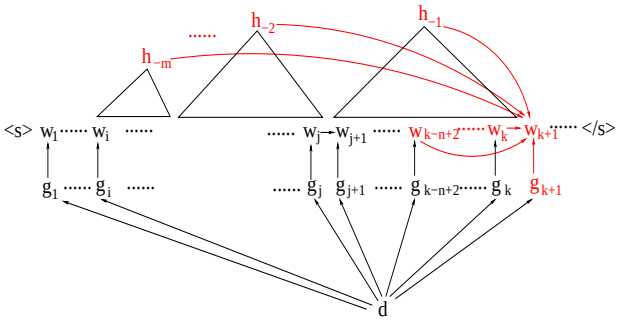

Figure 1: *A composite n-gram/m-SLM/PLSA language model where the hidden information is the parse tree T and semantic content g. The WORD-PREDICTOR generates the next word w_{k+1} with probability $p(w_{k+1}|w_{k-n+2}^{k}h_{-m}^{-1}g_{k+1})$ instead of $p(w_{k+1}|w_{k-n+2}^{k})$, $p(w_{k+1}|h_{-m}^{-1})$ and $p(w_{k+1}|g_{k+1})$ respectively.*

3 Training algorithm

Under the composite n-gram/m-SLM/PLSA language model, the likelihood of a training corpus $\mathcal{D}$, a collection of documents, can be written as

$$\mathcal{L}(\mathcal{D},p)=\prod_{d\in\mathcal{D}}\left(\prod_{l}\left(\sum_{G^l}\left(\sum_{T^l}P_p(W^l,T^l,G^l|d)\right)\right)\right) \quad (1)$$

where (W^l,T^l,G^l,d) denote the joint sequence of the lth sentence W^l with its parse tree structure T^l and semantic annotation string G^l in document d. This sequence is produced by a unique sequence of model actions: WORD-PREDICTOR, TAGGER, CONSTRUCTOR, SEMANTIZER moves, its probability is obtained by chaining the probabilities of these moves

$$\begin{aligned}
&P_p(W^l,T^l,G^l|d)\\
=&\prod_{g\in\mathcal{G}}\left(p(g|d)^{\#(g,W^l,G^l,d)}\prod_{h_{-1},\cdots,h_{-m}\in\mathcal{H}}\right.\\
&\prod_{w,w_{-1},\cdots,w_{-n+1}\in\mathcal{V}}p(w|w_{-n+1}^{-1}h_{-m}^{-1}g)^{\#(w_{-n+1}^{-1}wh_{-m}^{-1}g,W^l,T^l,G^l,d)}\\
&\prod_{t\in\mathcal{O}}p(t|wh_{-m}^{-1}.\text{tag})^{\#(t,wh_{-m}^{-1}.\text{tag},W^l,T^l,d)}\\
&\left.\prod_{a\in\mathcal{A}}p(a|h_{-m}^{-1})^{\#(a,h_{-m}^{-1},W^l,T^l,d)}\right)
\end{aligned}$$

where $\#(g,W^l,G^l,d)$ is the count of semantic content g in semantic annotation string G^l of the lth sentence W^l in document d, $\#(w_{-n+1}^{-1}wh_{-m}^{-1}g,W^l,T^l,G^l,d)$ is the count of n-grams, its m most recent exposed headwords and semantic content g in parse T^l and semantic annotation string G^l of the lth sentence W^l in document d, $\#(twh_{-m}^{-1}.\text{tag},W^l,T^l,d)$ is the count of tag t predicted by word w and the tags of m most recent exposed headwords in parse tree T^l of the lth sentence W^l in document d, and finally $\#(ah_{-m}^{-1},W^l,T^l,d)$ is the count of constructor move a conditioning on m exposed headwords h_{-m}^{-1} in parse tree T^l of the lth sentence W^l in document d.

The objective of maximum likelihood estimation is to maximize the likelihood $\mathcal{L}(\mathcal{D},p)$ respect to model parameters. For a given sentence, its parse tree and semantic content are hidden and the number of parse trees grows faster than exponential with sentence length, Wang et al. (2006) have derived a generalized inside-outside algorithm by applying the standard EM algorithm. However, the complexity of this algorithm is 6th order of sentence length, thus it is computationally too expensive to be practical for a large corpus even with the use of pruning on charts (Jelinek and Chelba, 1999; Jelinek, 2004).

3.1 N-best list approximate EM

Similar to SLM (Chelba and Jelinek, 2000), we adopt an N-best list approximate EM re-estimation with modular modifications to seamlessly incorporate the effect of n-gram and PLSA components. Instead of maximizing the likelihood $\mathcal{L}(\mathcal{D},p)$, we maximize the N-best list likelihood,

$$\begin{aligned}
\max_{\mathcal{T'}_N}\mathcal{L}(\mathcal{D},p,\mathcal{T'}_N)=\prod_{d\in\mathcal{D}}\left(\prod_{l}\left(\max_{\mathcal{T'}^l_N\in\mathcal{T'}_N}\sum_{G^l}\right.\right.\\
\left.\left.\left(\sum_{T^l\in\mathcal{T'}^l_N,||\mathcal{T'}^l_N||=N}P_p(W^l,T^l,G^l|d)\right)\right)\right)
\end{aligned}$$

where $\mathcal{T'}^l_N$ is a set of N parse trees for sentence W^l in document d and $||\cdot||$ denotes the cardinality and $\mathcal{T'}_N$ is a collection of $\mathcal{T'}^l_N$ for sentences over entire corpus $\mathcal{D}$.

The N-best list approximate EM involves two steps:

1. N-best list search: For each sentence W in document d, find N-best parse trees,

$$\mathcal{T}^l_N=\arg\max_{\mathcal{T'}^l_N}\left\{\sum_{G^l}\sum_{T^l\in\mathcal{T'}^l_N}P_p(W^l,T^l,G^l|d),||\mathcal{T'}^l_N||=N\right\}$$

   and denote $\mathcal{T}_N$ as the collection of N-best list parse trees for sentences over entire corpus $\mathcal{D}$ under model parameter p.

2. EM update: Perform one iteration (or several iterations) of EM algorithm to estimate model

parameters that maximizes N-best-list likelihood of the training corpus $\mathcal{D}$,

$$\tilde{\mathcal{L}}(\mathcal{D}, p, \mathcal{T}_N) = \prod_{d \in \mathcal{D}} (\prod_{l} (\sum_{G^l} (\sum_{T^l \in \mathcal{T}_N^l, \in \mathcal{T}_N} P_p(W^l, T^l, G^l | d))))$$

That is,

(a) E-step: Compute the auxiliary function of the N-best-list likelihood

$$\tilde{Q}(p', p, \mathcal{T}_N) = \sum_{d \in \mathcal{D}} \sum_{l} \sum_{G^l} \sum_{T^l \in \mathcal{T}_N^l, \in \mathcal{T}_N} P_p(T^l, G^l | W^l, d) \log P_{p'}(W^l, T^l, G^l | d)$$

(b) M-step: Maximize $\tilde{Q}(p', p, \mathcal{T}_N)$ with respect to p' to get new update for p.

Iterate steps (1) and (2) until the convergence of the N-best-list likelihood. Due to space constraints, we omit the proof of the convergence of the N-best list approximate EM algorithm which uses Zangwill's global convergence theorem (Zangwill, 1969).

N-best list search strategy: To extract the N-best parse trees, we adopt a synchronous, multi-stack search strategy that is similar to the one in (Chelba and Jelinek, 2000), which involves a set of stacks storing partial parses of the most likely ones for a given prefix W_k and the less probable parses are purged. Each stack contains hypotheses (partial parses) that have been constructed by the same number of WORD-PREDICTOR and the same number of CONSTRUCTOR operations. The hypotheses in each stack are ranked according to the $\log(\sum_{G_k} P_p(W_k, T_k, G_k|d))$ score with the highest on top, where $P_p(W_k, T_k, G_k|d)$ is the joint probability of prefix $W_k = w_0, \cdots, w_k$ with its parse structure T_k and semantic annotation string $G_k = g_1, \cdots, g_k$ in a document d. A stack vector consists of the ordered set of stacks containing partial parses with the same number of WORD-PREDICTOR operations but different number of CONSTRUCTOR operations. In WORD-PREDICTOR and TAGGER operations, some hypotheses are discarded due to the maximum number of hypotheses the stack can contain at any given time. In CONSTRUCTOR operation, the resulting hypotheses are discarded due to either finite stack size or the log-probability threshold: the maximum tolerable difference between the log-probability score of the top-most hypothesis and the bottom-most hypothesis at any given state of the stack.

EM update: Once we have the N-best parse trees for each sentence in document d and N-best topics for document d, we derive the EM algorithm to estimate model parameters.

In E-step, we compute the expected count of each model parameter over sentence W^l in document d in the training corpus $\mathcal{D}$. For the WORD-PREDICTOR and the SEMANTIZER, the number of possible semantic annotation sequences is exponential, we use forward-backward recursive formulas that are similar to those in hidden Markov models to compute the expected counts. We define the forward vector $\alpha^l(g|d)$ to be

$$\alpha^l_{k+1}(g|d) = \sum_{G^l_k} P_p(W^l_k, T^l_k, w^k_{k-n+2} w_{k+1} h^{-1}_{-m} g, G^l_k | d)$$

that can be recursively computed in a forward manner, where W^l_k is the word k-prefix for sentence W^l, T^l_k is the parse for k-prefix. We define backward vector $\beta^l(g|d)$ to be

$$\beta^l_{k+1}(g|d) = \sum_{G^l_{k+1,\cdot}} P_p(W^l_{k+1,\cdot}, T^l_{k+1,\cdot}, G^l_{k+1,\cdot} | w^k_{k-n+2} w_{k+1} h^{-1}_{-m} g, d)$$

that can be computed in a backward manner, here $W^l_{k+1,\cdot}$ is the subsequence after k+1th word in sentence W^l, $T^l_{k+1,\cdot}$ is the incremental parse structure after the parse structure T^l_{k+1} of word k+1-prefix W^l_{k+1} that generates parse tree T^l, $G^l_{k+1,\cdot}$ is the semantic subsequence in G^l relevant to $W^l_{k+1,\cdot}$. Then, the expected count of $w^{-1}_{-n+1} w h^{-1}_{-m} g$ for the WORD-PREDICTOR on sentence W^l in document d is

$$\sum_{G^l} P_p(T^l, G^l | W^l, d) \#(w^{-1}_{-n+1} w h^{-1}_{-m} g, W^l, T^l, G^l, d)$$
$$= \sum_{l} \sum_{k} \alpha^l_{k+1}(g|d) \beta^l_{k+1}(g|d) p(g|d)$$
$$\delta(w^k_{k-n+2} w_{k+1} h^{-1}_{-m} g_{k+1} = w^{-1}_{-n+1} w h^{-1}_{-m} g) / P_p(W^l | d)$$

where $\delta(\cdot)$ is an indicator function and the expected count of g for the SEMANTIZER on sentence W^l in document d is

$$\sum_{G^l} P_p(T^l, G^l | W^l, d) \#(g, W^l, G^l, d)$$
$$= \sum_{k=0}^{j-1} \alpha^l_{k+1}(g|d) \beta^l_{k+1}(g|d) p(g|d) / P_p(W^l | d)$$

For the TAGGER and the CONSTRUCTOR, the expected count of each event of $t w h^{-1}_{-m}.\mathrm{tag}$ and $a h^{-1}_{-m}$ over parse T^l of sentence W^l in

document d is the real count appeared in parse tree T^l of sentence W^l in document d times the conditional distribution $P_p(T^l|W^l,d) = P_p(T^l,W^l|d)/\sum_{T^l\in\mathcal{T}^l} P_p(T^l,W^l|d)$ respectively.

In M-step, the recursive linear interpolation scheme (Jelinek and Mercer, 1981) is used to obtain a smooth probability estimate for each model component, WORD-PREDICTOR, TAGGER, and CONSTRUCTOR. The TAGGER and CONSTRUCTOR are conditional probabilistic models of the type $p(u|z_1,\cdots,z_n)$ where $u, z_1,\cdots,z_n$ belong to a mixed set of words, POS tags, NTtags, CONSTRUCTOR actions (u only), and $z_1,\cdots,z_n$ form a linear Markov chain. The recursive mixing scheme is the standard one among relative frequency estimates of different orders $k = 0,\cdots,n$ as explained in (Chelba and Jelinek, 2000). The WORD-PREDICTOR is, however, a conditional probabilistic model $p(w|w_{-n+1}^{-1}h_{-m}^{-1}g)$ where there are three kinds of context w_{-n+1}^{-1}, h_{-m}^{-1} and g, each forms a linear Markov chain. The model has a combinatorial number of relative frequency estimates of different orders among three linear Markov chains. We generalize Jelinek and Mercer's original recursive mixing scheme (Jelinek and Mercer, 1981) and form a lattice to handle the situation where the context is a mixture of Markov chains.

3.2 Follow-up EM

As explained in (Chelba and Jelinek, 2000), for the SLM component, a large fraction of the partial parse trees that can be used for assigning probability to the next word do not survive in the synchronous, multi-stack search strategy, thus they are not used in the N-best approximate EM algorithm for the estimation of WORD-PREDICTOR to improve its predictive power. To remedy this weakness, we estimate WORD-PREDICTOR using the algorithm below.

The *language model* probability assignment for the word at position k+1 in the input sentence of document d can be computed as

$$P_p(w_{k+1}|W_k,d) = \sum_{h_{-m}^{-1}\in T_k; T_k\in Z_k, g_{k+1}\in\mathcal{G}_d} p(w_{k+1}|w_{k-n+2}^{k}h_{-m}^{-1}g_{k+1}) P_p(T_k|W_k,d)p(g_{k+1}|d) \quad (2)$$

where $P_p(T_k|W_k,d) = \frac{\sum_{G_k} P_p(W_k,T_k,G_k|d)}{\sum_{T_k\in Z_k}\sum_{G_k} P_p(W_k,T_k,G_k|d)}$ and Z_k is the set of all parses present in the stacks at the current stage k during the synchronous multi-stack pruning strategy and it is a function of the word k-prefix W_k.

The likelihood of a training corpus $\mathcal{D}$ under this language model probability assignment that uses partial parse trees generated during the process of the synchronous, multi-stack search strategy can be written as

$$\tilde{\mathcal{L}}(\mathcal{D},p) = \prod_{d\in\mathcal{D}}\prod_{l}\Big(\sum_{k} P_p(w_{k+1}^{(l)}|W_k^l,d)\Big) \quad (3)$$

We employ a second stage of parameter re-estimation for $p(w_{k+1}|w_{k-n+2}^{k}h_{-m}^{-1}g_{k+1})$ and $p(g_{k+1}|d)$ by using EM again to maximize Equation (3) to improve the predictive power of WORD-PREDICTOR.

3.3 Distributed architecture

When using very large corpora to train our composite language model, both the data and the parameters can't be stored in a single machine, so we have to resort to distributed computing. The topic of large scale distributed language models is relatively new, and existing works are restricted to n-grams only (Brants et al., 2007; Emami et al., 2007; Zhang et al., 2006). Even though all use distributed architectures that follow the client-server paradigm, the real implementations are in fact different. Zhang et al. (2006) and Emami et al. (2007) store training corpora in suffix arrays such that one sub-corpus per server serves raw counts and test sentences are loaded in a client. This implies that when computing the language model probability of a sentence in a client, all servers need to be contacted for each n-gram request. The approach by Brants et al. (2007) follows a standard MapReduce paradigm (Dean and Ghemawat, 2004): the corpus is first divided and loaded into a number of clients, and n-gram counts are collected at each client, then the n-gram counts mapped and stored in a number of servers, resulting in exactly one server being contacted per n-gram when computing the language model probability of a sentence. We adopt a similar approach to Brants et al. and make it suitable to perform iterations of N-best list approximate EM algorithm, see Figure 2. The corpus is divided and loaded into a number of clients. We use a public available parser to parse the sentences in each client to get the initial counts for $w_{-n+1}^{-1}wh_{-m}^{-1}g$ etc., finish the Map part, and then the counts for a particular $w_{-n+1}^{-1}wh_{-m}^{-1}g$ at different clients are summed up and stored in one

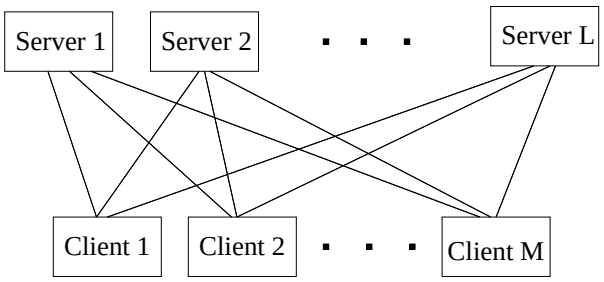

Figure 2: *Distributed architecture is essentially a MapReduce paradigm: clients store partitioned data and perform E-step: compute expected counts, this is Map; servers store parameters (counts) for M-step where counts of $w_{-n+1}^{-1}wh_{-m}^{-1}g$ are hashed by word w_{-1} (or h_{-1}) and its topic g to evenly distribute these model parameters into servers as much as possible, this is Reduce.*

of the servers by hashing through the word w_{-1} (or h_{-1}) and its topic g, finish the Reduce part. This is the initialization of the N-best list approximate EM step. Each client then calls the servers for parameters to perform synchronous multi-stack search for each sentence to get the N-best list parse trees. Again, the expected count for a particular parameter of $w_{-n+1}^{-1}wh_{-m}^{-1}g$ at the clients are computed, thus we finish a Map part, then summed up and stored in one of the servers by hashing through the word w_{-1} (or h_{-1}) and its topic g, thus we finish the Reduce part. We repeat this procedure until convergence.

Similarly, we use a distributed architecture as in Figure 2 to perform the follow-up EM algorithm to re-estimate WORD-PREDICTOR.

4 Experimental results

We have trained our language models using three different training sets: one has 44 million tokens, another has 230 million tokens, and the other has 1.3 billion tokens. An independent test set which has 354 k tokens is chosen. The independent check data set used to determine the linear interpolation coefficients has 1.7 million tokens for the 44 million tokens training corpus, 13.7 million tokens for both 230 million and 1.3 billion tokens training corpora. All these data sets are taken from the LDC English Gigaword corpus with non-verbalized punctuation and we remove all punctuation. Table 1 gives the detailed information on how these data sets are chosen from the LDC English Gigaword corpus.

The vocabulary sizes in all three cases are:

- word (also WORD-PREDICTOR operation) vocabulary: 60 k, open - all words outside the vocabulary are mapped to the <unk> token, these 60 k words are chosen from the most frequently occurred words in 44 millions tokens corpus;
- POS tag (also TAGGER operation) vocabulary: 69, closed;
- non-terminal tag vocabulary: 54, closed;
- CONSTRUCTOR operation vocabulary: 157, closed.

Table 1: The corpora used in our experiments are selected from the LDC English Gigaword corpus and specified in this table, AFP, AFW, NYT, XIN and CNA denote the sections of the LDC English Gigaword corpus.

Similar to SLM (Chelba and Jelinek, 2000), after the parses undergo headword percolation and binarization, each model component of WORD-PREDICTOR, TAGGER, and CONSTRUCTOR is initialized from a set of parsed sentences. We use the "openNLP" software (Northedge, 2005) to parse a large amount of sentences in the LDC English Gigaword corpus to generate an automatic treebank, which has a slightly different word-tokenization than that of the manual treebank such as the Upenn Treebank used in (Chelba and Jelinek, 2000). For the 44 and 230 million tokens corpora, all sentences are automatically parsed and used to initialize model parameters, while for 1.3 billion tokens corpus, we parse the sentences from a portion of the corpus that

contain 230 million tokens, then use them to initialize model parameters. The parser at "openNLP" is trained by Upenn treebank with 1 million tokens and there is a mismatch between Upenn treebank and LDC English Gigaword corpus. Nevertheless, experimental results show that this approach is effective to provide initial values of model parameters.

As we have explained, the proposed EM algorithms can be naturally cast into a MapReduce framework, see more discussion in (Lin and Dyer, 2010). If we have access to a large cluster of machines with Hadoop installed that are powerful enough to process a billion tokens level corpus, we just need to specify a map function and a reduce function etc., Hadoop will automatically parallelize and execute programs written in this functional style. Unfortunately, we don't have this kind of resources available. Instead, we have access to a supercomputer at a supercomputer center with MPI installed that has more than 1000 core processors usable. Thus we implement our algorithms using C++ under MPI on the supercomputer, where we have to write C++ codes for Map part and Reduce part, and the MPI is used to take care of massage passing, scheduling, synchronization, etc. between clients and servers. This involves a fair amount of programming work, even though our implementation under MPI is not as reliable as under Hadoop but it is more efficient. We use up to 1000 core processors to train the composite language models for 1.3 billion tokens corpus where 900 core processors are used to store the parameters alone. We decide to use linearly smoothed trigram as the baseline model for 44 million token corpus, linearly smoothed 4-gram as the baseline model for 230 million token corpus, and linearly smoothed 5-gram as the baseline model for 1.3 billion token corpus. Model size is a big issue, we have to keep only a small set of topics due to the consideration in both computational time and resource demand. Table 2 shows the perplexity results and computation time of composite n-gram/PLSA language models that are trained on three corpora when the pre-defined number of total topics is 200 but different numbers of most likely topics are kept for each document in PLSA, the rest are pruned. For composite 5-gram/PLSA model trained on 1.3 billion tokens corpus, 400 cores have to be used to keep top 5 most likely topics. For composite trigram/PLSA model trained on 44M tokens corpus, the computation time increases drastically with less than 5% percent perplexity improvement. So in the following experiments, we keep top 5 topics for each document from total 200 topics and all other 195 topics are pruned.

All composite language models are first trained by performing N-best list approximate EM algorithm until convergence, then EM algorithm for a second stage of parameter re-estimation for WORD-PREDICTOR and SEMANTIZER until convergence. We fix the size of topics in PLSA to be 200 and then prune to 5 in the experiments, where the unpruned 5 topics in general account for 70% probability in $p(g|d)$. Table 3 shows comprehensive perplexity results for a variety of different models such as composite n-gram/m-SLM, n-gram/PLSA, m-SLM/PLSA, their linear combinations, etc., where we use online EM with fixed learning rate to re-estimate the parameters of the SEMANTIZER of test document. The m-SLM performs competitively with its counterpart n-gram (n=m+1) on large scale corpus. In Table 3, for composite n-gram/m-SLM model ($n = 3, m = 2$ and $n = 4, m = 3$) trained on 44 million tokens and 230 million tokens, we cut off its fractional expected counts that are less than a threshold 0.005, this significantly reduces the number of predictor's types by 85%. When we train the composite language on 1.3 billion tokens corpus, we have to both aggressively prune the parameters of WORD-PREDICTOR and shrink the order of n-gram and m-SLM in order to store them in a supercomputer having 1000 cores. In particular, for composite 5-gram/4-SLM model, its size is too big to store, thus we use its approximation, a linear combination of 5-gram/2-SLM and 2-gram/4-SLM, and for 5-gram/2-SLM or 2-gram/4-SLM, again we cut off its fractional expected counts that are less than a threshold 0.005, this significantly reduces the number of predictor's types by 85%. For composite 4-SLM/PLSA model, we cut off its fractional expected counts that are less than a threshold 0.002, again this significantly reduces the number of predictor's types by 85%. For composite 4-SLM/PLSA model or its linear combination with models, we ignore all the tags and use only the words in the 4 head words. In this table, we have three items missing (marked by —), since the size of corresponding model is

CORPUS	n	# OF TOPICS	PPL	TIME (HOURS)	# OF SERVERS	# OF CLIENTS	# OF TYPES OF $ww_{-n+1}^{-1}g$

n-GRAM/m-SLM/PLSA	176	32.8%	—	—	—	—

Table 3: Perplexity results for various language models on test corpus, where + denotes linear combination, / denotes composite model; n denotes the order of n-gram and m denotes the order of SLM; the topic nodes are pruned from 200 to 5.

too big to store in the supercomputer. The composite n-gram/m-SLM/PLSA model gives significant perplexity reductions over baseline n-grams, $n = 3, 4, 5$ and m-SLMs, $m = 2, 3, 4$. The majority of gains comes from PLSA component, but when adding SLM component into n-gram/PLSA, there is a further 10% relative perplexity reduction.

We have applied our composite 5-gram/2-SLM+2-gram/4-SLM+5-gram/PLSA language model that is trained by 1.3 billion word corpus for the task of re-ranking the N-best list in statistical machine translation. We used the same 1000-best list that is used by Zhang et al. (2006). This list was generated on 919 sentences from the MT03 Chinese-English evaluation set by Hiero (Chiang, 2005; Chiang, 2007), a state-of-the-art parsing-based translation model. Its decoder uses a trigram language model trained with modified Kneser-Ney smoothing (Kneser and Ney, 1995) on a 200 million tokens corpus. Each translation has 11 features and language model is one of them. We substitute our language model and use MERT (Och, 2003) to optimize the BLEU score (Papineni et al., 2002). We partition the data into ten pieces, 9 pieces are used as training data to optimize the BLEU score (Papineni et al., 2002) by MERT (Och,

2003), a remaining single piece is used to re-rank the 1000-best list and obtain the BLEU score. The cross-validation process is then repeated 10 times (the folds), with each of the 10 pieces used exactly once as the validation data. The 10 results from the folds then can be averaged (or otherwise combined) to produce a single estimation for BLEU score. Table 4 shows the BLEU scores through 10-fold cross-validation. The composite 5-gram/2-SLM+2-gram/4-SLM+5-gram/PLSA language model gives 1.57% BLEU score improvement over the baseline and 0.79% BLEU score improvement over the 5-gram. This is because there is not much diversity on the 1000-best list, and essentially only $20 \sim 30$ distinct sentences are there in the 1000-best list. Chiang (2007) studied the performance of machine translation on Hiero, the BLEU score is 33.31% when n-gram is used to re-rank the N-best list, however, the BLEU score becomes significantly higher 37.09% when the n-gram is embedded directly into Hiero's one pass decoder, this is because there is not much diversity in the N-best list. It is expected that putting the our composite language into a one pass decoder of both phrase-based (Koehn et al., 2003) and parsing-based (Chiang, 2005; Chiang, 2007) MT systems should result in much improved BLEU scores.

SYSTEM MODEL	MEAN (%)
BASELINE	31.75
5-GRAM	32.53
5-GRAM/2-SLM+2-GRAM/4-SLM	32.87
5-GRAM/PLSA	33.01
5-GRAM/2-SLM+2-GRAM/4-SLM +5-GRAM/PLSA	33.32

Table 4: 10-fold cross-validation BLEU score results for the task of re-ranking the N-best list.

Besides reporting the BLEU scores, we look at the "readability" of translations similar to the study conducted by Charniak et al. (2003). The translations are sorted into four groups: good/bad syntax crossed with good/bad meaning by human judges, see Table 5. We find that many more sentences are perfect, many more are grammatically correct, and many more are semantically correct. The syntactic language model (Charniak, 2001; Charniak, 2003) only improves translations to have good grammar, but does not improve translations to preserve meaning. The composite 5-gram/2-SLM+2-gram/4-SLM+5-gram/PLSA language model improves both significantly. Bear in mind that Charniak et al. (2003) integrated Charniak's language model with the syntax-based translation model Yamada and Knight proposed (2001) to rescore a tree-to-string translation forest, whereas we use only our language model for N-best list re-ranking. Also, in the same study in (Charniak, 2003), they found that the outputs produced using the n-grams received higher scores from BLEU; ours did not. The difference between human judgments and BLEU scores indicate that closer agreement may be possible by incorporating syntactic structure and semantic information into the BLEU score evaluation. For example, semantically similar words like "insure" and "ensure" in the example of BLEU paper (Papineni et al., 2002) should be substituted in the formula, and there is a weight to measure the goodness of syntactic structure. This modification will lead to a better metric and such information can be provided by our composite language models.

SYSTEM MODEL	P	S	G	W
BASELINE	95	398	20	406
5-GRAM	122	406	24	367
5-GRAM/2-SLM +2-GRAM/4-SLM +5-GRAM/PLSA	151	425	33	310

Table 5: Results of "readability" evaluation on 919 translated sentences, P: perfect, S: only semantically correct, G: only grammatically correct, W: wrong.

5 Conclusion

As far as we know, this is the first work of building a complex large scale distributed language model with a principled approach that is more powerful than n-grams when both trained on a very large corpus with up to a billion tokens. We believe our results still hold on web scale corpora that have trillion tokens, since the composite language model effectively encodes long range dependencies of natural language that n-gram is not viable to consider. Of course, this implies that we have to take a huge amount of resources to perform the computation, nevertheless this becomes feasible, affordable, and cheap in the era of cloud computing.

Abstract

State-of-the-art statistical machine translation (MT) systems have made significant progress towards producing user-acceptable translation output. However, there is still no efficient way for MT systems to inform users which words are likely translated correctly and how confident it is about the whole sentence. We propose a novel framework to predict word-level and sentence-level MT errors with a large number of novel features. Experimental results show that the MT error prediction accuracy is increased from 69.1 to 72.2 in F-score. The Pearson correlation between the proposed confidence measure and the human-targeted translation edit rate (HTER) is 0.6. Improvements between 0.4 and 0.9 TER reduction are obtained with the n-best list reranking task using the proposed confidence measure. Also, we present a visualization prototype of MT errors at the word and sentence levels with the objective to improve post-editor productivity.

1 Introduction

State-of-the-art Machine Translation (MT) systems are making progress to generate more usable translation outputs. In particular, statistical machine translation systems (Koehn et al., 2007; Bach et al., 2007; Shen et al., 2008) have advanced to a state that the translation quality for certain language pairs (e.g. Spanish-English, French-English, Iraqi-English) in certain domains (e.g. broadcasting news, force-protection, travel) is acceptable to users.

However, a remaining open question is how to predict confidence scores for machine translated words and sentences. An MT system typically returns the best translation candidate from its search space, but still has no reliable way to inform users which word is likely to be correctly translated and how confident it is about the whole sentence. Such information is vital to realize the utility of machine translation in many areas. For example, a post-editor would like to quickly identify which sentences might be incorrectly translated and in need of correction. Other areas, such as cross-lingual question-answering, information extraction and retrieval, can also benefit from the confidence scores of MT output. Finally, even MT systems can leverage such information to do n-best list reranking, discriminative phrase table and rule filtering, and constraint decoding (Hildebrand and Vogel, 2008).

Numerous attempts have been made to tackle the confidence estimation problem. The work of Blatz et al. (2004) is perhaps the best known study of sentence and word level features and their impact on translation error prediction. Along this line of research, improvements can be obtained by incorporating more features as shown in (Quirk, 2004; Sanchis et al., 2007; Raybaud et al., 2009; Specia et al., 2009). Soricut and Echihabi (2010) developed regression models which are used to predict the expected BLEU score of a given translation hypothesis. Improvement also can be obtained by using target part-of-speech and null dependency link in a MaxEnt classifier (Xiong et al., 2010). Ueffing and Ney (2007) introduced word posterior probabilities (WPP) features and applied them in the n-best list reranking. From the usability point of view, back-translation is a tool to help users to assess the accuracy level of MT output (Bach et al., 2007). Literally, it translates backward the MT output into the source language to see whether the output of backward translation matches the original source sentence.

However, previous studies had a few shortcomings. First, source-side features were not extensively investigated. Blatz et al.(2004) only investigated source n-gram frequency statistics and source language model features, while other work mainly focused on target side features. Second, previous work attempted to incorporate more features but faced scalability issues, i.e., to train many features we need many training examples and to train discriminatively we need to search through all possible translations of each training example. Another issue of previous work was that they are all trained with BLEU/TER score computing against

Portland, Oregon, June 19-24, 2011.

the translation references which is different from predicting the human-targeted translation edit rate (HTER) which is crucial in post-editing applications (Snover et al., 2006; Papineni et al., 2002). Finally, the back-translation approach faces a serious issue when forward and backward translation models are symmetric. In this case, back-translation will not be very informative to indicate forward translation quality.

In this paper, we predict error types of each word in the MT output with a confidence score, extend it to the sentence level, then apply it to n-best list reranking task to improve MT quality, and finally design a visualization prototype. We try to answer the following questions:

- Can we use a rich feature set such as source-side information, alignment context, and dependency structures to improve error prediction performance?
- Can we predict more translation error types i.e substitution, insertion, deletion and shift?
- How good do our prediction methods correlate with human correction?
- Do confidence measures help the MT system to select a better translation?
- How confidence score can be presented to improve end-user perception?

In Section 2, we describe the models and training method for the classifier. We describe novel features including source-side, alignment context, and dependency structures in Section 3. Experimental results and analysis are reported in Section 4. Section 5 and 6 present applications of confidence scores.

2 Confidence Measure Model

2.1 Problem setting

Confidence estimation can be viewed as a sequential labelling task in which the word sequence is MT output and word labels can be $Bad/Good$ or $Insertion/Substitution/Shift/Good$. We first estimate each individual word confidence and extend it to the whole sentence. Arabic text is fed into an Arabic-English SMT system and the English translation outputs are corrected by humans in two phases. In phase one, a bilingual speaker corrects the MT system translation output. In phase two, another bilingual speaker does quality checking for the correction done in phase one. If bad corrections were spotted, they correct them again. In this paper we use the final correction data from phase two as the reference thus HTER can be used as an evaluation metric. We have 75 thousand sentences with 2.4 million words in total from the human correction process described above.

We obtain training labels for each word by performing TER alignment between MT output and the phase-two human correction. From TER alignments we observed that out of total errors are 48% substitution, 28% deletion, 13% shift, and 11% insertion errors. Based on the alignment, each word produced by the MT system has a label: good, insertion, substitution and shift. Since a deletion error occurs when it only appears in the reference translation, not in the MT output, our model will not predict deletion errors in the MT output.

2.2 Word-level model

In our problem, a training instance is a word from MT output, and its label when the MT sentence is aligned with the human correction. Given a training instance x, y is the true label of x; f stands for its feature vector $f(x, y)$; and w is feature weight vector. We define a feature-rich classifier $score(x, y)$ as follow

$$score(x, y) = w.f(x, y) \tag{1}$$

To obtain the label, we choose the class with the highest score as the predicted label for that data instance. To learn optimized weights, we use the Margin Infused Relaxed Algorithm or MIRA (Crammer and Singer, 2003; McDonald et al., 2005) which is an online learner closely related to both the support vector machine and perceptron learning framework. MIRA has been shown to provide state-of-the-art performance for sequential labelling task (Rozenfeld et al., 2006), and is also able to provide an efficient mechanism to train and optimize MT systems with lots of features (Watanabe et al., 2007; Chiang et al., 2009). In general, weights are updated at each step time t according to the following rule:

$$\begin{aligned} & w_{t+1} = \arg\min_{w_{t+1}} ||w_{t+1} - w_t|| \\ \text{s.t.} \quad & score(x, y) \geq score(x, y') + L(y, y') \end{aligned} \tag{2}$$

where $L(y, y')$ is a measure of the loss of using y' instead of the true label y. In this problem $L(y, y')$ is 0-1 loss function. More specifically, for each instance x_i in the training data at a time t we find the label with the highest score:

$$y' = \arg\max_{y} score(x_i, y) \tag{3}$$

the weight vector is updated as follow

$$w_{t+1} = w_t + \tau(f(x_i, y) - f(x_i, y')) \tag{4}$$

τ can be interpreted as a step size; when τ is a large number we want to update our weights aggressively, otherwise weights are updated conservatively.

$$\begin{aligned} \tau &= \max(0, \alpha) \\ \alpha &= \min\left\{C, \frac{L(y,y') - (score(x_i,y) - score(x_i,y'))}{||f(x_i,y) - f(x_i,y')||_2^2}\right\} \end{aligned} \tag{5}$$

where C is a positive constant used to cap the maximum possible value of τ. In practice, a cut-off threshold n is the parameter which decides the number of features kept (whose occurrence is at least n) during

training. Note that MIRA is sensitive to constant C, the cut-off feature threshold n, and the number of iterations. The final weight is typically normalized by the number of training iterations and the number of training instances. These parameters are tuned on a development set.

2.3 Sentence-level model

Given the feature sets and optimized weights, we use the Viterbi algorithm to find the best label sequence. To estimate the confidence of a sentence S we rely on the information from the forward-backward inference. One approach is to directly use the conditional probabilities of the whole sequence. However, this quantity is the confidence measure for the label sequence predicted by the classifier and it does not represent the goodness of the whole MT output. Another more appropriated method is to use the marginal probability of $Good$ label which can be defined as follow:

$$p(y_i = Good|S) = \frac{\alpha(y_i|S)\beta(y_i|S)}{\sum_j \alpha(y_j|S)\beta(y_j|S)} \quad (6)$$

$p(y_i = Good|S)$ is the marginal probability of label $Good$ at position i given the MT output sentence S. $\alpha(y_i|S)$ and $\beta(y_i|S)$ are forward and backward values. Our confidence estimation for a sentence S of k words is defined as follow

$$goodness(S) = \frac{\sum_{i=1}^{k} p(y_i = Good|S)}{k} \quad (7)$$

$goodness(S)$ is ranging between 0 and 1, where 0 is equivalent to an absolutely wrong translation and 1 is a perfect translation. Essentially, $goodness(S)$ is the arithmetic mean which represents the goodness of translation per word in the whole sentence.

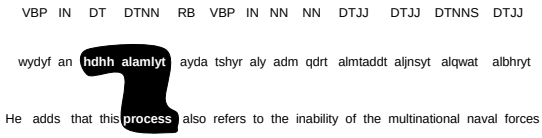
3 Confidence Measure Features

Features are generated from feature types: abstract templates from which specific features are instantiated. Features sets are often parameterized in various ways. In this section, we describe three new feature sets introduced on top of our baseline classifier which has WPP and target POS features (Ueffing and Ney, 2007; Xiong et al., 2010).

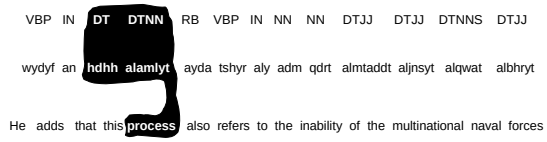
3.1 Source-side features

From MT decoder log, we can track which source phrases generate target phrases. Furthermore, one can infer the alignment between source and target words within the phrase pair using simple aligners such as IBM Model-1 alignment.

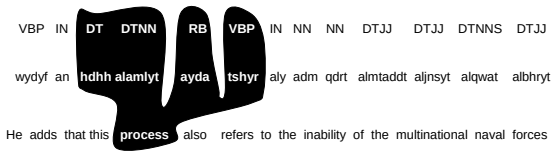
Source phrase features: These features are designed to capture the likelihood that source phrase and target word co-occur with a given error label. The intuition behind them is that if a large percentage of the source phrase and target have often been seen together with the same label, then the produced target word should have this label in the future. Figure 1a illustrates this feature template where the first line is source POS tags, the second line is the Buckwalter romanized source Arabic sequence, and the third line is MT output. The source phrase feature is defined as follow



(a) Source phrase



(b) Source POS



(c) Source POS and phrase in right context

Figure 1: Source-side features.

$$f_{102}(process) = \begin{cases} 1 & \text{if source-phrase="}\textit{hdhh alamlyt}\text{"} \\ 0 & \text{otherwise} \end{cases}$$

Source POS: Source phrase features might be susceptible to sparseness issues. We can generalize source phrases based on their POS tags to reduce the number of parameters. For example, the example in Figure 1a is generalized as in Figure 1b and we have the following feature:

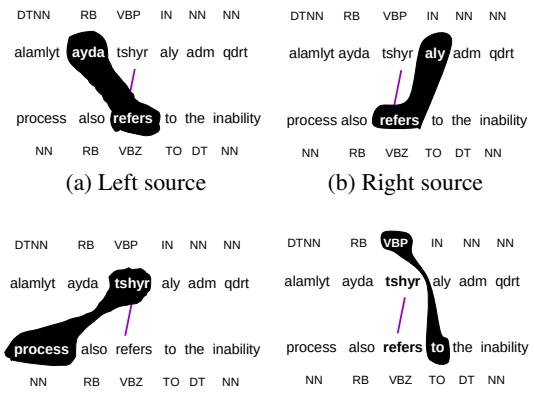
$$f_{103}(process) = \begin{cases} 1 & \text{if source-POS="}\textit{ DT DTNN }\text{"} \\ 0 & \text{otherwise} \end{cases}$$

Source POS and phrase context features: This feature set allows us to look at the surrounding context of the source phrase. For example, in Figure 1c we have "*hdhh alamlyt*" generates "*process*". We also have other information such as on the right hand side the next two phrases are "*ayda*" and "*tshyr*" or the sequence of source target POS on the right hand side is "*RB VBP*". An example of this type of feature is

$$f_{104}(process) = \begin{cases} 1 & \text{if source-POS-context="}\textit{ RB VBP }\text{"} \\ 0 & \text{otherwise} \end{cases}$$

3.2 Alignment context features

The IBM Model-1 feature performed relatively well in comparison with the WPP feature as shown by Blatz et al. (2004). In our work, we incorporate not only the



(a) Left source (b) Right source

(c) Left target (d) Source POS & right target

Figure 2: Alignment context features.

IBM Model-1 feature but also the surrounding alignment context. The key intuition is that collocation is a reliable indicator for judging if a target word is generated by a particular source word (Huang, 2009). Moreover, the IBM Model-1 feature was already used in several steps of a translation system such as word alignment, phrase extraction and scoring. Also the impact of this feature alone might fade away when the MT system is scaled up.

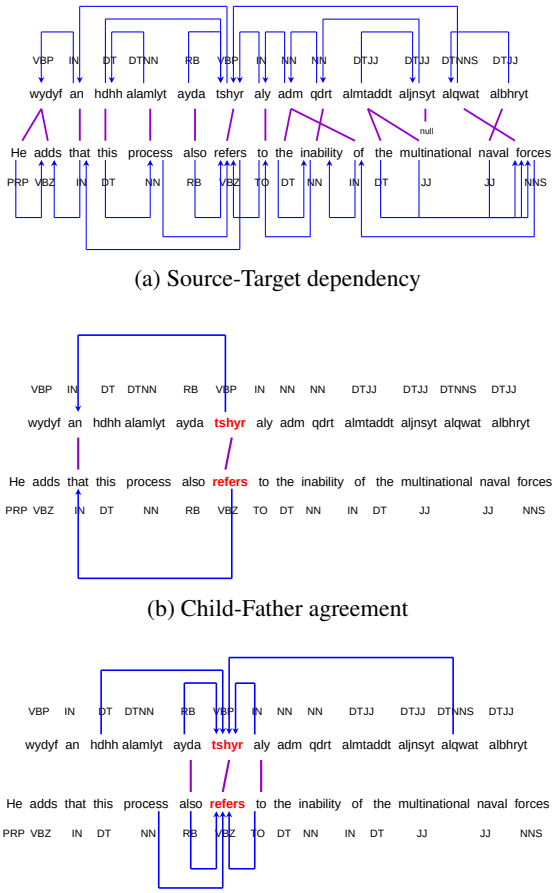
We obtain word-to-word alignments by applying IBM Model-1 to bilingual phrase pairs that generated the MT output. The IBM Model-1 assumes one target word can only be aligned to one source word. Therefore, given a target word we can always identify which source word it is aligned to.

Source alignment context feature: We anchor the target word and derive context features surrounding its source word. For example, in Figure 2a and 2b we have an alignment between "*tshyr*" and "*refers*" The source contexts "*tshyr*" with a window of one word are "*ayda*" to the left and "*aly*" to the right.

Target alignment context feature: Similar to source alignment context features, we anchor the source word and derive context features surrounding the aligned target word. Figure 2c shows a left target context feature of word "*refers*". Our features are derived from a window of four words.

Combining alignment context with POS tags: Instead of using lexical context we have features to look at source and target POS alignment context. For instance, the feature in Figure 2d is

$$f_{141}(refers) = \begin{cases} 1 & \text{if source-POS = "}VBP\text{"} \\ & \text{and target-context = "}to\text{"} \\ 0 & \text{otherwise} \end{cases}$$



(a) Source-Target dependency

(b) Child-Father agreement

(c) Children agreement

Figure 3: Dependency structures features.

3.3 Source and target dependency structure features

The contextual and source information in the previous sections only take into account surface structures of source and target sentences. Meanwhile, dependency structures have been extensively used in various translation systems (Shen et al., 2008; Ma et al., 2008; Bach et al., 2009). The adoption of dependency structures might enable the classifier to utilize deep structures to predict translation errors. Source and target structures are unlikely to be isomorphic as shown in Figure 3a. However, we expect some high-level linguistic structures are likely to transfer across certain language pairs. For example, prepositional phrases (PP) in Arabic and English are similar in a sense that PPs generally appear at the end of the sentence (after all the verbal arguments) and to a lesser extent at its beginning (Habash and Hu, 2009). We use the Stanford parser to obtain dependency trees and POS tags (Marneffe et al., 2006).

Child-Father agreement: The motivation is to take advantage of the long distance dependency relations between source and target words. Given an alignment between a source word s_i and a target word t_j. A child-

father agreement exists when s_k is aligned to t_l, where s_k and t_l are father of s_i and t_j in source and target dependency trees, respectively. Figure 3b illustrates that "*tshyr*" and "*refers*" have a child-father agreement. To verify our intuition, we analysed 243K words of manual aligned Arabic-English bitext. We observed 29.2% words having child-father agreements. In term of structure types, we found 27.2% of copula verb and 30.2% prepositional structures, including object of a preposition, prepositional modifier, and prepositional complement, are having child-father agreements.

Children agreement: In the child-father agreement feature we look up in the dependency tree, however, we also can look down to the dependency tree with a similar motivation. Essentially, given an alignment between a source word s_i and a target word t_j, how many children of s_i and t_j are aligned together? For example, "*tshyr*" and "*refers*" have 2 aligned children which are "*ayda-also*" and "*aly-to*" as shown in Figure 3c.

4 Experiments

4.1 Arabic-English translation system

The SMT engine is a phrase-based system similar to the description in (Tillmann, 2006), where various features are combined within a log-linear framework. These features include source-to-target phrase translation score, source-to-target and target-to-source word-to-word translation scores, language model score, distortion model scores and word count. The training data for these features are 7M Arabic-English sentence pairs, mostly newswire and UN corpora released by LDC. The parallel sentences have word alignment automatically generated with HMM and MaxEnt word aligner (Ge, 2004; Ittycheriah and Roukos, 2005). Bilingual phrase translations are extracted from these word-aligned parallel corpora. The language model is a 5-gram model trained on roughly 3.5 billion English words.

Our training data contains 72k sentences Arabic-English machine translation with human corrections which include of 2.2M words in newswire and weblog domains. We have a development set of 2,707 sentences, 80K words (dev); an unseen test set of 2,707 sentences, 79K words (test). Feature selection and parameter tuning has been done on the development set in which we experimented values of C, n and iterations in range of [0.5:10], [1:5], and [50:200] respectively. The final MIRA classifier was trained by using pocket crf toolkit[1] with 100 iterations, hyper-parameter C was 5 and cut-off feature threshold n was 1.

We use precision (P), recall (R) and F-score (F) to evaluate the classifier performance and they are computed as follow:

$$\begin{aligned} P &= \frac{\text{the number of correctly tagged labels}}{\text{the number of tagged labels}} \\ R &= \frac{\text{the number of correctly tagged labels}}{\text{the number of reference labels}} \\ F &= \frac{2*P*R}{P+R} \end{aligned} \quad (8)$$

4.2 Contribution of feature sets

We designed our experiments to show the impact of each feature separately as well as their cumulative impact. We trained two types of classifiers to predict the error type of each word in MT output, namely Good/Bad with a binary classifier and Good/Insertion/Substitution/Shift with a 4-class classifier. Each classifier is trained with different feature sets as follow:

- WPP: we reimplemented WPP calculation based on n-best lists as described in (Ueffing and Ney, 2007).
- WPP + target POS: only WPP and target POS features are used. This is a similar feature set used by Xiong et al. (2010).
- Our features: the classifier has source side, alignment context, and dependency structure features; WPP and target POS features are excluded.
- WPP + our features: adding our features on top of WPP.
- WPP + target POS + our features: using all features.

	binary		4-class	
	dev	test	dev	test
WPP	69.3	68.7	64.4	63.7
+ source side	72.1	**71.6**	66.2	**65.7**
+ alignment context	71.4	70.9	65.7	65.3
+ dependency structures	69.9	69.5	64.9	64.3
WPP+ target POS	69.6	69.1	64.4	63.9
+ source side	72.3	**71.8**	66.3	**65.8**
+ alignment context	71.9	71.2	66	65.6
+ dependency structures	70.4	70	65.1	64.4

Table 1: Contribution of different feature sets measure in F-score.

To evaluate the effectiveness of each feature set, we apply them on two different baseline systems: using WPP and WPP+target POS, respectively. We augment each baseline with our feature sets separately. Table 1 shows the contribution in F-score of our proposed feature sets. Improvements are consistently obtained when combining the proposed features with baseline features. Experimental results also indicate that source-side information, alignment context and dependency

Figure 4: Performance of binary and 4-class classifiers trained with different feature sets on the development and unseen test sets.

structures have unique and effective levers to improve the classifier performance. Among the three proposed feature sets, we observe the source side information contributes the most gain, which is followed by the alignment context and dependency structure features.

4.3 Performance of classifiers

We trained several classifiers with our proposed feature sets as well as baseline features. We compare their performances, including a naive baseline All-Good classifier, in which all words in the MT output are labelled as good translations. Figure 4 shows the performance of different classifiers trained with different feature sets on development and unseen test sets. On the unseen test set our proposed features outperform WPP and target POS features by 2.8 and 2.4 absolute F-score respectively. Improvements of our features are consistent in development and unseen sets as well as in binary and 4-class classifiers. We reach the best performance by combining our proposed features with WPP and target POS features. Experiments indicate that the gaps in F-score between our best system with the naive All-Good system is 12.9 and 6.8 in binary and 4-class cases, respectively. Table 2 presents precision, recall, and F-score of individual class of the best binary and 4-class classifiers. It shows that *Good* label is better predicted than other labels, meanwhile, $Substitution$ is generally easier to predict than $Insertion$ and $Shift$.

4.4 Correlation between Goodness and HTER

We estimate sentence level confidence score based on Equation 7. Figure 5 illustrates the correlation between our proposed $goodness$ sentence level confidence score and the human-targeted translation edit rate (HTER). The Pearson correlation between $goodness$ and HTER is 0.6, while the correlation of WPP and HTER is 0.52. This experiment shows that $goodness$ has a large correlation with HTER. The black bar is the linear regression line. Blue and red bars are thresholds used to visualize good and bad sentences respectively. We also experimented $goodness$ computation in Equation 7 using geometric mean and harmonic mean; their Pearson correlation values are 0.5 and 0.35 respectively.

	Label	P	R	F
Binary	Good	74.7	80.6	77.5
	Bad	68	60.1	63.8
4-class	Good	70.8	87	78.1
	Insertion	37.5	16.9	23.3
	Substitution	57.8	44.9	50.5
	Shift	35.2	14.1	20.1

5 Improving MT quality with N-best list reranking

Experiments reporting in Section 4 indicate that the proposed confidence measure has a high correlation with HTER. However, it is not very clear if the core MT system can benefit from confidence measure by providing better translations. To investigate this question we present experimental results for the n-best list reranking task.

The MT system generates top n hypotheses and for each hypothesis we compute sentence-level confidence scores. The best candidate is the hypothesis with highest confidence score. Table 3 shows the performance of reranking systems using $goodness$ scores from our best classifier in various n-best sizes. We obtained 0.7 TER reduction and 0.4 BLEU point improvement on the development set with a 5-best list. On the unseen test, we obtained 0.6 TER reduction and 0.2 BLEU point improvement. Although, the improvement of BLEU score

	Dev		Test	
	TER	BLEU	TER	BLEU
Baseline	49.9	31.0	50.2	30.6
2-best	49.5	31.4	49.9	30.8
5-best	**49.2**	**31.4**	**49.6**	**30.8**
10-best	49.2	31.2	49.5	30.8
20-best	49.1	31.0	49.3	30.7
30-best	49.0	31.0	49.3	30.6
40-best	49.0	31.0	49.4	30.5
50-best	49.1	30.9	49.4	30.5
100-best	49.0	30.9	49.3	30.5

Table 3: Reranking performance with *goodness* score.

is not obvious, TER reductions are consistent in both development and unseen sets. Figure 6 shows the improvement of reranking with *goodness* score. Besides, the figure illustrates the upper and lower bound performances with TER metric in which the lower bound is our baseline system and the upper bound is the best hypothesis in a given n-best list. Oracle scores of each n-best list are computed by choosing the translation candidate with lowest TER score.

6 Visualizing translation errors

Besides the application of confidence score in the n-best list reranking task, we propose a method to visualize translation error using confidence scores. Our purpose is to visualize word and sentence-level confidence scores with the following objectives 1) easy for spotting translations errors; 2) simple and intuitive; and 3) helpful for post-editing productivity. We define three categories of translation quality (good/bad/decent) on both word and sentence level. On word level, the marginal probability of good label is used to visualize translation errors as follow:

$$L_i = \begin{cases} good & \text{if } p(y_i = Good|S) \geq 0.8 \\ bad & \text{if } p(y_i = Good|S) \leq 0.45 \\ decent & \text{otherwise} \end{cases}$$

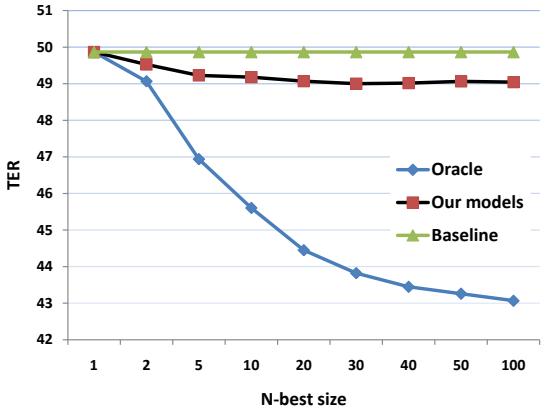

Figure 6: A comparison between reranking and oracle scores with different n-best size in TER metric on the development set.

On sentence level, the goodness score is used as follow:

$$L_S = \begin{cases} good & \text{if } goodness(S) \geq 0.7 \\ bad & \text{if } goodness(S) \leq 0.5 \\ decent & \text{otherwise} \end{cases}$$

	Choices	Intention
Font size	big	bad
	small	good
	medium	decent
Colors	red	bad
	black	good
	orange	decent

Table 4: Choices of layout

Different font sizes and colors are used to catch the attention of post-editors whenever translation errors are likely to appear as shown in Table 4. Colors are applied on word level, while font size is applied on both word and sentence level. The idea of using font size and colour to visualize translation confidence is similar to the idea of using tag/word cloud to describe the content of websites[2]. The reason we are using big font size and red color is to attract post-editors' attention and help them find translation errors quickly. Figure 7 shows an example of visualizing confidence scores by font size and colours. It shows that "*not to deprive yourself*", displayed in big font and red color, is likely to be bad translations. Meanwhile, other words, such as "*you*", "*different*", "*from*", and "*assimilation*", displayed in small font and black color, are likely to be good translation. Medium font and orange color words are decent translations.

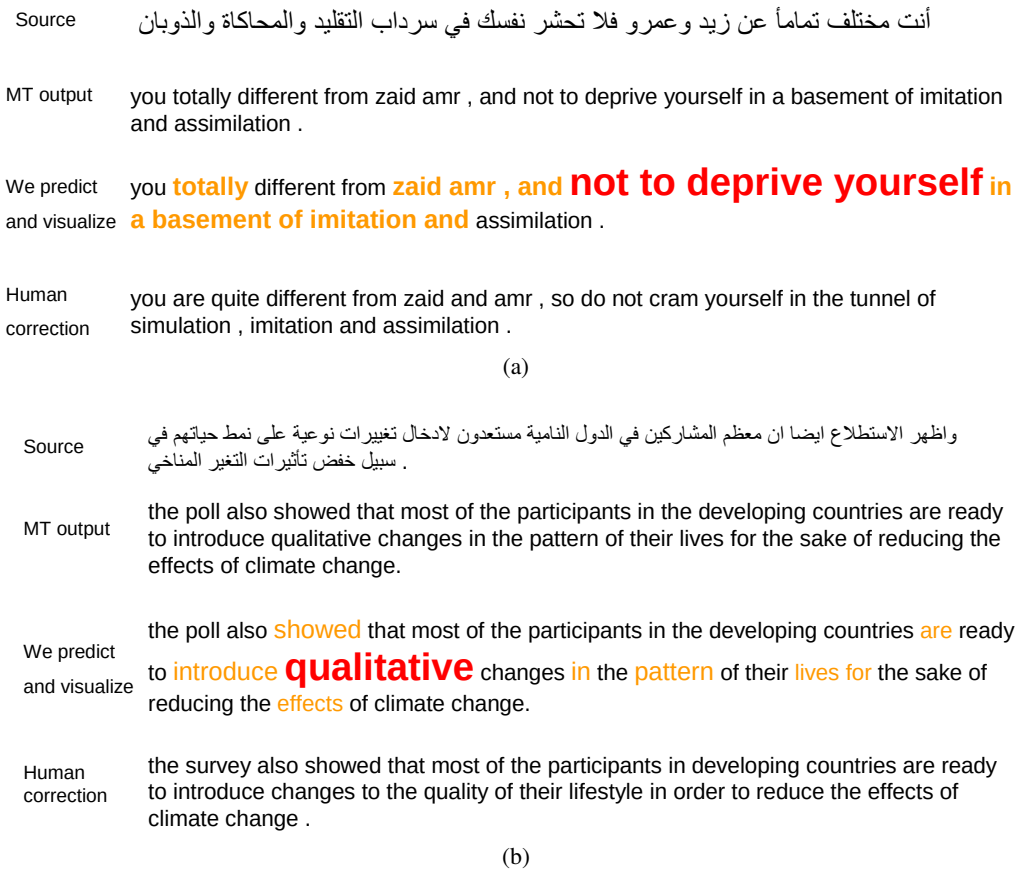

Figure 7: MT errors visualization based on confidence scores.

7 Conclusions

In this paper we proposed a method to predict confidence scores for machine translated words and sentences based on a feature-rich classifier using linguistic and context features. Our major contributions are three novel feature sets including source side information, alignment context, and dependency structures. Experimental results show that by combining the source side information, alignment context, and dependency structure features with word posterior probability and target POS context (Ueffing & Ney 2007; Xiong et al., 2010), the MT error prediction accuracy is increased from 69.1 to 72.2 in F-score. Our framework is able to predict error types namely insertion, substitution and shift. The Pearson correlation with human judgement increases from 0.52 to 0.6. Furthermore, we show that the proposed confidence scores can help the MT system to select better translations and as a result improvements between 0.4 and 0.9 TER reduction are obtained. Finally, we demonstrate a prototype to visualize translation errors.

This work can be expanded in several directions. First, we plan to apply confidence estimation to perform a second-pass constraint decoding. After the first pass decoding, our confidence estimation model can label which word is likely to be correctly translated. The second-pass decoding utilizes the confidence information to constrain the search space and hopefully can find a better hypothesis than in the first pass. This idea is very similar to the multi-pass decoding strategy employed by speech recognition engines. Moreover, we also intend to perform a user study on our visualization prototype to see if it increases the productivity of post-editors.

MEANT: An inexpensive, high-accuracy, semi-automatic metric for evaluating translation utility via semantic frames

Abstract

We introduce a novel semi-automated metric, MEANT, that assesses translation utility by matching semantic role fillers, producing scores that correlate with human judgment as well as HTER but at much lower labor cost. As machine translation systems improve in lexical choice and fluency, the shortcomings of widespread n-gram based, fluency-oriented MT evaluation metrics such as BLEU, which fail to properly evaluate adequacy, become more apparent. But more accurate, non-automatic adequacy-oriented MT evaluation metrics like HTER are highly labor-intensive, which bottlenecks the evaluation cycle. We first show that when using untrained monolingual readers to annotate semantic roles in MT output, the non-automatic version of the metric HMEANT achieves a 0.43 correlation coefficient with human adequacy judgments at the sentence level, far superior to BLEU at only 0.20, and equal to the far more expensive HTER. We then replace the human semantic role annotators with automatic shallow semantic parsing to further automate the evaluation metric, and show that even the semi-automated evaluation metric achieves a 0.34 correlation coefficient with human adequacy judgment, which is still about 80% as closely correlated as HTER despite an even lower labor cost for the evaluation procedure. The results show that our proposed metric is significantly better correlated with human judgment on adequacy than current widespread automatic evaluation metrics, while being much more cost effective than HTER.

1 Introduction

In this paper we show that evaluating machine translation by assessing the translation accuracy of each argument in the semantic role framework correlates with human judgment on translation *adequacy* as well as HTER, at a significantly lower labor cost. The correlation of this new metric, MEANT, with human judgment is far superior to BLEU and other automatic n-gram based evaluation metrics.

We argue that BLEU (Papineni *et al.*, 2002) and other automatic n-gram based MT evaluation metrics do not adequately capture the similarity in meaning between the machine translation and the reference translation—which, ultimately, is essential for MT output to be useful. N-gram based metrics assume that "good" translations tend to share the same lexical choices as the reference translations. While BLEU score performs well in capturing the translation fluency, Callison-Burch *et al.* (2006) and Koehn and Monz (2006) report cases where BLEU strongly disagree with human judgment on translation quality. The underlying reason is that lexical similarity does not adequately reflect the similarity in meaning. As MT systems improve, the shortcomings of the n-gram based evaluation metrics are becoming more apparent. State-of-the-art MT systems are often able to output fluent translations that are nearly grammatical and contain roughly the correct words, but still fail to express meaning that is close to the input.

At the same time, although HTER (Snover *et al.*, 2006) is more adequacy-oriented, it is only employed in very large scale MT system evaluation instead of day-to-day research activities. The underlying reason is that it requires rigorously trained human experts to make difficult combinatorial decisions on the minimal number of edits so as to make the MT output convey the same meaning as the reference translation—a highly labor-intensive, costly process that bottlenecks the evaluation cycle.

Instead, with MEANT, we adopt at the outset the principle that a good translation is one that is *useful*, in the sense that human readers may successfully understand at least the basic event structure—"*who* did *what* to *whom*, *when*, *where* and *why*" (Pradhan *et al.*, 2004)—representing the central meaning of the source utterances. It is true that limited tasks might exist for which inadequate translations are still useful. But for meaningful tasks, generally speaking, for a translation to be useful, at least the basic event structure must be correctly understood. Therefore, our objective is to evaluate *translation utility*: from a user's point of view, how well is

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 220–229,
Portland, Oregon, June 19-24, 2011.

the most essential semantic information being captured by machine translation systems?

In this paper, we detail the methodology that underlies MEANT, which extends and implements preliminary directions proposed in (Lo and Wu, 2010a) and (Lo and Wu, 2010b). We present the results of evaluating translation utility by measuring the accuracy within a semantic role labeling (SRL) framework. We show empirically that our proposed SRL based evaluation metric, which uses untrained monolingual humans to annotate semantic frames in MT output, correlates with human adequacy judgments as well as HTER, and far better than BLEU and other commonly used metrics. Finally, we show that replacing the human semantic role labelers with an automatic shallow semantic parser in our proposed metric yields an approximation that is about 80% as closely correlated with human judgment as HTER, at an even lower cost—and is still far better correlated than n-gram based evaluation metrics.

2 Related work

Lexical similarity based metrics BLEU (Papineni *et al.*, 2002) is the most widely used MT evaluation metric despite the fact that a number of large scale meta-evaluations (Callison-Burch *et al.*, 2006; Koehn and Monz, 2006) report cases where it strongly disagree with human judgment on translation accuracy. Other lexical similarity based automatic MT evaluation metrics, like NIST (Doddington, 2002), METEOR (Banerjee and Lavie, 2005), PER (Tillmann *et al.*, 1997), CDER (Leusch *et al.*, 2006) and WER (Nießen *et al.*, 2000), also perform well in capturing translation fluency, but share the same problem that although evaluation with these metrics can be done very quickly at low cost, their underlying assumption—that a "good" translation is one that shares the same lexical choices as the reference translation—is not justified semantically. Lexical similarity does not adequately reflect similarity in meaning. State-of-the-art MT systems are often able to output translations containing roughly the correct words, yet expressing meaning that is not close to that of the input.

We argue that a translation metric that reflects meaning similarity is better based on similarity in semantic structure, rather than simply flat lexical similarity.

HTER (non-automatic) Despite the fact that Human-targeted Translation Edit Rate (HTER) as proposed by Snover *et al.* (2006) shows a high correlation with human judgment on translation adequacy, it is not widely used in day-to-day machine translation evaluation because of its high labor cost. HTER not only requires human experts to understand the meaning expressed in both the reference translation and the machine translation, but also requires them to propose the minimum number of edits to the MT output such that the post-edited MT output conveys the same meaning as the reference translation. Requiring such heavy manual decision making greatly increases the cost of evaluation, bottlenecking the evaluation cycle.

To reduce the cost of evaluation, we aim to reduce any human decisions in the evaluation cycle to be as simple as possible, such that even untrained humans can quickly complete the evaluation. The human decisions should also be defined in a way that can be closely approximated by automatic methods, so that similar objective functions might potentially be used for tuning in MT system development cycles.

Task based metrics (non-automatic) Voss and Tate (2006) proposed a task-based approach to MT evaluation that is in some ways similar in spirit to ours, but rather than evaluating how well people understand the meaning as a whole conveyed by a sentence translation, they measured the recall with which humans can extract *one* of the *who*, *when*, or *where* elements from MT output—and without attaching them to any predicate or frame. A large number of human subjects were instructed to extract only *one* particular type of *wh*-item from each sentence. They evaluated only whether the role fillers were correctly identified, without checking whether the roles were appropriately attached to the correct predicate. Also, the actor, experiencer, and patient were all conflated into the undistinguished *who* role, while other crucial elements, like the action, purpose, manner, were ignored.

Instead, we argue, evaluating meaning similarity should be done by evaluating the semantic structure as a whole: (a) *all* core semantic roles should be checked, and (b) not only should we evaluate the presence of semantic role fillers in isolation, but also their relations to the frames' predicates.

Syntax based metrics Unlike Voss and Tate, Liu and Gildea (2005) proposed a structural approach, but it was based on syntactic rather than semantic structure, and focused on checking the correctness of the role *structure* without checking the correctness of the role *fillers*. Their subtree metric (STM) and headword chain metric (HWC) address the failure of BLEU to evaluate translation *grammaticality*; however, the problem remains that a grammatical translation can achieve a high syntax-based score even if contains meaning errors arising from confusion of semantic roles.

STM was the first proposed metric to incorporate syntactic features in MT evaluation, and STM underlies most other recently proposed syntactic MT evaluation metrics, for example the evaluation metric based on lexical-functional grammar of Owczarzak *et al.* (2008). STM is a precision-based metric that measures what fraction of subtree *structures* are shared between the parse trees of

machine translations and reference translations (averaging over subtrees up to some depth threshold). Unlike Voss and Tate, however, STM does not check whether the role *fillers* are correctly translated.

HWC is similar, but is based on dependency trees containing lexical as well as syntactic information. HWC measures what fraction of headword chains (a sequence of words corresponding to a path in the dependency tree) also appear in the reference dependency tree. This can be seen as a similarity measure on n-grams of dependency chains. Note that the HWC's notion of lexical similarity still requires exact word match.

Although STM-like syntax-based metrics are an improvement over flat lexical similarity metrics like BLEU, they are still more fluency-oriented than adequacy-oriented. Similarity of syntactic rather than semantic structure still inadequately reflects meaning preservation. Moreover, properly measuring translation *utility* requires verifying whether role *fillers* have been correctly translated—verifying only the abstract structures fails to penalize when role fillers are confused.

Semantic roles as features in aggregate metrics Giménez and Màrquez (2007, 2008) introduced ULC, an automatic MT evaluation metric that aggregates many types of features, including several shallow semantic similarity features: semantic role overlapping, semantic role matching, and semantic structure overlapping. Unlike Liu and Gildea (2007) who use discriminative training to tune the weight on each feature, ULC uses uniform weights. Although the metric shows an improved correlation with human judgment of translation quality (Callison-Burch *et al.*, 2007; Giménez and Màrquez, 2007; Callison-Burch *et al.*, 2008; Giménez and Màrquez, 2008), it is not commonly used in large-scale MT evaluation campaigns, perhaps due to its high time cost and/or the difficulty of interpreting its score because of its highly complex combination of many heterogenous types of features.

Specifically, note that the feature based representations of semantic roles used in these aggregate metrics do not actually capture the structural predicate-argument relations. "Semantic structure overlapping" can be seen as the shallow semantic version of STM: it only measures the similarity of the tree structure of the semantic roles, without considering the lexical realization. "Semantic role overlapping" calculates the degree of lexical overlap between semantic roles of the same type in the machine translation and its reference translation, using simple bag-of-words counting; this is then aggregated into an average over all semantic role types. "Semantic role matching" is just like "semantic role overlapping", except that bag-of-words degree of similarity is replaced (rather harshly) by a boolean indicating whether the role fillers are an exact string match. It is important to note that "semantic role overlapping" and "semantic role matching" both use flat feature based representations which do not capture the structural relations in semantic frames, i.e., the predicate-argument relations.

Like system combination approaches, ULC is a vastly more complex aggregate metric compared to widely used metrics like BLEU or STM. We believe it is important to retain a focus on developing *simpler* metrics which not only correlate well with human adequacy judgments, but nevertheless still directly provide *representational transparency* via simple, clear, and transparent scoring schemes that are (a) easily human readable to support error analysis, and (b) potentially directly usable for automatic credit/blame assignment in tuning tree-structured SMT systems. We also believe that to provide a foundation for better design of efficient automated metrics, making use of *humans* for annotating semantic roles and judging the role translation accuracy in MT output is an essential step that should not be bypassed, in order to adequately understand the upper bounds of such techniques.

We agree with Przybocki *et al.* (2010), who observe in the NIST MetricsMaTr 2008 report that "human [adequacy] assessments only pertain to the translations evaluated, and are of no use even to updated translations from the same systems". Instead, we aim for MT evaluation metrics that provide fine-grained scores in a way that also directly reflects interpretable insights on the strengths and weaknesses of MT systems rather than simply replicating human assessments.

3 MEANT: SRL for MT evaluation

A good translation is one from which human readers may successfully understand at least the basic event structure—"*who* did *what* to *whom*, *when*, *where* and *why*" (Pradhan *et al.*, 2004)—which represents the most essential meaning of the source utterances.

MEANT measures this as follows. First, semantic role labeling is performed (either manually or automatically) on both the reference translation and the machine translation. The semantic frame structures thus obtained for the MT output are compared to those in the reference translations, frame by frame, argument by argument. The frame translation accuracy is a weighted sum of the number of correctly translated arguments. Conceptually, MEANT is defined in terms of f-score, with respect to the precision/recall for sentence translation accuracy as calculated by averaging the translation accuracy for all frames in the MT output across the number of frames in the MT output/reference translations. Details are given below.

3.1 Annotating semantic frames

In designing a semantic MT evaluation metric, one important issue that should be addressed is how to evaluate the similarity of meaning objectively and systematically

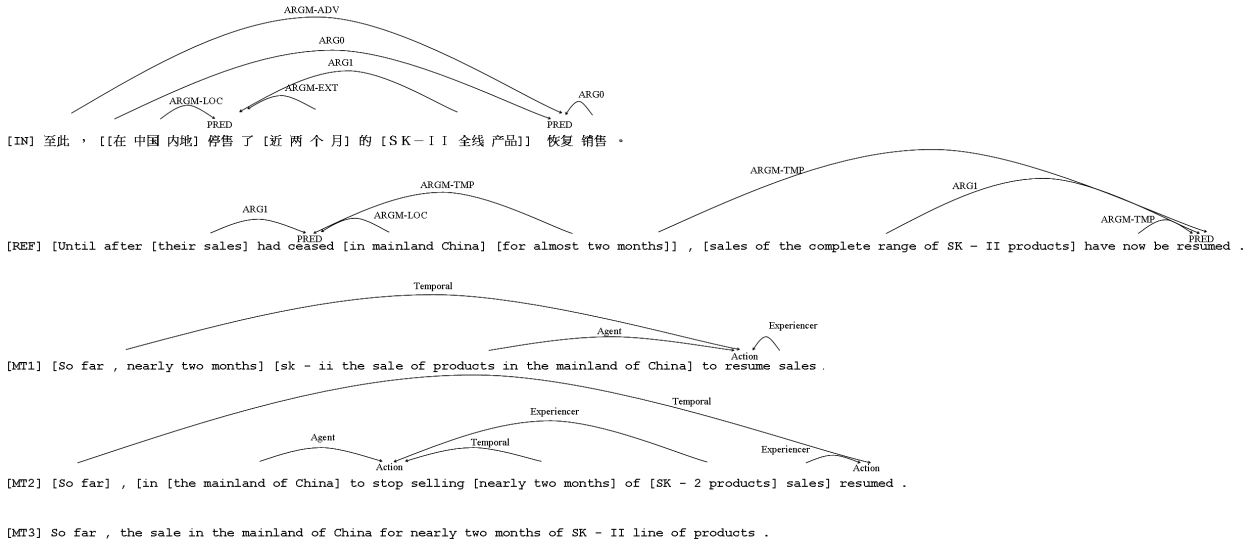

Figure 1: Example of source sentence and reference translation with reconstructed semantic frames in Propbank format and MT output with reconstructed semantic frames by minimal trained human annotators. Following Propbank, there are no semantic frames for MT3 because there is no predicate.

using fine-grained measures. We adopted the Propbank SRL style predicate-argument framework, which captures the basic event structure in a sentence in a way that clearly indicates many strengths and weaknesses of MT. Figure 1 shows the reference translation with reconstructed semantic frames in Propbank format and the corresponding MT output with reconstructed semantic frames by minimal trained human annotators.

3.2 Comparing semantic frames

After annotating the semantic frames, we must determine the translation accuracy for each semantic role filler in the reference and machine translations. Although ultimately it would be nice to do this automatically, it is essential to first understand extremely well the upper bound of accuracy for MT evaluation via semantic frame theory. Thus, instead of resorting to excessively permissive bag-of-words matching or excessively restrictive exact string matching, for the experiments reported here we employed a group of human judges to evaluate the correctness of each role filler translation between the reference and machine translations.

In order to facilitate a finer-grained measurement of utility, the human judges were not only allowed to mark each role filler translation as "correct" or "incorrect", but also "partial". Translations of role fillers are judged "correct" if they express the same meaning as that of the reference translations (or the original source input, in the bilinguals experiment discussed later). Translations may also be judged "partial" if only part of the meaning is correctly translated. Extra meaning in a role filler is not penalized unless it belongs in another role. We also assume that a wrongly translated predicate means that the entire semantic frame is incorrect; therefore, the "correct" and "partial" argument counts are collected only if their associated predicate is correctly translated in the first place.

Table 1 shows an example of SRL annotation of MT1 in Figure 1 by one of the annotators, along with the human judgment on translation accuracy of each argument. The predicate ceased in the reference translation did not match with any predicate annotated in MT1, while the predicate resumed matched with the predicate resume annotated in MT1. All arguments of the untranslated ceased are automatically considered incorrect (with no need to consider each argument individually), under our assumption that a wrongly translated predicate causes the entire event frame to be considered mistranslated. The ARGM-TMP argument, Until after their sales had ceased in mainland China for almost two months, in the reference translation is partially translated to ARGM-TMP argument, So far , nearly two months, in MT1. Similar decisions are made for the ARG1 argument and the other ARGM-TMP argument; now in the reference translation is missing in MT1.

3.3 Quantifying semantic frame match

To quantify the above in a summary metric, we define MEANT in terms of an f-score that balances the precision and recall analysis of the comparative matrices collected from the human judges, as follows.

$C_{i,j}$ = # correct fillers of ARG j for PRED i in MT
$P_{i,j}$ = # partial fillers of ARG j for PRED i in MT
$M_{i,j}$ = total # fillers of ARG j for PRED i in MT
$R_{i,j}$ = total # fillers of ARG j of PRED i in REF

Table 1: SRL annotation of MT1 in Figure 1 and the human judgment of translation accuracy for each argument (see text).

SRL	REF	MT1	Decision
PRED (Action)	ceased	–	no match
PRED (Action)	resumed	resume	match
ARG0 (Agent)	–	sk - ii the sale of products in the mainland of China	incorrect
ARG1 (Experiencer)	sales of complete range of SK - II products	sales	partial
ARGM-TMP (Temporal)	Until after , their sales had ceased in mainland China for almost two months	So far , nearly two months	partial
ARGM-TMP (Temporal)	now	–	incorrect

$$C_{\text{precision}} = \sum_{\text{matched i}} \frac{w_{\text{pred}} + \sum_j w_{\text{j}} C_{\text{i,j}}}{w_{\text{pred}} + \sum_j w_{\text{j}} M_{\text{i,j}}}$$

$$C_{\text{recall}} = \sum_{\text{matched i}} \frac{w_{\text{pred}} + \sum_j w_{\text{j}} C_{\text{i,j}}}{w_{\text{pred}} + \sum_j w_{\text{j}} R_{\text{i,j}}}$$

$$P_{\text{precision}} = \sum_{\text{matched i}} \frac{\sum_j w_{\text{j}} P_{\text{i,j}}}{w_{\text{pred}} + \sum_j w_{\text{j}} M_{\text{i,j}}}$$

$$P_{\text{recall}} = \sum_{\text{matched i}} \frac{\sum_j w_{\text{j}} P_{\text{i,j}}}{w_{\text{pred}} + \sum_j w_{\text{j}} R_{\text{i,j}}}$$

$$\text{precision} = \frac{C_{\text{precision}} + (w_{\text{partial}} \times P_{\text{precision}})}{\text{total \# predicates in MT}}$$

$$\text{recall} = \frac{C_{\text{recall}} + (w_{\text{partial}} \times P_{\text{recall}})}{\text{total \# predicates in REF}}$$

$$\text{f-score} = \frac{2 * \text{precision} * \text{recall}}{\text{precision} + \text{recall}}$$

$C_{\text{precision}}$, $P_{\text{precision}}$, C_{recall} and P_{recall} are the sum of the fractional counts of correctly or partially translated semantic frames in the MT output and the reference, respectively, which can be viewed as the true positive for precision and recall of the whole semantic structure in one source utterence. Therefore, the SRL based MT evaluation metric is equivalent to the f-score, i.e., the translation accuracy for the whole predicate-argument structure.

Note that w_{pred}, w_{j} and w_{partial} are the weights for the matched predicate, arguments of type j, and partial translations. These weights can be viewed as the importance of meaning preservation for each different category of semantic roles, and the penalty for partial translations. We will describe below how these weights are estimated.

If all the reconstructed semantic frames in the MT output are completely identical to those annotated in the reference translation, and all the arguments in the reconstructed frames express the same meaning as the corresponding arguments in the reference translations, then the f-score will be equal to 1.

For instance, consider MT1 in Figure 1. The number of frames in MT1 and the reference translation are 1 and 2, respectively. The total number of participants (including both predicates and arguments) of the resume frame in both MT1 and the reference translation is 4 (one predicate and three arguments), with 2 of the arguments (one ARG1/experiencer and one ARGM-TMP/temporal) only partially translated. Assuming for now that the metric aggregates ten types of semantic roles with uniform weight for each role (optimization of weights will be discussed later), then $w_{\text{pred}} = w_j = 0.1$, and so $C_{\text{precision}}$ and C_{recall} are both zero while $P_{\text{precision}}$ and $P_{\text{recall}}$are both 0.5. If we further assume that $w_{\text{partial}} = 0.5$, then precison and recall are 0.25 and 0.125 respectively. Thus the f-score for this example is 0.17.

Both human and semi-automatic variants of the MEANT translation evaluation metric were meta-evaluated, as described next.

4 Meta-evaluation methodology

4.1 Evaluation Corpus

We leverage work from Phase 2.5 of the DARPA GALE program in which both a subset of the Chinese source sentences, as well as their English reference, are being annotated with semantic role labels in Propbank style. The corpus also includes three participating state-of-the-art MT systems' output. For present purposes, we randomly drew 40 sentences from the newswire genre of the corpus to form a meta-evaluation corpus. To maintain a controlled environment for experiments and consistent comparison, the evaluation corpus is fixed throughout this work.

4.2 Correlation with human judgements on adequacy

We followed the benchmark assessment procedure in WMT and NIST MetricsMaTr (Callison-Burch *et al.*, 2008, 2010), assessing the performance of the proposed evaluation metric at the sentence level using ranking preference consistency, which also known as Kendall's τ rank correlation coefficient, to evaluate the correlation of the proposed metric with human judgments on translation adequacy ranking. A higher value for τ indicates more similarity to the ranking by the evaluation metric to the human judgment. The range of possible values of correlation coefficient is [-1,1], where 1 means the systems are ranked

Table 2: List of semantic roles that human judges are requested to label.

Label	Event	Label	Event
Agent	who	Location	where
Action	did	Purpose	why
Experiencer	what	Manner	how
Patient	whom	Degree or Extent	how
Temporal	when	Other adverbial arg.	how

in the same order as the human judgment and -1 means the systems are ranked in the reverse order as the human judgment.

5 Experiment: Using human SRL

The first experiment aims to provide a more concrete understanding of one of the key questions as to the upper bounds of the proposed evaluation metric: how well can human annotators perform in reconstructing the semantic frames in MT output? This is important since MT output is still not close to perfectly grammatical for a good syntactic parsing—applying automatic shallow semantic parsers, which are trained on grammatical input and valid syntactic parse trees, on MT output may significantly underestimate translation utility.

5.1 Experimental setup

We thus introduce HMEANT, a variant of MEANT based on the idea that semantic role labeling can be simplified into a task that is easy and fast even for untrained humans. The human annotators are given only very simple instructions of less than half a page, along with two examples. Table 2 shows the list of labels annotators are requested to annotate, where the semantic role labeling instructions are given in the intuitive terms of "who did what to whom, when, where, why and how". To facilitate the inter-annotator agreement experiments discussed later, each sentence is independently assigned to at least two annotators.

After calculating the SRL scores based on the confusion matrix collected from the annotation and evaluation, we estimate the weights using grid search to optimize correlation with human adequacy judgments.

5.2 Results: Correlation with human judgement

Table 3 shows results indicating that HMEANT correlates with human judgment on adequacy as well as HTER does (0.432), and is far superior to BLEU (0.198) or other surface-oriented metrics.

Inspection of the cross validation results shown in Table 4 indicates that the estimated weights are not overfitting. Recall that the weights used in HMEANT are globally estimated (by grid search) using the evaluation corpus. To analyze stability, the corpus is also partitioned randomly into four folds of equal size. For each fold, another grid search is also run. R_{HMEANT} is the rank at which the Kendall's correlation for HMEANT is found, if the Kendall's correlations for all points in the grid search space are sorted. Many similar weight-vectors produce the same Kendall's correlation score, so "distinct R" shows how many distinct Kendall's correlation scores exist in each case—between 16 and 29. HMEANT's weight settings always produce Kendall's correlation scores among the top 5, regardless of which fold is chosen, indicating good stability of HMEANT's weight-vector.

Table 3: Sentence-level correlation with human adequacy judgments, across the evaluation metrics.

Metrics	Kendall τ
HMEANT	**0.4324**
HTER	**0.4324**
NIST	0.2883
BLEU	0.1982
METEOR	0.1982
TER	0.1982
PER	0.1982
CDER	0.1171
WER	0.0991

Table 4: Analysis of stability for HMEANT's weight settings, with R_{HMEANT} rank and Kendall's τ correlation scores (see text).

	Fold 0	Fold 1	Fold 2	Fold 3
R_{HMEANT}	3	1	3	5
distinct R	16	29	19	17
τ_{HMEANT}	0.33	0.48	0.48	0.40
τ_{HTER}	0.59	0.41	0.44	0.30
τ_{CV} train	0.45	0.42	0.40	0.43
τ_{CV} test	0.33	0.37	0.48	0.40

Next, Kendall's τ correlation scores are shown for HMEANT on each fold. They vary from 0.33 to 0.48, and are at least as stable as those shown for HTER, where τ varies from 0.30 to 0.59.

Finally, τ_{CV} shows Kendall's correlations if the weight-vector is instead subjected to full cross-validation training and testing, again demonstrating good stability. In fact, the correlations for the training set in three of the folds (0, 2, and 3) are identical to those for HMEANT.

5.3 Results: Cost of evaluating

The time needed for training non-expert humans to carry out our annotation protocol is significantly less than HTER and gold standard Propbank annotation. The half-page instructions given to annotators required only between 5 to 15 minutes for all annotators, including time

for asking questions if necessary. Aside from providing two annotated examples, no further training was given.

Similarly, the time needed for running the evaluation metric is also significantly less than HTER—under at most 5 minutes per sentence, even for non-expert humans using no computer-assisted UI tools. The average time used for annotating each sentence was lower bounded by 2 minutes and upper bounded by 3 minutes, and the time used for determing the translation accuracy of role fillers averaged under 2 minutes.

Note that these figures are for unskilled non-experts. These times tend to diminish significantly after annotators acquire experience.

6 Experiment: Monolinguals vs. bilinguals

We now show that using monolingual annotators is essentially just as effective as using more expensive bilingual annotators. We study the cost/benefit trade-off of using human annotators from different language backgrounds for the proposed evaluation metric, and compare whether providing the original source text helps. Note that this experiment focuses on the SRL annotation step, rather than the judgments of role filler paraphrasing accuracy, because the latter is only a simple three-way decision between "correct", "partial", and "incorrect" that is far less sensitive to the annotators' language backgrounds.

MT output is typically poor. Therefore, readers of MT output often guess the original meaning in the source input using their own language background knowledge. Readers' language background thus affects their understanding of the translation, which could affect the accuracy of capturing the key semantic roles in the translation.

6.1 Experimental Setup

Both English monolinguals and Chinese-English bilinguals (Chinese as first language and English as second language) were employed to annotate the semantic roles. For bilinguals, we also experimented with the difference in guessing constraints by optionally providing the original source input together with the translation. Therefore, there are three variations in the experiment setup: monolinguals seeing translation output only; bilinguals seeing translation output only; and bilinguals seeing both input and output.

The aim here is to do a rough sanity check on the effect of the variation of language background of the annotators; thus for these experiments we have not run the weight estimation step after SRL based f-score calculation. Instead, we simply assigned a uniform weight to all the semantic elements, and evaluated the variation under the same weight settings. (The correlation scores reported in this section are thus expected to be lower than that reported in the last section.)

Table 5: Sentence-level correlation with human adequacy judgments, for monolinguals vs. bilinguals. Uniform rather than optimized weights are used.

Metrics	**Kendall τ**
HMEANT - bilinguals	0.3514
HMEANT - monolinguals	0.3153
HMEANT - bilinguals with input	0.3153

6.2 Results

Table 5 of our results shows that using more expensive bilinguals for SRL annotation instead of monolinguals improves the correlation only slightly. The correlation coefficient of the SRL based evaluation metric driven by bilingual human annotators (0.351) is slightly better than that driven by monolingual human annotators (0.315); however, using bilinguals in the evaluation process is more costly than using monolinguals.

The results show that even allowing the bilinguals to see the input as well as the translation output for SRL annotation does not help the correlation. The correlation coefficient of the SRL based evaluation metric driven by bilingual human annotators who see also the source input sentences is 0.315 which is the same as that driven by monolingual human annotators. We find that the correlation coefficient of the proposed with human judgment on adequacy drops when bilinguals are shown to the source input sentence during annotation. Error analyses lead us to believe that annotators will drop some parts of the meaning in the translations when trying to align them to the source input.

This suggests that HMEANT requires only monolingual English annotators, who can be employed at low cost.

7 Inter-annotator agreement

One of the concerns of the proposed metric is that, given only minimal training on the task, humans would annotate the semantic roles so inconsistently as to reduce the reliability of the evaluation metric. Inter-annotator agreement (IAA) measures the consistency of human in performing the annotation task. A high IAA suggests that the annotation is consistent and the evaluation results are reliable and reproducible.

To obtain a clear analysis on where any inconsistency might lie, we measured IAA in two steps: role identification and role classification.

7.1 Experimental setup

Role identification Since annotators are not consistent in handling articles or punctuation at the beginning or the end of the annotated arguments, the agreement of semantic role identification is counted over the matching of

Table 6: Inter-annotator agreement rate on role identification (matching of word span)

Experiments	REF	MT
bilinguals working on output only	76%	72%
monolinguals working on output only	93%	75%
bilinguals working on input-output	75%	73%

Table 7: Inter-annotator agreement rate on role classification (matching of role label associated with matched word span)

Experiments	Ref	MT
bilinguals working on output only	69%	65%
monolinguals working on output only	88%	70%
bilinguals working on input-output	70%	69%

word span in the annotated role fillers with a tolerance of ±1 word in mismatch. The inter-annotator agreement rate (IAA) on the role identification task is calculated as follows. A_1 and A_2 denote the number of annotated predicates and arguments by annotator 1 and annotator 2 respectively. M_{span} denotes the number of annotated predicates and arguments with matching word span between annotators.

$$P_{\text{identification}} = \frac{M_{\text{span}}}{A_1}$$
$$R_{\text{identification}} = \frac{M_{\text{span}}}{A_2}$$
$$\text{IAA}_{\text{identification}} = \frac{2 * P_{\text{identification}} * R_{\text{identification}}}{P_{\text{identification}} + R_{\text{identification}}}$$

Role classification The agreement of classified roles is counted over the matching of the semantic role labels within two aligned word spans. The IAA on the role classification task is calculated as follows. M_{label} denotes the number of annotated predicates and arguments with matching role label between annotators.

$$P_{\text{classification}} = \frac{M_{\text{label}}}{A_1}$$
$$R_{\text{classification}} = \frac{M_{\text{label}}}{A_2}$$
$$\text{IAA}_{\text{classification}} = \frac{2 * P_{\text{classification}} * R_{\text{classification}}}{P_{\text{classification}} + R_{\text{classification}}}$$

7.2 Results

The high inter-annotator agreement suggests that the annotation instructions provided to the annotators are in general sufficient and the evaluation is repeatable and could be automated in the future. Table 6 and 7 show the annotators reconstructed the semantic frames quite consistently, even they were given only simple and minimal training.

We have noticed that the agreement on role identification is higher than that on role classification. This suggests that there are role confusion errors among the annotators. We expect a slightly more detailed instructions and explanations on different roles will further improve the IAA on role classification.

The results also show that monolinguals seeing output only have the highest IAA in semantic frame reconstruction. Data analyses lead us to believe the monolinguals are the most constrained group in the experiments. The monolingual annotators can only guess the meaning in the MT output using their English language knowledge. Therefore, they all understand the translation almost the same way, even if the translation is incorrect.

On the other hand, bilinguals seeing both the input and output discover the mistranslated portions, and often unconsciously try to compensate by re-interpreting the MT output with information not necessarily appearing in the translation, in order to better annotate what they think it should have conveyed. Since there are many degrees of freedom in this sort of compensatory re-interpretation, this group achieved a lower IAA than the monolinguals.

Bilinguals seeing only output appear to take this even a step further: confronted with a poor translation, they often unconsciously try to guess what the original input might have been. Consequently, they agree the least, because they have the most freedom in applying their own knowledge of the unseen input language, when compensating for poor translations.

8 Experiment: Using automatic SRL

In the previous experiment, we showed that the proposed evaluation metric driven by human semantic role annotators performed as well as HTER. It is now worth asking a deeper question: can we further reduce the labor cost of MEANT by using automatic shallow semantic parsing instead of humans for semantic role labeling?

Note that this experiment focuses on understanding the cost/benefit trade-off for the semantic frame reconstruction step. For SRL annotation, we replace humans with automatic shallow semantic parsing. We decouple this from the ternary judgments of role filler accuracy, which are still made by humans. However, we believe the evaluation of role filler accuracy will also be automatable.

8.1 Experimental setup

We performed three variations of the experiments to assess the performance degradation from the automatic approximation of semantic frame reconstruction in each translation (reference translation and MT output): we applied automatic shallow semantic parsing on the MT output only; on the reference translation only; and on both reference translation and MT output. For the semantic

Table 8: Sentence-level correlation with human adequacy judgments. *The weights for individual roles in the metric are tuned by optimizing the correlation.

Metrics	Kendall τ
HTER	0.4324

BLEU / METEOR / TER / PER	0.1982
CDER	0.1171
WER	0.0991

parser, we used ASSERT (Pradhan *et al.*, 2004) which achieves roughly 87% semantic role labeling accuracy.

8.2 Results

Table 8 shows that the proposed SRL based evaluation metric correlates slightly worse than HTER with a much lower labor cost. The correlation with human judgment on adequacy of the fully automated SRL annotation version, i.e., applying ASSERT on both the reference translation and the MT output, of the SRL based evaluation metric is about 80% of that of HTER. The results also show that the correlation with human judgment on adequacy of either one side of translation using automatic SRL is in the 85% to 95% range of that HTER.

9 Conclusion

We have presented MEANT, a novel semantic MT evaluation metric that assesses the translation accuracy via Propbank-style semantic predicates, roles, and fillers. MEANT provides an intuitive picture on how much information is correctly translated in the MT output.

MEANT can be run using inexpensive untrained monolinguals and yet correlates with human judgments on adequacy as well as HTER with a lower labor cost. In contrast to HTER, which requires rigorous training of human experts to find a minimum edit of the translation (an exponentially large search space), MEANT requires untrained humans to make well-defined, bounded decisions on annotating semantic roles and judging translation correctness. The process by which MEANT reconstructs the semantic frames in a translation and then judges translation correctness of the role fillers conceptually models how humans read and understand translation output.

We also showed that using automatic shallow semantic parser to further reduce the labor cost of the proposed metric successfully approximates roughly 80% of the correlation with human judgment on adequacy. The results suggest future potential for a fully automatic variant of MEANT that could out-perform current automatic MT evaluation metrics and still perform near the level of HTER.

Numerous intriguing questions arise from this work. A further investigation into the correlation of each of the individual roles to human adequacy judgments is detailed elsewhere, along with additional improvements to the MEANT family of metrics (Lo and Wu, 2011). Another interesting investigation would then be to similarly replicate this analysis of the impact of each individual role, but using automatically rather than manually labeled semantic roles, in order to ascertain whether the more difficult semantic roles for automatic semantic parsers might also correspond to the less important aspects of end-to-end MT utility.

An exponential translation model for target language morphology

Michael Subotin
Paxfire, Inc.
Department of Linguistics & UMIACS, University of Maryland
msubotin@gmail.com

Abstract

This paper presents an exponential model for translation into highly inflected languages which can be scaled to very large datasets. As in other recent proposals, it predicts target-side phrases and can be conditioned on source-side context. However, crucially for the task of modeling morphological generalizations, it estimates feature parameters from the entire training set rather than as a collection of separate classifiers. We apply it to English-Czech translation, using a variety of features capturing potential predictors for case, number, and gender, and one of the largest publicly available parallel data sets. We also describe generation and modeling of inflected forms unobserved in training data and decoding procedures for a model with non-local target-side feature dependencies.

1 Introduction

Translation into languages with rich morphology presents special challenges for phrase-based methods. Thus, Birch et al (2008) find that translation quality achieved by a popular phrase-based system correlates significantly with a measure of target-side, but not source-side morphological complexity. Recently, several studies (Bojar, 2007; Avramidis and Koehn, 2009; Ramanathan et al., 2009; Yeniterzi and Oflazer, 2010) proposed modeling target-side morphology in a phrase-based factored models framework (Koehn and Hoang, 2007). Under this approach linguistic annotation of source sentences is analyzed using heuristics to identify relevant structural phenomena, whose occurrences are in turn used to compute additional relative frequency (maximum likelihood) estimates predicting target-side inflections. This approach makes it difficult to handle the complex interplay between different predictors for inflections. For example, the accusative case is usually preserved in translation, so that nouns appearing in the direct object position of English clauses tend to be translated to words with accusative case markings in languages with richer morphology, and vice versa. However, there are exceptions. For example, some verbs that place their object in the accusative case in Czech may be rendered as prepositional constructions in English (Naughton, 2005):

David was looking for Jana
David hledal Janu
David searched Jana-ACC

Conversely, direct objects of some English verbs can be translated by nouns with genitive case markings in Czech:

David asked Jana where Karel was
David zeptal se Jany kde je Karel
David asked SELF Jana-GEN where is Karel

Furthermore, English noun modifiers are often rendered by Czech possessive adjectives and a verbal complement in one language is commonly translated by a nominalizing complement in another language, so that the part of speech (POS) of its head need not be preserved. These complications make it difficult to model morphological phenomena using

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 230–238,
Portland, Oregon, June 19-24, 2011.

closed-form estimates. This paper presents an alternative approach based on exponential phrase models, which can straightforwardly handle feature sets with arbitrarily elaborate source-side dependencies.

2 Hierarchical phrase-based translation

We take as our starting point David Chiang's Hiero system, which generalizes phrase-based translation to substrings with gaps (Chiang, 2007). Consider for instance the following set of context-free rules with a single non-terminal symbol:

$\langle A\,,\, A\rangle \rightarrow \langle A_1\, A_2\,,\, A_1\, A_2\rangle$
$\langle A\,,\, A\rangle \rightarrow \langle\ d'\, A_1\, idées\, A_2\,,\, A_1\, A_2\, ideas\rangle$
$\langle A\,,\, A\rangle \rightarrow \langle incolores\,,\, colorless\rangle$
$\langle A\,,\, A\rangle \rightarrow \langle vertes\,,\, green\rangle$
$\langle A\,,\, A\rangle \rightarrow \langle dorment\, A\,,\, sleep\, A\rangle$
$\langle A\,,\, A\rangle \rightarrow \langle furieusement\,,\, furiously\rangle$

It is one of many rule sets that would suffice to generate the English translation 1b for the French sentence 1a.

1a. *d' incolores idées vertes dorment furieusement*
1b. *colorless green ideas sleep furiously*

As shown by Chiang (2007), a weighted grammar of this form can be collected and scored by simple extensions of standard methods for phrase-based translation and efficiently combined with a language model in a CKY decoder to achieve large improvements over a state-of-the-art phrase-based system. The translation is chosen to be the target-side yield of the highest-scoring synchronous parse consistent with the source sentence. Although a variety of scores interpolated into the decision rule for phrase-based systems have been investigated over the years, only a handful have been discovered to be consistently useful. In this work we concentrate on extending the target-given-source phrase model[1].

3 Exponential phrase models with shared features

The model used in this work is based on the familiar equation for conditional exponential models:

$$p(Y|X) = \frac{e^{\vec{w}\cdot\vec{f}(X,Y)}}{\sum_{Y'\in GEN(X)} e^{\vec{w}\cdot\vec{f}(X,Y')}}$$

where $\vec{f}(X,Y)$ is a vector of feature functions, $\vec{w}$ is a corresponding weight vector, so that $\vec{w}\cdot\vec{f}(X,Y) = \sum_i w_i f_i(X,Y)$, and $GEN(X)$ is a set of values corresponding to Y. For a target-given-source phrase model the predicted outcomes are target-side phrases r^y, the model is conditioned on a source-side phrase r^x together with some context, and each $GEN(X)$ consists of target phrases r^y co-occurring with a given source phrase r^x in the grammar.

Maximum likelihood estimation for exponential model finds the values of weights that maximize the likelihood of the training data, or, equivalently, its logarithm:

$$LL(\vec{w}) = \log \prod_{m=1}^{M} p(Y_m|X_m) = \sum_{m=1}^{M} \log\, p(Y_m|X_m)$$

where the expressions range over all training instances $\{m\}$. In this work we extend the objective using an ℓ_2 regularizer (Ng, 2004; Gao et al., 2007). We obtain the counts of instances and features from the standard heuristics used to extract the grammar from a word-aligned parallel corpus.

Exponential models and other classifiers have been used in several recent studies to condition phrase model probabilities on source-side context (Chan et al 2007; Carpuat and Wu 2007a; Carpuat and Wu 2007b). However, this has been generally accomplished by training independent classifiers associated with different source phrases. This approach is not well suited to modeling target-language inflections, since parameters for the features associated with morphological markings and their predictors would be estimated separately from many, generally very small training sets, thereby preventing the model from making precisely the kind of generalization beyond specific phrases that we seek to obtain. Instead we continue the approach proposed in Subotin (2008), where a single model defined by the equations above is trained on all of the data, so that parameters for features that are shared by rule sets with difference source sides reflect cumulative feature counts, while the standard relative

[1]To avoid confusion with features of the exponential models described below we shall use the term "model" rather than "feature" for the terms interpolated using MERT.

frequency model can be obtained as a special case of maximum likelihood estimation for a model containing only the features for rules.[2] Recently, Jeong et al (2010) independently proposed an exponential model with shared features for target-side morphology in application to lexical scores in a treelet-based system.

4 Features

The feature space for target-side inflection models used in this work consists of features tracking the source phrase and the corresponding target phrase together with its complete morphological tag, which will be referred to as *rule features* for brevity. The feature space also includes features tracking the source phrase together with the lemmatized representation of the target phrase, called *lemma features* below. Since there is little ambiguity in lemmatization for Czech, the lemma representations were for simplicity based on the most frequent lemma for each token. Finally, we include features associating aspects of source-side annotation with inflections of aligned target words. The models include features for three general classes of morphological types: number, case, and gender. We add inflection features for all words aligned to at least one English verb, adjective, noun, pronoun, or determiner, excepting definite and indefinite articles. A separate feature type marks cases where an intended inflection category is not applicable to a target word falling under these criteria due to a POS mismatch between aligned words.

4.1 Number

The inflection for number is particularly easy to model in translating from English, since it is generally marked on the source side, and POS taggers based on the Penn treebank tag set attempt to infer it in cases where it is not. For word pairs whose source-side word is a verb, we add a feature marking the number of its subject, with separate features for noun and pronoun subjects. For word pairs whose source side is an adjective, we add a feature marking the number of the head of the smallest noun phrase that contains it.

[2]Note that this model is estimated from the *full* parallel corpus, rather than a held-out development set.

4.2 Case

Among the inflection types of Czech nouns, the only type that is not generally observed in English and does not belong to derivational morphology is inflection for case. Czech marks seven cases: nominal, genitive, dative, accusative, vocative, locative, and instrumental. Not all of these forms are overtly distinguished for all lexical items, and some words that function syntactically as nouns do not inflect at all. Czech adjectives also inflect for case and their case has to match the case of their governing noun. However, since the source sentence and its annotation contain a variety of predictors for case, we model it using only source-dependent features. The following feature types for case were included:

- The structural role of the aligned source word or the head of the smallest noun phrase containing the aligned source word. Features were included for the roles of subject, direct object, and nominal predicate.
- The preposition governing the smallest noun phrase containing the aligned source word, if it is governed by a preposition.
- An indicator for the presence of a possessive marker modifying the aligned source word or the head of the smallest noun phrase containing the aligned source word.
- An indicator for the presence of a numeral modifying the aligned source word or the head of the smallest noun phrase containing the aligned source word.
- An indication that aligned source word modified by quantifiers *many*, *most*, *such*, or *half*. These features would be more properly defined based on the identity of the target word aligned to these quantifiers, but little ambiguity seems to arise from this substitution in practice.
- The lemma of the verb governing the aligned source word or the head of the smallest noun phrase containing the aligned source word. This is the only lexicalized feature type used in the model and we include only those features which occur over 1,000 times in the training data.

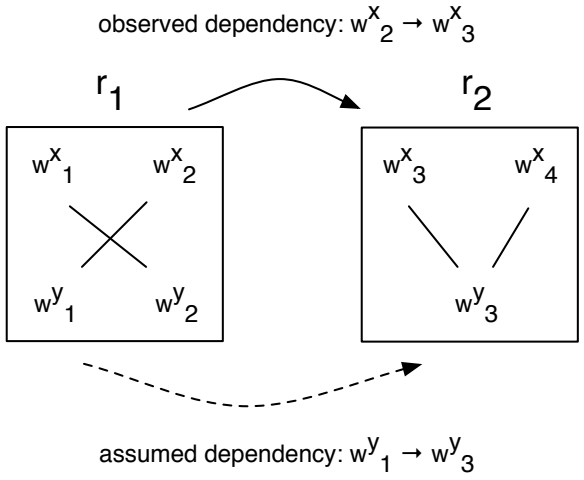

Figure 1: Inferring syntactic dependencies.

Features corresponding to aspects of the source word itself and features corresponding to aspects of the head of a noun phrase containing it were treated as separate types.

4.3 Gender

Czech nouns belong to one of three cases: feminine, masculine, and neuter. Verbs and adjectives have to agree with nouns for gender, although this agreement is not marked in some forms of the verb. In contrast to number and case, Czech gender generally cannot be predicted from any aspect of the English source sentence, which necessitates the use of features that depend on another target-side word. This, in turn, requires a more elaborate decoding procedure, described in the next section. For verbs we add a feature associating the gender of the verb with the gender of its subject. For adjectives, we add a feature tracking the gender of the governing nouns. These dependencies are inferred from source-side annotation via word alignments, as depicted in figure 1, without any use of target-side dependency parses.

5 Decoding with target-side model dependencies

The procedure for decoding with non-local target-side feature dependencies is similar in its general outlines to the standard method of decoding with a language model, as described in Chiang (2007). The search space is organized into arrays called *charts*, each containing a set of items whose scores can be compared with one another for the purposes of pruning. Each rule that has matched the source sentence belongs to a *rule chart* associated with its location-anchored sequence of non-terminal and terminal source-side symbols and any of its aspects which may affect the score of a translation hypothesis when it is combined with another rule. In the case of the language model these aspects include any of its target-side words that are part of still incomplete n-grams. In the case of non-local target-side dependencies this includes any information about features needed for this rule's estimate and tracking some target-side inflection beyond it or features tracking target-side inflections within this rule and needed for computation of another rule's estimate. We shall refer to both these types of information as *messages*, alluding to the fact that it will need to be conveyed to another point in the derivation to finish the computation. Thus, a rule chart for a rule with one non-terminal can be denoted as as $\left\langle x_{i+1}^{i_1} A x_{j_1+1}^{j}, \mu \right\rangle$, where we have introduced the symbol μ to represent the set of messages associated with a given item in the chart. Each item in the chart is associated with a score s, based on any submodels and heuristic estimates that can already be computed for that item and used to arrange the chart items into a priority queue. Combinations of one or more rules that span a substring of terminals are arranged into a different type of chart which we shall call *span charts*. A span chart has the form $[i_1, j_1; \mu_1]$, where μ_1 is a set of messages, and its items are likewise prioritized by a partial score s_1.

The decoding procedure used in this work is based on the *cube pruning* method, fully described in Chiang (2007). Informally, whenever a rule chart is combined with one or more span charts corresponding to its non-terminals, we select best-scoring items from each chart and update derivation scores by performing any model computations that become possible once we combine the corresponding items. Crucially, whenever an item in one of the charts crosses a pruning threshold, we discard the rest of that chart's items, even though one of them could generate a better-scoring partial derivation in com-

bination with an item from another chart. It is therefore important to estimate incomplete model scores as well as we can. We estimate these scores by computing exponential models using all features without non-local dependencies.

Schematically, our decoding procedure can be illustrated by three elementary cases. We take the example of computing an estimate for a rule whose only terminal on both sides is a verb and which requires a feature tracking the target-side gender inflection of the subject. We make use of a cache storing all computed numerators and denominators of the exponential model, which makes it easy to recompute an estimate given an additional feature and use the difference between it and the incomplete estimate to update the score of the partial derivation. In the simplest case, illustrated in figure 2, the non-local feature depends on the position within the span of the rule's non-terminal symbol, so that its model estimate can be computed when its rule chart is combined with the span chart for its non-terminal symbol. This is accomplished using a *feature message*, which indicates the gender inflection for the subject and is denoted as $m_f(i)$, where the index i refers to the position of its "recipient". Figure 3 illustrates the case where the non-local feature lies outside the rule's span, but the estimated rule lies inside a non-terminal of the rule which contains the feature dependency. This requires sending a *rule message* $m_r(i)$, which includes information about the estimated rule (which also serves as a pointer to the score cache) and its feature dependency. The final example, shown in figure 4, illustrates the case where both types of messages need to be propagated until we reach a rule chart that spans both ends of the dependency. In this case, the full estimate for a rule is computed while combining charts neither of which corresponds directly to that rule.

A somewhat more formal account of the decoding procedure is given in figure 5, which shows a partial set of inference rules, generally following the formalism used in Chiang (2007), but simplifying it in several ways for brevity. Aside from the notation introduced above, we also make use of two updating functions. The message-updating function $u_m(\mu)$ takes a set of messages and outputs another set that includes those messages $m_r(k)$ and $m_f(k)$ whose destination k lies outside the span i, j of the

chart. The score-updating function $u_s(\mu)$ computes those model estimates which can be completed using a message in the set μ and returns the difference between the new and old scores.

6 Modeling unobserved target inflections

As a consequence of translating into a morphologically rich language, some inflected forms of target words are unobserved in training data and cannot be generated by the decoder under standard phrase-based approaches. Exponential models with shared features provide a straightforward way to estimate probabilities of unobserved inflections. This is accomplished by extending the sets of target phrases $GEN(X)$ over which the model is normalized by including some phrases which have not been observed in the original sets. When additional rule features with these unobserved target phrases are included in the model, their weights will be estimated even though they never appear in the training examples (i.e, in the numerator of their likelihoods).

We generate unobserved morphological variants for target phrases starting from a generation procedure for target words. Morphological variants for words were generated using the ÚFAL MORPHO tool (Kolovratník and Přikryl, 2008). The forms produced by the tool from the lemma of an observed inflected word form were subjected to several restrictions:

- For nouns, generated forms had to match the original form for number.
- For verbs, generated forms had to match the original form for tense and negation.
- For adjectives, generated forms had to match the original form for degree of comparison and negation.
- For pronouns, excepting relative and interrogative pronouns, generated forms had to match the original form for number, case, and gender.
- Non-standard inflection forms for all POS were excluded.

The following criteria were used to select rules for which expanded inflection sets were generated:

- The target phrase had to contain exactly one word for which inflected forms could be generated according to the criteria given above.
- If the target phrase contained prepositions or numerals, they had to be in a position not adjacent to the inflected word. The rationale for this criterion was the tendency of prepositions and numerals to determine the inflection of adjacent words.
- The lemmatized form of the phrase had to account for at least 25% of target phrases extracted for a given source phrase.

The standard relative frequency estimates for the $p(X|Y)$ phrase model and the lexical models do not provide reasonable values for the decoder scores for unobserved rules and words. In contrast, exponential models with surface and lemma features can be straightforwardly trained for all of them. For the experiments described below we trained an exponential model for the $p(Y|X)$ lexical model. For greater speed we estimate the probabilities for the other two models using interpolated Kneser-Ney smoothing (Chen and Goodman, 1998), where the surface form of a rule or an aligned word pair plays to role of a trigram, the pairing of the source surface form with the lemmatized target form plays the role of a bigram, and the source surface form alone plays the role of a unigram.

7 Corpora and baselines

We investigate the models using the 2009 edition of the parallel treebank from ÚFAL (Bojar and Žabokrtský, 2009), containing 8,029,801 sentence pairs from various genres. The corpus comes with automatically generated annotation and a randomized split into training, development, and testing sets. Thus, the annotation for the development and testing sets provides a realistic reflection of what could be obtained for arbitrary source text. The English-side annotation follows the standards of the Penn Treebank and includes dependency parses and structural role labels such as subject and object. The Czech side is labeled with several layers of annotation, of which only the morphological tags and lemmas are used in this study. The Czech tags follow the standards of the Prague Dependency Treebank 2.0.

The impact of the models on translation accuracy was investigated for two experimental conditions:

- Small data set: trained on the news portion of the data, containing 140,191 sentences; development and testing sets containing 1500 sentences of news text each.
- Large data set: trained on all the training data; developing and testing sets each containing 1500 sentences of EU, news, and fiction data in equal portions. The other genres were excluded from the development and testing sets because manual inspection showed them to contain a considerable proportion of non-parallel sentences pairs.

All conditions use word alignments produced by sequential iterations of IBM model 1, HMM, and IBM model 4 in GIZA++, followed by "diag-and" symmetrization (Koehn et al., 2003). Thresholds for phrase extraction and decoder pruning were set to values typical for the baseline system (Chiang, 2007). Unaligned words at the outer edges of rules or gaps were disallowed. A 5-gram language model with modified interpolated Kneser-Ney smoothing (Chen and Goodman, 1998) was trained by the SRILM toolkit (Stolcke, 2002) on a set of 208 million running words of text obtained by combining the monolingual Czech text distributed by the 2010 ACL MT workshop with the Czech portion of the training data. The decision rule was based on the standard log-linear interpolation of several models, with weights tuned by MERT on the development set (Och, 2003). The baselines consisted of the language model, two phrase translation models, two lexical models, and a brevity penalty.

The proposed exponential phrase model contains several modifications relative to a standard phrase model (called *baseline A* below) with potential to improve translation accuracy, including smoothed estimates and estimates incorporating target-side tags. To gain better insight into the role played by different elements of the model, we also tested a second baseline phrase model (baseline B), which attempted to isolate the exponential model itself from auxiliary modifications. Baseline B was different from the experimental condition in using a grammar limited to observed inflections and in replacing the exponential $p(Y|X)$ phrase model by a relative frequency phrase model. It was different from baseline A in computing the frequencies for the $p(Y|X)$ phrase model based on counts of *tagged* target phrases and in using the same smoothed estimates in the other models as were used in the experimental condition.

8 Parameter estimation

Parameter estimation was performed using a modified version of the maximum entropy module from SciPy (Jones et al., 2001) and the LBFGS-B algorithm (Byrd et al., 1995). The objective included an ℓ_2 regularizer with the regularization trade-off set to 1. The amount of training data presented a practical challenge for parameter estimation. Several strategies were pursued to reduce the computational expenses. Following the approach of Mann et al (2009), the training set was split into many approximately equal portions, for which parameters were estimated separately and then averaged for features observed in multiple portions. The sets of target phrases for each source phrase prior to generation of additional inflected variants were truncated by discarding extracted rules which were observed with frequency less than the 200-th most frequent target phrase for that source phrase.

Additional computational challenges remained

due to an important difference between models with shared features and usual phrase models. Features appearing with source phrases found in development and testing data share their weights with features appearing with other source phrases, so that filtering the training set for development and testing data affects the solution. Although there seems to be no reason why this would positively affect translation accuracy, to be methodologically strict we estimate parameters for rule and lemma features without inflection features for larger models, and then combine them with weights for inflection feature estimated from a smaller portion of training data. This should affect model performance negatively, since it precludes learning trade-offs between evidence provided by the different kinds of features, and therefore it gives a conservative assessment of the results that could be obtained at greater computational costs. The large data model used parameters for the inflection features estimated from the small data set. In the runs where exponential models were used they replaced the corresponding baseline phrase translation model.

9 Results and discussion

Table 1 shows the results. Aside from the two baselines described in section 7 and the full exponential model, the table also reports results for an exponential model that excluded gender-based features (and hence non-local target-side dependencies). The highest scores were achieved by the full exponential model, although baseline B produced surprisingly disparate effects for the two data sets. This suggests a complex interplay of the various aspects of the model and training data whose exploration could further improve the scores. Inclusion of gender-based features produced small but consistent improvements. Table 2 shows a summary of the grammars.

We further illustrate general properties of these models using toy examples and the actual parameters estimated from the large data set. Table 3 shows representative rules with two different source sides. The column marked "no infl." shows model estimates computed without inflection features. One can see that for both rule sets the estimated probabilities for rules observed a single time is only slightly higher than probabilities for generated unobserved rules. However, rules with relatively high counts in the second set receive proportionally higher estimates, while the difference between the singleton rule and the most frequent rule in the second set, which was observed 3 times, is smoothed away to an even greater extent. The last two columns show model estimates when various inflection features are included. There is a grammatical match between nominative case for the target word and subject position for the aligned source word and between accusative case for the target word and direct object role for the aligned source word. The other pairings represent grammatical mismatches. One can see that the probabilities for rules leading to correct case matches are considerably higher than the alternatives with incorrect case matches.

Condition	Small set	Large set
Baseline A	0.1964	0.2562

10 Conclusion

This paper has introduced a scalable exponential phrase model for target languages with complex morphology that can be trained on the full parallel corpus. We have showed how it can provide estimates for inflected forms unobserved in the training data and described decoding procedures for features with non-local target-side dependencies. The results suggest that the model should be especially useful for languages with sparser resources, but that performance improvements can be obtained even for a very large parallel corpus.

Bayesian Inference for Zodiac and Other Homophonic Ciphers

Abstract

We introduce a novel Bayesian approach for deciphering complex substitution ciphers. Our method uses a decipherment model which combines information from letter n-gram language models as well as word dictionaries. Bayesian inference is performed on our model using an efficient sampling technique. We evaluate the quality of the Bayesian decipherment output on simple and homophonic letter substitution ciphers and show that unlike a previous approach, our method consistently produces almost 100% accurate decipherments. The new method can be applied on more complex substitution ciphers and we demonstrate its utility by cracking the famous Zodiac-408 cipher in a fully automated fashion, which has never been done before.

1 Introduction

Substitution ciphers have been used widely in the past to encrypt secrets behind messages. These ciphers replace (English) plaintext letters with cipher symbols in order to generate the ciphertext sequence.

There exist many published works on automatic decipherment methods for solving simple letter-substitution ciphers. Many existing methods use dictionary-based attacks employing huge word dictionaries to find plaintext patterns within the ciphertext (Peleg and Rosenfeld, 1979; Ganesan and Sherman, 1993; Jakobsen, 1995; Olson, 2007). Most of these methods are heuristic in nature and search for the best deterministic key during decipherment. Others follow a probabilistic decipherment approach. Knight et al. (2006) use the Expectation Maximization (EM) algorithm (Dempster et al., 1977) to search for the best probabilistic key using letter n-gram models. Ravi and Knight (2008) formulate decipherment as an integer programming problem and provide an exact method to solve simple substitution ciphers by using letter n-gram models along with deterministic key constraints. Corlett and Penn (2010) work with large ciphertexts containing thousands of characters and provide another exact decipherment method using an A* search algorithm. Diaconis (2008) presents an analysis of Markov Chain Monte Carlo (MCMC) sampling algorithms and shows an example application for solving simple substitution ciphers.

Most work in this area has focused on solving simple substitution ciphers. But there are variants of substitution ciphers, such as homophonic ciphers, which display increasing levels of difficulty and present significant challenges for decipherment. The famous Zodiac serial killer used one such cipher system for communication. In 1969, the killer sent a three-part cipher message to newspapers claiming credit for recent shootings and crimes committed near the San Francisco area. The 408-character message (Zodiac-408) was manually decoded by hand in the 1960's. Oranchak (2008) presents a method for solving the Zodiac-408 cipher automatically with a dictionary-based attack using a genetic algorithm. However, his method relies on using plaintext words from the known solution to solve the cipher, which departs from a strict decipherment scenario.

In this paper, we introduce a novel method for

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 239–247,
Portland, Oregon, June 19-24, 2011.

solving substitution ciphers using Bayesian learning. Our novel contributions are as follows:

- We present a new probabilistic decipherment approach using Bayesian inference with sparse priors, which can be used to solve different types of substitution ciphers.
- Our new method combines information from word dictionaries along with letter n-gram models, providing a robust decipherment model which offsets the disadvantages faced by previous approaches.
- We evaluate the Bayesian decipherment output on three different types of substitution ciphers and show that unlike a previous approach, our new method solves all the ciphers completely.
- Using the Bayesian decipherment, we show for the first time a truly automated system that successfully solves the Zodiac-408 cipher.

2 Letter Substitution Ciphers

We use natural language processing techniques to attack letter substitution ciphers. In a letter substitution cipher, every letter p in the natural language (plaintext) sequence is replaced by a cipher token c, according to some substitution key.

For example, an English plaintext

"H E L L O _ W O R L D ..."

may be enciphered as:

"N O E E I _ T I M E L ..."

according to the key:

p: ABCDEFGHIJKLMNOPQRSTUVWXYZ_
c: XYZLOHANBCDEFGIJKMPQRSTUVW_

where, "_" represents the space character (word boundary) in the English and ciphertext messages.

If the recipients of the ciphertext message have the substitution key, they can use it (in reverse) to recover the original plaintext. The sender can encrypt the message using one of many different cipher systems. The particular type of cipher system chosen determines the properties of the key. For example, the substitution key can be deterministic in both the encipherment and decipherment directions as shown in the above example—i.e., there is a 1-to-1 correspondence between the plaintext letters and ciphertext symbols. Other types of keys exhibit nondeterminism either in the encipherment (or decipherment) or both directions.

2.1 Simple Substitution Ciphers

The key used in a simple substitution cipher is deterministic in both the encipherment and decipherment directions, i.e., there is a 1-to-1 mapping between plaintext letters and ciphertext symbols. The example shown earlier depicts how a simple substitution cipher works.

Data: In our experiments, we work with a 414-letter simple substitution cipher. We encrypt an original English plaintext message using a randomly generated simple substitution key to create the ciphertext. During the encipherment process, we preserve spaces between words and use this information for decipherment—i.e., plaintext character "_" maps to ciphertext character "_". Figure 1 (top) shows a portion of the ciphertext along with the original plaintext used to create the cipher.

2.2 Homophonic Ciphers

A homophonic cipher uses a substitution key that maps a plaintext letter to more than one cipher symbol.

For example, the English plaintext:

"H E L L O _ W O R L D ..."

may be enciphered as:

"65 82 51 84 05 _ 60 54 42 51 45 ..."

according to the key:

A: 09 12 33 47 53 67 78 92
B: 48 81
...
E: 14 16 24 44 46 55 57 64 74 82 87
...
L: 51 84
...
Z: 02

Here, "_" represents the space character in both English and ciphertext. Notice the non-determinism involved in the enciphering direction—the English

letter "L" is substituted using different symbols (51, 84) at different positions in the ciphertext.

These ciphers are more complex than simple substitution ciphers. Homophonic ciphers are generated via a non-deterministic encipherment process—the key is 1-to-many in the enciphering direction. The number of potential cipher symbol substitutes for a particular plaintext letter is often proportional to the frequency of that letter in the plaintext language—for example, the English letter "E" is assigned more cipher symbols than "Z". The objective of this is to flatten out the frequency distribution of ciphertext symbols, making a frequency-based cryptanalysis attack difficult.

The substitution key is, however, deterministic in the decipherment direction—each ciphertext symbol maps to a single plaintext letter. Since the ciphertext can contain more than 26 types, we need a larger alphabet system—we use a numeric substitution alphabet in our experiments.

Data: For our decipherment experiments on homophonic ciphers, we use the same 414-letter English plaintext used in Section 2.1. We encrypt this message using a homophonic substitution key (available from *http://www.simonsingh.net/The_Black_Chamber/homophoniccipher.htm*). As before, we preserve spaces between words in the ciphertext. Figure 1 (middle) displays a section of the homophonic cipher (with spaces) and the original plaintext message used in our experiments.

2.3 Homophonic Ciphers without spaces (Zodiac-408 cipher)

In the previous two cipher systems, the word-boundary information was preserved in the cipher. We now consider a more difficult homophonic cipher by removing space characters from the original plaintext.

The English plaintext from the previous example now looks like this:

"HELLOWORLD ..."

and the corresponding ciphertext is:

"65 82 51 84 05 60 54 42 51 45 ..."

Without the word boundary information, typical dictionary-based decipherment attacks fail on such ciphers.

Zodiac-408 cipher: Homophonic ciphers without spaces have been used extensively in the past to encrypt secret messages. One of the most famous homophonic ciphers in history was used by the infamous Zodiac serial killer in the 1960's. The killer sent a series of encrypted messages to newspapers and claimed that solving the ciphers would reveal clues to his identity. The identity of the Zodiac killer remains unknown to date. However, the mystery surrounding this has sparked much interest among cryptanalysis experts and amateur enthusiasts.

The Zodiac messages include two interesting ciphers: (1) a 408-symbol homophonic cipher without spaces (which was solved manually by hand), and (2) a similar looking 340-symbol cipher that has yet to be solved.

Here is a sample of the Zodiac-408 cipher message:

...

and the corresponding section from the original English plaintext message:

I L I K E K I L L I N G P E O P L
E B E C A U S E I T I S S O M U C
H F U N I T I S M O R E F U N T H
A N K I L L I N G W I L D G A M E
I N T H E F O R R E S T B E C A U
S E M A N I S T H E M O S T D A N
G E R O U E A N A M A L O F A L L
T O K I L L S O M E T H I N G G I

...

Besides the difficulty with missing word boundaries and non-determinism associated with the key, the Zodiac-408 cipher poses several additional challenges which makes it harder to solve than any standard homophonic cipher. There are spelling mistakes in the original message (for example, the English word "PARADISE" is misspelt as

"PARADICE") which can divert a dictionary-based attack. Also, the last 18 characters of the plaintext message does not seem to make any sense ("EBEORIETEMETHHPITI").

Data: Figure 1 (bottom) displays the Zodiac-408 cipher (consisting of 408 tokens, 54 symbol types) along with the original plaintext message. We run the new decipherment method (described in Section 3.1) and show that our approach can successfully solve the Zodiac-408 cipher.

3 Decipherment

Given a ciphertext message $c_1...c_n$, the goal of decipherment is to uncover the hidden plaintext message $p_1...p_n$. The size of the keyspace (i.e., number of possible key mappings) that we have to navigate during decipherment is huge—a simple substitution cipher has a keyspace size of 26!, whereas a homophonic cipher such as the Zodiac-408 cipher has 26^{54} possible key mappings.

Next, we describe a new Bayesian decipherment approach for tackling substitution ciphers.

3.1 Bayesian Decipherment

Bayesian inference methods have become popular in natural language processing (Goldwater and Griffiths, 2007; Finkel et al., 2005; Blunsom et al., 2009; Chiang et al., 2010). Snyder et al. (2010) proposed a Bayesian approach in an archaeological decipherment scenario. These methods are attractive for their ability to manage uncertainty about model parameters and allow one to incorporate prior knowledge during inference. A common phenomenon observed while modeling natural language problems is *sparsity*. For simple letter substitution ciphers, the original substitution key exhibits a 1-to-1 correspondence between the plaintext letters and cipher types. It is not easy to model such information using conventional methods like EM. But we can easily specify priors that favor sparse distributions within the Bayesian framework.

Here, we propose a novel approach for deciphering substitution ciphers using Bayesian inference. Rather than enumerating all possible keys (26! for a simple substitution cipher), our Bayesian framework requires us to sample only a small number of keys during the decipherment process.

Probabilistic Decipherment: Our decipherment method follows a noisy-channel approach. We are faced with a ciphertext sequence $c = c_1...c_n$ and we want to find the (English) letter sequence $p = p_1...p_n$ that maximizes the probability $P(p|c)$.

We first formulate a generative story to model the process by which the ciphertext sequence is generated.

1. Generate an English plaintext sequence $p = p_1...p_n$, with probability $P(p)$.
2. Substitute each plaintext letter p_i with a ciphertext token c_i, with probability $P(c_i|p_i)$ in order to generate the ciphertext sequence $c = c_1...c_n$.

We build a statistical English language model (LM) for the plaintext source model $P(p)$, which assigns a probability to any English letter sequence. Our goal is to estimate the channel model parameters θ in order to maximize the probability of the observed ciphertext c:

$$\arg\max_{\theta} P(c) = \arg\max_{\theta} \sum_{p} P_\theta(p, c) \quad (1)$$

$$= \arg\max_{\theta} \sum_{p} P(p) \cdot P_\theta(c|p) \quad (2)$$

$$= \arg\max_{\theta} \sum_{p} P(p) \cdot \prod_{i=1}^{n} P_\theta(c_i|p_i) \quad (3)$$

We estimate the parameters θ using Bayesian learning. In our decipherment framework, a Chinese Restaurant Process formulation is used to model both the source and channel. The detailed generative story using CRPs is shown below:

1. $i \leftarrow 1$
2. Generate the English plaintext letter p_1, with probability $P_0(p_1)$
3. Substitute p_1 with cipher token c_1, with probability $P_0(c_1|p_1)$
4. $i \leftarrow i + 1$
5. Generate English plaintext letter p_i, with probability

$$\frac{\alpha \cdot P_0(p_i|p_{i-1}) + C_1^{i-1}(p_{i-1}, p_i)}{\alpha + C_1^{i-1}(p_{i-1})}$$

Figure 1: Samples from the ciphertext sequence, corresponding English plaintext message and output from Bayesian decipherment (using word+3-gram LM) for three different ciphers: (a) Simple Substitution Cipher (top), (b) Homophonic Substitution Cipher with spaces (middle), and (c) Zodiac-408 Cipher (bottom).

6. Substitute p_i with cipher token c_i, with probability

$$\frac{\beta \cdot P_0(c_i|p_i) + C_1^{i-1}(p_i, c_i)}{\beta + C_1^{i-1}(p_i)}$$

7. With probability P_{quit}, quit; else go to Step 4.

This defines the probability of any given derivation, i.e., any plaintext hypothesis corresponding to the given ciphertext sequence. The base distribution P_0 represents prior knowledge about the model parameter distributions. For the plaintext source model, we use probabilities from an English language model and for the channel model, we specify a uniform distribution (i.e., a plaintext letter can be substituted with any given cipher type with equal probability). C_1^{i-1} represents the count of events occurring before plaintext letter p_i in the derivation (we call this the "cache"). α and β represent Dirichlet prior hyperparameters over the source and channel models respectively. A large prior value implies that characters are generated from the base distribution P_0, whereas a smaller value biases characters to be generated with reference to previous decisions inside the cache (favoring sparser distributions).

Efficient inference via type sampling: We use a Gibbs sampling (Geman and Geman, 1984) method for performing inference on our model. We could follow a point-wise sampling strategy, where we sample plaintext letter choices for every cipher token, one at a time. But we already know that the substitution ciphers described here exhibit determinism in the deciphering direction,[1] i.e., although we have no idea about the key mappings themselves, we do know that there exists only a single plaintext letter mapping for every cipher symbol type in the true key. So sampling plaintext choices for every cipher token separately is not an efficient strategy—our sampler may spend too much time exploring invalid keys (which map the same cipher symbol to different plaintext letters).

Instead, we use a *type sampling* technique similar to the one proposed by Liang et al. (2010). Under this scheme, we sample plaintext letter choices for each cipher symbol type. In every step, we sample a new plaintext letter for a cipher type and update the entire plaintext hypothesis (i.e., plaintext letters at all corresponding positions) to reflect this change. For example, if we sample a new choice p_{new} for a cipher symbol which occurs at positions $4, 10, 18$, then we update plaintext letters p_4, p_{10} and p_{18} with the new choice p_{new}.

Using the property of exchangeability, we derive an incremental formula for re-scoring the probability of a new derivation based on the probability of the old derivation—when sampling at position i, we pretend that the area affected (within a context window around i) in the current plaintext hypothesis occurs at the end of the corpus, so that both the old and new derivations share the same cache.[2] While we may make corpus-wide changes to a derivation in every sampling step, exchangeability allows us to perform scoring in an efficient manner.

Combining letter n-gram language models with word dictionaries: Many existing probabilistic approaches use statistical letter n-gram language models of English to assign $P(p)$ probabilities to plaintext hypotheses during decipherment. Other decryption techniques rely on word dictionaries (using words from an English dictionary) for attacking substitution ciphers.

Unlike previous approaches, our decipherment method combines information from both sources—letter n-grams and word dictionaries. We build an interpolated *word+n-gram* LM and use it to assign $P(p)$ probabilities to any plaintext letter sequence $p_1 ... p_n$.[3] The advantage is that it helps direct the sampler towards plaintext hypotheses that resemble natural language—high probability letter sequences which form valid words such as "H E L L O" instead of sequences like "T X H R T". But in addition to this, using letter n-gram information makes

[1] This assumption does not strictly apply to the Zodiac-408 cipher where a few cipher symbols exhibit non-determinism in the decipherment direction as well.

[2] The relevant context window that is affected when sampling at position i is determined by the word boundaries to the left and right of i.

[3] We set the interpolation weights for the word and n-gram LM as (0.9, 0.1). The word-based LM is constructed from a dictionary consisting of 9,881 frequently occurring words collected from Wikipedia articles. We train the letter n-gram LM on 50 million words of English text available from the Linguistic Data Consortium.

our model robust against variations in the original plaintext (for example, unseen words or misspellings as in the case of Zodiac-408 cipher) which can easily throw off dictionary-based attacks. Also, it is hard for a point-wise (or type) sampler to "find words" starting from a random initial sample, but easier to "find n-grams".

Sampling for ciphers without spaces: For ciphers without spaces, dictionaries are hard to use because we do not know where words start and end. We introduce a new sampling operator which counters this problem and allows us to perform inference using the same decipherment model described earlier. In a first sampling pass, we sample from 26 plaintext letter choices (e.g., "A", "B", "C", ...) for every cipher symbol type as before. We then run a second pass using a new sampling operator that iterates over adjacent plaintext letter pairs p_{i-1}, p_i in the current hypothesis and samples from two choices—(1) add a word boundary (space character "_") between p_{i-1} and p_i, or (2) remove an existing space character between p_{i-1} and p_i.

For example, given the English plaintext hypothesis "`... A B O Y ...`", there are two sampling choices for the letter pair `A,B` in the second step. If we decide to add a word boundary, our new plaintext hypothesis becomes "`... A _ B O Y ...`".

We compute the derivation probability of the new sample using the same efficient scoring procedure described earlier. The new strategy allows us to apply Bayesian decipherment even to ciphers without spaces. As a result, we now have a new decipherment method that consistently works for a range of different types of substitution ciphers.

Decoding the ciphertext: After the sampling run has finished,[4] we choose the final sample as our English plaintext decipherment output.

[4]For letter substitution decipherment we want to keep the language model probabilities fixed during training, and hence we set the prior on that model to be high ($\alpha = 10^4$). We use a sparse prior for the channel ($\beta = 0.01$). We instantiate a key which matches frequently occurring plaintext letters to frequent cipher symbols and use this to generate an initial sample for the given ciphertext and run the sampler for 5000 iterations. We use a linear annealing schedule during sampling decreasing the temperature from $10 \rightarrow 1$.

4 Experiments and Results

We run decipherment experiments on different types of letter substitution ciphers (described in Section 2). In particular, we work with the following three ciphers:

(a) 414-letter Simple Substitution Cipher

(b) 414-letter Homophonic Cipher (with spaces)

(c) Zodiac-408 Cipher

Methods: For each cipher, we run and compare the output from two different decipherment approaches:

1. **EM Method** using letter n-gram LMs following the approach of Knight et al. (2006). They use the EM algorithm to estimate the channel parameters θ during decipherment training. The given ciphertext c is then decoded by using the Viterbi algorithm to choose the plaintext decoding p that maximizes $P(p) \cdot P_\theta(c|p)^3$, stretching the channel probabilities.

2. **Bayesian Decipherment** method using word+n-gram LMs (novel approach described in Section 3.1).

Evaluation: We evaluate the quality of a particular decipherment as the percentage of cipher tokens that are decoded correctly.

Results: Figure 2 compares the decipherment performance for the EM method with Bayesian decipherment (using type sampling and sparse priors) on three different types of substitution ciphers. Results show that our new approach (Bayesian) outperforms the EM method on all three ciphers, solving them completely. Even with a 3-gram letter LM, our method yields a +63% improvement in decipherment accuracy over EM on the homophonic cipher with spaces. We observe that the word+3-gram LM proves highly effective when tackling more complex ciphers and cracks the Zodiac-408 cipher. Figure 1 shows samples from the Bayesian decipherment output for all three ciphers. For ciphers without spaces, our method automatically guesses the word boundaries for the plaintext hypothesis.

Method	LM	Accuracy (%) on 414-letter Simple Substitution Cipher	Accuracy (%) on 414-letter Homophonic Substitution Cipher (with spaces)	Accuracy (%) on Zodiac-408 Cipher
1. EM	2-gram	83.6	30.9	_
	3-gram	99.3	32.6	0.3* (*28.8 *with 100 restarts*)
2. Bayesian	3-gram	**100.0**	95.2	23.0
	word+2-gram	**100.0**	**100.0**	_
	word+3-gram	**100.0**	**100.0**	**97.8**

Figure 2: Comparison of decipherment accuracies for EM *versus* Bayesian method when using different language models of English on the three substitution ciphers: (a) 414-letter Simple Substitution Cipher, (b) 414-letter Homophonic Substitution Cipher (with spaces), and (c) the famous Zodiac-408 Cipher.

For the Zodiac-408 cipher, we compare the performance achieved by Bayesian decipherment under different settings:

- *Letter n-gram* versus *Word+n-gram* LMs—Figure 2 shows that using a word+3-gram LM instead of a 3-gram LM results in +75% improvement in decipherment accuracy.
- *Sparse* versus *Non-sparse* priors—We find that using a sparse prior for the channel model (β = 0.01 versus 1.0) helps for such problems and produces better decipherment results (97.8% versus 24.0% accuracy).
- *Type* versus *Point-wise* sampling—Unlike point-wise sampling, type sampling quickly converges to better decipherment solutions. After 5000 sampling passes over the entire data, decipherment output from type sampling scores 97.8% accuracy compared to 14.5% for the point-wise sampling run.[5]

We also perform experiments on shorter substitution ciphers. On a 98-letter simple substitution cipher, EM using 3-gram LM achieves 41% accuracy, whereas the method from Ravi and Knight (2009) scores 84% accuracy. Our Bayesian method performs the best in this case, achieving 100% with word+3-gram LM.

5 Conclusion

In this work, we presented a novel Bayesian decipherment approach that can effectively solve a variety of substitution ciphers. Unlike previous approaches, our method combines information from letter n-gram language models and word dictionaries and provides a robust decipherment model. We empirically evaluated the method on different substitution ciphers and achieve perfect decipherments on all of them. Using Bayesian decipherment, we can successfully solve the Zodiac-408 cipher—the first time this is achieved by a fully automatic method in a strict decipherment scenario.

For future work, there are other interesting decipherment tasks where our method can be applied. One challenge is to crack the unsolved Zodiac-340 cipher, which presents a much harder problem than the solved version.

[5]Both sampling runs were seeded with the same random initial sample.

Abstract

Topic models have been used extensively as a tool for corpus exploration, and a cottage industry has developed to tweak topic models to better encode human intuitions or to better model data. However, creating such extensions requires expertise in machine learning unavailable to potential end-users of topic modeling software. In this work, we develop a framework for allowing users to iteratively refine the topics discovered by models such as latent Dirichlet allocation (LDA) by adding constraints that enforce that sets of words must appear together in the same topic. We incorporate these constraints interactively by selectively removing elements in the state of a Markov Chain used for inference; we investigate a variety of methods for incorporating this information and demonstrate that these interactively added constraints improve topic usefulness for simulated and actual user sessions.

1 Introduction

Probabilistic topic models, as exemplified by probabilistic latent semantic indexing (Hofmann, 1999) and latent Dirichlet allocation (LDA) (Blei et al., 2003) are unsupervised statistical techniques to discover the thematic topics that permeate a large corpus of text documents. Topic models have had considerable application beyond natural language processing in computer vision (Rob et al., 2005), biology (Shringarpure and Xing, 2008), and psychology (Landauer et al., 2006) in addition to their canonical application to text.

For text, one of the few real-world applications of topic models is corpus exploration. Unannotated, noisy, and ever-growing corpora are the norm rather than the exception, and topic models offer a way to quickly get the gist a large corpus.[1]

Contrary to the impression given by the tables shown in topic modeling papers, topics discovered by topic modeling don't always make sense to ostensible end users. Part of the problem is that the objective function of topic models doesn't always correlate with human judgements (Chang et al., 2009). Another issue is that topic models — with their bag-of-words vision of the world — simply lack the necessary information to create the topics as end-users expect.

There has been a thriving cottage industry adding more and more information to topic models to correct these shortcomings; either by modeling perspective (Paul and Girju, 2010; Lin et al., 2006), syntax (Wallach, 2006; Gruber et al., 2007), or authorship (Rosen-Zvi et al., 2004; Dietz et al., 2007). Similarly, there has been an effort to inject human knowledge into topic models (Boyd-Graber et al., 2007; Andrzejewski et al., 2009; Petterson et al., 2010).

However, these are *a priori* fixes. They don't help a frustrated **consumer** of topic models staring at a collection of topics that don't make sense. In this paper, we propose interactive topic modeling (ITM), an *in situ* method for incorporating human knowledge into topic models. In Section 2, we review prior work on creating probabilistic models that incorporate human knowledge, which we extend in Section 3 to apply to ITM sessions. Section 4 discusses the implementation of this process during the inference process. Via a motivating example in Section 5, simulated ITM sessions in Section 6, and a real interactive test in Section 7, we demonstrate that our approach is able to focus a user's desires in a topic model, better capture the key properties of a corpus, and capture diverse interests from users on the web.

2 Putting Knowledge in Topic Models

At a high level, topic models such as LDA take as input a number of topics K and a corpus. As output, a topic model discovers K distributions over words — the namesake topics — and associations between documents and topics. In LDA both of these outputs are multinomial distributions; typically they are presented to users in summary form by listing the elements with highest probability. For an example of topics discovered from a 20-topic model of New York Times editorials, see Table 1.

When presented with poor topics learned from data, users can offer a number of complaints:[2] these documents should have similar topics but don't (Daumé III, 2009); this topic should have syntactic coherence (Gruber et al., 2007; Boyd-Graber and Blei, 2008); this topic doesn't make any sense at all (Newman et al., 2010); this topic shouldn't be associated with this document but is (Ramage et al., 2009); these words shouldn't be the in same topic but are (Andrzejewski et al., 2009); or these words should be in the same topic but aren't (Andrzejewski et al., 2009).

Many of these complaints can be addressed by using "must-link" constraints on topics, retaining Andrzejewski et al's (2009) terminology borrowed from the database literature. A "must-link" constraint is a group of words whose probability must be correlated in the topic. For example, Figure 1 shows an example constraint: {plant, factory}. After this constraint is added, the probabilities of "plant" and "factory" in each topic are likely to both be high or both be low. It's unlikely for "plant" to have high probability in a topic and "factory" to have a low probability. In the next section, we demonstrate how such constraints can be built into a model and how they can even be added while inference is underway.

In this paper, we view constraints as transitive; if "plant" is in a constraint with "factory" and "factory" is in a constraint with "production," then "plant" is in a constraint with "production." Making this assumption can simplify inference slightly, which we take advantage of in Section 3.1, but the real reason for this assumption is because not doing so would

[2]Citations in this litany of complaints are offline solutions for addressing the problem; the papers also give motivation why such complaints might arise.

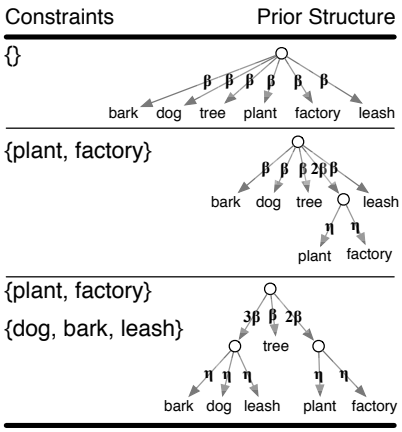

Figure 1: How adding constraints (left) creates new topic priors (right). The trees represent correlated distributions (assuming $\eta >> \beta$). After the {plant, factory} constraint is added, it is now highly unlikely for a topic drawn from the distribution to have a high probability for "plant" and a low probability for "factory" or vice versa. The bottom panel adds an additional constraint, so now dog-related words are also correlated. Notice that the two constraints themselves are uncorrelated. It's possible for both, either, or none of "bark" and "plant" (for instance) to have high probability in a topic.

introduce ambiguity over the path associated with an observed token in the generative process. As long as a word is either in a single constraint or in the general vocabulary, there is only a single path. The details of this issue are further discussed in Section 4.

3 Constraints Shape Topics

As discussed above, LDA views topics as distributions over words, and each document expresses an admixture of these topics. For "vanilla" LDA (no constraints), these are symmetric Dirichlet distributions. A document is composed of a number of observed words, which we call tokens to distinguish specific observations from the more abstract word (type) associated with each token. Because LDA assumes a document's tokens are interchangeable, it treats the document as a bag-of-words, ignoring potential relations between words.

This problem with vanilla LDA can be solved by encoding constraints, which will "guide" different words into the same topic. Constraints can be added to vanilla LDA by replacing the multinomial distribution over words for each topic with a collection of

tree-structured multinomial distributions drawn from a prior as depicted in Figure 1. By encoding word distributions as a tree, we can preserve conjugacy and relatively simple inference while encouraging correlations between related concepts (Boyd-Graber et al., 2007; Andrzejewski et al., 2009; Boyd-Graber and Resnik, 2010). Each topic has a top-level distribution over words and constraints, and each constraint in each topic has second-level distribution over the words in the constraint. Critically, the per-constraint distribution over words is engineered to be non-sparse and close to uniform. The top level distribution encodes which constraints (and unconstrained words) to include; the lower-level distribution forces the probabilities to be correlated for each of the constraints.

In LDA, a document's token is produced in the generative process by choosing a topic z and sampling a word from the multinomial distribution ϕ_z of topic z. For a constrained topic, the process now can take two steps. First, a first-level node in the tree is selected from ϕ_z. If that is an unconstrained word, the word is emitted and the generative process for that token is done. Otherwise, if the first level node is constraint l, then choose a word to emit from the constraint's distribution over words $\pi_{z,l}$.

More concretely, suppose for a corpus with M documents we have a set of constraints $\mathbf{\Omega}$. The prior structure has B branches (one branch for each word not in a constraint and one for each constraint). Then the generative process for constrained LDA is:

1. For each topic $i \in \{1, \dots K\}$:
   (a) draw a distribution over the B branches (words and constraints) $\phi_i \sim \text{Dir}(\vec{\beta})$, and
   (b) for each constraint $\Omega_j \in \mathbf{\Omega}$, draw a distribution over the words in the constraint $\pi_{i,j} \sim \text{Dir}(\eta)$, where $\pi_{i,j}$ is a distribution over the words in Ω_j
2. Then for each document $d \in \{1, \dots M\}$:
   (a) first draw a distribution over topics $\theta_d \sim \text{Dir}(\alpha)$,
   (b) then for each token $n \in \{1, \dots N_d\}$:
      i. choose a topic assignment $z_{d,n} \sim \text{Mult}(\theta_d)$, and then
      ii. choose either a constraint or word from $\text{Mult}(\phi_{z_{d,n}})$:
         A. if we chose a word, emit that word $w_{d,n}$
         B. otherwise if we chose a constraint index $l_{d,n}$, emit a word $w_{d,n}$ from the constraint's distribution over words in topic $z_{d,n}$: $w_{d,n} \sim \text{Mult}(\pi_{z_{d,n},l_{d,n}})$.

In this model, α, β, and η are Dirichlet hyperparameters set by the user; their role is explained below.

3.1 Gibbs Sampling for Topic Models

In topic modeling, collapsed Gibbs sampling (Griffiths and Steyvers, 2004) is a standard procedure for obtaining a Markov chain over the latent variables in the model. Given certain technical conditions, the stationary distribution of the Markov chain is the posterior (Neal, 1993). Given M documents the state of a Gibbs sampler for LDA consists of topic assignments for each token in the corpus and is represented as $Z = \{z_{1,1} \dots z_{1,N_1}, z_{2,1}, \dots z_{M,N_M}\}$. In each iteration, every token's topic assignment $z_{d,n}$ is resampled based on topic assignments for all the tokens except for $z_{d,n}$. (This subset of the state is denoted $\boldsymbol{Z}_{-(d,n)}$). The sampling equation for $z_{d,n}$ is

$$p(z_{d,n} = k|\mathbf{Z}_{-(d,n)}, \alpha, \beta) \propto \frac{T_{d,k} + \alpha}{T_{d,\cdot} + K\alpha} \frac{P_{k,w_{d,n}} + \beta}{P_{k,\cdot} + V\beta} \quad (1)$$

where $T_{d,k}$ is the number of times topic k is used in document d, $P_{k,w_{d,n}}$ is the number of times the type $w_{d,n}$ is assigned to topic k, and α, β are the hyperparameters of the two Dirichlet distributions, and B is the number of top-level branches (this is the vocabulary size for vanilla LDA). When a dot replaces a subscript of a count, it represents the marginal sum over all possible topics or words, e.g. $T_{d,\cdot} = \sum_k T_{d,k}$. The count statistics P and T provide summaries of the state. Typically, these only change based on assignments of latent variables in the sampler; in Section 4 we describe how changes in the model's *structure* (in addition to the latent state) can be reflected in these count statistics.

Contrasting with the above inference is the inference for a constrained model. (For a derivation, see Boyd-Graber, Blei, and Zhu (2007) for the general case or Andrzejewski, Zhu, and Craven (2009) for the specific case of constraints.) In this case the sampling equation for $z_{d,n}$ is changed to $p(z_{d,n} = k|\mathbf{Z}_{-(d,n)}, \alpha, \beta, \eta)$

$$\propto \begin{cases} \frac{T_{d,k}+\alpha}{T_{d,\cdot}+K\alpha} \frac{P_{k,w_{d,n}}+\beta}{P_{k,\cdot}+V\beta} & \text{if } \forall l, w_{d,n} \notin \Omega_l \\ \frac{T_{d,k}+\alpha}{T_{d,\cdot}+K\alpha} \frac{P_{k,l}+C_l\beta}{P_{k,\cdot}+V\beta} \frac{W_{k,l,w_{d,n}}+\eta}{W_{k,l,\cdot}+C_l\eta} & w_{d,n} \in \Omega_l \end{cases}, \quad (2)$$

where $P_{k,w_{d,n}}$ is the number of times the unconstrained word $w_{d,n}$ appears in topic k; $P_{k,l}$ is the

number of times any word of constraint Ω_l appears in topic k; $W_{k,l,w_{d,n}}$ is the number of times word $w_{d,n}$ appears in constraint Ω_l in topic k; V is the vocabulary size; C_l is the number of words in constraint Ω_l. Note the differences between these two samplers for constrained words; however, for unconstrained LDA and for unconstrained words in constrained LDA, the conditional probability is the same.

In order to make the constraints effective, we set the constraint word-distribution hyperparameter η to be much larger than the hyperparameter for the distribution over constraints and vocabulary β. This gives the constraints higher weight. Normally, estimating hyperparameters is important for topic modeling (Wallach et al., 2009). However, in ITM, sampling hyperparameters often (but not always) undoes the constraints (by making η comparable to β), so we keep the hyperparameters fixed.

4 Interactively adding constraints

For a static model, inference in ITM is the same as in previous models (Andrzejewski et al., 2009). In this section, we detail how interactively changing constraints can be accommodated in ITM, smoothly transitioning from unconstrained LDA (n.b. Equation 1) to constrained LDA (n.b. Equation 2) with one constraint, to constrained LDA with two constraints, etc.

A central tool that we will use is the strategic unassignment of states, which we call ablation (distinct from feature ablation in supervised learning). As described in the previous section, a sampler stores the topic assignment of each token. In the implementation of a Gibbs sampler, unassignment is done by setting a token's topic assignment to an invalid topic (e.g. -1, as we use here) and decrementing any counts associated with that word.

The constraints created by users implicitly signal that words in constraints don't belong in a given topic. In other models, this input is sometimes used to "fix," i.e. deterministically hold constant topic assignments (Ramage et al., 2009). Instead, we change the underlying model, using the current topic assignments as a starting position for a new Markov chain with some states strategically unassigned. How much of the existing topic assignments we use leads to four different options, which are illustrated in Figure 2.

	Previous	New
All	[bark:2, dog:3, leash:3 dog:2] [bark:2, bark:2, plant:2, tree:3] [tree:2,play:2,forest:1,leash:2]	[bark:-1, dog:-1, leash:-1 dog:-1] [bark:-1, bark:-1, plant:-1, tree:-1] [tree:-1,play:-1,forest:-1,leash:-1]
Doc	[bark:2, dog:3, leash:3 dog:2] [bark:2, bark:2, plant:2, tree:3] [tree:2,play:2,forest:1,leash:2]	[bark:-1, dog:-1, leash:-1 dog:-1] [bark:-1, bark:-1, plant:-1, tree:-1] [tree:2,play:2,forest:1,leash:2]
Term	[bark:2, dog:3, leash:3 dog:3] [bark:2, bark:2, plant:2, tree:3] [tree:2,play:2,forest:1,leash:2]	[bark:-1, dog:-1, leash:3 dog:-1] [bark:-1, bark:-1, plant:2, tree:3] [tree:2,play:2,forest:1,leash:2]
None	[bark:2, dog:3, leash:3 dog:2] [bark:2, bark:2, plant:2, tree:3] [tree:2,play:2,forest:1,leash:2]	[bark:2, dog:3, leash:3 dog:2] [bark:2, bark:2, plant:2, tree:3] [tree:2,play:2,forest:1,leash:2]

Figure 2: Four different strategies for state ablation after the words "dog" and "bark" are added to the constraint {"leash," "puppy"} to make the constraint {"dog," "bark," "leash," "puppy"}. The state is represented by showing the current topic assignment after each word (e.g. "leash" in the first document has topic 3, while "forest" in the third document has topic 1). On the left are the assignments before words were added to constraints, and on the right are the ablated assignments. Unassigned words are given the new topic assignment -1 and are highlighted in red.

All We could revoke all state assignments, essentially starting the sampler from scratch. This does not allow *interactive* refinement, as there is nothing to enforce that the new topics will be in any way consistent with the existing topics. Once the topic assignments of all states are revoked, the counts for T, P and W (as described in Section 3.1) will be zero, retaining no information about the state the user observed.

Doc Because topic models treat the document context as exchangeable, a document is a natural context for partial state ablation. Thus if a user adds a set of words $\boldsymbol{S}$ to constraints, then we have reason to suspect that all documents containing any one of $\boldsymbol{S}$ may have incorrect topic assignments. This is reflected in the state of the sampler by performing the UNASSIGN (Algorithm 1) operation for each word in any document containing a word added to a constraint.

Algorithm 1 UNASSIGN$(d, n, w_{d,n}, z_{d,n} = k)$

1: $T:\ T_{d,k} \leftarrow T_{d,k} - 1$
2: If $w_{d,n} \notin \Omega^{old}$,
  $P:\ P_{k,w_{d,n}} \leftarrow P_{k,w_{d,n}} - 1$
3: Else: suppose $w_{d,n} \in \Omega^{old}_m$,
  $P:\ P_{k,m} \leftarrow P_{k,m} - 1$
  $W:\ W_{k,m,w_{d,n}} \leftarrow W_{k,m,w_{d,n}} - 1$

This is equivalent to the Gibbs2 sampler of Yao et al. (2009) for incorporating new documents in a streaming context. Viewed in this light, a user is using words to select documents that should be treated as "new" for this refined model.

Term Another option is to perform ablation only on the topic assignments of tokens whose words have added to a constraint. This applies the unassignment operation (Algorithm 1) only to tokens whose corresponding word appears in added constraints (i.e. a subset of the Doc strategy). This makes it less likely that other tokens in similar contexts will follow the words explicitly included in the constraints to new topic assignments.

None The final option is to move words into constraints but keep the topic assignments fixed. Thus, P and W change, but not T, as described in Algorithm 2.[3] This is arguably the simplest option, and in principle is sufficient, as the Markov chain should find a stationary distribution regardless of the starting position. In practice, however, this strategy is less interactive, as users don't feel that their constraints are actually incorporated in the model, and inertia can keep the chain from reflecting the constraints.

Algorithm 2 MOVE$(d, n, w_{d,n}, z_{d,n} = k, \Omega_l)$

1: If $w_{d,n} \notin \Omega^{old}$,
$P:\ P_{k,w_{d,n}} \leftarrow P_{k,w_{d,n}} - 1,\ \ P_{k,l} \leftarrow P_{k,l} + 1$
$W:\ W_{k,l,w_{d,n}} \leftarrow W_{k,l,w_{d,n}} + 1$
2: Else, suppose $w_{d,n} \in \Omega^{old}_m$,
$P:\ P_{k,m} \leftarrow P_{k,m} - 1,\ P_{k,l} \leftarrow P_{k,l} + 1$
$W:\ W_{k,m,w_{d,n}} \leftarrow W_{k,m,w_{d,n}} - 1$
$W_{k,l,w_{d,n}} \leftarrow W_{k,l,w_{d,n}} + 1$

Regardless of what ablation scheme is used, after the state of the Markov chain is altered, the next step is to actually run inference forward, sampling assignments for the unassigned tokens for the "first" time and changing the topic assignment of previously assigned tokens. How many additional iterations are required after adding constraints is a delicate tradeoff between interactivity and effectiveness, which we investigate further in the next sections.

[3]This assumes that there is only one possible path in the constraint tree that can generate a word; in other words, this assumes that constraints are transitive, as discussed at the end of Section 2. In the more general case, when words lack a unique path in the constraint tree, an additional latent variable specifies which possible paths in the constraint tree produced the word; this would have to be sampled. All other updating strategies are immune to this complication, as the assignments are left unassigned.

5 Motivating Example

To examine the viability of ITM, we begin with a qualitative demonstration that shows the potential usefulness of ITM. For this task, we used a corpus of about 2000 New York Times editorials from the years 1987 to 1996. We started by finding 20 initial topics with no constraints, as shown in Table 1 (left).

Notice that topics 1 and 20 both deal with Russia. Topic 20 seems to be about the Soviet Union, with topic 1 about the post-Soviet years. We wanted to combine the two into a single topic, so we created a constraint with all of the clearly Russian or Soviet words (*boris, communist, gorbachev, mikhail, russia, russian, soviet, union, yeltsin*). Running inference forward 100 iterations with the **Doc** ablation strategy yields the topics in Table 1 (right). The two Russia topics were combined into Topic 20. This combination also pulled in other relevant words that not near the top of either topic before: "moscow" and "relations." Topic 1 is now more about elections in countries other than Russia. The other 18 topics changed little.

While we combined the Russian topics, other researchers analyzing large corpora might preserve the Soviet vs. post-Soviet distinction but combine topics about American government. ITM allows tuning for specific tasks.

6 Simulation Experiment

Next, we consider a process for evaluating our ITM using automatically derived constraints. These constraints are meant to simulate a user with a predefined list of categories (e.g. reviewers for journal submissions, e-mail folders, etc.). The categories grow more and more specific during the session as the simulated users add more constraint words.

To test the ability of ITM to discover relevant subdivisions in a corpus, we use a dataset with predefined, intrinsic labels and assess how well the discovered latent topic structure can reproduce the corpus's inherent structure. Specifically, for a corpus with M classes, we use the per-document topic distribution as a feature vector in a supervised classi-

Topic	Words

Table 1: Five topics from a 20 topic topic model on the editorials from the New York times before adding a constraint (left) and after (right). After the constraint was added, which encouraged Russian and Soviet terms to be in the same topic, non-Russian terms gained increased prominence in Topic 1, and "Moscow" (which was not part of the constraint) appeared in Topic 20.

fier (Hall et al., 2009). The lower the classification error rate, the better the model has captured the structure of the corpus.[4]

6.1 Generating automatic constraints

We used the 20 Newsgroups corpus, which contains 18846 documents divided into 20 constituent newsgroups. We use these newsgroups as ground-truth labels.[5]

We simulate a user's constraints by ranking words in the training split by their information gain (IG).[6] After ranking the top 200 words for each class by IG, we delete words associated with multiple labels to prevent constraints for different labels from merging. The smallest class had 21 words remaining after removing duplicates (due to high overlaps of 125 words between "talk.religion.misc" and "soc.religion.christian," and 110 words between "talk.religion.misc" and "alt.atheism"), so the top 21 words for each class were the ingredients for our simulated constraints. For example, for the class "soc.religion.christian," the 21 constraint words include "catholic, scripture, resurrection, pope, sabbath, spiritual, pray, divine, doctrine, orthodox." We simulate a user's ITM session by adding a word to each of the 20 constraints until each of the constraints has 21 words.

6.2 Simulation scheme

Starting with 100 base iterations, we perform successive rounds of refinement. In each round a new constraint is added corresponding to the newsgroup labels. Next, we perform one of the strategies for state ablation, add additional iterations of Gibbs sampling, use the newly obtained topic distribution of each document as the feature vector, and perform classification on the test / train split. We do this for 21 rounds until each label has 21 constraint words. The number of LDA topics is set to 20 to match the number of newsgroups. The hyperparameters for all experiments are $\alpha = 0.1, \beta = 0.01$, and $\eta = 100$.

At 100 iterations, the chain is clearly not converged. However, we chose this number of iterations because it more closely matches the likely use case as users do not wait for convergence. Moreover, while investigations showed that the patterns shown in Fig-

[4]Our goal is to understand the phenomena of ITM, not classification, so these classification results are well below state of the art. However, adding interactively selected topics to the state of the art features (tf-idf unigrams) gives a relative error reduction of 5.1%, while just adding topics from vanilla LDA gives a relative error reduction of 1.1%. Both measurements were obtained without tuning or weighting features, so presumably better results are possible.

[5]http://people.csail.mit.edu/jrennie/20Newsgroups/
In preprocessing, we deleted short documents, leaving 15160 documents, including 9131 training documents and 6029 test documents (default split). Tokenization, lemmatization, and stopword removal was performed using the Natural Language Toolkit (Loper and Bird, 2002). Topic modeling was performed using the most frequent 5000 lemmas as the vocabulary.

[6]IG is computed by the Rainbow toolbox http://www.cs.umass.edu/ mccallum/bow/rainbow/

ure 4 were broadly consistent with larger numbers of iterations, such configurations sometimes had too much inertia to escape from local extrema. More iterations make it harder for the constraints to influence the topic assignment.

6.3 Investigating Ablation Strategies

First, we investigate which ablation strategy best allows constraints to be incorporated. Figure 3 shows the classification error of six different ablation strategies based on the number of words in each constraint, ranging from 0 to 21. Each is averaged over five different chains using 10 additional iterations of Gibbs sampling per round (other numbers of iterations are discussed in Section 6.4). The model runs forward 10 iterations after the first round, another 10 iterations after the second round, etc. In general, as the number of words per constraint increases, the error decreases as models gain more information about the classes.

Strategy **Null** is the non-interactive baseline that contains no constraints (vanilla LDA), but runs inference for a comparable number of rounds. **All Initial** and **All Full** are non-interactive baselines with all constraints known *a priori*. **All Initial** runs the model for the only the initial number of iterations (100 iterations in this experiment), while **All Full** runs the model for the total number of iterations added for the interactive version. (That is, if there were 21 rounds and each round of interactive modeling added 10 iterations, **All Full** would have 210 iterations more than **All Initial**).

While **Null** sees no constraints, it serves as an upper baseline for the error rate (lower error being better) but shows the effect of additional inference. **All Full** is a lower baseline for the error rate since it both sees the constraints at the beginning and also runs for the maximum number of total iterations. **All Initial** sees the constraints before the other ablation techniques but it has fewer total iterations.

The **Null** strategy does not perform as well as the interactive versions, especially with larger constraints. Both **All Initial** and **All Full**, however, show a larger variance (as denoted by error bands around the average trends) than the interactive schemes. This can be viewed as akin to simulated annealing, as the interactive search has more freedom to explore in early rounds. As more constraint words are added each round, the model is less free to explore.

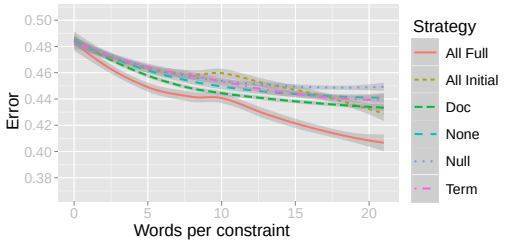

Figure 3: Error rate (y-axis, lower is better) using different ablation strategies as additional constraints are added (x-axis). **Null** represents standard LDA, as the unconstrained baseline. **All Initial** and **All Full** are non-interactive, constrained baselines. The results of **None**, **Term**, **Doc** are more stable (as denoted by the error bars), and the error rate is reduced gradually as more constraint words are added.

The error rate of each interactive ablation strategy is (as expected) between the lower and upper baselines. Generally, the constraints will influence not only the topics of the constraint words, but also the topics of the constraint words' context in the same document. **Doc** ablation gives more freedom for the constraints to overcome the inertia of the old topic distribution and move towards a new one influenced by the constraints.

6.4 How many iterations do users have to wait?

Figure 4 shows the effect of using different numbers of Gibbs sampling iterations after changing a constraint. For each of the ablation strategies, we run $\{10, 20, 30, 50, 100\}$ additional Gibbs sampling iterations. As expected, more iterations reduce error, although improvements diminish beyond 100 iterations. With more constraints, the impact of additional iterations is lessened, as the model has more *a priori* knowledge to draw upon.

For all numbers of additional iterations, while the **Null** serves as the upper baseline on the error rate in all cases, the **Doc** ablation clearly outperforms the other ablation schemes, consistently yielding a lower error rate. Thus, there is a benefit when the model has a chance to relearn the document context when constraints are added. The difference is even larger with more iterations, suggesting **Doc** needs more iterations to "recover" from unassignment.

The luxury of having hundreds or thousands of additional iterations for each constraint would be im-

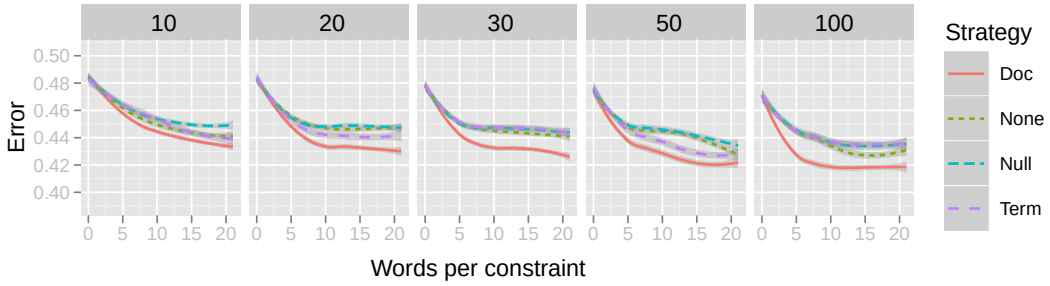

Figure 4: Classification accuracy by strategy and number of additional iterations. The **Doc** ablation strategy performs best, suggesting that the document context is important for ablation constraints. While more iterations are better, there is a tradeoff with interactivity.

practical. For even moderately sized datasets, even one iteration per second can tax the patience of individuals who want to use the system interactively. Based on these results and an *ad hoc* qualitative examination of the resulting topics, we found that 30 additional iterations of inference was acceptable; this is used in later experiments.

7 Getting Humans in the Loop

To move beyond using simulated users adding the same words regardless of what topics were discovered by the model, we needed to expose the model to human users. We solicited approximately 200 judgments from Mechanical Turk, a popular crowdsourcing platform that has been used to gather linguistic annotations (Snow et al., 2008), measure topic quality (Chang et al., 2009), and supplement traditional inference techniques for topic models (Chang, 2010). After presenting our interface for collecting judgments, we examine the results from these ITM sessions both quantitatively and qualitatively.

7.1 Interface for soliciting refinements

Figure 5 shows the interface used in the Mechanical Turk tests. The left side of the screen shows the current topics in a scrollable list, with the top 30 words displayed for each topic.

Users create constraints by clicking on words from the topic word lists. The word lists use a color-coding scheme to help the users keep track of which words they are currently grouping into constraints. The right side of the screen displays the existing constraints. Users can click on icons to edit or delete each one. The constraint currently being built is also shown.

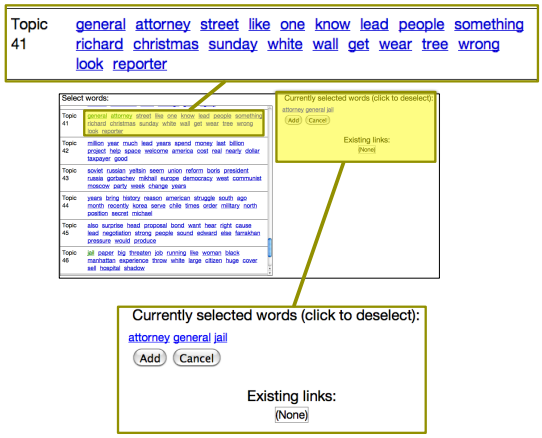

Figure 5: Interface for Mechanical Turk experiments. Users see the topics discovered by the model and select words (by clicking on them) to build constraints to be added to the model.

Clicking on a word will remove that word from the current constraint.

As in Section 6, we can compute the classification error for these users as they add words to constraints. The best users, who seemed to understand the task well, were able to decrease classification error. (Figure 6). The median user, however, had an error reduction indistinguishable from zero. Despite this, we can examine the users' behavior to better understand their goals and how they interact with the system.

7.2 Untrained users and ITM

Most of the large (10+ word) user-created constraints corresponded to the themes of the individual newsgroups, which users were able to infer from the discovered topics. Common constraint themes that

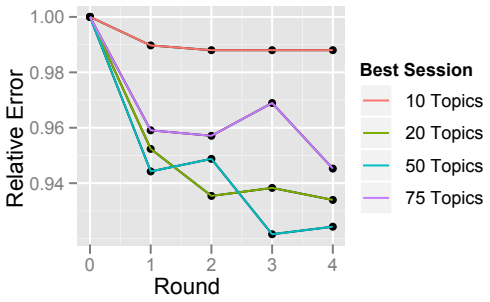

Figure 6: The relative error rate (using round 0 as a baseline) of the best Mechanical Turk user session for each of the four numbers of topics. While the 10-topic model does not provide enough flexibility to create good constraints, the best users could clearly improve classification with more topics.

matched specific newsgroups included religion, space exploration, graphics, and encryption. Other common themes were broader than individual newsgroups (e.g. sports, government and computers). Others matched sub-topics of a single newsgroup, such as homosexuality, Israel or computer programming.

Some users created inscrutable constraints, like ("better, people, right, take, things") and ("fbi, let, says"). They may have just clicked random words to finish the task quickly. While subsequent users could delete poor constraints, most chose not to. Because we wanted to understand broader behavior we made no effort to squelch such responses.

The two-word constraints illustrate an interesting contrast. Some pairs are linked together in the corpus, like ("jesus, christ") and ("solar, sun"). With others, like ("even, number") and ("book, list"), the users seem to be encouraging collocations to be in the same topic. However, the collocations may not be in any document in this corpus. Another user created a constraint consisting of male first names. A topic did emerge with these words, but the rest of the words in that topic seemed random, as male first names are not likely to co-occur in the same document.

Not all sensible constraints led to successful topic changes. Many users grouped "mac" and "windows" together, but they were almost never placed in the same topic. The corpus includes separate newsgroups for Macintosh and Windows hardware, and divergent contexts of "mac" and "windows" overpowered the prior distribution.

The constraint size ranged from one word to over 40. In general, the more words in the constraint, the more likely it was to noticeably affect the topic distribution. This observation makes sense given our ablation method. A constraint with more words will cause the topic assignments to be reset for more documents.

8 Discussion

In this work, we introduced a means for end-users to refine and improve the topics discovered by topic models. ITM offers a paradigm for non-specialist consumers of machine learning algorithms to refine models to better reflect their interests and needs. We demonstrated that even novice users are able to understand and build constraints using a simple interface and that their constraints can improve the model's ability to capture the latent structure of a corpus.

As presented here, the technique for incorporating constraints is closely tied to inference with Gibbs sampling. However, most inference techniques are essentially optimization problems. As long as it is possible to define a transition on the state space that moves from one less-constrained model to another more-constrained model, other inference procedures can also be used.

We hope to engage these algorithms with more sophisticated users than those on Mechanical Turk to measure how these models can help them better explore and understand large, uncurated data sets. As we learn their needs, we can add more avenues for interacting with topic models.

Faster and Smaller N-Gram Language Models

Adam Pauls Dan Klein

Abstract

N-gram language models are a major resource bottleneck in machine translation. In this paper, we present several language model implementations that are both highly compact and fast to query. Our fastest implementation is as fast as the widely used SRILM while requiring only 25% of the storage. Our most compact representation can store all 4 billion n-grams and associated counts for the Google n-gram corpus in 23 bits per n-gram, the most compact lossless representation to date, and even more compact than recent *lossy* compression techniques. We also discuss techniques for improving query speed during decoding, including a simple but novel language model caching technique that improves the query speed of our language models (and SRILM) by up to 300%.

1 Introduction

For modern statistical machine translation systems, language models must be both fast and compact. The largest language models (LMs) can contain as many as several hundred *billion* n-grams (Brants et al., 2007), so storage is a challenge. At the same time, decoding a single sentence can trigger hundreds of thousands of queries to the language model, so speed is also critical. As always, trade-offs exist between time, space, and accuracy, with many recent papers considering small-but-approximate noisy LMs (Chazelle et al., 2004; Guthrie and Hepple, 2010) or small-but-slow compressed LMs (Germann et al., 2009).

In this paper, we present several *lossless* methods for compactly but efficiently storing large LMs in memory. As in much previous work (Whittaker and Raj, 2001; Hsu and Glass, 2008), our methods are conceptually based on tabular trie encodings wherein each n-gram key is stored as the concatenation of one word (here, the last) and an offset encoding the remaining words (here, the context). After presenting a bit-conscious basic system that typifies such approaches, we improve on it in several ways. First, we show how the last word of each entry can be implicitly encoded, almost entirely eliminating its storage requirements. Second, we show that the deltas between adjacent entries can be efficiently encoded with simple variable-length encodings. Third, we investigate block-based schemes that minimize the amount of compressed-stream scanning during lookup.

To speed up our language models, we present two approaches. The first is a front-end cache. Caching itself is certainly not new to language modeling, but because well-tuned LMs are essentially lookup tables to begin with, naive cache designs only speed up slower systems. We present a direct-addressing cache with a fast key identity check that speeds up our systems (or existing fast systems like the widely-used, speed-focused SRILM) by up to 300%.

Our second speed-up comes from a more fundamental change to the language modeling interface. Where classic LMs take word tuples and produce counts or probabilities, we propose an LM that takes a word-and-context encoding (so the context need not be re-looked up) and returns both the probability and also the context encoding for the *suffix* of the original query. This setup substantially accelerates the scrolling queries issued by decoders, and also exploits language model state equivalence (Li and Khudanpur, 2008).

Overall, we are able to store the 4 billion n-grams of the Google Web1T (Brants and Franz, 2006) cor-

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 258–267,
Portland, Oregon, June 19-24, 2011.

pus, with associated counts, in 10 GB of memory, which is smaller than state-of-the-art *lossy* language model implementations (Guthrie and Hepple, 2010), and significantly smaller than the best published lossless implementation (Germann et al., 2009). We are also able to simultaneously outperform SRILM in both total size and speed. Our LM toolkit, which is implemented in Java and compatible with the standard ARPA file formats, is available on the web.[1]

2 Preliminaries

Our goal in this paper is to provide data structures that map n-gram keys to values, i.e. probabilities or counts. Maps are fundamental data structures and generic implementations of mapping data structures are readily available. However, because of the sheer number of keys and values needed for n-gram language modeling, generic implementations do not work efficiently "out of the box." In this section, we will review existing techniques for encoding the keys and values of an n-gram language model, taking care to account for every bit of memory required by each implementation.

To provide absolute numbers for the storage requirements of different implementations, we will use the Google Web1T corpus as a benchmark. This corpus, which is on the large end of corpora typically employed in language modeling, is a collection of nearly 4 billion n-grams extracted from over a trillion tokens of English text, and has a vocabulary of about 13.5 million words.

2.1 Encoding Values

In the Web1T corpus, the most frequent n-gram occurs about 95 billion times. Storing this count explicitly would require 37 bits, but, as noted by Guthrie and Hepple (2010), the corpus contains only about 770 000 *unique* counts, so we can enumerate all counts using only 20 bits, and separately store an array called the *value rank array* which converts the rank encoding of a count back to its raw count. The additional array is small, requiring only about 3MB, but we save 17 bits per n-gram, reducing value storage from around 16GB to about 9GB for Web1T.

We can rank encode probabilities and back-offs in the same way, allowing us to be agnostic to whether we encode counts, probabilities and/or back-off weights in our model. In general, the number of bits per value required to encode all value ranks for a given language model will vary – we will refer to this variable as v .

2.2 Trie-Based Language Models

The data structure of choice for the majority of modern language model implementations is a *trie* (Fredkin, 1960). Tries or variants thereof are implemented in many LM tool kits, including SRILM (Stolcke, 2002), IRSTLM (Federico and Cettolo, 2007), CMU SLM (Whittaker and Raj, 2001), and MIT LM (Hsu and Glass, 2008). Tries represent collections of n-grams using a tree. Each node in the tree encodes a word, and paths in the tree correspond to n-grams in the collection. Tries ensure that each n-gram prefix is represented only once, and are very efficient when n-grams share common prefixes. Values can also be stored in a trie by placing them in the appropriate nodes.

Conceptually, trie nodes can be implemented as records that contain two entries: one for the word in the node, and one for either a pointer to the parent of the node or a list of pointers to children. At a low level, however, naive implementations of tries can waste significant amounts of space. For example, the implementation used in SRILM represents a trie node as a C `struct` containing a 32-bit integer representing the word, a 64-bit memory[2] pointer to the list of children, and a 32-bit floating point number representing the value stored at a node. The total storage for a node alone is 16 bytes, with additional overhead required to store the list of children. In total, the most compact implementation in SRILM uses 33 bytes per n-gram of storage, which would require around 116 GB of memory to store Web1T.

While it is simple to implement a trie node in this (already wasteful) way in programming languages that offer low-level access to memory allocation like C/C++, the situation is even worse in higher level programming languages. In Java, for example, C-style `structs` are not available, and records are most naturally implemented as objects that carry an additional 64 bits of overhead.

[1] `http://code.google.com/p/berkeleylm/`

[2] While 32-bit architectures are still in use today, their limited address space is insufficient for modern language models and we will assume all machines use a 64-bit architecture.

Despite its relatively large storage requirements, the implementation employed by SRILM is still widely in use today, largely because of its speed – to our knowledge, SRILM is the fastest freely available language model implementation. We will show that we can achieve access speeds comparable to SRILM but using only 25% of the storage.

2.3 Implicit Tries

A more compact implementation of a trie is described in Whittaker and Raj (2001). In their implementation, nodes in a trie are represented implicitly as entries in an array. Each entry encodes a word with enough bits to index all words in the language model (24 bits for Web1T), a quantized value, and a 32-bit[3] offset that encodes the contiguous block of the array containing the children of the node. Note that 32 bits is sufficient to index all n-grams in Web1T; for larger corpora, we can always increase the size of the offset.

Effectively, this representation replaces system-level memory pointers with offsets that act as logical pointers that can reference other entries in the array, rather than arbitrary bytes in RAM. This representation saves space because offsets require fewer bits than memory pointers, but more importantly, it permits straightforward implementation in any higher-level language that provides access to arrays of integers.[4]

2.4 Encoding n-grams

Hsu and Glass (2008) describe a variant of the implicit tries of Whittaker and Raj (2001) in which each node in the trie stores the prefix (i.e. parent). This representation has the property that we can refer to each n-gram $\mathbf{w}_1^n$ by its last word w_n and the offset $c(\mathbf{w}_1^{n-1})$ of its prefix $\mathbf{w}_1^{n-1}$, often called the *context*. At a low-level, we can efficiently encode this pair $(w_n, c(\mathbf{w}_1^{n-1}))$ as a single 64-bit integer, where the first 24 bits refer to w_n and the last 40 bits encode $c(\mathbf{w}_1^{n-1})$. We will refer to this encoding as a *context encoding*.

Note that typically, n-grams are encoded in tries in the reverse direction (first-rest instead of last-rest), which enables a more efficient computation of back-offs. In our implementations, we found that the speed improvement from switching to a first-rest encoding and implementing more efficient queries was modest. However, as we will see in Section 4.2, the last-rest encoding allows us to exploit the scrolling nature of queries issued by decoders, which results in speedups that far outweigh those achieved by reversing the trie.

3 Language Model Implementations

In the previous section, we reviewed well-known techniques in language model implementation. In this section, we combine these techniques to build simple data structures in ways that are to our knowledge novel, producing language models with state-of-the-art memory requirements and speed. We will also show that our data structures can be very effectively compressed by implicitly encoding the word w_n, and further compressed by applying a variable-length encoding on context deltas.

3.1 Sorted Array

A standard way to implement a map is to store an array of key/value pairs, sorted according to the key. Lookup is carried out by performing binary search on a key. For an n-gram language model, we can apply this implementation with a slight modification: we need n sorted arrays, one for each n-gram order. We construct keys $(w_n, c(\mathbf{w}_1^{n-1}))$ using the context encoding described in the previous section, where the context offsets c refer to entries in the sorted array of $(n-1)$-grams. This data structure is shown graphically in Figure 1.

Because our keys are sorted according to their context-encoded representation, we cannot straightforwardly answer queries about an n-gram $\mathbf{w}$ without first determining its context encoding. We can do this efficiently by building up the encoding incrementally: we start with the context offset of the unigram w_1, which is simply its integer representation, and use that to form the context encoding of the bigram $\mathbf{w}_1^2 = (w_2, c(w_1))$. We can find the offset of

[3] The implementation described in the paper represents each 32-bit integer compactly using only 16 bits, but this representation is quite inefficient, because determining the full 32-bit offset requires a binary search in a look up table.

[4] Typically, programming languages only provide support for arrays of *bytes*, not bits, but it is of course possible to simulate arrays with arbitrary numbers of bits using byte arrays and bit manipulation.

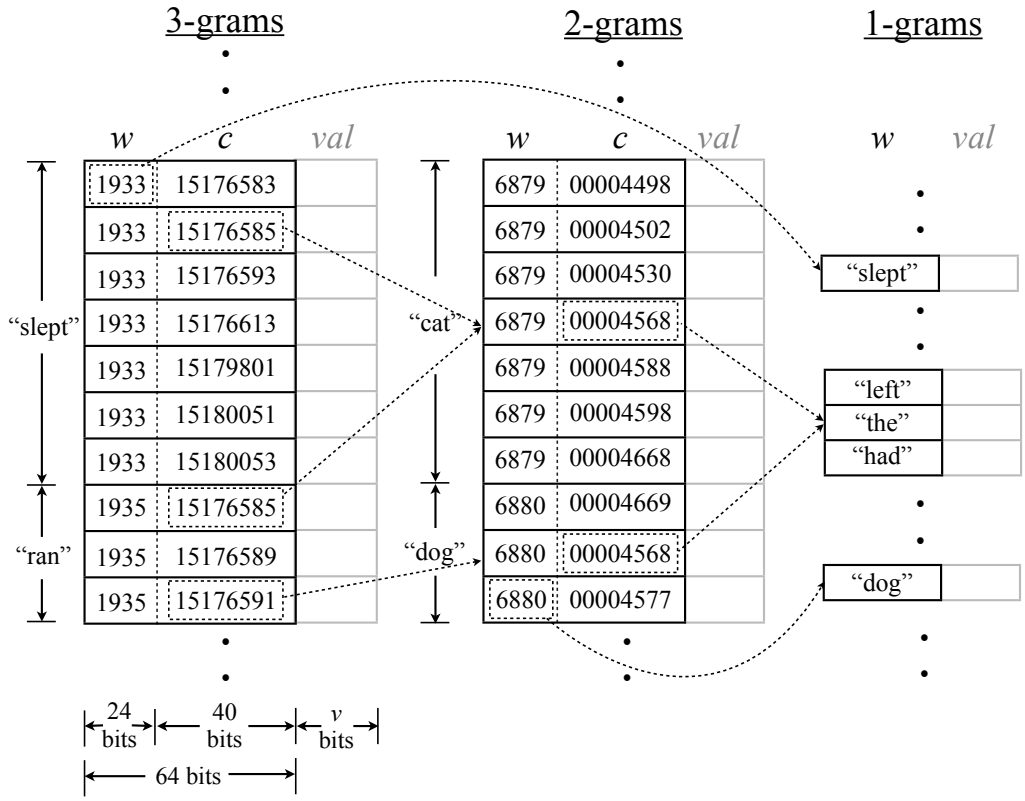

Figure 1: Our SORTED implementation of a trie. The dotted paths correspond to "the cat slept", "the cat ran", and "the dog ran". Each node in the trie is an entry in an array with 3 parts: w represents the word at the node; val represents the (rank encoded) value; and c is an offset in the array of $n-1$ grams that represents the parent (prefix) of a node. Words are represented as offsets in the unigram array.

the bigram using binary search, and form the context encoding of the trigram, and so on. Note, however, that if our queries arrive in context-encoded form, queries are faster since they involve only one binary search in the appropriate array. We will return to this later in Section 4.2

This implementation, SORTED, uses 64 bits for the integer-encoded keys and v bits for the values. Lookup is linear in the length of the key and logarithmic in the number of n-grams. For Web1T ($v = 20$), the total storage is 10.5 bytes/n-gram or about 37GB.

3.2 Hash Table

Hash tables are another standard way to implement associative arrays. To enable the use of our context encoding, we require an implementation in which we can refer to entries in the hash table via array offsets. For this reason, we use an *open address* hash map that uses linear probing for collision resolution.

As in the sorted array implementation, in order to insert an n-gram $\mathbf{w}_1^n$ into the hash table, we must form its context encoding incrementally from the offset of w_1. However, unlike the sorted array implementation, at query time, we only need to be able to check equality between the query key $\mathbf{w}_1^n = (w_n, c(\mathbf{w}_1^{n-1}))$ and a key $\mathbf{w}_1'^n = (w'_n, c(\mathbf{w}_1'^{n-1}))$ in the table. Equality can easily be checked by first checking if $w_n = w'_n$, then recursively checking equality between $\mathbf{w}_1^{n-1}$ and $\mathbf{w}_1'^{n-1}$, though again, equality is even faster if the query is already context-encoded.

This HASH data structure also uses 64 bits for integer-encoded keys and v bits for values. However, to avoid excessive hash collisions, we also allocate additional empty space according to a user-defined parameter that trades off speed and time – we used about 40% extra space in our experiments. For Web1T, the total storage for this implementation is 15 bytes/n-gram or about 53 GB total.

Look up in a hash map is linear in the length of an n-gram and constant with respect to the number

of n-grams. Unlike the sorted array implementation, the hash table implementation also permits efficient insertion and deletion, making it suitable for stream-based language models (Levenberg and Osborne, 2009).

3.3 Implicitly Encoding w_n

The context encoding we have used thus far still wastes space. This is perhaps most evident in the sorted array representation (see Figure 1): all n-grams ending with a particular word w_i are stored contiguously. We can exploit this redundancy by storing only the context offsets in the main array, using as many bits as needed to encode all context offsets (32 bits for Web1T). In auxiliary arrays, one for each n-gram order, we store the beginning and end of the range of the trie array in which all (w_i, c) keys are stored for each w_i. These auxiliary arrays are negligibly small – we only need to store $2n$ offsets for each word.

The same trick can be applied in the hash table implementation. We allocate contiguous blocks of the main array for n-grams which all share the same last word w_i, and distribute keys within those ranges using the hashing function.

This representation reduces memory usage for keys from 64 bits to 32 bits, reducing overall storage for Web1T to 6.5 bytes/n-gram for the sorted implementation and 9.1 bytes for the hashed implementation, or about 23GB and 32GB in total. It also increases query speed in the sorted array case, since to find (w_i, c), we only need to search the range of the array over which w_i applies. Because this implicit encoding reduces memory usage without a performance cost, we will assume its use for the rest of this paper.

3.4 A Compressed Implementation

3.4.1 Variable-Length Coding

The distribution of value ranks in language modeling is Zipfian, with far more n-grams having low counts than high counts. If we ensure that the value rank array sorts raw values by descending order of frequency, then we expect that small ranks will occur much more frequently than large ones, which we can exploit with a variable-length encoding.

To compress n-grams, we can exploit the context encoding of our keys. In Figure 2, we show a portion

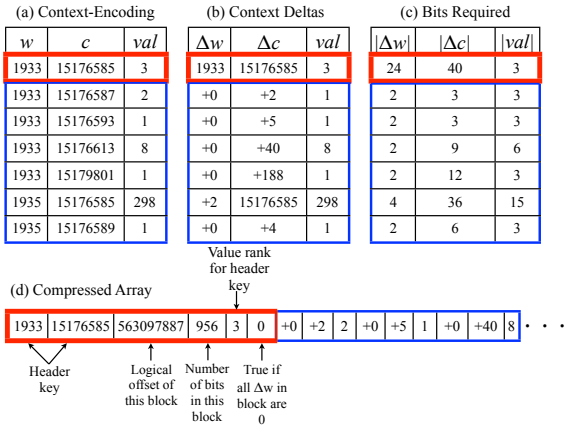

Figure 2: Compression using variable-length encoding. (a) A snippet of an (uncompressed) context-encoded array. (b) The context and word deltas. (c) The number of bits required to encode the context and word deltas as well as the value ranks. Word deltas use variable-length block coding with $k = 1$, while context deltas and value ranks use $k = 2$. (d) A snippet of the compressed encoding array. The header is outlined in bold.

of the key array used in our sorted array implementation. While we have already exploited the fact that the 24 word bits repeat in the previous section, we note here that consecutive context offsets tend to be quite close together. We found that for 5-grams, the median difference between consecutive offsets was about 50, and 90% of offset deltas were smaller than 10000. By using a variable-length encoding to represent these deltas, we should require far fewer than 32 bits to encode context offsets.

We used a very simple variable-length coding to encode offset deltas, word deltas, and value ranks. Our encoding, which is referred to as "variable-length block coding" in Boldi and Vigna (2005), works as follows: we pick a (configurable) radix $r = 2^k$. To encode a number m, we determine the number of digits d required to express m in base r. We write d in unary, i.e. $d - 1$ zeroes followed by a one. We then write the d digits of m in base r, each of which requires k bits. For example, using $k = 2$, we would encode the decimal number 7 as 010111. We can choose k separately for deltas and value indices, and also tune these parameters to a given language model.

We found this encoding outperformed other standard prefix codes, including Golomb codes (Golomb, 1966; Church et al., 2007)

and Elias γ and δ codes. We also experimented with the ζ codes of Boldi and Vigna (2005), which modify variable-length block codes so that they are optimal for certain power law distributions. We found that ζ codes performed no better than variable-length block codes and were slightly more complex. Finally, we found that Huffman codes outperformed our encoding slightly, but came at a much higher computational cost.

3.4.2 Block Compression

We could in principle compress the entire array of key/value pairs with the encoding described above, but this would render binary search in the array impossible: we cannot jump to the mid-point of the array since in order to determine what key lies at a particular point in the compressed bit stream, we would need to know the entire history of offset deltas.

Instead, we employ block compression, a technique also used by Harb et al. (2009) for smaller language models. In particular, we compress the key/value array in blocks of 128 bytes. At the beginning of the block, we write out a header consisting of: an explicit 64-bit key that begins the block; a 32-bit integer representing the offset of the header key in the uncompressed array;[5] the number of bits of compressed data in the block; and the variable-length encoding of the value rank of the header key. The remainder of the block is filled with as many compressed key/value pairs as possible. Once the block is full, we start a new block. See Figure 2 for a depiction.

When we encode an offset delta, we store the delta of the word portion of the key separately from the delta of the context offset. When an entire block shares the same word portion of the key, we set a single bit in the header that indicates that we do not encode any word deltas.

To find a key in this compressed array, we first perform binary search over the header blocks (which are predictably located every 128 bytes), followed by a linear search within a compressed block.

Using $k = 6$ for encoding offset deltas and $k = 5$ for encoding value ranks, this COMPRESSED implementation stores Web1T in less than 3 bytes per n-gram, or about 10.2GB in total. This is about 6GB less than the storage required by Germann et al. (2009), which is the best published lossless compression to date.

[5] We need this because n-grams refer to their contexts using array offsets.

4 Speeding up Decoding

In the previous section, we provided compact and efficient implementations of associative arrays that allow us to query a value for an arbitrary n-gram. However, decoders do not issue language model requests at random. In this section, we show that language model requests issued by a standard decoder exhibit two patterns we can exploit: they are highly *repetitive*, and also exhibit a *scrolling* effect.

4.1 Exploiting Repetitive Queries

In a simple experiment, we recorded all of the language model queries issued by the Joshua decoder (Li et al., 2009) on a 100 sentence test set. Of the 31 million queries, only about 1 million were unique. Therefore, we expect that keeping the results of language model queries in a cache should be effective at reducing overall language model latency.

To this end, we added a very simple cache to our language model. Our cache uses an array of key/value pairs with size fixed to $2^b - 1$ for some integer b (we used 24). We use a b-bit hash function to compute the address in an array where we will always place a given n-gram and its fully computed language model score. Querying the cache is straightforward: we check the address of a key given by its b-bit hash. If the key located in the cache array matches the query key, then we return the value stored in the cache. Otherwise, we fetch the language model probability from the language model and place the new key and value in the cache, evicting the old key in the process. This scheme is often called a *direct-mapped* cache because each key has exactly one possible address.

Caching n-grams in this way reduces overall latency for two reasons: first, lookup in the cache is extremely fast, requiring only a single evaluation of the hash function, one memory lookup to find the cache key, and one equality check on the key. In contrast, even our fastest (HASH) implementation may have to perform multiple memory lookups and equality checks in order to resolve collisions. Second, when calculating the probability for an n-gram

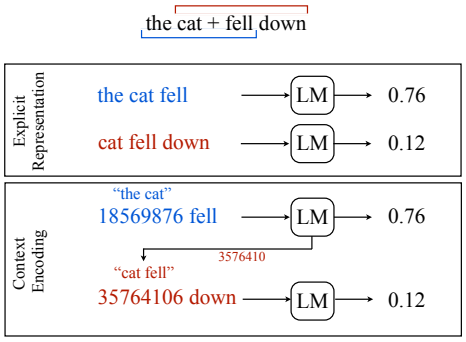

Figure 3: Queries issued when scoring trigrams that are created when a state with LM context "the cat" combines with "fell down". In the standard explicit representation of an n-gram as list of words, queries are issued atomically to the language model. When using a context-encoding, a query from the n-gram "the cat fell" returns the context offset of "cat fell", which speeds up the query of "cat fell down".

not in the language model, language models with back-off schemes must in general perform multiple queries to fetch the necessary back-off information. Our cache retains the full result of these calculations and thus saves additional computation.

Federico and Cettolo (2007) also employ a cache in their language model implementation, though based on traditional hash table cache with linear probing. Unlike our cache, which is of fixed size, their cache must be cleared after decoding a sentence. We would not expect a large performance increase from such a cache for our faster models since our HASH implementation is *already* a hash table with linear probing. We found in our experiments that a cache using linear probing provided marginal performance increases of about 40%, largely because of cached back-off computation, while our simpler cache increases performance by about 300% even over our HASH LM implementation. More timing results are presented in Section 5.

4.2 Exploiting Scrolling Queries

Decoders with integrated language models (Och and Ney, 2004; Chiang, 2005) score partial translation hypotheses in an incremental way. Each partial hypothesis maintains a language model context consisting of at most $n-1$ target-side words. When we combine two language model contexts, we create several new n-grams of length of n, each of which generate a query to the language model. These new

WMT2010

2gm	61,865,588
3gm	123,158,761
4gm	217,869,981
5gm	269,614,330
Total	676,875,055

WEB1T	
Order	#n-grams
1gm	13,588,391
2gm	314,843,401
3gm	977,069,902
4gm	1,313,818,354
5gm	1,176,470,663
Total	3,795,790,711

Table 1: Sizes of the two language models used in our experiments.

n-grams exhibit a *scrolling* effect, shown in Figure 3: the $n-1$ suffix words of one n-gram form the $n-1$ prefix words of the next.

As discussed in Section 3, our LM implementations can answer queries about context-encoded n-grams faster than explicitly encoded n-grams. With this in mind, we augment the values stored in our language model so that for a key $(w_n, c(\mathbf{w}_1^{n-1}))$, we store the offset of the *suffix* $c(\mathbf{w}_2^n)$ as well as the normal counts/probabilities. Then, rather than represent the LM context in the decoder as an explicit list of words, we can simply store context offsets. When we query the language model, we get back both a language model score and context offset $c(\hat{\mathbf{w}}_{\mathbf{1}}^{\mathbf{n-1}})$, where $\hat{\mathbf{w}}_{\mathbf{1}}^{\mathbf{n-1}}$ is the the longest suffix of $\mathbf{w}_1^{n-1}$ contained in the language model. We can then quickly form the context encoding of the next query by simply concatenating the new word with the offset $c(\hat{\mathbf{w}}_1^{n-1})$ returned from the previous query.

In addition to speeding up language model queries, this approach also automatically supports an equivalence of LM states (Li and Khudanpur, 2008): in standard back-off schemes, whenever we compute the probability for an n-gram $(w_n, c(\mathbf{w}_1^{n-1}))$ when $\mathbf{w}_1^{n-1}$ is not in the language model, the result will be the same as the result of the query $(w_n, c(\hat{\mathbf{w}}_1^{n-1}))$. It is therefore only necessary to store as much of the context as the language model contains instead of all $n-1$ words in the context. If a decoder maintains LM states using the context offsets returned by our language model, then the decoder will automatically exploit this equivalence and the size of the search space will be reduced. This same effect is exploited explicitly by some decoders (Li and Khudanpur, 2008).

WMT2010

LM Type	bytes/ key	bytes/ value	bytes/ n-gram	Total Size
SRILM-H	–	–	42.2	26.6G
SRILM-S	–	–	33.5	21.1G
HASH	5.6	6.0	11.6	7.5G
SORTED	4.0	4.5	8.5	5.5G
TPT	–	–	7.5**	4.7G**
COMPRESSED	**2.1**	**3.8**	**5.9**	**3.7**G

Table 2: Memory usages of several language model implementations on the WMT2010 language model. A ** indicates that the storage in bytes per n-gram is reported for a different language model of comparable size, and the total size is thus a rough projection.

5 Experiments

5.1 Data

To test our LM implementations, we performed experiments with two different language models. Our first language model, WMT2010, was a 5-gram Kneser-Ney language model which stores probability/back-off pairs as values. We trained this language model on the English side of all French-English corpora provided[6] for use in the WMT 2010 workshop, about 2 billion tokens in total. This data was tokenized using the `tokenizer.perl` script provided with the data. We trained the language model using SRILM. We also extracted a count-based language model, WEB1T, from the Web1T corpus (Brants and Franz, 2006). Since this data is provided as a collection of 1- to 5-grams and associated counts, we used this data without further preprocessing. The make up of these language models is shown in Table 1.

5.2 Compression Experiments

We tested our three implementations (HASH, SORTED, and COMPRESSED) on the WMT2010 language model. For this language model, there are about 80 million unique probability/back-off pairs, so $v \approx 36$. Note that here v includes both the cost per key of storing the value rank as well as the (amortized) cost of storing two 32 bit floating point numbers (probability and back-off) for each unique value. The results are shown in Table 2.

[6] `www.statmt.org/wmt10/translation-task.html`

WEB1T

LM Type	bytes/ key	bytes/ value	bytes/ n-gram	Total Size
Gzip	–	–	7.0	24.7G
T-MPHR†	–	–	3.0	10.5G
COMPRESSED	1.3	1.6	2.9	10.2G

Table 3: Memory usages of several language model implementations on the WEB1T. A † indicates lossy compression.

We compare against three baselines. The first two, SRILM-H and SRILM-S, refer to the hash table- and sorted array-based trie implementations provided by SRILM. The third baseline is the Tightly-Packed Trie (TPT) implementation of Germann et al. (2009). Because this implementation is not freely available, we use their published memory usage in bytes per n-gram on a language model of similar size and project total usage.

The memory usage of all of our models is considerably smaller than SRILM – our HASH implementation is about 25% the size of SRILM-H, and our SORTED implementation is about 25% the size of SRILM-S. Our COMPRESSED implementation is also smaller than the state-of-the-art compressed TPT implementation.

In Table 3, we show the results of our COMPRESSED implementation on WEB1T and against two baselines. The first is compression of the ASCII text count files using `gzip`, and the second is the Tiered Minimal Perfect Hash (T-MPHR) of Guthrie and Hepple (2010). The latter is a *lossy* compression technique based on Bloomier filters (Chazelle et al., 2004) and additional variable-length encoding that achieves the best published compression of WEB1T to date. Our COMPRESSED implementation is even smaller than T-MPHR, despite using a *lossless* compression technique. Note that since T-MPHR uses a lossy encoding, it is possible to reduce the storage requirements arbitrarily at the cost of additional errors in the model. We quote here the storage required when keys[7] are encoded using 12-bit hash codes, which gives a false positive rate of about 2^{-12} =0.02%.

[7] Guthrie and Hepple (2010) also report additional savings by quantizing values, though we could perform the same quantization in our storage scheme.

LM Type	No Cache	Cache	Size
COMPRESSED	9264±73ns	565±7ns	3.7G
SORTED	1405±50ns	243±4ns	5.5G
HASH	495±10ns	179±6ns	7.5G
SRILM-H	428±5ns	159±4ns	26.6G
HASH+SCROLL	323±5ns	139±6ns	10.5G

Table 4: Raw query speeds of various language model implementations. Times were averaged over 3 runs on the same machine. For HASH+SCROLL, all queries were issued to the decoder in context-encoded form, which speeds up queries that exhibit scrolling behaviour. Note that memory usage is higher than for HASH because we store suffix offsets along with the values for an n-gram.

LM Type	No Cache	Cache	Size
COMPRESSED	9880±82s	1547±7s	3.7G
SRILM-H	1120±26s	938±11s	26.6G
HASH	1146±8s	943±16s	7.5G

Table 5: Full decoding times for various language model implementations. Our HASH LM is as fast as SRILM while using 25% of the memory. Our caching also reduces total decoding time by about 20% for our fastest models and speeds up COMPRESSED by a factor of 6. Times were averaged over 3 runs on the same machine.

5.3 Timing Experiments

We first measured pure query speed by logging all LM queries issued by a decoder and measuring the time required to query those n-grams in isolation. We used the the Joshua decoder[8] with the WMT2010 model to generate queries for the first 100 sentences of the French 2008 News test set. This produced about 30 million queries. We measured the time[9] required to perform each query in order with and without our direct-mapped caching, not including any time spent on file I/O.

The results are shown in Table 4. As expected, HASH is the fastest of our implementations, and comparable[10] in speed to SRILM-H, but using significantly less space. SORTED is slower but of course more memory efficient, and COMPRESSED is the slowest but also the most compact representation. In HASH+SCROLL, we issued queries to the language model using the context encoding, which speeds up queries substantially. Finally, we note that our direct-mapped cache is very effective. The query speed of all models is boosted substantially. In particular, our COMPRESSED implementation with caching is nearly as fast as SRILM-H without caching, and even the already fast HASH implementation is 300% faster in raw query speed with caching enabled.

We also measured the effect of LM performance on overall decoder performance. We modified Joshua to optionally use our LM implementations during decoding, and measured the time required to decode all 2051 sentences of the 2008 News test set. The results are shown in Table 5. Without caching, SRILM-H and HASH were comparable in speed, while COMPRESSED introduces a performance penalty. With caching enabled, overall decoder speed is improved for both HASH and SRILM-H, while the COMPRESSED implementation is only about 50% slower that the others.

6 Conclusion

We have presented several language model implementations which are state-of-the-art in both size and speed. Our experiments have demonstrated improvements in query speed over SRILM and compression rates against state-of-the-art lossy compression. We have also described a simple caching technique which leads to performance increases in overall decoding time.

[8] We used a grammar trained on all French-English data provided for WMT 2010 using the `make` scripts provided at `http://sourceforge.net/projects/joshua/files/joshua/1.3/wmt2010-experiment.tgz/download`

[9] All experiments were performed on an Amazon EC2 High-Memory Quadruple Extra Large instance, with an Intel Xeon X5550 CPU running at 2.67GHz and 8 MB of cache.

[10] Because we implemented our LMs in Java, we issued queries to SRILM via Java Native Interface (JNI) calls, which introduces a performance overhead. When called natively, we found that SRILM was about 200 ns/query faster. Unfortunately, it is not completely fair to compare our LMs against either of these numbers: although the JNI overhead slows down SRILM, implementing our LMs in Java instead of C++ slows down our LMs. In the tables, we quote times which include the JNI overhead, since this reflects the true cost to a decoder written in Java (e.g. Joshua).

Abstract

This paper presents a novel approach for leveraging automatically extracted textual knowledge to improve the performance of control applications such as games. Our ultimate goal is to enrich a stochastic player with high-level guidance expressed in text. Our model jointly learns to identify text that is relevant to a given game state in addition to learning game strategies guided by the selected text. Our method operates in the Monte-Carlo search framework, and learns both text analysis and game strategies based only on environment feedback. We apply our approach to the complex strategy game Civilization II using the official game manual as the text guide. Our results show that a linguistically-informed game-playing agent significantly outperforms its language-unaware counterpart, yielding a 27% absolute improvement and winning over 78% of games when playing against the built-in AI of Civilization II. [1]

1 Introduction

In this paper, we study the task of grounding linguistic analysis in control applications such as computer games. In these applications, an agent attempts to optimize a utility function (e.g., game score) by learning to select situation-appropriate actions. In complex domains, finding a winning strategy is challenging even for humans. Therefore, human players typically rely on manuals and guides that describe promising tactics and provide general advice about the underlying task. Surprisingly, such textual information has never been utilized in control algorithms despite its potential to greatly improve performance.

[1]The code, data and complete experimental setup for this work are available at http://groups.csail.mit.edu/rbg/code/civ.

> *The natural resources available where a population settles affects its ability to produce food and goods. Build your city on a plains or grassland square with a river running through it if possible.*

Figure 1: An excerpt from the user manual of the game Civilization II.

Consider for instance the text shown in Figure 1. This is an excerpt from the user manual of the game Civilization II.[2] This text describes game locations where the action "build-city" can be effectively applied. A stochastic player that does not have access to this text would have to gain this knowledge the hard way: it would repeatedly attempt this action in a myriad of states, thereby learning the characterization of promising state-action pairs based on the observed game outcomes. In games with large state spaces, long planning horizons, and high-branching factors, this approach can be prohibitively slow and ineffective. An algorithm with access to the text, however, could learn correlations between words in the text and game attributes – e.g., the word "river" and places with rivers in the game – thus leveraging strategies described in text to better select actions.

The key technical challenge in leveraging textual knowledge is to automatically extract relevant information from text and incorporate it effectively into a control algorithm. Approaching this task in a supervised framework, as is common in traditional information extraction, is inherently difficult. Since the game's state space is extremely large, and the states that will be encountered during game play cannot be known a priori, it is impractical to manually annotate the information that would be relevant to those states. Instead, we propose to learn text analysis based on a feedback signal inherent to the control application, such as game score.

[2]http://en.wikipedia.org/wiki/Civilization_II

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 268–277,
Portland, Oregon, June 19-24, 2011.

Our general setup consists of a game in a stochastic environment, where the goal of the player is to maximize a given utility function $R(s)$ at state s. We follow a common formulation that has been the basis of several successful applications of machine learning to games. The player's behavior is determined by an action-value function $Q(s, a)$ that assesses the goodness of an action a in a given state s based on the features of s and a. This function is learned based solely on the utility $R(s)$ collected via simulated game-play in a Monte-Carlo framework.

An obvious way to enrich the model with textual information is to augment the action-value function with word features in addition to state and action features. However, adding all the words in the document is unlikely to help since only a small fraction of the text is relevant for a given state. Moreover, even when the relevant sentence is known, the mapping between raw text and the action-state representation may not be apparent. This representation gap can be bridged by inducing a predicate structure on the sentence—e.g., by identifying words that describe actions, and those that describe state attributes.

In this paper, we propose a method for learning an action-value function augmented with linguistic features, while simultaneously modeling sentence relevance and predicate structure. We employ a multilayer neural network where the hidden layers represent sentence relevance and predicate parsing decisions. Despite the added complexity, all the parameters of this non-linear model can be effectively learned via Monte-Carlo simulations.

We test our method on the strategy game Civilization II, a notoriously challenging game with an immense action space.[3] As a source of knowledge for guiding our model, we use the official game manual. As a baseline, we employ a similar Monte-Carlo search based player which does not have access to textual information. We demonstrate that the linguistically-informed player significantly outperforms the baseline in terms of number of games won. Moreover, we show that modeling the deeper linguistic structure of sentences further improves performance. In full-length games, our algorithm yields a 27% improvement over a language unaware baseline, and wins over 78% of games against the built-in, hand-crafted AI of Civilization II.[4]

2 Related Work

Our work fits into the broad area of grounded language acquisition where the goal is to learn linguistic analysis from a situated context (Oates, 2001; Siskind, 2001; Yu and Ballard, 2004; Fleischman and Roy, 2005; Mooney, 2008a; Mooney, 2008b; Branavan et al., 2009; Vogel and Jurafsky, 2010). Within this line of work, we are most closely related to reinforcement learning approaches that learn language by proactively interacting with an external environment (Branavan et al., 2009; Branavan et al., 2010; Vogel and Jurafsky, 2010). Like the above models, we use environment feedback (in the form of a utility function) as the main source of supervision. The key difference, however, is in the language interpretation task itself. Previous work has focused on the interpretation of instruction text where input documents specify a set of actions to be executed in the environment. In contrast, game manuals provide high-level advice but do not directly describe the correct actions for every potential game state. Moreover, these documents are long, and use rich vocabularies with complex grammatical constructions. We do not aim to perform a comprehensive interpretation of such documents. Rather, our focus is on language analysis that is sufficiently detailed to help the underlying control task.

The area of language analysis situated in a game domain has been studied in the past (Eisenstein et al., 2009). Their method, however, is different both in terms of the target interpretation task, and the supervision signal it learns from. They aim to learn the rules of a given game, such as which moves are valid, given documents describing the rules. Our goal is more open ended, in that we aim to learn winning game strategies. Furthermore, Eisenstein et al. (2009) rely on a different source of supervision – game traces collected a priori. For complex games, like the one considered in this paper, collecting such game traces is prohibitively expensive. Therefore our approach learns by actively playing the game.

[3] Civilization II was #3 in IGN's 2007 list of top video games of all time (http://top100.ign.com/2007/ign_top_game_3.html)

[4] In this paper, we focus primarily on the linguistic aspects of our task and algorithm. For a discussion and evaluation of the non-linguistic aspects please see Branavan et al. (2011).

3 Monte-Carlo Framework for Computer Games

Our method operates within the Monte-Carlo search framework (Tesauro and Galperin, 1996), which has been successfully applied to complex computer games such as Go, Poker, Scrabble, multi-player card games, and real-time strategy games, among others (Gelly et al., 2006; Tesauro and Galperin, 1996; Billings et al., 1999; Sheppard, 2002; Schäfer, 2008; Sturtevant, 2008; Balla and Fern, 2009). Since Monte-Carlo search forms the foundation of our approach, we briefly describe it in this section.

Game Representation The game is defined by a large Markov Decision Process $\langle S, A, T, R \rangle$. Here S is the set of possible states, A is the space of legal actions, and $T(s'|s,a)$ is a stochastic state transition function where $s, s' \in S$ and $a \in A$. Specifically, a state encodes attributes of the game world, such as available resources and city locations. At each step of the game, a player executes an action a which causes the current state s to change to a new state s' according to the transition function $T(s'|s,a)$. While this function is not known a priori, the program encoding the game can be viewed as a black box from which transitions can be sampled. Finally, a given utility function $R(s) \in \mathbb{R}$ captures the likelihood of winning the game from state s (e.g., an intermediate game score).

Monte-Carlo Search Algorithm The goal of the Monte-Carlo search algorithm is to dynamically select the best action for the current state s_t. This selection is based on the results of multiple *roll-outs* which measure the outcome of a sequence of actions in a simulated game – e.g., simulations played against the game's built-in AI. Specifically, starting at state s_t, the algorithm repeatedly selects and executes actions, sampling state transitions from T. On game completion at time τ, we measure the final utility $R(s_\tau)$.[5] The actual game action is then selected as the one corresponding to the roll-out with the best final utility. See Algorithm 1 for details.

The success of Monte-Carlo search is based on its ability to make a fast, local estimate of the action quality at each step of the roll-outs. States and actions are evaluated by an *action-value function* $Q(s,a)$, which is an estimate of the expected outcome of action a in state s. This action-value function is used to guide action selection during the roll-outs. While actions are usually selected to maximize the action-value function, sometimes other actions are also randomly explored in case they are more valuable than predicted by the current estimate of $Q(s,a)$. As the accuracy of $Q(s,a)$ improves, the quality of action selection improves and vice

procedure PlayGame ()

Initialize game state to fixed starting state
$s_1 \leftarrow s_0$

for $t = 1 \dots T$ **do**

  Run N simulated games
  for $i = 1 \dots N$ **do**
    $(a_i, r_i) \leftarrow \text{SimulateGame}(s)$
  end

  Compute average observed utility for each action
  $a_t \leftarrow \arg\max_a \frac{1}{N_a} \sum_{i:a_i=a} r_i$

  Execute selected action in game
  $s_{t+1} \leftarrow T(s'|s_t, a_t)$
end

procedure SimulateGame (s_t)

for $u = t \dots \tau$ **do**

  Compute Q function approximation
  $Q(s,a) = \vec{w} \cdot \vec{f}(s,a)$

  Sample action from action-value function in ϵ-greedy fashion:
  $$a_u \sim \begin{cases} \text{uniform}(a \in A) & \text{with probability } \epsilon \\ \arg\max_a Q(s,a) & \text{otherwise} \end{cases}$$

  Execute selected action in game:
  $s_{u+1} \leftarrow T(s'|s_u, a_u)$

  if game is won or lost **break**
end

Update parameters $\vec{w}$ of $Q(s,a)$

Return action and observed utility:
return $a_t, R(s_\tau)$

Algorithm 1: The general Monte-Carlo algorithm.

[5] In general, roll-outs are run till game completion. However, if simulations are expensive as is the case in our domain, roll-outs can be truncated after a fixed number of steps.

versa, in a cycle of continual improvement (Sutton and Barto, 1998).

In many games, it is sufficient to maintain a distinct action-value for each unique state and action in a large search tree. However, when the branching factor is large it is usually beneficial to approximate the action-value function, so that the value of many related states and actions can be learned from a reasonably small number of simulations (Silver, 2009). One successful approach is to model the action-value function as a linear combination of state and action attributes (Silver et al., 2008):

$$Q(s,a) = \vec{w} \cdot \vec{f}(s,a).$$

Here $\vec{f}(s,a) \in \mathbb{R}^n$ is a real-valued feature function, and $\vec{w}$ is a weight vector. We take a similar approach here, except that our feature function includes latent structure which models language.

The parameters $\vec{w}$ of $Q(s,a)$ are learned based on feedback from the roll-out simulations. Specifically, the parameters are updated by stochastic gradient descent by comparing the current predicted $Q(s,a)$ against the observed utility at the end of each roll-out. We provide details on parameter estimation in the context of our model in Section 4.2.

The roll-outs themselves are fully guided by the action-value function. At every step of the simulation, actions are selected by an ϵ-greedy strategy: with probability ϵ an action is selected uniformly at random; otherwise the action is selected greedily to maximize the current action-value function, $\arg\max_a Q(s,a)$.

4 Adding Linguistic Knowledge to the Monte-Carlo Framework

In this section we describe how we inform the simulation-based player with information automatically extracted from text – in terms of both model structure and parameter estimation.

4.1 Model Structure

To inform action selection with the advice provided in game manuals, we modify the action-value function $Q(s,a)$ to take into account words of the document in addition to state and action information. Conditioning $Q(s,a)$ on all the words in the document is unlikely to be effective since only a small fraction of the document provides guidance relevant to the current state, while the remainder of the text is likely to be irrelevant. Since this information is not known a priori, we model the decision about a sentence's relevance to the current state as a hidden variable. Moreover, to fully utilize the information presented in a sentence, the model identifies the words that describe *actions* and those that describe *state attributes*, discriminating them from the rest of the sentence. As with the relevance decision, we model this labeling using hidden variables.

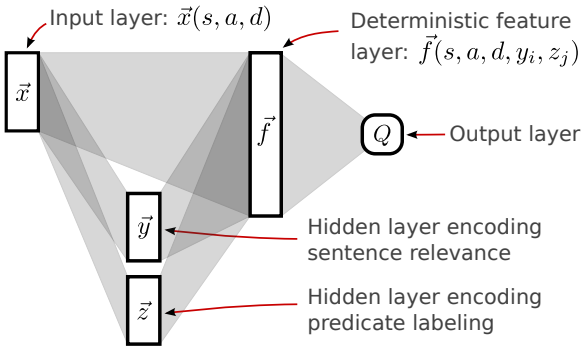

Figure 2: The structure of our model. Each rectangle represents a collection of units in a layer, and the shaded trapezoids show the connections between layers. A fixed, real-valued feature function $\vec{x}(s,a,d)$ transforms the game state s, action a, and strategy document d into the input vector $\vec{x}$. The first hidden layer contains two disjoint sets of units $\vec{y}$ and $\vec{z}$ corresponding to linguistic analyzes of the strategy document. These are softmax layers, where only one unit is active at any time. The units of the second hidden layer $\vec{f}(s,a,d,y_i,z_i)$ are a set of fixed real valued feature functions on s, a, d and the active units y_i and z_i of $\vec{y}$ and $\vec{z}$ respectively.

As shown in Figure 2, our model is a four layer neural network. The *input layer* $\vec{x}$ represents the current state s, candidate action a, and document d. The *second layer* consists of two disjoint sets of units $\vec{y}$ and $\vec{z}$ which encode the sentence-relevance and predicate-labeling decisions respectively. Each of these sets of units operates as a stochastic 1-of-n softmax selection layer (Bridle, 1990) where only a single unit is activated. The activation function for units in this layer is the standard softmax function:

$$p(y_i = 1|\vec{x}) = e^{\vec{u}_i \cdot \vec{x}} \Big/ \sum_k e^{\vec{u}_k \cdot \vec{x}},$$

where y_i is the i^{th} hidden unit of $\vec{y}$, and $\vec{u}_i$ is the weight vector corresponding to y_i. Given this acti-

vation function, the second layer effectively models sentence relevance and predicate labeling decisions via log-linear distributions, the details of which are described below.

The third *feature layer* $\vec{f}$ of the neural network is deterministically computed given the active units y_i and z_j of the softmax layers, and the values of the input layer. Each unit in this layer corresponds to a fixed feature function $f_k(s_t, a_t, d, y_i, z_j) \in \mathbb{R}$. Finally the *output layer* encodes the action-value function $Q(s, a, d)$, which now also depends on the document d, as a weighted linear combination of the units of the feature layer:

$$Q(s_t, a_t, d) = \vec{w} \cdot \vec{f},$$

where $\vec{w}$ is the weight vector.

Modeling Sentence Relevance Given a strategy document d, we wish to identify a sentence y_i that is most relevant to the current game state s_t and action a_t. This relevance decision is modeled as a log-linear distribution over sentences as follows:

$$p(y_i|s_t, a_t, d) \propto e^{\vec{u}\cdot\phi(y_i, s_t, a_t, d)}.$$

Here $\phi(y_i, s_t, a_t, d) \in \mathbb{R}^n$ is a feature function, and $\vec{u}$ are the parameters we need to estimate.

Modeling Predicate Structure Our goal here is to label the words of a sentence as either *action-description*, *state-description* or *background*. Since these word label assignments are likely to be mutually dependent, we model predicate labeling as a sequence prediction task. These dependencies do not necessarily follow the order of words in a sentence, and are best expressed in terms of a syntactic tree. For example, words corresponding to *state-description* tend to be descendants of *action-description* words. Therefore, we label words in dependency order — i.e., starting at the root of a given dependency tree, and proceeding to the leaves. This allows a word's label decision to condition on the label of the corresponding dependency tree parent.

Given sentence y_i and its dependency parse q_i, we model the distribution over predicate labels $\vec{e}_i$ as:

$$\begin{aligned} p(\vec{e}_i\,|y_i, q_i) &= \prod_j p(e_j|j, \vec{e}_{1:j-1}, y_i, q_i), \\ p(e_j|j, \vec{e}_{1:j-1}, y_i, q_i) &\propto e^{\vec{v}\cdot\psi(e_j, j, \vec{e}_{1:j-1}, y_i, q_i)}. \end{aligned}$$

Here e_j is the predicate label of the j^{th} word being labeled, and $\vec{e}_{1:j-1}$ is the partial predicate labeling constructed so far for sentence y_i.

In the second layer of the neural network, the units $\vec{z}$ represent a predicate labeling $\vec{e}_i$ of every sentence $y_i \in d$. However, our intention is to incorporate, into action-value function Q, information from only the most relevant sentence. Thus, in practice, we only perform a predicate labeling of the sentence selected by the relevance component of the model.

Given the sentence selected as relevant and its predicate labeling, the output layer of the network can now explicitly learn the correlations between textual information, and game states and actions – for example, between the word "grassland" in Figure 1, and the action of building a city. This allows our method to leverage the automatically extracted textual information to improve game play.

4.2 Parameter Estimation

Learning in our method is performed in an online fashion: at each game state s_t, the algorithm performs a simulated game roll-out, observes the outcome of the game, and updates the parameters $\vec{u}$, $\vec{v}$ and $\vec{w}$ of the action-value function $Q(s_t, a_t, d)$. These three steps are repeated a fixed number of times at each actual game state. The information from these roll-outs is used to select the actual game action. The algorithm re-learns $Q(s_t, a_t, d)$ for every new game state s_t. This specializes the action-value function to the subgame starting from s_t.

Since our model is a non-linear approximation of the underlying action-value function of the game, we learn model parameters by applying non-linear regression to the observed final utilities from the simulated roll-outs. Specifically, we adjust the parameters by stochastic gradient descent, to minimize the mean-squared error between the action-value $Q(s, a)$ and the final utility $R(s_\tau)$ for each observed game state s and action a. The resulting update to model parameters θ is of the form:

$$\begin{aligned} \Delta\theta &= -\frac{\alpha}{2}\nabla_\theta \left[R(s_\tau) - Q(s, a)\right]^2 \\ &= \alpha \left[R(s_\tau) - Q(s, a)\right] \nabla_\theta Q(s, a; \theta), \end{aligned}$$

where α is a learning rate parameter.

This minimization is performed via standard error backpropagation (Bryson and Ho, 1969; Rumelhart

et al., 1986), which results in the following online updates for the output layer parameters $\vec{w}$:

$$\vec{w} \leftarrow \vec{w} + \alpha_w \left[Q - R(s_\tau)\right] \vec{f}(s, a, d, y_i, z_j),$$

where α_w is the learning rate, and $Q = Q(s, a, d)$. The corresponding updates for the sentence relevance and predicate labeling parameters $\vec{u}$ and $\vec{v}$ are:

$$\vec{u}_i \leftarrow \vec{u}_i + \alpha_u \left[Q - R(s_\tau)\right] Q \vec{x} \left[1 - p(y_i|\cdot)\right],$$

$$\vec{v}_i \leftarrow \vec{v}_i + \alpha_v \left[Q - R(s_\tau)\right] Q \vec{x} \left[1 - p(z_i|\cdot)\right].$$

5 Applying the Model

We apply our model to playing the turn-based strategy game, Civilization II. We use the official manual [6] of the game as the source of textual strategy advice for the language aware algorithms.

Civilization II is a multi-player game set on a grid-based map of the world. Each grid location represents a tile of either land or sea, and has various resources and terrain attributes. For example, land tiles can have hills with rivers running through them. In addition to multiple cities, each player controls various units – e.g., settlers and explorers. Games are won by gaining control of the entire world map. In our experiments, we consider a two-player game of Civilization II on a grid of 1000 squares, where we play against the built-in AI player.

Game States and Actions We define the game state of Civilization II to be the map of the world, the attributes of each map tile, and the attributes of each player's cities and units. Some examples of the attributes of states and actions are shown in Figure 3. The space of possible actions for a given city or unit is known given the current game state. The actions of a player's cities and units combine to form the action space of that player. In our experiments, on average a player controls approximately 18 units, and each unit can take one of 15 actions. This results in a very large action space for the game – i.e., 10^{21}. To effectively deal with this large action space, we assume that given the state, the actions of a single unit are independent of the actions of all other units of the same player.

Utility Function The Monte-Carlo algorithm uses the utility function to evaluate the outcomes of simulated game roll-outs. In the typical application of the algorithm, the final game outcome is used as the utility function (Tesauro and Galperin, 1996). Given the complexity of Civilization II, running simulation roll-outs until game completion is impractical. The game, however, provides each player with a *game score*, which is a noisy indication of how well they are currently playing. Since we are playing a two-player game, we use the ratio of the game score of the two players as our utility function.

Map tile attributes:
- Terrain type (e.g. grassland, mountain, etc)
- Tile resources (e.g. wheat, coal, wildlife, etc)

City attributes:
- City population
- Amount of food produced

Unit attributes:
- Unit type (e.g., worker, explorer, archer, etc)
- Is unit in a city ?

$$f_1(s, a, v, \vec{e}) = \begin{cases} 1 \text{ if action=build-city} \\ \quad \& \text{ tile-has-river=true} \\ \quad \& \text{ action-words=\{build,city\}} \\ \quad \& \text{ state-words=\{river,hill\}} \\ 0 \text{ otherwise} \end{cases}$$

$$\phi_1(v, s, a) = \begin{cases} 1 \text{ if action=build-city} \\ \quad \& \text{ tile-has-river=true} \\ \quad \& \text{ words=\{build,city,river\}} \\ 0 \text{ otherwise} \end{cases}$$

$$\psi_1(e_i, i, \vec{e}_{1:i-1}, v, z_v) = \begin{cases} 1 \text{ if label=action} \\ \quad \& \text{ word-type='build'} \\ \quad \& \text{ parent-label=action} \\ 0 \text{ otherwise} \end{cases}$$

Figure 3: Example attributes of the game (box above), and features computed using the game manual and these attributes (box below).

Features The sentence relevance features $\vec{\phi}$ and the action-value function features $\vec{f}$ consider the attributes of the game state and action, and the words of the sentence. Some of these features compute text overlap between the words of the sentence, and text labels present in the game. The feature function $\vec{\psi}$ used for predicate labeling on the other hand operates only on a given sentence and its dependency parse. It computes features which are the Cartesian product of the candidate predicate label with word attributes such as type, part-of-speech tag, and dependency parse information. Overall, $\vec{f}$, $\vec{\phi}$ and $\vec{\psi}$ compute approximately 306,800, 158,500, and 7,900 features respectively. Figure 3 shows some examples of these features.

6 Experimental Setup

Datasets We use the official game manual for Civilization II as our strategy guide. This manual uses a large vocabulary of 3638 words, and is composed of 2083 sentences, each on average 16.9 words long.

Experimental Framework To apply our method to the Civilization II game, we use the game's open source implementation *Freeciv*.[7] We instrument the game to allow our method to programmatically measure the current state of the game and to execute game actions. The Stanford parser (de Marneffe et al., 2006) was used to generate the dependency parse information for sentences in the game manual.

Across all experiments, we start the game at the same initial state and run it for 100 steps. At each step, we perform 500 Monte-Carlo roll-outs. Each roll-out is run for 20 simulated game steps before halting the simulation and evaluating the outcome. For our method, and for each of the baselines, we run 200 independent games in the above manner, with evaluations averaged across the 200 runs. We use the same experimental settings across all methods, and all model parameters are initialized to zero.

The test environment consisted of typical PCs with single Intel Core i7 CPUs (4 hyper-threaded cores each), with the algorithms executing 8 simulation roll-outs in parallel. In this setup, a single game of 100 steps runs in approximately 1.5 hours.

Evaluation Metrics We wish to evaluate two aspects of our method: how well it leverages textual information to improve game play, and the accuracy of the linguistic analysis it produces. We evaluate the first aspect by comparing our method against various baselines in terms of the percentage of games won against the built-in AI of Freeciv. This AI is a fixed algorithm designed using extensive knowledge of the game, with the intention of challenging human players. As such, it provides a good open-reference baseline. Since full games can last for multiple days, we compute the percentage of games won within the first 100 game steps as our primary evaluation. To confirm that performance under this evaluation is meaningful, we also compute the percentage of full games won over 50 independent runs, where each game is run to completion.

Method	% Win	% Loss	Std. Err.
Random	0	100	—
Built-in AI	0	0	—
Game only	17.3	5.3	± 2.7
Sentence relevance	46.7	2.8	± 3.5
Full model	**53.7**	5.9	± 3.5
Random text	40.3	4.3	± 3.4
Latent variable	26.1	3.7	± 3.1

Table 1: Win rate of our method and several baselines within the first 100 game steps, while playing against the built-in game AI. Games that are neither won nor lost are still ongoing. Our model's win rate is statistically significant against all baselines except *sentence relevance*. All results are averaged across 200 independent game runs. The standard errors shown are for percentage wins.

Method	% Wins	Standard Error
Game only	45.7	± 7.0
Latent variable	62.2	± 6.9
Full model	**78.8**	± 5.8

Table 2: Win rate of our method and two baselines on 50 full length games played against the built-in AI.

7 Results

Game performance As shown in Table 1, our language aware Monte-Carlo algorithm substantially outperforms several baselines – on average winning 53.7% of all games within the first 100 steps. The dismal performance, on the other hand, of both the *random* baseline and the game's own *built-in AI* (playing against itself) is an indicator of the difficulty of the task. This evaluation is an underestimate since it assumes that any game not won within the first 100 steps is a loss. As shown in Table 2, our method wins over 78% of full length games.

To characterize the contribution of the language components to our model's performance, we compare our method against two ablative baselines. The first of these, *game-only*, does not take advantage of any textual information. It attempts to model the action value function $Q(s, a)$ only in terms of the attributes of the game state and action. The performance of this baseline – a win rate of 17.3% – effectively confirms the benefit of automatically extracted textual information in the context of our task. The second ablative baseline, *sentence-relevance*, is

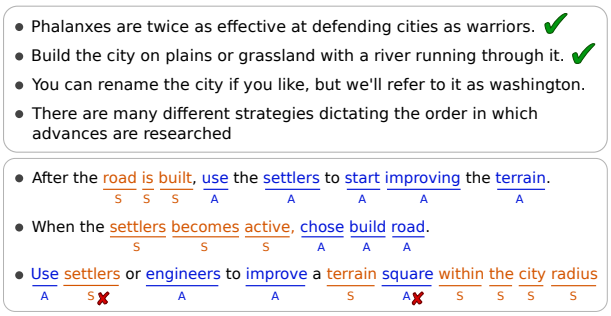

Figure 4: Examples of our method's sentence relevance and predicate labeling decisions. The box above shows two sentences (identified by check marks) which were predicted as relevant, and two which were not. The box below shows the predicted predicate structure of three sentences, with "S" indicating *state* description,"A" *action* description and *background* words unmarked. Mistakes are identified with crosses.

identical to our model, but lacks the predicate labeling component. This method wins 46.7% of games, showing that while identifying the text relevant to the current game state is essential, a deeper structural analysis of the extracted text provides substantial benefits.

One possible explanation for the improved performance of our method is that the non-linear approximation simply models game characteristics better, rather than modeling textual information. We directly test this possibility with two additional baselines. The first, *random-text*, is identical to our full model, but is given a document containing random text. We generate this text by randomly permuting the word locations of the actual game manual, thereby maintaining the document's overall statistical properties. The second baseline, *latent variable*, extends the linear action-value function $Q(s, a)$ of the *game only* baseline with a set of latent variables – i.e., it is a four layer neural network, where the second layer's units are activated only based on game information. As shown in Table 1 both of these baselines significantly underperform with respect to our model, confirming the benefit of automatically extracted textual information in the context of this task.

Sentence Relevance Figure 4 shows examples of the sentence relevance decisions produced by our method. To evaluate the accuracy of these decisions, we ideally require a ground-truth relevance annotation of the game's user manual. This however, is

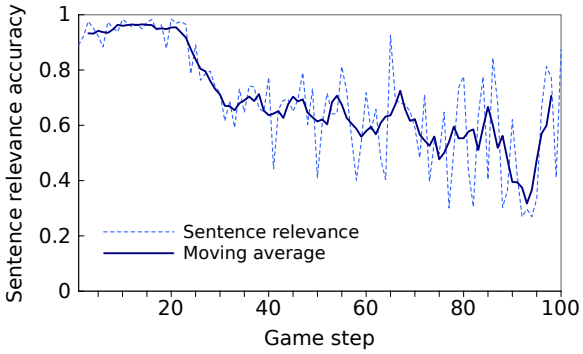

Figure 5: Accuracy of our method's sentence relevance predictions, averaged over 100 independent runs.

impractical since the relevance decision is dependent on the game context, and is hence specific to each time step of each game instance. Therefore, for the purposes of this evaluation, we modify the game manual by adding to it sentences randomly selected from the Wall Street Journal corpus (Marcus et al., 1993) – sentences that are highly unlikely to be relevant to game play. We then evaluate the accuracy with which sentences from the original manual are picked as relevant.

In this evaluation, our method achieves an average accuracy of 71.8%. Given that our model only has to differentiate between the game manual text and the Wall Street Journal, this number may seem disappointing. Furthermore, as can be seen from Figure 5, the sentence relevance accuracy varies widely as the game progresses, with a high average of 94.2% during the initial 25 game steps.

In reality, this pattern of high initial accuracy followed by a lower average is not entirely surprising: the official game manual for Civilization II is written for first time players. As such, it focuses on the initial portion of the game, providing little strategy advice relevant to subsequence game play.[8] If this is the reason for the observed sentence relevance trend, we would also expect the final layer of the neural network to emphasize game features over text features after the first 25 steps of the game. This is indeed the case, as can be seen from Figure 6.

To further test this hypothesis, we perform an experiment where the first 50 steps of the game are played using our full model, and the subsequent 50 steps are played without using any textual informa-

[8]This is reminiscent of *opening books* for games like Chess or Go, which aim to guide the player to a playable middle game.

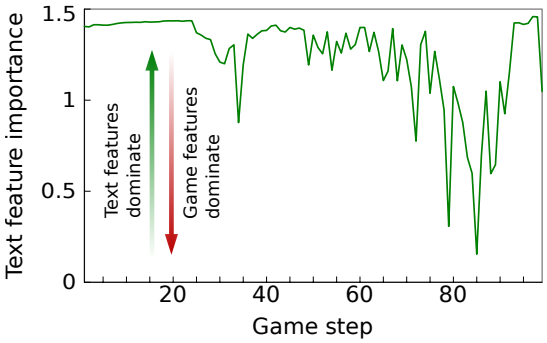

Figure 6: Difference between the norms of the text features and game features of the output layer of the neural network. Beyond the initial 25 steps of the game, our method relies increasingly on game features.

tion. This hybrid method performs as well as our full model, achieving a 53.3% win rate, confirming that textual information is most useful during the initial phase of the game. This shows that our method is able to accurately identify relevant sentences when the information they contain is most pertinent to game play.

Predicate Labeling Figure 4 shows examples of the predicate structure output of our model. We evaluate the accuracy of this labeling by comparing it against a gold-standard annotation of the game manual. Table 3 shows the performance of our method in terms of how accurately it labels words as *state*, *action* or *background*, and also how accurately it differentiates between *state* and *action* words. In addition to showing a performance improvement over the random baseline, these results display two clear trends: first, under both evaluations, labeling accuracy is higher during the initial stages of the game. This is to be expected since the model relies heavily on textual features only during the beginning of the game (see Figure 6). Second, the model clearly performs better in differentiating between state and action words, rather than in the three-way labeling.

To verify the usefulness of our method's predicate labeling, we perform a final set of experiments where predicate labels are selected uniformly at random within our full model. This random labeling results in a win rate of 44% – a performance similar to the *sentence relevance* model which uses no predicate information. This confirms that our method is able identify a predicate structure which, while noisy, provides information relevant to game play.

Method	S/A/B	S/A
Random labeling	33.3%	50.0%
Model, first 100 steps	45.1%	78.9%
Model, first 25 steps	48.0%	92.7%

Table 3: Predicate labeling accuracy of our method and a random baseline. Column "S/A/B" shows performance on the three-way labeling of words as *state*, *action* or *background*, while column "S/A" shows accuracy on the task of differentiating between state and action words.

game attribute	word
state: grassland	"city"
state: grassland	"build"
action: settlers_build_city	"city"
action: set_research	"discovery"

Figure 7: Examples of word to game attribute associations that are learned via the feature weights of our model.

Figure 7 shows examples of how this textual information is grounded in the game, by way of the associations learned between words and game attributes in the final layer of the full model.

8 Conclusions

In this paper we presented a novel approach for improving the performance of control applications by automatically leveraging high-level guidance expressed in text documents. Our model, which operates in the Monte-Carlo framework, jointly learns to identify text relevant to a given game state in addition to learning game strategies guided by the selected text. We show that this approach substantially outperforms language-unaware alternatives while learning only from environment feedback.

Creative Language Retrieval:
A Robust Hybrid of Information Retrieval and Linguistic Creativity

Tony Veale
School of Computer Science and Informatics,
University College Dublin,
Belfield, Dublin D4, Ireland.
Tony.Veale@UCD.ie

Abstract

Information retrieval (IR) and figurative language processing (FLP) could scarcely be more different in their treatment of language and meaning. IR views language as an open-ended set of mostly stable signs with which texts can be indexed and retrieved, focusing more on a text's potential relevance than its potential meaning. In contrast, FLP views language as a system of *unstable* signs that can be used to talk about the world in creative new ways. There is another key difference: IR is practical, scalable and robust, and in daily use by millions of casual users. FLP is neither scalable nor robust, and not yet practical enough to migrate beyond the lab. This paper thus presents a mutually beneficial hybrid of IR and FLP, one that enriches IR with new operators to enable the non-literal retrieval of creative expressions, and which also transplants FLP into a robust, scalable framework in which practical applications of linguistic creativity can be implemented.

1 Introduction

Words should not always be taken at face value. Figurative devices like metaphor can communicate far richer meanings than are evident from a superficial – and perhaps *literally* nonsensical – reading. Figurative Language Processing (FLP) thus uses a variety of special mechanisms and representations, to assign non-literal meanings not just to metaphors, but to similes, analogies, epithets, puns and other creative uses of language (see Martin, 1990; Fass, 1991; Way, 1991; Indurkhya, 1992; Fass, 1997; Barnden, 2006; Veale and Butnariu, 2010).

Computationalists have explored heterodox solutions to the procedural and representational challenges of metaphor, and FLP more generally, ranging from flexible representations (e.g. the *preference semantics* of Wilks (1978) and the *collative semantics* of Fass (1991, 1997)) to processes of cross-domain structure alignment (e.g. *structure mapping theory*; see Gentner (1983) and Falkenhainer *et al.* 1989) and even structural inversion (Veale, 2006). Though thematically related, each approach to FLP is broadly distinct, giving computational form to different cognitive demands of creative language: thus, some focus on inter-domain mappings (e.g. Gentner, 1983) while others focus more on intra-domain inference (e.g. Barnden, 2006). However, while computationally interesting, none has yet achieved the scalability or robustness needed to make a significant practical impact outside the laboratory. Moreover, such systems tend to be developed in isolation, and are rarely designed to cohere as part of a larger framework of creative reasoning (e.g. Boden, 1994).

In contrast, Information Retrieval (IR) is both scalable and robust, and its results translate easily from the laboratory into practical applications (e.g. see Salton, 1968; Van Rijsbergen, 1979). Whereas FLP derives its utility *and* its fragility from its attempts to identify deeper meanings beneath the surface, the widespread applicability of IR stems directly from its superficial treatment of language

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 278–287,
Portland, Oregon, June 19-24, 2011.

and meaning. IR does not distinguish between creative and conventional uses of language, or between literal and non-literal meanings. IR is also remarkably modular: its components are designed to work together interchangeably, from stemmers and indexers to heuristics for query expansion and document ranking. Yet, because IR treats all language as literal language, it relies on literal matching between queries and the texts that they retrieve. Documents are retrieved precisely because they contain stretches of text that literally resemble the query. This works well in the main, but it means that IR falls flat when the goal of retrieval is not to identify relevant documents but to retrieve new and creative ways of expressing a given idea. To retrieve creative language, and to be potentially surprised or inspired by the results, one needs to facilitate a non-literal relationship between queries and the texts that they match.

The complementarity of FLP and IR suggests a productive hybrid of both paradigms. If the most robust elements of FLP are used to provide new non-literal query operators for IR, then IR can be used to retrieve potentially new and creative ways of speaking about a topic from a large text collection. In return, IR can provide a stable, robust and extensible platform on which to use these operators to build FLP systems that exhibit linguistic creativity. In the next section we consider the related work on which the current realization of these ideas is founded, before presenting a specific trio of new semantic query operators in section 3. We describe three simple but practical applications of this creative IR paradigm in section 4. Empirical support for the FLP intuitions that underpin our new operators is provided in section 5. The paper concludes with some closing observations about future goals and developments in section 6.

2 Related Work and Ideas

IR works on the premise that a user can turn an information need into an effective query by anticipating the language that is used to talk about a given topic in a target collection. If the collection uses creative language in speaking about a topic, then a query must also contain the seeds of this creative language. Veale (2004) introduces the idea of *creative information retrieval* to explore how an IR system can itself provide a degree of creative anticipation, acting as a mediator between the literal specification of a meaning and the retrieval of creative articulations of this meaning. This anticipation ranges from simple re-articulation (e.g. a text may implicitly evoke "*Qur'an*" even if it only contains "*Muslim bible*") to playful allusions and epithets (e.g. the CEO of a rubber company may be punningly described as a "*rubber baron*"). A creative IR system may even anticipate out-of-dictionary words, like *chocoholic* and *sexoholic*.

Conventional IR systems use a range of query expansion techniques to automatically bolster a user's query with additional keywords or weights, to permit the retrieval of relevant texts it might not otherwise match (e.g. Vernimb, 1977; Voorhees, 1994). Techniques vary, from the use of stemmers and morphological analysis to the use of thesauri (such as WordNet; see Fellbaum, 1998; Voorhees, 1998) to pad a query with synonyms, to the use of statistical analysis to identify more appropriate context-sensitive associations and near-synonyms (e.g. Xu and Croft, 1996). While some techniques may suggest conventional metaphors that have become lexicalized in a language, they are unlikely to identify relatively novel expressions. Crucially, expansion improves recall at the expense of overall precision, making automatic techniques even more dangerous when the goal is to retrieve results that are creative *and* relevant. Creative IR must balance a need for fine user control with the statistical breadth and convenience of automatic expansion.

Fortunately, statistical corpus analysis is an obvious area of overlap for IR and FLP. Distributional analyses of large corpora have been shown to produce nuanced models of lexical similarity (e.g. Weeds and Weir, 2005) as well as context-sensitive thesauri for a given domain (Lin, 1998). Hearst (1992) shows how a pattern like "*Xs and other Ys*" can be used to construct more fluid, context-specific taxonomies than those provided by WordNet (e.g. "*athletes and other celebrities*" suggests a context in which athletes are viewed as stars). Mason (2004) shows how statistical analysis can automatically detect and extract conventional metaphors from corpora, though creative metaphors still remain a tantalizing challenge. Hanks (2005) shows how the "*Xs like A, B and C*" construction allows us to derive flexible ad-hoc categories from corpora, while Hanks (2006) argues for a gradable conception of metaphoricity based on word-sense distributions in corpora.

Veale and Hao (2007) exploit the simile frame "*as X as Y*" to harvest a great many common similes and their underlying stereotypes from the web (e.g. "as *hot* as an oven"), while Veale and Hao (2010) show that the pattern "*about as X as Y*" retrieves an equally large collection of creative (if mostly ironic) comparisons. These authors demonstrate that a large vocabulary of stereotypical ideas (over 4000 nouns) and their salient properties (over 2000 adjectives) can be harvested from the web.

We now build on these results to develop a set of new semantic operators, that use corpus-derived knowledge to support finely controlled non-literal matching and automatic query expansion.

3 Creative Text Retrieval

In language, creativity is always a matter of construal. While conventional IR queries articulate a need for information, creative IR queries articulate a need for expressions to convey the same meaning in a fresh or unusual way. A query and a matching phrase can be figuratively construed to have the same meaning if there is a non-literal mapping between the elements of the query and the elements of the phrase. In creative IR, this non-literal mapping is facilitated by the query's explicit use of *semantic wildcards* (e.g. see Mihalcea, 2002).

The wildcard * is a boon for power-users of the Google search engine, precisely because it allows users to focus on the retrieval of matching phrases rather than relevant documents. For instance, * can be used to find alternate ways of instantiating a culturally-established linguistic pattern, or "snowclone": thus, the Google queries "*In * no one can hear you scream*" (from *Alien*), "*Reader, I * him*" (from *Jane Eyre*) and "*This is your brain on **" (from a famous TV advert) find new ways in which old patterns have been instantiated for humorous effect on the Web. On a larger scale, Veale and Hao (2007) used the * wildcard to harvest web similes, but reported that harvesting cultural data with wildcards is not a straightforward process. Google and other engines are designed to maximize document relevance and to rank results accordingly. They are not designed to maximize the diversity of results, or to find the largest set of wildcard bindings. Nor are they designed to find the most commonplace bindings for wildcards.

Following Guilford's (1950) pioneering work, diversity is widely considered a key component in the psychology of creativity. By focusing on the phrase level rather than the document level, and by returning phrase sets rather than document sets, creative IR maximizes diversity by finding as many bindings for its wildcards as a text collection will support. But we need more flexible and precise wildcards than *. We now consider three varieties of semantic wildcards that build on insights from corpus-linguistic approaches to FLP.

3.1 The *Neighborhood* Wildcard ?X

Semantic query expansion replaces a query term **X** with a set $\{X, X_1, X_2, \ldots, X_n\}$ where each X_i is related to **X** by a prescribed lexico-semantic relationship, such as synonymy, hyponymy or meronymy. A generic, lightweight resource like WordNet can provide these relations, or a richer ontology can be used if one is available (e.g. see Navigli and Velardi, 2003). Intuitively, each query term suggests other terms from its semantic neighborhood, yet there are practical limits to this intuition. X_i may not be an obvious or natural substitute for X. A neighborhood can be drawn too small, impacting recall, or too large, impacting precision.

Corpus analysis suggests an approach that is both semantic *and* pragmatic. As noted in Hanks (2005), languages provide constructions for building ad-hoc sets of items that can be considered comparable in a given context. For instance, a coordination of bare plurals suggests that two ideas are related at a generic level, as in "*priests and imams*" or "*mosques and synagogues*". More generally, consider the pattern "*X and Y*", where X and Y are proper-names (e.g., "*Zeus and Hera*"), or X and Y are inflected nouns or verbs with the same inflection (e.g., the plurals "*cats and dogs*" or the verb forms "*kicking and screaming*"). Millions of matches for this pattern can be found in the Google 3-grams (Brants and Franz, 2006), allowing us to build a map of comparable terms by linking the root-forms of X and Y with a similarity score obtained via a WordNet-based measure (e.g. see Budanitsky and Hirst (2006) for a good selection).

The pragmatic neighborhood of a term X can be defined as $\{X, X_1, X_2, \ldots, X_n\}$, so that for each X_i, the Google 3-grams contain "*X+inf and X_i+inf*" or "*X+inf and X_i+inf*". The boundaries of neighborhoods are thus set by usage patterns: if **?X** denotes the neighborhood of X, then **?artist**

matches not just *artist*, *composer* and *poet*, but *studio*, *portfolio* and *gallery,* and many other terms that are semantically dissimilar but pragmatically linked to *artist*. Since each $X_i \in$ **?X** is ranked by similarity to **X**, query matches can also be ranked by similarity.

When X is an adjective, then **?X** matches any element of {X, X_i, X_2, …, X_n}, where each X_i pragmatically reinforces X, and X pragmatically reinforces each X_i. To ensure X and X_i really are mutually reinforcing adjectives, we use the double-ground simile pattern "*as* X *and* X_i *as*" to harvest {X_1, …, X_n} for each X. Moreover, to maximize recall, we use the Google API (rather than Google ngrams) to harvest suitable bindings for X and X_i from the web. For example, **@witty** = {*charming, clever, intelligent, entertaining, ..., edgy, fun*}.

3.2 The *Cultural Stereotype* Wildcard @X

Dickens claims in *A Christmas Carol* that "the wisdom of a people is in the simile". Similes exploit familiar stereotypes to describe a less familiar concept, so one can learn a great deal about a culture and its language from the similes that have the most currency (Taylor, 1954). The wildcard **@X** builds on the results of Veale and Hao (2007) to allow creative IR queries to retrieve matches on the basis of cultural expectations. This foundation provides a large set of adjectival features (over 2000) for a larger set of nouns (over 4000) denoting stereotypes for which these features are salient.

If N is a noun, then **@N** matches any element of the set {A_1, A_2, …, A_n}, where each A_i is an adjective denoting a stereotypical property of N. For example, **@diamond** matches any element of {*transparent, immutable, beautiful, tough, expensive, valuable, shiny, bright, lasting, desirable, strong, ..., hard*} . If A is an adjective, then **@A** matches any element of the set {N_1, N_2, …, N_n}, where each N_i is a noun denoting a stereotype for which A is a culturally established property. For example, **@tall** matches any element of {*giraffe, skyscraper, tree, redwood, tower, sunflower, lighthouse, beanstalk, rocket, ..., supermodel*}.

Stereotypes crystallize in a language as clichés, so one can argue that stereotypes and clichés are little or no use to a creative IR system. Yet, as demonstrated in Fishlov (1992), creative language is replete with stereotypes, not in their clichéd guises, but in novel and often incongruous combinations. The creative value of a stereotype lies in how it is used, as we'll show later in section 4.

3.3 The *Ad-Hoc Category* Wildcard ^X

Barsalou (1983) introduced the notion of an *ad-hoc category*, a cross-cutting collection of often disparate elements that cohere in the context of a specific task or goal. The ad-hoc nature of these categories is reflected in the difficulty we have in naming them concisely: the cumbersome "things to take on a camping trip" is Barsalou's most cited example. But ad-hoc categories do not replace natural kinds; rather, they supplement an existing system of more-or-less rigid categories, such as the categories found in WordNet.

The semantic wildcard **^C** matches C and any element of {C_1, C_2, …, C_n}, where each C_i is a member of the category named by C. **^C** can denote a fixed category in a resource like WordNet or even Wikipedia; thus, **^fruit** matches any member of {*apple, orange, pear, ..., lemon*} and **^animal** any member of *{dog, cat, mouse, ..., deer, fox}*.

Ad-hoc categories arise in creative IR when the results of a query – or more specifically, the bindings for a query wildcard – are funneled into a new user-defined category. For instance, the query *"^**fruit** juice*" matches any phrase in a text collection that denotes a named fruit juice, from "*lemon juice*" to "*pawpaw juice*". A user can now funnel the bindings for **^fruit** in this query into an ad-hoc category **juicefruit**, to gather together those fruits that are used for their juice. Elements of *^juicefruit* are ranked by the corpus frequencies discovered by the original query; low-frequency **juicefruit** members in the Google ngrams include *coffee*, *raisin*, *almond*, *carob* and *soybean*. Ad-hoc categories allow users of IR to remake a category system in their own image, and create a new vocabulary of categories to serve their own goals and interests, as when "***^food** pizza*" is used to suggest disparate members for the ad-hoc category **pizzatopping**.

The more subtle a query, the more disparate the elements it can funnel into an ad-hoc category. We now consider how basic semantic wildcards can be combined to generate even more diverse results.

3.4 Compound Operators

Each wildcard maps a query term onto a set of ex-

pansion terms. The compositional semantics of a wildcard combination can thus be understood in set-theoretic terms. The most obvious and useful combinations of **?**, **@** and ^ are described below:

?? *Neighbor-of-a-neighbor*: if **?X** matches any element of {X, X_1, X_2, …, X_n} then **??X** matches any of **?X** ∪ **?X_1** ∪ … ∪ **?X_n**, where the ranking of X_{ij} in **??X** is a function of the ranking of X_i in **?X** and the ranking of X_{ij} in **?X_i**. Thus, **??artist** matches far more terms than **?artist**, yielding more diversity, more noise, and more creative potential.

@@ *Stereotype-of-a-stereotype*: if **@X** matches any element of {X_1, X_2, …, X_n} then **@@X** matches any of **@X_1** ∪ **@X_2** ∪ … ∪ **@X_n**. For instance, **@@diamond** matches any stereotype that shares a salient property with *diamond*, and **@@sharp** matches any salient property of any noun for which *sharp* is a stereotypical property.

?@ *Neighborhood-of-a-stereotype*: if **@X** matches any element of {X_1, X_2, …, X_n} then **?@X** matches any of **?X_1** ∪ **?X_2** ∪ … ∪ **?X_n**. Thus, **?@cunning** matches any term in the pragmatic neighborhood of a stereotype for *cunning*, while **?@knife** matches any property that mutually reinforces any stereotypical property of *knife*

@? *Stereotypes-in-a-neighborhood*: if **?X** matches any of {X, X_1, X_2, …, X_n} then **@?X** matches any of **@X** ∪ **@X_1** ∪ … ∪ **@X_n**. Thus, **@?corpse** matches any salient property of any stereotype in the neighborhood of *corpse*, while **@?fast** matches any stereotype noun with a salient property that is similar to, and reinforced by, *fast*.

?^ *Neighborhood-of-a-category*: if **^C** matches any of {C, C_1, C_2, …, C_n} then **?^C** matches any of **?C** ∪ **?C_1** ∪ … ∪ **?C_n**.

^? *Categories-in-a-neighborhood*: if **?X** matches any of {X, X_1, X_2, …, X_n} then **^?X** matches any of **^X** ∪ **^X_1** ∪ … ∪ **^X_n**.

@^ *Stereotypes-in-a-category*: if **^C** matches any of {C, C_1, C_2, …, C_n} then **@^C** matches any of **@C** ∪ **@C_1** ∪ … ∪ **@C_n**.

^@ *Members-of-a-stereotype-category*: if **@X** matches any element of {X_1, X_2, …, X_n} then **^@X** matches any of **^X_1** ∪ **^X_2** ∪ … ∪ **^X_n**. So **^@strong** matches any member of a category (such as *warrior*) that is stereotypically *strong*.

4 Applications of Creative Retrieval

The Google ngrams comprise a vast array of extracts from English web texts, of 1 to 5 words in length (Brants and Franz, 2006). Many extracts are well-formed phrases that give lexical form to many different ideas. But an even greater number of ngrams are not linguistically well-formed. The Google ngrams can be seen as a *lexicalized idea space*, embedded within a larger sea of noise. Creative IR can be used to explore this idea space.

Each creative query is a jumping off point in a space of lexicalized ideas that is implied by a large corpus, with each successive match leading the user deeper into the space. By turning matches into queries, a user can perform a creative exploration of the space of phrases and ideas (see Boden, 1994) while purposefully sidestepping the noise of the Google ngrams. Consider the pleonastic query "*Catholic* ***?pope***". Retrieved phrases include, in descending order of lexical similarity, "*Catholic president*", "*Catholic politician*", "*Catholic king*", "*Catholic emperor*" and "*Catholic patriarch*". Suppose a user selects "*Catholic king*": the new query "*Catholic* ***?king***" now retrieves "*Catholic queen*", "*Catholic court*", "*Catholic knight*", "*Catholic kingdom*" and "*Catholic throne*". The subsequent query "*Catholic* ***?kingdom***" in turn retrieves "*Catholic dynasty*" and "*Catholic army*", among others. In this way, creative IR allows a user to explore the text-supported ramifications of a metaphor like *Popes are Kings* (e.g., if popes are kings, they too might have queens, command armies, found dynasties, or sit on thrones).

Creative IR gives users the tools to conduct their own explorations of language. The more wildcards a query contains, the more degrees of freedom it offers to the explorer. Thus, the query "***?scientist*** *'s* ***?laboratory***" uncovers a plethora of analogies for the relationship between scientists and their labs: matches in the Google 3-grams include "*technician's workshop*", "*artist's studio*", "*chef's kitchen*" and "*gardener's greenhouse*".

4.1 Metaphors with *Aristotle*

For a term X, the wildcard **?X** suggests those other terms that writers have considered to be comparable to X, while **??X** extrapolates beyond the corpus evidence to suggest an even larger space of potential comparisons. A meaningful metaphor can be constructed for X by framing X with any stereotype to which it is pragmatically comparable, that is, any stereotype in **?X**. Collectively, these stereotypes can impart the properties **@?X** to X.

Suppose one wants to metaphorically ascribe the property P to X. The set **@P** contains those stereotypes for which P is culturally salient. Thus, close metaphors for X (what MacCormac (1985) dubs *epiphors*) in the context of P are suggested by **?X ∩ @P**. More distant metaphors (MacCormac dubs these *diaphors*) are suggested by **??X ∩ @P**. For instance, to describe a *scholar* as *wise*, one can use *poet*, *yogi*, *philosopher* or *rabbi* as comparisons. Yet even a simple metaphor will impart other features to a topic. If $\mathbf{\hat{}P_S}$ denotes the ad-hoc set of additional properties that may be inferred for X when a stereotype S is used to convey property P, then $\mathbf{\hat{}P_S}$ = **?P ∩ @@P**. The query "$\mathbf{\hat{}P_S}$ **X**" now finds corpus-attested elements of $\mathbf{\hat{}P_S}$ that can meaningfully be used to modify X.

These IR formulations are used by *Aristotle*, an online metaphor generator, to generate targeted metaphors that highlight a property P in a topic X. *Aristotle* uses the Google ngrams to supply values for **?X**, **??X**, **?P** and $\mathbf{\hat{}P_S}$. The system can be accessed at: *www.educatedinsolence.com/aristotle*

4.2 Expressing Attitude with *Idiom Savant*

Our retrieval goals in IR are often affective in nature: we want to find a way of speaking about a topic that expresses a particular sentiment and carries a certain tone. However, affective categories are amongst the most cross-cutting structures in language. Words for disparate ideas are grouped according to the sentiments in which they are generally held. We respect *judges* but dislike *critics*; we respect *heroes* but dislike *killers*; we respect *sharpshooters* but dislike *snipers*; and respect *rebels* but dislike *insurgents*. It seems therefore that the particulars of sentiment are best captured by a set of culture-specific ad-hoc categories.

We thus construct two ad-hoc categories, **^posword** and **^negword**, to hold the most obviously positive or negative words in Whissell's (1989) *Dictionary of Affect*. We then grow these categories to include additional reinforcing elements from their pragmatic neighborhoods, **?^posword** and **?^negword**. As these categories grow, so too do their neighborhoods, allowing a simple semi-automated bootstrapping process to significantly grow the categories over several iterations. We construct two phrasal equivalents of these categories, **^posphrase** and **^negphrase**, using the queries "***^posword - ^pastpart***" (e.g., matching "*high-minded*" and "*sharp-eyed*") and "***^negword - ^pastpart***" (e.g., matching "*flat-footed*" and "*dead-eyed*") to mine affective phrases from the Google 3-grams. The resulting ad-hoc categories (of ~600 elements each) are manually edited to fix any obvious mis-categorizations.

Idiom Savant is a web application that uses **^posphrase** and **^negphrase** to suggest flattering and insulting epithets for a given topic. The query "**^posphrase ?X**" retrieves phrases for a topic X that put a positive spin on a related topic to which X is sometimes compared, while "**^negphrase ?X**" conversely imparts a negative spin. Thus, for *politician*, the Google 4-grams provide the flattering epithets "*much-needed leader*", "*awe-inspiring leader*", "*hands-on boss*" and "*far-sighted statesman*", as well as insults like "*power-mad leader*", "*back-stabbing boss*", "*ice-cold technocrat*" and "*self-promoting hack*". Riskier diaphors can be retrieved via "**^posphrase ??X**" and "**^negphrase ??X**". *Idiom Savant* is accessible online at: *www.educatedinsolence.com/idiom-savant/*

4.3 Poetic Similes with *The Jigsaw Bard*

The well-formed phrases of a large corpus can be viewed as the linguistic equivalent of *objets trouvés* in art: readymade or "found" objects that might take on fresh meanings in a creative context. The phrase "*robot fish*", for instance, denotes a more-or-less literal object in the context of autonomous robotic submersibles, but can also be used to convey a figurative meaning as part of a creative comparison (e.g., "*he was as cold as a robot fish*").

Fishlov (1992) argues that poetic comparisons are most resonant when they combine mutually-reinforcing (if distant) ideas, to create memorable images and evoke nuanced feelings. Building on Fishlov's argument, creative IR can be used to turn

the readymade phrases of the Google ngrams into vehicles for creative comparison. For a topic X and a property P, simple similes of the form "***X is as P as S***" are easily generated, where **S** ∈ **@P** ∩ **??X**.

Fishlov would dub these *non-poetic similes* (NPS). However, the query "***?P @P***" will retrieve corpus-attested elaborations of stereotypes in **@P** to suggest similes of the form "***X is as P as*** $\mathbf{P_1}$ ***S***", where $\mathbf{P_1}$ ∈ **?P**. These similes exhibit elements of what Fishlov dubs *poetic similes* (PS). Why say "*as cold as a fish*" when you can say "*as cold as a wet fish*", "*a dead haddock*", "*a wet January*", "*a frozen corpse*", or "*a heartless robot*"? Complex queries can retrieve more creative combinations, so "***@P @P***" (e.g. "*robot fish*" or "*snow storm*" for *cold*), "**?P @P @P**" (e.g. "*creamy chocolate mousse*" for *rich*) and "***@P - ^pastpart @P***" (e.g. "*snow-covered graveyard*" and "*bullet-riddled corpse*" for *cold*) each retrieve ngrams that blend two different but overlapping stereotypes.

Blended properties also make for nuanced similes of the form "*as **P** and **?P** as **S***", where **S** ∈ **@P** ∩ **@?P**. While one can be "*as rich as a fat king*", something can be "*as rich and enticing as a chocolate truffle*", "*a chocolate brownie*", "*a chocolate fruitcake*", and even "*a chocolate king*".

The *Jigsaw Bard* is a web application that harnesses the readymades of the Google ngrams to formulate novel similes from existing phrases. By mapping blended properties to ngram phrases that combine multiple stereotypes, the *Bard* expands its generative scope considerably, allowing this application to generate hundreds of thousands of evocative comparisons. The *Bard* can be accessed online at: *www.educatedinsolence.com/jigsaw/*

5 Empirical Evaluation

Though ^ is the most overtly categorical of our wildcards, all three wildcards – **?**, **@** and ^ – are categorical in nature. Each has a semantic or pragmatic membership function that maps a term onto an expansion set of related members. The membership functions for specific uses of ^ are created in an ad-hoc fashion by the users that exploit it; in contrast, the membership functions for uses of **@** and **?** are derived automatically, via pattern-matching and corpus analysis. Nonetheless, ad-hoc categories in creative IR are often populated with the bindings produced by uses of **@** and **?** and combinations thereof. In a sense, **?X** and **@X** and their variations are themselves ad-hoc categories. But how well do they serve as categories? Are they large, but noisy? Or too small, with limited coverage? We can evaluate the effectiveness of **?** and **@**, and indirectly that of ^ too, by comparing the use of **?** and **@** as category builders to a hand-crafted gold standard like WordNet.

Other researchers have likewise used WordNet as a gold standard for categorization experiments, and we replicate here the experimental set-up of Almuhareb and Poesio (2004, 2005), which is designed to measure the effectiveness of web-acquired conceptual descriptions. Almuhareb and Poesio choose 214 English nouns from 13 of WordNet's upper-level semantic categories, and proceed to harvest property values for these concepts from the web using the Hearst-like pattern "*a|an|the * C is|was*". This pattern yields a combined total of 51,045 values for all 214 nouns; these values are primarily adjectives, such as *hot* and *black* for *coffee*, but noun-modifiers of C are also allowed, such as *fruit* for *cake*. They also harvest 8934 attribute nouns, such as *temperature* and *color*, using the query "*the * of the C is|was*". These values and attributes are then used as the basis of a clustering algorithm to partition the 214 nouns back into their original 13 categories. Comparing these clusters with the original WordNet-based groupings, Almuhareb and Poesio report a cluster accuracy of **71.96%** using just values like *hot* and *black* (51,045 values), an accuracy of **64.02%** using just attributes like *temperature* and *color* (8,934 attributes), and an accuracy of **85.5%** using both together (a combined 59,979 features).

How concisely and accurately does **@X** describe a noun X for purposes of categorization? Let **^AP** denote the set of 214 WordNet nouns used by Almuhareb and Poesio. Then **@^AP** denotes a set of 2,209 adjectival properties; this should be contrasted with the space of 51,045 adjectival values used by Almuhareb and Poesio. Using the same clustering algorithm over this feature set, **@X** achieves a clustering accuracy (as measured via cluster purity) of **70.2%**, compared to **71.96%** for Almuhareb and Poesio. However, when **@X** is used to harvest a further set of attribute nouns for X, via web queries of the form "***the P * of X***" (where P ∈ **@X**), then **@X** augmented with this additional set of attributes (like *hands* for surgeon)

produces a larger space of 7,183 features. This in turn yields a cluster accuracy of **90.2%** which contrasts with Almuhareb and Poesio's **85.5%** for 59,979 features. In either case, **@X** produces comparable clustering quality to Almuhareb and Poesio, with just a small fraction of the features.

So how concisely and accurately does **?X** describe a noun X for purposes of categorization? While **@X** denotes a set of salient adjectives, **?X** denotes a set of comparable nouns. So this time, **?^AP** denotes a set of 8,300 nouns in total, to act as a feature space for the 214 nouns of Almuhareb and Poesio. Remember, the contents of each **?X**, and of **?^AP** overall, are determined entirely by the contents of the Google 3-grams; the elements of **?X** are not ranked in any way, and all are treated as equals. When the 8,300 features in **?^AP** are clustered into 13 categories, the resulting clusters have a purity of **93.4%** relative to WordNet. The pragmatic neighborhood of X, **?X**, appears to be an accurate and concise proxy for the meaning of X.

What about adjectives? Almuhareb and Poesio's set of 214 words does not contain adjectives, and besides, WordNet does not impose a category structure on its adjectives. In any case, the role of adjectives in the applications of section 4 is largely an affective one: if X is a noun, then one must have confidence that the adjectives in **@X** are consonant with our understanding of X, and if P is a property, that the adjectives in **?P** evoke much the same mood and sentiment as P. Our evaluation of **@X** and **?P** should thus be an affective one.

So how well do the properties in **@X** capture our sentiments about a noun X? Well enough to estimate the pleasantness of X from the adjectives in **@X**, perhaps? Whissell's (1989) dictionary of affect provides pleasantness ratings for a sizeable number of adjectives and nouns (over 8,000 words in total), allowing us to estimate the pleasantness of X as a weighted average of the pleasantness of each X_i in **@X** (the weights here are web frequencies for the similes that underpin @ in section 3.2). We thus estimate the affect of all stereotype nouns for which Whissell also records a score. A two-tailed Pearson test ($p < 0.05$) shows a positive correlation of **0.5** between these estimates and the pleasantness scores assigned by Whissell. In contrast, estimates based on the pleasantness of adjectives found in corresponding WordNet glosses show a positive correlation of just **0.278**.

How well do the elements of **?P** capture our sentiments toward an adjective P? After all, we hypothesize that the adjectives in **?P** are highly suggestive of P, and vice versa. *Aristotle* and the *Jigsaw Bard* each rely on **?P** to suggest adjectives that evoke an unstated property in a metaphor or simile, or to suggest coherent blends of properties. When we estimate the pleasantness of each adjective P in Whissell's dictionary via the weighted mean of the pleasantness of adjectives in **?P** (again using web frequencies as weights), a two-tailed Pearson test ($p < 0.05$) shows a correlation of **0.7** between estimates and actual scores. It seems **?P** does a rather good job of capturing the feel of P.

6 Concluding Remarks

Creative information retrieval is not a single application, but a paradigm that allows us to conceive of many different kinds of application for creatively manipulating text. It is also a tool-kit for implementing such an application, as shown here in the cases of *Aristotle*, *Idiom Savant* and *Jigsaw Bard*.

The wildcards **@**, **?** and ^ allow users to formulate their own task-specific ontologies of ad-hoc categories. In a fully automated application, they provide developers with a simple but powerful vocabulary for describing the range and relationships of the words, phrases and ideas to be manipulated.

The **@**, **?** and ^ wildcards are just a start. We expect other aspects of figurative language to be incorporated into the framework whenever they prove robust enough for use in an IR context. In this respect, we aim to position Creative IR as an open, modular platform in which diverse results in FLP, from diverse researchers, can be meaningfully integrated. One can imagine wildcards for matching potential puns, portmanteau words and other novel forms, as well as wildcards for figurative processes like metonymy, synecdoche, hyperbolae and even irony. Ultimately, it is hoped that creative IR can serve as a textual bridge between high-level creativity and the low-level creative potentials that are implicit in a large corpus.

Abstract

This paper proposes the use of local histograms (LH) over character n-grams for authorship attribution (AA). LHs are enriched histogram representations that preserve sequential information in documents; they have been successfully used for text categorization and document visualization using *word* histograms. In this work we explore the suitability of LHs over n-grams at the *character-level* for AA. We show that LHs are particularly helpful for AA, because they provide useful information for uncovering, to some extent, the writing style of authors. We report experimental results in AA data sets that confirm that LHs over character n-grams are more helpful for AA than the usual global histograms, yielding results far superior to state of the art approaches. We found that LHs are even more advantageous in challenging conditions, such as having imbalanced and small training sets. Our results motivate further research on the use of LHs for modeling the writing style of authors for related tasks, such as authorship verification and plagiarism detection.

1 Introduction

Authorship attribution (AA) is the task of deciding whom, from a set of candidates, is the author of a given document (Houvardas and Stamatatos, 2006; Luyckx and Daelemans, 2010; Stamatatos, 2009b). There is a broad field of application for AA methods, including spam filtering (de Vel et al., 2001), fraud detection, computer forensics (Lambers and Veenman, 2009), cyber bullying (Pillay and Solorio, 2010) and plagiarism detection (Stamatatos, 2009a). Therefore, the development of automated AA techniques has received much attention recently (Stamatatos, 2009b). The AA problem can be naturally posed as one of single-label multiclass classification, with as many classes as candidate authors. However, unlike usual text categorization tasks, where the core problem is modeling the thematic content of documents (Sebastiani, 2002), the goal in AA is modeling authors' writing style (Stamatatos, 2009b). Hence, document representations that reveal information about writing style are required to achieve good accuracy in AA.

Word and character based representations have been used in AA with some success so far (Houvardas and Stamatatos, 2006; Luyckx and Daelemans, 2010; Plakias and Stamatatos, 2008b). Such representations can capture style information through word or character usage, but they lack sequential information, which can reveal further stylistic information. In this paper, we study the use of richer document representations for the AA task. In particular, we consider local histograms over n-grams at the character-level obtained via the locally-weighted bag of words (LOWBOW) framework (Lebanon et al., 2007).

Under LOWBOW, a document is represented by a set of local histograms, computed across the whole document but smoothed by kernels centered on different document locations. In this way, document

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 288–298,
Portland, Oregon, June 19-24, 2011.

representations preserve both word/character usage and sequential information (i.e., information about the positions in which words or characters occur), which can be more helpful for modeling the writing style of authors. We report experimental results in an AA data set used in previous studies under several conditions (Houvardas and Stamatatos, 2006; Plakias and Stamatatos, 2008b; Plakias and Stamatatos, 2008a). Results confirm that local histograms of character n-grams are more helpful for AA than the usual global histograms of words or character n-grams (Luyckx and Daelemans, 2010); our results are superior to those reported in related works. We also show that local histograms over character n-grams are more helpful than local histograms over words, as originally proposed by (Lebanon et al., 2007). Further, we performed experiments with imbalanced and small training sets (i.e., under a realistic AA setting) using the aforementioned representations. We found that the LOWBOW-based representation resulted even more advantageous in these challenging conditions. The contributions of this work are as follows:

- We show that the LOWBOW framework can be helpful for AA, giving evidence that sequential information encoded in local histograms is useful for modeling the writing style of authors.
- We propose the use of local histograms over character-level n-grams for AA. We show that character-level representations, which have proved to be very effective for AA (Luyckx and Daelemans, 2010), can be further improved by adopting a local histogram formulation. Also, we empirically show that local histograms at the character-level are more helpful than local histograms at the word-level for AA.
- We study several kernels for a support vector machine AA classifier under the local histograms formulation. Our study confirms that the diffusion kernel (Lafferty and Lebanon, 2005) is the most effective among those we tried, although competitive performance can be obtained with simpler kernels.
- We report experimental results that are superior to state of the art approaches (Plakias and Stamatatos, 2008b; Plakias and Stamatatos, 2008a), with improvements ranging from $2\% - 6\%$ in balanced data sets and from $14\% - 30\%$ in imbalanced data sets.

2 Related Work

AA can be faced as a multiclass classification task with as many classes as candidate authors. Standard classification methods have been applied to this problem, including support vector machine (SVM) classifiers (Houvardas and Stamatatos, 2006) and variants thereon (Plakias and Stamatatos, 2008b; Plakias and Stamatatos, 2008a), neural networks (Tearle et al., 2008), Bayesian classifiers (Coyotl-Morales et al., 2006), decision tree methods (Koppel et al., 2009) and similarity based techniques (Keselj et al., 2003; Lambers and Veenman, 2009; Stamatatos, 2009b; Koppel et al., 2009). In this work, we chose an SVM classifier as it has reported acceptable performance in AA and because it will allow us to directly compare results with previous work that has used this same classifier.

A broad diversity of features has been used to represent documents in AA (Stamatatos, 2009b). However, as in text categorization (Sebastiani, 2002), word-based and character-based features are among the most widely used features (Stamatatos, 2009b; Luyckx and Daelemans, 2010). With respect to word-based features, word histograms (i.e., the bag-of-words paradigm) are the most frequently used representations in AA (Zhao and Zobel, 2005; Argamon and Levitan, 2005; Stamatatos, 2009b). Some researchers have gone a step further and have attempted to capture sequential information by using n-grams at the word-level (Peng et al., 2004) or by discovering maximal frequent word sequences (Coyotl-Morales et al., 2006). Unfortunately, because of computational limitations, the latter methods cannot discover *enough* sequential information from documents (e.g., word n-grams are often restricted to $n \in \{1, 2, 3\}$, while full sequential information would be obtained with $n \in \{1 \dots D\}$ where D is the maximum number of words in a document).

With respect to character-based features, n-grams at the character level have been widely used in AA as well (Plakias and Stamatatos, 2008b; Peng et al., 2003; Luyckx and Daelemans, 2010). Peng et al. (2003) propose the use of language models at the n-gram character-level for AA, whereas Keselj et al. (2003) build author profiles based on a selection of frequent n-grams for each author. Stamatatos and co-workers have studied the impact of feature selection, with character n-grams, in AA (Houvardas and Stamatatos, 2006; Stamatatos, 2006a), ensemble learning with character n-grams (Stamatatos, 2006b) and novel classification techniques based

on characters at the n-gram level (Plakias and Stamatatos, 2008a).

Acceptable performance in AA has been reported with character n-gram representations. However, as with word-based features, character n-grams are unable to incorporate sequential information from documents in their original form (in terms of the positions in which the terms appear across a document). We believe that sequential clues can be helpful for AA because different authors are expected to use different character n-grams or words in different parts of the document. Accordingly, in this work we adopt the popular character-based and word-based representations, but we enrich them in a way that they incorporate sequential information via the LOWBOW framework. Hence, the proposed features preserve sequential information besides capturing character and word usage information. Our hypothesis is that the combination of sequential and frequency information can be particularly helpful for AA.

The LOWBOW framework has been mainly used for document visualization (Lebanon et al., 2007; Mao et al., 2007), where researchers have used information derived from local histograms for displaying a 2D representation of document's content. More recently, Chasanis et al. (2009) used the LOWBOW framework for segmenting movies into chapters and scenes. LOWBOW representations have also been applied to discourse segmentation (AMIDA, 2007) and have been suggested for text summarization (Das and Martins, 2007). However, to the best of our knowledge the use of the LOWBOW framework for AA has not been studied elsewhere. Actually, the only two references using this framework for text categorization are (Lebanon et al., 2007; AMIDA, 2007). The latter can be due to the fact that local histograms provide little gain over usual global histograms for thematic classification tasks. In this paper we show that LOWBOW representations provide important improvements over global histograms for AA; in particular, local histograms at the character-level achieve the highest performance in our experiments.

3 Background

This section describes preliminary information on document representations and pattern classification with SVMs.

3.1 Bag of words representations

In the bag of words (BOW) representation, documents are represented by histograms over the vocabulary[1] that was used to generate a collection of documents; that is, a document i is represented as:

$$\mathbf{d}_i = [x_{i,1}, \ldots, x_{i,|V|}] \quad (1)$$

where V is the vocabulary and $|V|$ is the number of elements in V, $\mathbf{d}_{i,j} = x_{i,j}$ is a weight that denotes the contribution of term j to the representation of document i; usually $x_{i,j}$ is related to the occurrence (binary weighting) or the weighted frequency of occurrence (e.g., the *tf-idf* weighting scheme) of the term j in document i.

3.2 Locally-weighted bag-of-words representation

Instead of using the BOW framework directly, we adopted the LOWBOW framework for document representation (Lebanon et al., 2007). The underlying idea in LOWBOW is to compute several local histograms per document, where these histograms are smoothed by a kernel function, see Figure 1. The parameters of the kernel specify the position of the kernel in the document (i.e., where the local histogram is centered) and its scale (i.e., to what extent it is smoothed). In this way the sequential information in the document is preserved together with term usage statistics.

Let $W_i = \{w_{i,1}, \ldots, w_{i,N_i}\}$, denote the terms (in order of appearance) in document i where N_i is the number of terms that appear in document i and $w_{i,j} \in V$ is the term appearing at position j; let $\mathbf{v}_i = \{v_{i,1}, \ldots, v_{i,N_i}\}$ be the set of indexes in the vocabulary V of the terms appearing in W_i, such that $v_{i,j}$ is the index in V of the term $w_{i,j}$; let $\mathbf{t} = [t_1, \ldots, t_{N_i}]$ be a set of (equally spaced) scalars that determine intervals, with $0 \leq t_j \leq 1$ and $\sum_{j=1}^{N_i} t_j = 1$, such that each t_j can be associated to a position in W_i. Given a kernel smoothing function $K^s_{\mu,\sigma} : [0,1] \rightarrow \mathbb{R}$ with location parameter μ and scale parameter σ, where $\sum_{j=1}^{k} K^s_{\mu,\sigma}(t_j) = 1$ and

[1] In the following we will refer to arbitrary vocabularies, which can be formed with terms from either words or character n-grams.

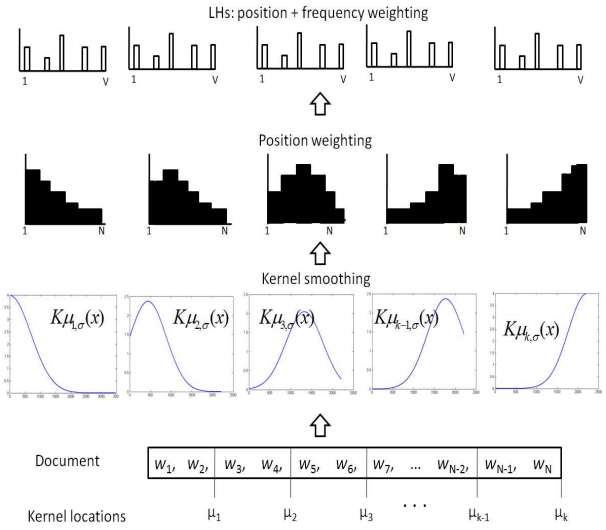

Figure 1: Diagram of the process for obtaining local histograms. Terms (w_i) appearing in different positions ($1, \ldots, N$) of the document are weighted according to the locations ($\mu_1, \ldots, \mu_k$) of the smoothing function $K_{\mu,\sigma}(x)$. Then, the term position weighting is combined with term frequency weighting for obtaining local histograms over the terms in the vocabulary ($1, \ldots, |V|$).

$\mu \in [0, 1]$. The LOWBOW framework computes a local histogram for each position $\mu_j \in \{\mu_1, \ldots, \mu_k\}$ as follows:

$$\mathbf{dl}^j_{i,\{v_{i,1},\ldots,v_{i,N_i}\}} = \mathbf{d}_{i,\{v_{i,1},\ldots,v_{i,N_i}\}} \times K^s_{\mu_j,\sigma}(\mathbf{t}) \quad (2)$$

where $\mathbf{dl}_{i,v_j:v_j \notin \mathbf{v}_i} = const$, a small constant value, and $\mathbf{d}_{i,j}$ is defined as above. Hence, a set $\mathbf{dl}_i^{\{1,\ldots,k\}}$ of k local histograms are computed for each document i. Each histogram $\mathbf{dl}_i^j$ carries information about the distribution of terms at a certain position μ_j of the document, where σ determines how the nearby terms to μ_j influence the local histogram j. Thus, sequential information of the document is considered throughout these local histograms. Note that when σ is small, most of the sequential information is preserved, as local histograms are calculated at very local scales; whereas when $\sigma \geq 1$, local histograms resemble the traditional BOW representation.

Under LOWBOW documents can be represented in two forms (Lebanon et al., 2007): as a single histogram $\mathbf{d}_i^L = const \times \sum_{j=1}^{k} \mathbf{dl}_i^j$ (hereafter LOWBOW histograms) or by the set of local histograms itself $\mathbf{dl}_i^{\{1,\ldots,k\}}$. We performed experiments with both forms of representation and considered words and n-grams at the character-level as terms (c.f. Section 5). Regarding the smoothing function, we considered the re-normalized Gaussian *pdf* restricted to [0, 1]:

$$K^s_{\mu,\sigma}(x) = \begin{cases} \frac{\mathcal{N}(x;\mu,\sigma)}{\phi(\frac{1-\mu}{\sigma}) - \phi(\frac{-\mu}{\sigma})} & \text{if } x \in [0,1] \\ 0 & \text{otherwise} \end{cases} \quad (3)$$

where $\phi(x)$ is the cumulative distribution function for a Gaussian with mean 0 and standard deviation 1, evaluated at x, see (Lebanon et al., 2007) for further details.

3.3 Support vector machines

Support vector machines (SVMs) are pattern classification methods that aim to find an optimal separating hyperplane between examples from two different classes (Shawe-Taylor and Cristianini, 2004). Let $\{\mathbf{x}_i, y_i\}_N$ be pairs of training patterns-outputs, where $\mathbf{x}_i \in \mathbb{R}^d$ and $y \in \{-1, 1\}$, with d the dimensionality of the problem. SVMs aim at learning a mapping from training instances to outputs. This is done by considering a linear function of the form: $f(\mathbf{x}) = W\mathbf{x} + b$, where parameters W and b are learned from training data. The particular linear function considered by SVMs is as follows:

$$f(\mathbf{x}) = \sum_i \alpha_i y_i K(\mathbf{x}_i, \mathbf{x}) - b \quad (4)$$

that is, a linear function over (a subset of) training examples, where α_i is the weight associated with training example i (those for which $\alpha_i > 0$ are the so called support vectors) and y_i is the label associated with training example i, $K(\mathbf{x}_i, \mathbf{x}_j)$ is a kernel[2] function that aims at mapping the input vectors, $(\mathbf{x}_i, \mathbf{x}_j)$, into the so called feature space, and b is a bias term. Intuitively, $K(\mathbf{x}_i, \mathbf{x}_j)$ evaluates how similar instances $\mathbf{x}_i$ and $\mathbf{x}_j$ are, thus the particular choice of kernel is problem dependent. The parameters in expression (4), namely $\alpha_{\{1,\ldots,N\}}$ and b, are learned by using exact optimization techniques (Shawe-Taylor and Cristianini, 2004).

[2]One should not confuse the kernel smoothing function, $K^s_{\mu,\sigma}(x)$, defined in Equation (3) with the Mercer kernel in Equation (4), as the former acts as a smoothing function and the latter acts as a similarity function.

4 Authorship Attribution with LOWBOW Representations

For AA we represent the training documents of each author using the framework described in Section 3.2, thus each document of each candidate author is either a LOWBOW histogram or a bag of local histograms (BOLH). Recall that LOWBOW histograms are an un-weighted sum of local histograms and hence can be considered a summary of term usage and sequential information; whereas the BOLH can be seen as term occurrence frequencies across different locations of the document.

For both types of representations we consider an SVM classifier under the one-vs-all formulation for facing the AA problem. We consider SVM as base classifier because this method has proved to be very effective in a large number of applications, including AA (Houvardas and Stamatatos, 2006; Plakias and Stamatatos, 2008b; Plakias and Stamatatos, 2008a); further, since SVMs are kernel-based methods, they allow us to use local histograms for AA by considering kernels that work over sets of histograms.

We build a multiclass SVM classifier by considering the pairs of patterns-outputs associated to documents-authors. Where each pattern can be either a LOWBOW histogram or the set of local histograms associated with the corresponding document, and the output associated to each pattern is a categorical random variable (outputs) that associates the representation of each document to its corresponding author $y_{1,\ldots,N} \in \{1,\ldots,C\}$, with C the number of candidate authors. For building the multiclass classifier we adopted the one-vs-all formulation, where C binary classifiers are built and where each classifier f_i discriminates among examples from class i (positive examples) and the rest $j : j \in \{1,\ldots,C\}, j \neq i$; despite being one of the simplest formulations, this approach has shown to obtain comparable and even superior performance to that obtained by more complex formulations (Rifkin and Klautau, 2004).

For AA using LOWBOW histograms, we consider a linear kernel since it has been successfully applied to a wide variety of problems (Shawe-Taylor and Cristianini, 2004), including AA (Houvardas and Stamatatos, 2006; Plakias and Stamatatos, 2008b). However, *standard* kernels cannot work for input spaces where each instance is described by a set of vectors. Therefore, usual kernels are not applicable for AA using BOLH. Instead, we rely on particular kernels defined for sets of vectors rather than for a single vector. Specifically, we consider kernels of the form (Rubner et al., 2001; Grauman, 2006):

$$K(P,Q) = \exp\big(-\frac{D(P,Q)^2}{\gamma}\big) \qquad (5)$$

where $D(P,Q)$ is the sum of the distances between the elements of the bag of local histograms associated to author P and the elements of the bag of histograms associated with author Q; γ is the scale parameter of K. Let $P = \{\mathbf{p}_1,\ldots,\mathbf{p}_k\}$ and $Q = \{\mathbf{q}_1,\ldots,\mathbf{q}_k\}$ be the elements of the bags of local histograms for instances P and Q, respectively, Table 1 presents the distance measures we consider for AA using local histograms.

Kernel	Distance
Diffusion	$D(P,Q) = \sum_{l=1}^{k} \arccos\left(\langle\sqrt{\mathbf{p}}_l \cdot \sqrt{\mathbf{q}}_l\rangle\right)$
EMD	$D(P,Q) = EMD(P,Q)$
Eucidean	$D(P,Q) = \sqrt{\sum_{l=1}^{k}(\mathbf{p}_l - \mathbf{q}_l).^2}$
χ^2	$D(P,Q) = \sqrt{\sum_{l=1}^{k} \frac{(\mathbf{p}_l - \mathbf{q}_l)^2}{(\mathbf{p}_l + \mathbf{q}_l)}}$

Table 1: Distance functions used to calculate the kernel defined in Equation (5).

Diffusion, Euclidean, and χ^2 kernels compare local histograms one to one, which means that the local histograms calculated at the same locations are compared to each other. We believe that for AA this is advantageous as it is expected that an author uses similar terms at similar locations of the document. The Earth mover's distance (EMD), on the other hand, is an estimate of the optimal cost in taking local histograms from Q to local histograms in P (Rubner et al., 2001); that is, this measure computes the optimal matching distance between local histograms from different authors that are not necessarily computed at similar locations.

5 Experiments and Results

For our experiments we considered the data set used in (Plakias and Stamatatos, 2008b; Plakias and Stamatatos, 2008a). This corpus is a subset of the RCV1 collection (Lewis et al., 2004) and comprises

documents authored by 10 authors. All of the documents belong to the same topic. Since this data set has predefined training and testing partitions, our results are comparable to those obtained by other researchers. There are 50 documents per author for training and 50 documents per author for testing.

We performed experiments with LOWBOW[3] representations at word and character-level. For the experiments with words, we took the top 2,500 most common words used across the training documents and obtained LOWBOW representations. We used this setting in agreement with previous work on AA (Houvardas and Stamatatos, 2006). For our character n-gram experiments, we obtained LOWBOW representations for character 3-grams (only n-grams of size $n = 3$ were used) considering the $2,500$ most common n-grams. Again, this setting was adopted in agreement with previous work on AA with character n-grams (Houvardas and Stamatatos, 2006; Plakias and Stamatatos, 2008b; Plakias and Stamatatos, 2008a; Luyckx and Daelemans, 2010). All our experiments use the SVM implementation provided by Canu et al. (2005).

5.1 Experimental settings

In order to compare our methods to related works we adopted the following experimental setting. We perform experiments using all of the training documents per author, that is, a balanced corpus (we call this setting **BC**). Next we evaluate the performance of classifiers over reduced training sets. We tried balanced reduced data sets with: $1, 3, 5$ and 10 documents per author (we call this configuration **RBC**). Also, we experimented with reduced-imbalanced data sets using the same imbalance rates reported in (Plakias and Stamatatos, 2008b; Plakias and Stamatatos, 2008a): we tried settings $2-10$, $5-10$, and $10-20$, where, for example, setting 2-10 means that we use at least 2 and at most 10 documents per author (we call this setting **IRBC**). **BC** setting represents the AA problem under ideal conditions, whereas settings **RBC** and **IRBC** aim at emulating a more realistic scenario, where limited sample documents are available and the whole data set is highly imbalanced (Plakias and Stamatatos, 2008b).

[3]We used LOWBOW code of G. Lebanon and Y. Mao available from http://www.cc.gatech.edu/∼ymao8/lowbow.htm

5.2 Experimental results in balanced data

We first compare the performance of the LOWBOW histogram representation to that of the traditional BOW representation. Table 2 shows the accuracy (i.e., percentage of documents in the test set that were associated to its correct author) for the BOW and LOWBOW histogram representations when using words and character n-grams information. For LOWBOW histograms, we report results with three different configurations for μ. As in (Lebanon et al., 2007), we consider uniformly distributed locations and we varied the number of locations that were included in each setting. We denote with k the number of local histograms. In preliminary experiments we tried several other values for k, although we found that representative results can be obtained with the values we considered here.

Method	Parameters	Words	Characters
BOW	-	78.2%	75.0%
LOWBOW	$k = 2; \sigma = 0.2$	75.8%	72.0%
LOWBOW	$k = 5; \sigma = 0.2$	77.4%	75.2%
LOWBOW	$k = 20; \sigma = 0.2$	77.4%	75.0%

Table 2: Authorship attribution accuracy for the BOW representation and LOWBOW histograms. Column 2 shows the parameters we used for the LOWBOW histograms; columns 3 and 4 show results using words and character n-grams, respectively.

From Table 2 we can see that the BOW representation is very effective, outperforming most of the LOWBOW histogram configurations. Despite a small difference in performance, BOW is advantageous over LOWBOW histograms because it is simpler to compute and it does not rely on parameter selection. Recall that the LOWBOW histogram representations are obtained by the combination of several local histograms calculated at different locations of the document, hence, it seems that the raw sum of local histograms results in a loss of useful information for representing documents. The worse performance was obtained when $k = 2$ local histograms are considered (see row 3 in Table 2). This result is somewhat expected since the larger the number of local histograms, the more LOWBOW histograms approach the BOW formulation (Lebanon et al., 2007).

We now describe the AA performance obtained when using the BOLH formulation; these results

are shown in Table 3. Most of the results from this table are superior to those reported in Table 2, showing that bags of local histograms are a better way to exploit the LOWBOW framework for AA. As expected, different kernels yield different results. However, the diffusion kernel outperformed most of the results obtained with other kernels; confirming the results obtained by other researchers (Lebanon et al., 2007; Lafferty and Lebanon, 2005).

Kernel	Euc.	Diffusion	EMD	χ^2
		Words		
Setting-1	78.6%	81.0%	75.0%	75.4%
Setting-2	77.6%	82.0%	76.8%	77.2%
Setting-3	79.2%	80.8%	77.0%	79.0%
		Characters		
Setting-1	83.4%	82.8%	84.4%	83.8%
Setting-2	83.4%	84.2%	82.2%	84.6%
Setting-3	83.6%	**86.4%**	81.0%	85.2%

Table 3: Authorship attribution accuracy when using bags of local histograms and different kernels for word-based and character-based representations. The **BC** data set is used. Settings 1, 2 and 3 correspond to $k = 2, 5$ and 20, respectively.

On average, the worse kernel was that based on the earth mover's distance (EMD), suggesting that the comparison of local histograms at different locations is not a fruitful approach (recall that this is the only kernel that compares local histograms at different locations). This result evidences that authors use similar word/character distributions at similar locations when writing different documents.

The best performance across settings and kernels was obtained with the diffusion kernel (in bold, column 3, row 9) (86.4%); that result is 8% higher than that obtained with the BOW representation and 9% better than the best configuration of LOWBOW histograms, see Table 2. Furthermore, that result is more than 5% higher than the best reported result in related work (80.8% as reported in (Plakias and Stamatatos, 2008b)). Therefore, the considered local histogram representations over character n-grams have proved to be very effective for AA.

One should note that, in general, better performance was obtained when using character-level rather than word-level information. This confirms the results already reported by other researchers that have used character-level and word-level information for AA (Houvardas and Stamatatos, 2006; Plakias and Stamatatos, 2008b; Plakias and Stamatatos, 2008a; Peng et al., 2003). We believe this can be attributed to the fact that character n-grams provide a representation for the document at a finer granularity, which can be better exploited with local histogram representations. Note that by considering 3-grams, words of length up to three are incorporated, and usually these words are function words (e.g., the, it, as, etc.), which are known to be indicative of writing style. Also, n-gram information is more dense in documents than word-level information. Hence, the local histograms are less sparse when using character-level information, which results in better AA performance.

Table 4: Confusion matrix (in terms of percentages) for the best result in the **BC** corpus (i.e., last row, column 3 in Table 3). Columns show the true author for test documents and rows show the authors predicted by the SVM.

Table 4 shows the confusion matrix for the setting that reached the best results (i.e., column 3, last row in Table 3). From this table we can see that 8 out of the 10 authors were recognized with an accuracy higher or equal to 80%. For these authors sequential information seems to be particularly helpful. However, low recognition performance was obtained for authors BL (B. K. Lim) and JM (J. MacArtney). The SVM with BOW representation of character n-grams achieved recognition rates of 40% and 50% for BL and JM respectively. Thus, we can state that sequential information was indeed helpful for modeling BL writing style (improvement of 28%), although it is an author that resulted very difficult to model. On the other hand, local histograms were not very useful for identifying documents written by JM (made it worse by -8%). The largest improvement (38%) of local histograms over the BOW formulation was obtained for author TN (T. Nissen). This

result gives evidence that TN uses a similar distribution of words in similar locations across the documents he writes. These results are interesting, although we would like to perform a careful analysis of results in order to determine for what type of authors it would be beneficial to use local histograms, and what type of authors are better modeled with a standard BOW approach.

5.3 Experimental results in imbalanced data

In this section we report results with **RBC** and **IRBC** data sets, which aim to evaluate the performance of our methods in a realistic setting. For these experiments we compare the performance of the BOW, LOWBOW histogram and BOLH representations; for the latter, we considered the best setting as reported in Table 3 (i.e., an SVM with diffusion kernel and $k = 20$). Tables 5 and 6 show the AA performances when using word and character information, respectively.

We first analyze the results in the **RBC** data set (recall that for this data set we consider 1, 3, 5, 10, and 50, randomly selected documents per author). From Tables 5 and 6 we can see that BOW and LOWBOW histogram representations obtained similar performance to each other across the different training set sizes, which agree with results in Table 2 for the **BC** data sets. The best performance across the different configurations of the **RBC** data set was obtained with the BOLH formulation (row 6 in Tables 5 and 6). The improvements of local histograms over the BOW formulation vary across different settings and when using information at word-level and character-level. When using words (columns 2-6 in Table 5) the differences in performance are of 15.6%, 6.2%, 6.8%, 2.9%, 3.8% when using 1, 3, 5, 10 and 50 documents per author, respectively. Thus, it is evident that local histograms are more beneficial when less documents are considered. Here, the lack of information is compensated by the availability of several histograms per author.

When using character n-grams (columns 2-6 in Table 6) the corresponding differences in performance are of 5.4%, 6.4%, 6.4%, 6% and 11.4%, when using 1, 3, 5, 10, and 50 documents per author, respectively. In this case, the larger improvement was obtained when 50 documents per author are available; nevertheless, one should note that results using character-level information are, in general, significantly better than those obtained with word-level information; hence, improvements are expected to be smaller.

When we compare the results of the BOLH formulation with the best reported results elsewhere (c.f. last row 6 in Tables 5 and 6) (Plakias and Stamatatos, 2008b), we found that the improvements range from 14% to 30.2% when using character n-grams and from 1.2% to 26% when using words. The differences in performance are larger when less information is used (e.g., when 5 documents are used for training) and we believe the differences would be even larger if results for 1 and 3 documents were available. These are very positive results; for example, we can obtain almost 71% of accuracy, using local histograms of character n-grams when a single document is available per author (recall that we have used all of the test samples for evaluating the performance of our methods).

We now analyze the performance of the different methods when using the **IRBC** data set (columns 7-9 in Tables 5 and 6). The same pattern as before can be observed in experimental results for these data sets as well: BOW and LOWBOW histograms obtained comparable performance to each other and the BOLH formulation performed the best. The BOLH formulation outperforms state of the art approaches by a considerable margin that ranges from 10% to 27%. Again, better results were obtained when using character n-grams for the local histograms. With respect to **RBC** data sets, the BOLH at the character-level resulted very robust to the reduction of training set size and the highly imbalanced data.

Summarizing, the results obtained in **RBC** and **IRBC** data sets show that the use of local histograms is advantageous under challenging conditions. An SVM under the BOLH representation is less sensitive to the number of training examples available and to the imbalance of data than an SVM using the BOW representation. Our hypothesis for this behavior is that local histograms can be thought of as expanding training instances, because for each training instance in the BOW formulation we have $k-$training instances under BOLH. The benefits of such expansion become more notorious as the number of available documents per author decreases.

WORDS								
Data set	**Balanced**					**Imbalanced**		
Setting	*1-doc*	*3-docs*	*5-docs*	*10-docs*	*50-docs*	*2-10*	*5-10*	*10-20*

6 Conclusions

We have described the use of local histograms (LH) over character n-grams for AA. LHs are enriched histogram representations that preserve sequential information in documents (in terms of the positions of terms in documents); we explored the suitability of LHs over n-grams at the *character-level* for AA. We showed evidence supporting our hypothesis that LHs are very helpful for AA; we believe that this is due to the fact that LOWBOW representations can uncover, to some extent, the writing preferences of authors. Our experimental results showed that LHs outperform traditional bag-of-words formulations and state of the art techniques in balanced, imbalanced, and reduced data sets. The improvements were larger in reduced and imbalanced data sets, which is a very positive result as in real AA applications one often faces highly imbalanced and small sample issues. Our results are promising and motivate further research on the use and extension of the LOWBOW framework for related tasks (e.g. authorship verification and plagiarism detection).

As future work we would like to explore the use of LOWBOW representations for profile-based AA and related tasks. Also, we would like to develop model selection strategies for learning what combination of hyperparameters works better for modeling each author.

Acknowledgments

We thank E. Stamatatos for making his data set available. Also, we are grateful for the thoughtful comments of L. A. Barrón and those of the anonymous reviewers. Word Maturity: Computational Modeling of Word Knowledge

Kirill Kireyev **Thomas K Landauer**

Pearson Education, Knowledge Technologies
Boulder, CO

{kirill.kireyev, tom.landauer}@pearson.com

Abstract

While computational estimation of difficulty of words in the lexicon is useful in many educational and assessment applications, the concept of scalar word difficulty and current corpus-based methods for its estimation are inadequate. We propose a new paradigm called *word meaning maturity* which tracks the degree of knowledge of each word at different stages of language learning. We present a computational algorithm for estimating word maturity, based on modeling language acquisition with Latent Semantic Analysis. We demonstrate that the resulting metric not only correlates well with external indicators, but captures deeper semantic effects in language.

1 Motivation

It is no surprise that through stages of language learning, different words are learned at different times and are known to different extents. For example, a common word like "dog" is familiar to even a first-grader, whereas a more advanced word like "focal" does not usually enter learners' vocabulary until much later. Although individual rates of learning words may vary between high- and low-performing students, it has been observed that "children […] acquire word meanings in roughly the same sequence" (Biemiller, 2008).

The aim of this work is to model the degree of knowledge of words at different learning stages. Such a metric would have extremely useful applications in personalized educational technologies, for the purposes of accurate assessment and personalized vocabulary instruction.

2 Rethinking Word Difficulty

Previously, related work in education and psychometrics has been concerned with measuring *word difficulty* or classifying words into different difficulty categories.

Examples of such approaches include creation of word lists for targeted vocabulary instruction at various grade levels that were compiled by educational experts, such as Nation (1993) or Biemiller (2008). Such word difficulty assignments are also implicitly present in some readability formulas that estimate difficulty of texts, such as Lexiles (Stenner, 1996), which include a lexical difficulty component based on the frequency of occurrence of words in a representative corpus, on the assumption that word difficulty is inversely correlated to corpus frequency. Additionally, research in psycholinguistics has attempted to outline and measure psycholinguistic dimensions of words such as *age-of-acquisition* and *familiarity*, which aim to track when certain words become known and how familiar they appear to an average person.

Importantly, all such word *difficulty* measures can be thought of as functions that assign a single scalar value to each word *w*:

$$difficulty : f(w) \rightarrow \mathbb{R} \qquad (1)$$

There are several important limitations to such metrics, regardless of whether they are derived from corpus frequency, expert judgments or other measures.

First, learning each word is a continual process, one that is interdependent with the rest of the vocabulary. Wolter (2001) writes:

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 299–308,
Portland, Oregon, June 19-24, 2011.

> […] Knowing a word is quite often not an either-or situation; some words are known well, some not at all, and some are known to varying degrees. […] How well a particular word is known may condition the connections made between that particular word and the other words in the mental lexicon.

Thus, instead of modeling *when* a particular word will become fully known, it makes more sense to model the *degree* to which a word is known at different levels of language exposure.

Second, word difficulty is inherently perspectival: the degree of word understanding depends not only on the word itself, but also on the sophistication of a given learner. Consider again the difference between "dog" and "focal": a typical first-grader will have much more difficulty understanding the latter word compared to the former, whereas a well-educated adult will be able to use these words with equal ease. Therefore, the degree, or *maturity,* of word knowledge is inherently a function of two parameters -- word *w* and learner level *l*:

$$maturity : f(w, l) \rightarrow \mathbb{R} \qquad (2)$$

As the level *l* increases (i.e. for more advanced learners), we would expect the degree of understanding of word *w* to approach its full value corresponding to perfect knowledge; this will happen at different rates for different words.

Ideally, we would obtain maturity values by testing word knowledge of learners across different levels (ages or school grades) for all the words in the lexicon. Such a procedure, however, is prohibitively expensive; so instead we would like to estimate word maturity by using computational models.

To summarize: our aim is to model the development of *meaning* of words as a function of increasing exposure to language, and ultimately - the degree to which the meaning of words at each stage of exposure resemble their "adult" meaning. We therefore define *word meaning maturity* to be the degree to which the understanding of the word (expected for the average learner of a particular level) resembles that of an ideal mature learner.

3 Modeling Word Meaning Acquisition with Latent Semantic Analysis

3.1 Latent Semantic Analysis (LSA)

An appealing choice for quantitatively modeling word meanings and their growth over time is Latent Semantic Analysis (LSA), an unsupervised method for representing word and document meaning in a multi-dimensional vector space.

The LSA vector representation is derived in an unsupervised manner, based on occurrence patterns of words in a large corpus of natural language documents. A Singular Value Decomposition on the high-dimensional matrix of word/document occurrence counts (*A*) in the corpus, followed by zeroing all but the largest *r* elements[1] of the diagonal matrix *S*, yields a lower-rank word vector matrix (*U)*. The dimensionality reduction has the effect of smoothing out incidental co-occurrences and preserving significant semantic relationships between words. The resulting word vectors[2] in *U* are positioned in such a way that semantically related words vectors point in similar directions or, equivalently, have higher cosine values between them. For more details, please refer to Landauer et al. (2007) and others.

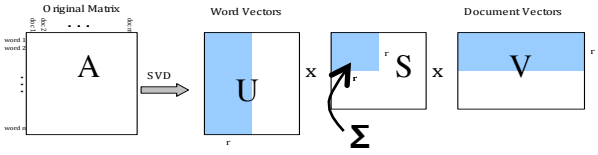

Figure 1. The SVD process in LSA illustrated. The original high-dimensional word-by-document matrix A is decomposed into word (U) and document (V) matrices of lower dimensionality.

In addition to merely measuring semantic relatedness, LSA has been shown to emulate the learning of word meanings from natural language (as can be evidenced by a broad range of applications from synonym tests to automated essay grading), at rates that resemble those of human learners (Laundauer et al, 1997). Landauer and Dumais (1997) have demonstrated empirically that LSA can emulate not only the rate of human language acquisition, but also more subtle phenomena, such as the effects of learning certain words on meaning of other words. LSA can model meaning with

[1] Typically the first approx. 300 dimensions are retained

[2] UΣ is used to project word vectors into V-space

high accuracy, as attested, for example, by 90% correlation with human judgments on assessing the quality of student essay content (Landauer, 2002).

3.2 Using LSA to Compute Word Maturity

In this work, the general procedure behind computationally estimating word maturity of a learner at a particular intermediate level (i.e. age or school grade level) is as follows:

1. Create an intermediate corpus for the given level. This corpus approximates the amount and sophistication of language encountered by a learner at the given level.
2. Build an LSA space on that corpus. The resulting LSA word vectors model the meaning of each word to the particular intermediate-level learner.
3. Compare the meaning representation of each word (its LSA vector) to the corresponding one in a reference model. The reference model is trained on a much larger corpus and approximates the word meanings by a mature adult learner.

We can repeat this process for each of a number of levels. These levels may directly correspond to school grades, learner ages or any other arbitrary gradations.

In summary, we estimate word maturity of a given word at a given learner level by comparing the word vector from an *intermediate* LSA model (trained on a corpus of size and sophistication comparable to that which a typical real student at the given level encounters) to the corresponding vector from a reference *adult* LSA model (trained on a larger corpus corresponding to a mature language learner). A high discrepancy between the vectors would suggest that an intermediate model's meaning of a particular word is quite different from the reference meaning, and thus the word maturity at the corresponding level is relatively low.

3.3 Procrustes Alignment (PA)

Comparing vectors across different LSA spaces is less straightforward, since the individual dimensions in LSA do not have a meaningful interpretation, and are an artifact of the content and ordering of the training corpus used. Therefore, direct comparisons across two different spaces, even of the same dimensionality, are meaningless, due to a mismatch in their coordinate systems.

Fortunately, we can employ a multivariate algebra technique known as Procrustes Alignment (or Procrustes Analysis) (PA) typically used to align two multivariate configurations of a corresponding set of points in two different geometric spaces. PA has been used in conjunction with LSA, for example, in cross-language information retrieval (Littman, 1998).

The basic idea behind PA is to derive a rotation matrix that allows one space to be rotated into the other. The rotation matrix is computed in such a way as to minimize the differences (namely: sum of squared distances) between corresponding points, which in the case of LSA can be common words or documents in the training set.

For more details, the reader is advised to consult chapter 5 of (Krzanowski, 2000) or similar literature on multivariate analysis. In summary, given two matrices containing coordinates of n corresponding points X and Y (and assuming mean-centering and equal number of dimensions, as is the case in this work), we would like to minimize the sum of squared distances between the points:

$$M^2 = \sum_{i=1}^{n} \sum_{j=1}^{n} (x_{ij} - y_{ij})^2$$

We try to find an orthogonal rotation matrix Q, which minimizes M^2 by rotating Y relative to X. That matrix can be obtained by solving the equation:

$$M^2 = trace(XX' + YY' - 2XQ'Y')$$

It turns out that the solution to Q is given by VU', where $U\Sigma V'$ is the singular value decomposition of the matrix $X'Y$.

In our situation, where there are two spaces, *adult* and *intermediate*, the alignment points are the corresponding document vectors corresponding to the documents that the training corpora of the two models have in common (recall that the adult corpus is a superset of each of the intermediate corpora). The result of the Procrustes Alignment of the two spaces is effectively a joint LSA space containing two distinct word vectors for each word (e.g. "*dog1*", "*dog2*"), corresponding to the vectors from each of the original spaces. After

merging using Procrustes Alignment, the comparison of word meanings becomes a simple problem of comparing word vectors in the joint space using the standard cosine metric.

4 Implementation Details

In our experiments we used passages from the MetaMetrics Inc. 2002 corpus[3], largely consisting of educational and literary content representative of the reading material used in American schools at different grade levels. The average length of each passage is approximately 135 words.

The first-level intermediate corpus was composed of 6,000 text passages, intended for school grade 1 or below. The grade level is approximated using the Coleman-Liau readability formula (Coleman, 1975), which estimates the US grade level necessary to comprehend a given text, based on its average sentence and word length statistics:

$$CLI = 0.0588L - 0.296S - 15.8 \qquad (4)$$

where L is the average number of letters per 100 words and S is the average number of sentences per 100 words.

Each subsequent intermediate corpus contains additional 6,000 new passages of the next grade level, in addition to the previous corpus. In this way, we create 14 levels. The adult corpus is twice as large, and of same grade level range (0-14) as the largest intermediate corpus.

In summary, the following describes the size and makeup of the corpora used:

Corpus	Size (passages)	Approx. Grade Level (Coleman-Liau Index)
Intermediate 1	6,000	0.0 - 1.0
Intermediate 2	12,000	0.0 - 2.0
Intermediate 3	18,000	0.0 - 3.0
Intermediate 4	24,000	0.0 - 4.0
…		
Intermediate 14	84,000	0.0 - 14.0
Adult	168,000	0.0 - 14.0

Table 1. Size and makeup of corpora. used for LSA models.

The particular choice of the Coleman-Liau readability formula (CLI) is not essential; our experiments show that other well-known readability formulas (such as Lexiles) work equally well. All that is needed is some *approximate* ordering of passages by difficulty, in order to mimic the way typical human learners encounter progressively more difficult materials at successive school grades.

After creating the corpora, we:

1. Build LSA spaces on the adult and each of the intermediate corpora
2. Merge the intermediate space for level l with the adult space, using Procrustes Alignment. This results in a joint space with two sets of vectors: the versions from the intermediate space $\{vl_w\}$, and adult space $\{va_w\}$.
3. Compute the cosine in the joint space between the two word vectors for the given word w

$$wm(w, l) = cos\ (vl_w, va_w) \qquad (5)$$

In the cases where a word w has not been encountered in a given intermediate space, or in the rare cases where the cosine value falls below 0, the word maturity value is set to 0. Hence, the range for the word maturity function falls in the closed interval [0.0, 1.0]. A higher cosine value means greater similarity in meaning between the reference and intermediate spaces, which implies a more mature meaning of word w at the level l, i.e. higher word meaning maturity. The scores between discrete levels are interpolated, resulting in a continuous word maturity curve for each word.

Figure 1 below illustrates resulting word maturity curves for some of the words.

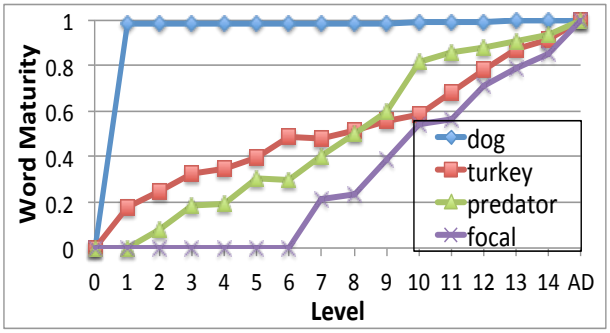

Figure 2. Word maturity curves for selected words.

Consistent with intuition, simple words like "dog" approach their adult meaning rather quickly, while "focal" takes much longer to become known to any degree.

An interesting example is "turkey", which has a noticeable plateau in the middle. This can be explained by the fact that this word has two distinct senses. Closer analysis of the corpus and the semantic near-neighbor word vectors at each in-

[3] We would like to acknowledge Jack Stenner and MetaMetrics for the use of their corpus.

termediate space, shows that earlier meaning deal almost exclusively with the first sense (bird), while later readings with the other (country). Therefore, even though the word "turkey" is quite prevalent in earlier readings, its full meaning is not learned until later levels. This demonstrates that our method takes into account the *meaning*, and not merely the frequency of occurrence.

5 Evaluation

5.1 Time-to-maturity

Evaluation of the word maturity metric against external data is not always straightforward because, to the best of our knowledge, data that contains word knowledge statistics *at different learner levels* does not exist. Instead, we often have to evaluate against external data consisting of scalar *difficulty* values (see Section 2 for discussion) for each word, such as age-of-acquisition norms described in the following subsection.

There are two ways to make such comparisons possible. One is to compute the word maturity at a particular level, obtaining a single number for each word. Another is by computing *time-to-maturity*: the minimum level (the value on the x-axis of the word maturity graph) at which the word maturity reaches[4] a particular threshold α:

$$ttm(w) = \min(l)\, s.t.\, wm(w,l) > \alpha \qquad (6)$$

Intuitively, this measure corresponds to the age in a learner's development when a given word becomes sufficiently understood. The parameter α can be estimated empirically (in practice α=0.45 gives good correlations with external measures). Since the values of word maturity are interpolated, the *ttm(w)* can take on fractional values.

It should be emphasized that such a collapsing of word *maturity* into a scalar value inherently results in loss of information; we only perform it in order to allow evaluation against external data sources.

As a baseline for these experiments we include word frequency, namely the document frequency of words in the adult corpus.

5.2 Age-of-Acquisition Norms

Age-of-Acquisition (AoA) is a psycholinguistic property of words originally reported by Carol & White (1973). Age of Acquisition approximates the age at which a word is first learned and has been proposed as a significant contributor to language and memory processes. With some exceptions, AoA norms are collected by subjective measures, typically by asking each of a large number of participants to estimate in years the age when they have learned the word. AoA estimates have been shown to be reliable and provide a valid estimate for the objective age at which a word is acquired; see (Davis, in press) for references and discussion.

In this experiment we compute Spearman correlations between time-to-maturity and two available collections of AoA norms: Gilhooly et al., (1980) norms[5], and Bristol norms[6] (Stadthagen-Gonzalez et al., 2010).

Measure	**Gilhooly** (n=1643)	**Bristol** (n=1402)
(-) Frequency	0.59	0.59
Time-to-Maturity (α=0.45)	*0.72*	*0.64*

Table 2. Correlations with Age of Acquisition norms.

5.3 Instruction Word Lists

In this experiment, we examine leveled lists of words, as created by Biemiller (2008) in the book entitled "Words Worth Teaching: Closing the Vocabulary Gap". Based on results of multiple-choice word comprehension tests administered to students of different grades as well as expert judgments, the author derives several word difficulty lists for vocabulary instruction in schools, including:

- Words known by most children in grade 2
- Words known by 40-80% of children in grade 2
- Words known by 40-80% of children in grade 6
- Words known by fewer than 40% of children in grade 6

One would expect the words in these four groups to increase in difficulty, in the order they are presented above.

[4] Values between discrete levels are obtained using piecewise linear interpolation

[5] http://www.psy.uwa.edu.au/mrcdatabase/uwa_mrc.htm

[6] http://language.psy.bris.ac.uk/bristol_norms.html

To verify how these word groups correspond to the word maturity metric, we assign each of the words in the four groups a difficulty rating 1-4 respectively, and measure the correlation with time-to-maturity.

Measure	Correlation
(-) Frequency	0.43
Time-to-maturity (α=0.45)	*0.49*

Table 3. Correlations with instruction word lists (n=4176).

The word maturity metric shows higher correlation with instruction word list norms than word frequency.

5.4 Text Complexity

Another way in which our metric can be evaluated is by examining the word maturity in texts that have been leveled, i.e. have been assigned ratings of difficulty. On average, we would expect more difficult texts to contain more difficult words. Thus, the correlation between text difficulty and our word maturity metric can serve as another validation of the metric.

For this purpose, we obtained a collection of readings that are used as reading comprehension tests by different state websites in the US[7]. The collection consists of 1,220 readings, each annotated with a US school grade level (in the range between 3-12) for which the reading is intended. The average length each passage was approximately 489 words.

In this experiment we computed the correlation of the grade level with time-to-maturity, and two other measures, namely:

- *Time-to-maturity*: average time-to-maturity of unique words in text (excluding stopwords) with α=0.45.
- *Coleman-Liau.* The Coleman-Liau readability index (Equation 4).
- *Frequency*. Average of corpus log-frequency for unique words in the text, excluding stopwords.

Measure	Correlation
Frequency (avg. of unique words)	0.60
Coleman-Liau	0.64
Time-to-maturity (α=0.45) (avg. of unique non-stopwords)	*0.70*

Table 4. Correlations of grade levels with different metrics.

6 Emphasis on Meaning

In this section, we would like to highlight certain properties of the LSA-based word maturity metric, particularly aiming to illustrate the fact that the metric tracks acquisition of meaning from exposure to language and not merely more shallow effects, such as word frequency in the training corpus.

6.1 Maturity based on Frequency

For a baseline that does not take meaning into account, let us construct a set of maturity-like curves based on frequency statistics alone. More specifically, we define the *frequency-maturity* for a particular word at a given level as the ratio of the number of occurrences at the intermediate corpus for that level (l) to the number of occurrences in the reference corpus (a):

$$fm(w,l) = \frac{num\_occur_l(w)}{num\_occur_a(w)}$$

Similarly to the original LSA-based word maturity metric, this ratio increases from 0 to 1 for each word as the amount of cumulative language exposure increases. The corpora used at each intermediate level are identical to the original word maturity model, but instead of creating LSA spaces we simply use the corpora to compute word frequency.

The following figure shows the Spearman correlations between the external measures used for experiments in Section 5, and time-to-maturity computed based on the two maturity metrics: the new frequency-based maturity and the original LSA-based word maturity.

[7] The collection was created as part of the "Aspects of Text Complexity" project funded by the Bill and Melinda Gates Foundation, 2010.

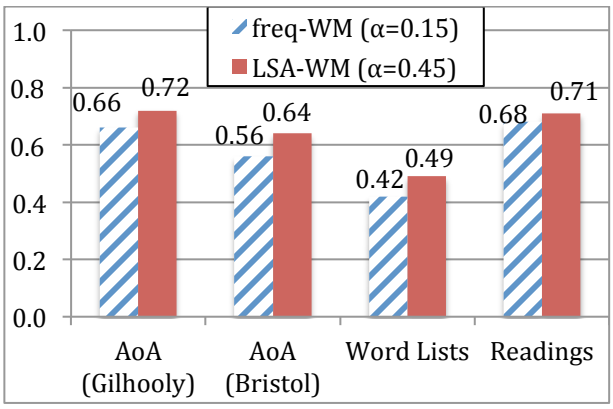

Figure 3. Correlations of word maturity computed using frequency (as well as the original) against external metrics described in Section 5.

The results indicate that the original LSA-based word maturity correlates better with real-world data than a maturity metric simply based on frequency.

6.2 Homographs

Another insight into the fact that the LSA-based word maturity metric tracks word meaning rather than mere frequency may be gained from analysis of words that are *homographs*: words that contain two or more unrelated meanings in the same written form, such as the word "turkey" illustrated in Section 4. (This is related to but distinct from the merely *polysemous* words that have several related meanings),

Because of the conflation of several unrelated meanings into the same orthographic form, homographs implicitly contain more semantic content in a single word. Therefore, one would expect the meaning of homographs to mature more slowly than would be predicted by frequency alone: all things being equal, a learner has to learn the meanings for all of the senses of a homograph word before the word can be considered fully known.

More specifically, one would expect the time-to-maturity of homographs to have greater values than words of similar frequency. To test this hypothesis, we obtained[8] a list 174 common English homographs. For each of them, we compared their time-to-maturity to the average time-to-maturity of words that have the same (+/- 1%) corpus frequency.

The results of a paired t-test confirms the hypothesis that the time-to-maturity of homographs is greater than other words of the same frequency, with the *p-value* = $5.9e^{-6}$. This is consistent with the observation that homographs will take longer to learn and serves as evidence that LSA-based word maturity approximates effects related to meaning.

6.3 Size of the Reference Corpus

Another area of investigation is the repercussions of the choice of the corpus for the reference (adult) model. The size (and content) of the corpus used to train the reference model is potentially important, since it affects the word maturity calculations, which are comparisons of the intermediate LSA spaces to the reference LSA space built on this corpus.

It is interesting to investigate how the word maturity model would be affected if the adult corpus were made significantly more sophisticated. If the word maturity metric were simply based on word frequency (including the frequency-based maturity baseline described in Section 6.1), one would expect the word maturity of the words at each level to *decrease* significantly if the reference model is made significantly larger, since each intermediate level will have encountered fewer words by comparison. Intuition about language learning, however, tells us that with enough language exposure a learner learns virtually all there is to know about any particular word; after the word reaches its adult maturity, subsequent encounters of natural readings do little to further change the knowledge of that word. Therefore, if word maturity were tracking something similar to real word knowledge, one would expect the word maturity for most words to plateau over time, and subsequently not change significantly, no matter how sophisticated the reference model becomes.

To evaluate this inquiry we created a reference corpus that is twice as large as before (four times as large and of the same difficulty range as the corpus for the last intermediate level), containing roughly 329,000 passages. We computed the word maturity model using this larger reference corpus, while keeping all the original intermediate corpora of the same size and content.

The results show that the average word maturity of words at the last intermediate level (14) de-

[8] http://en.wikipedia.org/wiki/List_of_English_homographs

creases by less than 14% as a result of doubling the adult corpus. Furthermore, this number is as low as 6%, if one only considers more common words that occur 50 times or more in the corpus. This relatively small difference, in spite of a two-fold increase of the adult corpus, is consistent with the idea that word knowledge should approach a plateau, after which further exposure to language does little to change most word meanings.

6.4 Integration into Lexicon

Another important consideration with respect to word learning mentioned in Wotler (2001), is the "connections made between [a] particular word and the other words in the mental lexicon." One implication of that is that measuring word maturity must take into account the way words in the language are integrated with other words.

One way to test this effect is to introduce readings where a large part of the important vocabulary is not well known to learners at a given level. One would expect learning to be impeded when the learning materials are inappropriate for the learner level.

This can be simulated in the word maturity model by rearranging the order of some of the training passages, by introducing certain advanced passages at a very early level. If the results of the word maturity metric were merely based on frequency, such a reordering would have no effect on the maturity of important words (measured after all the passages containing these words have been encountered), since the total number of relevant word encounters does not change as a result of this reshuffling. If, however, the metric reflected at least some degree of semantics, we would expect word maturities for important words in these readings to be lower as a result of such rearranging, due to the fact that they are being introduced in contexts consisting of words that are not well known at the early levels.

To test this effect, we first collected all passages in the training corpus of intermediate models containing some advanced words from different topics, namely: "chromosome", "neutron" and "filibuster" together with their plural variants. We changed the order of inclusion of these 89 passages into the intermediate models in each of the two following ways:

1. All the passages were introduced at the first level (*l=1*) intermediate corpus
2. All the passages were introduced at the last level (*l=14*) intermediate corpus.

This resulted in two new variants of word maturity models, which were computed in all the same ways as before, except that all of these 89 advanced passages were introduced either at the very first level or at the very last level. We then computed the word maturity at the levels they were introduced. The hypothesis consistent with a meaning-based maturity method would be that less learning (i.e. lower word maturity) of the relevant words will occur when passages are introduced prematurely (at level 1). Table 5 shows the word maturities measured for each of those cases, at the level (*1* or *14*) when all of the passages have been introduced.

Word	**Introduced at *l=1*** (WM at *l=1*)	**Introduced at *l=14*** (WM at *l=14*)
chromosome	0.51	0.73
neutron	0.51	0.72
filibuster	0.58	0.85

Table 5. Word maturity of words resulting when all the relevant passages are introduced early vs late.

Indeed, the results show lower word maturity values when advanced passages are introduced too early, and higher ones when the passages are introduced at a later stage, when the rest of the supporting vocabulary is known.

7 Conclusion

We have introduced a new metric for estimating the degree of knowledge of words by learners at different levels. We have also proposed and evaluated an implementation of this metric using Latent Semantic Analysis.

The implementation is based on unsupervised word meaning acquisition from natural text, from corpora that resemble in volume and complexity the reading materials a typical human learner might encounter.

The metric correlates better than word frequency to a range of external measures, including vocabulary word lists, psycholinguistic norms and leveled texts. Furthermore, we have shown that the metric is based on word meaning (to the extent that it can be approximated with LSA), and not merely on shallow measures like word frequency.

Many interesting research questions still remain pertaining to the best way to select and partition the training corpora, align adult and intermediate LSA models, correlate the results with real school grade levels, as well as other free parameters in the model. Nevertheless, we have shown that LSA can be employed to usefully mimic model word knowledge. The models are currently used (at Pearson Education) to create state-of-the-art personalized vocabulary instruction and assessment tools.

Abstract

Consumers increasingly rate, review and research products online (Jansen, 2010; Litvin et al., 2008). Consequently, websites containing consumer reviews are becoming targets of *opinion spam*. While recent work has focused primarily on manually identifiable instances of opinion spam, in this work we study *deceptive opinion spam*—fictitious opinions that have been deliberately written to sound authentic. Integrating work from psychology and computational linguistics, we develop and compare three approaches to detecting deceptive opinion spam, and ultimately develop a classifier that is nearly 90% accurate on our *gold-standard* opinion spam dataset. Based on feature analysis of our learned models, we additionally make several theoretical contributions, including revealing a relationship between deceptive opinions and imaginative writing.

1 Introduction

With the ever-increasing popularity of review websites that feature user-generated opinions (e.g., TripAdvisor[1] and Yelp[2]), there comes an increasing potential for monetary gain through *opinion spam*—inappropriate or fraudulent reviews. Opinion spam can range from annoying self-promotion of an unrelated website or blog to deliberate review fraud, as in the recent case[3] of a Belkin employee who hired people to write positive reviews for an otherwise poorly reviewed product.[4]

While other kinds of spam have received considerable computational attention, regrettably there has been little work to date (see Section 2) on opinion spam detection. Furthermore, most previous work in the area has focused on the detection of DISRUPTIVE OPINION SPAM—uncontroversial instances of spam that are easily identified by a human reader, e.g., advertisements, questions, and other irrelevant or non-opinion text (Jindal and Liu, 2008). And while the presence of disruptive opinion spam is certainly a nuisance, the risk it poses to the user is minimal, since the user can always choose to ignore it.

We focus here on a potentially more insidious type of opinion spam: DECEPTIVE OPINION SPAM—fictitious opinions that have been deliberately written to sound authentic, in order to deceive the reader. For example, one of the following two hotel reviews is truthful and the other is *deceptive opinion spam*:

1. I have stayed at many hotels traveling for both business and pleasure and I can honestly stay that The James is tops. The service at the hotel is first class. The rooms are modern and very comfortable. The location is perfect within walking distance to all of the great sights and restaurants. Highly recommend to both business travellers and couples.
2. My husband and I stayed at the James Chicago Hotel for our anniversary. This place is fantastic! We knew as soon as we arrived we made the right choice! The rooms are BEAUTIFUL and the staff very attentive and wonderful!! The area of the hotel is great, since I love to shop I couldn't ask for more!! We will definatly be

[2] http://yelp.com
[3] http://news.cnet.com/8301-1001_3-10145399-92.html
[4] It is also possible for opinion spam to be negative, potentially in order to sully the reputation of a competitor.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 309–319,
Portland, Oregon, June 19-24, 2011.

back to Chicago and we will for sure be back to the James Chicago.

Typically, these deceptive opinions are neither easily ignored nor even identifiable by a human reader;[5] consequently, there are few good sources of labeled data for this research. Indeed, in the absence of gold-standard data, related studies (see Section 2) have been forced to utilize ad hoc procedures for evaluation. In contrast, one contribution of the work presented here is the creation of the first large-scale, publicly available[6] dataset for deceptive opinion spam research, containing 400 truthful and 400 *gold-standard* deceptive reviews.

To obtain a deeper understanding of the nature of deceptive opinion spam, we explore the relative utility of three potentially complementary framings of our problem. Specifically, we view the task as: (a) a standard *text categorization* task, in which we use n-gram–based classifiers to label opinions as either deceptive or truthful (Joachims, 1998; Sebastiani, 2002); (b) an instance of *psycholinguistic deception detection*, in which we expect deceptive statements to exemplify the psychological effects of lying, such as increased negative emotion and psychological distancing (Hancock et al., 2008; Newman et al., 2003); and, (c) a problem of *genre identification*, in which we view deceptive and truthful writing as sub-genres of imaginative and informative writing, respectively (Biber et al., 1999; Rayson et al., 2001).

We compare the performance of each approach on our novel dataset. Particularly, we find that machine learning classifiers trained on features traditionally employed in (a) psychological studies of deception and (b) genre identification are both outperformed at statistically significant levels by n-gram–based text categorization techniques. Notably, a combined classifier with both n-gram and psychological deception features achieves nearly 90% cross-validated accuracy on this task. In contrast, we find deceptive opinion spam detection to be well beyond the capabilities of most human judges, who perform roughly at-chance—a finding that is consistent with decades of traditional deception detection research (Bond and DePaulo, 2006).

[5]The second example review is deceptive opinion spam.

[6]Available by request at: `http://www.cs.cornell.edu/~myleott/op_spam`

Additionally, we make several theoretical contributions based on an examination of the feature weights learned by our machine learning classifiers. Specifically, we shed light on an ongoing debate in the deception literature regarding the importance of considering the context and motivation of a deception, rather than simply identifying a universal set of deception cues. We also present findings that are consistent with recent work highlighting the difficulties that liars have encoding spatial information (Vrij et al., 2009). Lastly, our study of deceptive opinion spam detection as a genre identification problem reveals relationships between deceptive opinions and imaginative writing, and between truthful opinions and informative writing.

The rest of this paper is organized as follows: in Section 2, we summarize related work; in Section 3, we explain our methodology for gathering data and evaluate human performance; in Section 4, we describe the features and classifiers employed by our three automated detection approaches; in Section 5, we present and discuss experimental results; finally, conclusions and directions for future work are given in Section 6.

2 Related Work

Spam has historically been studied in the contexts of e-mail (Drucker et al., 2002), and the Web (Gyöngyi et al., 2004; Ntoulas et al., 2006). Recently, researchers have began to look at *opinion spam* as well (Jindal and Liu, 2008; Wu et al., 2010; Yoo and Gretzel, 2009).

Jindal and Liu (2008) find that opinion spam is both widespread and different in nature from either e-mail or Web spam. Using product review data, and in the absence of gold-standard deceptive opinions, they train models using features based on the review text, reviewer, and product, to distinguish between *duplicate* opinions[7] (considered deceptive spam) and *non-duplicate* opinions (considered truthful). Wu et al. (2010) propose an alternative strategy for detecting deceptive opinion spam in the absence

[7]Duplicate (or near-duplicate) opinions are opinions that appear more than once in the corpus with the same (or similar) text. While these opinions are likely to be deceptive, they are unlikely to be representative of deceptive opinion spam in general. Moreover, they are potentially detectable via off-the-shelf plagiarism detection software.

of gold-standard data, based on the distortion of popularity rankings. Both of these heuristic evaluation approaches are unnecessary in our work, since we compare *gold-standard* deceptive and truthful opinions.

Yoo and Gretzel (2009) gather 40 truthful and 42 deceptive hotel reviews and, using a standard statistical test, manually compare the psychologically relevant linguistic differences between them. In contrast, we create a much larger dataset of 800 opinions that we use to develop and evaluate *automated* deception classifiers.

Research has also been conducted on the related task of *psycholinguistic deception detection*. Newman et al. (2003), and later Mihalcea and Strapparava (2009), ask participants to give both their true and untrue views on personal issues (e.g., their stance on the death penalty). Zhou et al. (2004; 2008) consider computer-mediated deception in role-playing games designed to be played over instant messaging and e-mail. However, while these studies compare n-gram–based deception classifiers to a random guess baseline of 50%, we additionally evaluate and compare two other computational approaches (described in Section 4), as well as the performance of human judges (described in Section 3.3).

Lastly, automatic approaches to determining *review quality* have been studied—directly (Weimer et al., 2007), and in the contexts of helpfulness (Danescu-Niculescu-Mizil et al., 2009; Kim et al., 2006; O'Mahony and Smyth, 2009) and credibility (Weerkamp and De Rijke, 2008). Unfortunately, most measures of quality employed in those works are based exclusively on human judgments, which we find in Section 3 to be poorly calibrated to detecting deceptive opinion spam.

3 Dataset Construction and Human Performance

While truthful opinions are ubiquitous online, deceptive opinions are difficult to obtain without resorting to heuristic methods (Jindal and Liu, 2008; Wu et al., 2010). In this section, we report our efforts to gather (and validate with human judgments) the first publicly available opinion spam dataset with *gold-standard* deceptive opinions.

Following the work of Yoo and Gretzel (2009), we compare truthful and deceptive **positive** reviews for hotels found on TripAdvisor. Specifically, we mine all 5-star truthful reviews from the 20 most popular hotels on TripAdvisor[8] in the Chicago area.[9] Deceptive opinions are gathered for those same 20 hotels using Amazon Mechanical Turk[10] (AMT). Below, we provide details of the collection methodologies for deceptive (Section 3.1) and truthful opinions (Section 3.2). Ultimately, we collect 20 truthful and 20 deceptive opinions for each of the 20 chosen hotels (800 opinions total).

3.1 Deceptive opinions via Mechanical Turk

Crowdsourcing services such as AMT have made large-scale data annotation and collection efforts financially affordable by granting anyone with basic programming skills access to a marketplace of anonymous online workers (known as *Turkers*) willing to complete small tasks.

To solicit gold-standard **deceptive** opinion spam using AMT, we create a pool of 400 *Human Intelligence Tasks* (HITs) and allocate them evenly across our 20 chosen hotels. To ensure that opinions are written by unique authors, we allow only a single submission per Turker. We also restrict our task to Turkers who are located in the United States, and who maintain an approval rating of at least 90%. Turkers are allowed a maximum of 30 minutes to work on the HIT, and are paid one US dollar for an accepted submission.

Each HIT presents the Turker with the name and website of a hotel. The HIT instructions ask the Turker to assume that they work for the hotel's marketing department, and to pretend that their boss wants them to write a fake review (as if they were a customer) to be posted on a travel review website; additionally, the review needs to sound realistic and portray the hotel in a positive light. A disclaimer

[8] TripAdvisor utilizes a proprietary ranking system to assess hotel popularity. We chose the 20 hotels with the greatest number of reviews, irrespective of the TripAdvisor ranking.

[9] It has been hypothesized that popular offerings are less likely to become targets of deceptive opinion spam, since the relative impact of the spam in such cases is small (Jindal and Liu, 2008; Lim et al., 2010). By considering only the most popular hotels, we hope to minimize the risk of mining opinion spam and labeling it as truthful.

[10] `http://mturk.com`

Time spent t (minutes)	
All submissions	$count$: 400 t_{min}: 0.08, t_{max}: 29.78 $\bar{t}$: 8.06, s: 6.32
Length ℓ (words)	
All submissions	ℓ_{min}: 25, ℓ_{max}: 425 $\bar{\ell}$: 115.75, s: 61.30
Time spent $t < 1$	$count$: 47 ℓ_{min}: 39, ℓ_{max}: 407 $\bar{\ell}$: 113.94, s: 66.24
Time spent $t \geq 1$	$count$: 353 ℓ_{min}: 25, ℓ_{max}: 425 $\bar{\ell}$: 115.99, s: 60.71

Table 1: Descriptive statistics for 400 deceptive opinion spam submissions gathered using AMT. s corresponds to the sample standard deviation.

indicates that any submission found to be of insufficient quality (e.g., written for the wrong hotel, unintelligible, unreasonably short,[11] plagiarized,[12] etc.) will be rejected.

It took approximately 14 days to collect 400 satisfactory deceptive opinions. Descriptive statistics appear in Table 1. Submissions vary quite dramatically both in length, and time spent on the task. Particularly, nearly 12% of the submissions were completed in *under one minute*. Surprisingly, an independent two-tailed t-test between the mean length of these submissions ($\bar{\ell}_{t<1}$) and the other submissions ($\bar{\ell}_{t\geq 1}$) reveals no significant difference ($p = 0.83$). We suspect that these "*quick*" users may have started working prior to having formally accepted the HIT, presumably to circumvent the imposed time limit. Indeed, the quickest submission took just 5 seconds and contained 114 words.

3.2 Truthful opinions from TripAdvisor

For truthful opinions, we mine all 6,977 reviews from the 20 most popular Chicago hotels on TripAdvisor. From these we eliminate:

- 3,130 non-5-star reviews;
- 41 non-English reviews;[13]
- 75 reviews with fewer than 150 characters since, by construction, deceptive opinions are at least 150 characters long (see footnote 11 in Section 3.1);
- 1,607 reviews written by *first-time authors*—new users who have not previously posted an opinion on TripAdvisor—since these opinions are more likely to contain opinion spam, which would reduce the integrity of our truthful review data (Wu et al., 2010).

Finally, we balance the number of truthful and deceptive opinions by selecting 400 of the remaining 2,124 truthful reviews, such that the document lengths of the selected truthful reviews are similarly distributed to those of the deceptive reviews. Work by Serrano et al. (2009) suggests that a *log-normal* distribution is appropriate for modeling document lengths. Thus, for each of the 20 chosen hotels, we select 20 truthful reviews from a log-normal (left-truncated at 150 characters) distribution fit to the lengths of the deceptive reviews.[14] Combined with the 400 deceptive reviews gathered in Section 3.1 this yields our final dataset of 800 reviews.

3.3 Human performance

Assessing human deception detection performance is important for several reasons. First, there are few other baselines for our classification task; indeed, related studies (Jindal and Liu, 2008; Mihalcea and Strapparava, 2009) have only considered a random guess baseline. Second, assessing human performance is necessary to validate the deceptive opinions gathered in Section 3.1. If human performance is low, then our deceptive opinions are convincing, and therefore, deserving of further attention.

Our initial approach to assessing human performance on this task was with Mechanical Turk. Unfortunately, we found that some Turkers selected among the choices seemingly at random, presumably to maximize their hourly earnings by obviating the need to read the review. While a similar effect has been observed previously (Akkaya et al., 2010), there remains no universal solution.

Instead, we solicit the help of three volunteer undergraduate university students to make judgments on a subset of our data. This balanced subset, corresponding to the first fold of our cross-validation

[11] A submission is considered unreasonably short if it contains fewer than 150 characters.

[12] Submissions are individually checked for plagiarism at `http://plagiarisma.net`.

[13] Language is determined using `http://tagthe.net`.

[14] We use the R package GAMLSS (Rigby and Stasinopoulos, 2005) to fit the left-truncated log-normal distribution.

			TRUTHFUL			DECEPTIVE		
		Accuracy	**P**	**R**	**F**	**P**	**R**	**F**
HUMAN	JUDGE 1	**61.9%**	57.9	87.5	**69.7**	74.4	36.3	48.7
	JUDGE 2	56.9%	53.9	**95.0**	68.8	**78.9**	18.8	30.3
	JUDGE 3	53.1%	52.3	70.0	59.9	54.7	36.3	43.6
META	MAJORITY	58.1%	54.8	92.5	68.8	76.0	23.8	36.2
	SKEPTIC	60.6%	**60.8**	60.0	60.4	60.5	**61.3**	**60.9**

Table 2: Performance of three human judges and two meta-judges on a subset of 160 opinions, corresponding to the first fold of our cross-validation experiments in Section 5. Boldface indicates the largest value for each column.

experiments described in Section 5, contains all 40 reviews from each of four randomly chosen hotels. Unlike the Turkers, our student volunteers are not offered a monetary reward. Consequently, we consider their judgements to be more honest than those obtained via AMT.

Additionally, to test the extent to which the individual human judges are biased, we evaluate the performance of two virtual meta-judges. Specifically, the MAJORITY meta-judge predicts "*deceptive*" when at least two out of three human judges believe the review to be deceptive, and the SKEPTIC meta-judge predicts "*deceptive*" when *any* human judge believes the review to be deceptive.

Human and meta-judge performance is given in Table 2. It is clear from the results that human judges are not particularly effective at this task. Indeed, a two-tailed binomial test fails to reject the null hypothesis that JUDGE 2 and JUDGE 3 perform at-chance ($p = 0.003, 0.10, 0.48$ for the three judges, respectively). Furthermore, all three judges suffer from *truth-bias* (Vrij, 2008), a common finding in deception detection research in which human judges are more likely to classify an opinion as truthful than deceptive. In fact, JUDGE 2 classified fewer than 12% of the opinions as deceptive! Interestingly, this bias is effectively smoothed by the SKEPTIC meta-judge, which produces nearly perfectly class-balanced predictions. A subsequent reevaluation of human performance on this task suggests that the truth-bias can be reduced if judges are given the class-proportions in advance, although such prior knowledge is unrealistic; and ultimately, performance remains similar to that of Table 2.

Inter-annotator agreement among the three judges, computed using Fleiss' kappa, is 0.11. While there is no precise rule for interpreting kappa scores, Landis and Koch (1977) suggest that scores in the range (0.00, 0.20] correspond to "*slight agreement*" between annotators. The largest pairwise Cohen's kappa is 0.12, between JUDGE 2 and JUDGE 3—a value far below generally accepted pairwise agreement levels. We suspect that agreement among our human judges is so low *precisely because* humans are poor judges of deception (Vrij, 2008), and therefore they perform nearly at-chance respective to one another.

4 Automated Approaches to Deceptive Opinion Spam Detection

We consider three automated approaches to detecting deceptive opinion spam, each of which utilizes classifiers (described in Section 4.4) trained on the dataset of Section 3. The features employed by each strategy are outlined here.

4.1 Genre identification

Work in computational linguistics has shown that the frequency distribution of *part-of-speech* (POS) tags in a text is often dependent on the genre of the text (Biber et al., 1999; Rayson et al., 2001). In our genre identification approach to deceptive opinion spam detection, we test if such a relationship exists for truthful and deceptive reviews by constructing, for each review, features based on the frequencies of each POS tag.[15] These features are also intended to provide a good baseline with which to compare our other automated approaches.

4.2 Psycholinguistic deception detection

The *Linguistic Inquiry and Word Count* (LIWC) software (Pennebaker et al., 2007) is a popular automated text analysis tool used widely in the social sciences. It has been used to detect personality

[15] We use the Stanford Parser (Klein and Manning, 2003) to obtain the relative POS frequencies.

traits (Mairesse et al., 2007), to study tutoring dynamics (Cade et al., 2010), and, most relevantly, to analyze deception (Hancock et al., 2008; Mihalcea and Strapparava, 2009; Vrij et al., 2007).

While LIWC does not include a text classifier, we can create one with features derived from the LIWC output. In particular, LIWC counts and groups the number of instances of nearly 4,500 keywords into 80 psychologically meaningful dimensions. We construct one feature for each of the 80 LIWC dimensions, which can be summarized broadly under the following four categories:

1. Linguistic processes: Functional aspects of text (e.g., the average number of words per sentence, the rate of misspelling, swearing, etc.)
2. Psychological processes: Includes all social, emotional, cognitive, perceptual and biological processes, as well as anything related to time or space.
3. Personal concerns: Any references to work, leisure, money, religion, etc.
4. Spoken categories: Primarily filler and agreement words.

While other features have been considered in past deception detection work, notably those of Zhou et al. (2004), early experiments found LIWC features to perform best. Indeed, the LIWC2007 software used in our experiments subsumes most of the features introduced in other work. Thus, we focus our psycholinguistic approach to deception detection on LIWC-based features.

4.3 Text categorization

In contrast to the other strategies just discussed, our text categorization approach to deception detection allows us to model both content and context with n-gram features. Specifically, we consider the following three n-gram feature sets, with the corresponding features lowercased and unstemmed: UNIGRAMS, BIGRAMS$^+$, TRIGRAMS$^+$, where the superscript $^+$ indicates that the feature set subsumes the preceding feature set.

4.4 Classifiers

Features from the three approaches just introduced are used to train Naïve Bayes and Support Vector Machine classifiers, both of which have performed well in related work (Jindal and Liu, 2008; Mihalcea and Strapparava, 2009; Zhou et al., 2008).

For a document $\vec{x}$, with label y, the *Naïve Bayes* (NB) classifier gives us the following decision rule:

$$\hat{y} = \arg\max_c \Pr(y = c) \cdot \Pr(\vec{x} \mid y = c) \quad (1)$$

When the class prior is *uniform*, for example when the classes are balanced (as in our case), (1) can be simplified to the maximum likelihood classifier (Peng and Schuurmans, 2003):

$$\hat{y} = \arg\max_c \Pr(\vec{x} \mid y = c) \quad (2)$$

Under (2), both the NB classifier used by Mihalcea and Strapparava (2009) and the language model classifier used by Zhou et al. (2008) are equivalent. Thus, following Zhou et al. (2008), we use the SRI Language Modeling Toolkit (Stolcke, 2002) to estimate individual language models, $\Pr(\vec{x} \mid y = c)$, for truthful and deceptive opinions. We consider all three n-gram feature sets, namely UNIGRAMS, BIGRAMS$^+$, and TRIGRAMS$^+$, with corresponding language models smoothed using the interpolated Kneser-Ney method (Chen and Goodman, 1996).

We also train *Support Vector Machine* (SVM) classifiers, which find a high-dimensional separating hyperplane between two groups of data. To simplify feature analysis in Section 5, we restrict our evaluation to *linear* SVMs, which learn a weight vector $\vec{w}$ and bias term b, such that a document $\vec{x}$ can be classified by:

$$\hat{y} = sign(\vec{w} \cdot \vec{x} + b) \quad (3)$$

We use SVM^{light} (Joachims, 1999) to train our linear SVM models on all three approaches and feature sets described above, namely POS, LIWC, UNIGRAMS, BIGRAMS$^+$, and TRIGRAMS$^+$. We also evaluate every combination of these features, but for brevity include only LIWC+BIGRAMS$^+$, which performs best. Following standard practice, document vectors are normalized to unit-length. For LIWC+BIGRAMS$^+$, we unit-length normalize LIWC and BIGRAMS$^+$ features individually before combining them.

			TRUTHFUL			DECEPTIVE		
Approach	**Features**	**Accuracy**	**P**	**R**	**F**	**P**	**R**	**F**
GENRE IDENTIFICATION	POS_{SVM}	73.0%	75.3	68.5	71.7	71.1	77.5	74.2

	$\text{BIGRAMS}^{+}_{\text{NB}}$	88.9%	89.8	87.8	88.7	88.0	90.0	89.0
	$\text{TRIGRAMS}^{+}_{\text{NB}}$	87.6%	87.7	87.5	87.6	87.5	87.8	87.6
HUMAN / META	JUDGE 1	**61.9%**	57.9	87.5	**69.7**	74.4	36.3	48.7
	JUDGE 2	56.9%	53.9	**95.0**	68.8	**78.9**	18.8	30.3
	SKEPTIC	60.6%	**60.8**	60.0	60.4	60.5	**61.3**	**60.9**

Table 3: Automated classifier performance for three approaches based on nested 5-fold cross-validation experiments. Reported precision, recall and F-score are computed using a micro-average, i.e., from the *aggregate* true positive, false positive and false negative rates, as suggested by Forman and Scholz (2009). Human performance is repeated here for JUDGE 1, JUDGE 2 and the SKEPTIC meta-judge, although they cannot be directly compared since the 160-opinion subset on which they are assessed only corresponds to the first cross-validation fold.

5 Results and Discussion

The deception detection strategies described in Section 4 are evaluated using a 5-fold *nested* cross-validation (CV) procedure (Quadrianto et al., 2009), where model parameters are selected for each test fold based on *standard* CV experiments on the training folds. Folds are selected so that each contains *all* reviews from four hotels; thus, learned models are always evaluated on reviews from unseen hotels.

Results appear in Table 3. We observe that automated classifiers outperform human judges for every metric, except truthful recall where JUDGE 2 performs best.[16] However, this is expected given that untrained humans often focus on unreliable cues to deception (Vrij, 2008). For example, one study examining deception in online dating found that humans perform at-chance detecting deceptive profiles because they rely on text-based cues that are unrelated to deception, such as second-person pronouns (Toma and Hancock, In Press).

Among the automated classifiers, baseline performance is given by the simple genre identification approach (POS_{SVM}) proposed in Section 4.1. Surprisingly, we find that even this simple automated classifier outperforms most human judges (one-tailed sign test $p = 0.06, 0.01, 0.001$ for the three judges, respectively, on the first fold). This result is best explained by theories of reality monitoring (Johnson and Raye, 1981), which suggest that truthful and deceptive opinions might be classified into informative and imaginative genres, respectively. Work by Rayson et al. (2001) has found strong distributional differences between informative and imaginative writing, namely that the former typically consists of more nouns, adjectives, prepositions, determiners, and coordinating conjunctions, while the latter consists of more verbs,[17] adverbs,[18] pronouns, and pre-determiners. Indeed, we find that the weights learned by POS_{SVM} (found in Table 4) are largely in agreement with these findings, notably except for adjective and adverb *superlatives*, the latter of which was found to be an exception by Rayson et al. (2001). However, that deceptive opinions contain more superlatives is not unexpected, since deceptive writing (but not necessarily imaginative writing in general) often contains exaggerated language (Buller and Burgoon, 1996; Hancock et al., 2008).

Both remaining automated approaches to detecting deceptive opinion spam outperform the simple

[16] As mentioned in Section 3.3, JUDGE 2 classified fewer than 12% of opinions as deceptive. While achieving 95% truthful recall, this judge's corresponding precision was not significantly better than chance (two-tailed binomial $p = 0.4$).

[17] *Past participle* verbs were an exception.

[18] *Superlative* adverbs were an exception.

TRUTHFUL/INFORMATIVE			DECEPTIVE/IMAGINATIVE		
Category	**Variant**	**Weight**	**Category**	**Variant**	**Weight**

ADVERBS	Superlative	**-0.094**	PRE-DETERMINERS	General	**0.017**

Table 4: Average feature weights learned by POS_{SVM}. Based on work by Rayson et al. (2001), we expect weights on the left to be positive (predictive of *truthful* opinions), and weights on the right to be negative (predictive of *deceptive* opinions). Boldface entries are at odds with these expectations. We report average feature weights of *unit-normalized* weight vectors, rather than *raw* weights vectors, to account for potential differences in magnitude between the folds.

genre identification baseline just discussed. Specifically, the psycholinguistic approach (LIWC_{SVM}) proposed in Section 4.2 performs 3.8% more accurately (one-tailed sign test $p = 0.02$), and the standard text categorization approach proposed in Section 4.3 performs between 14.6% and 16.6% more accurately. However, best performance overall is achieved by combining features from these two approaches. Particularly, the combined model $\text{LIWC+BIGRAMS}^{+}_{\text{SVM}}$ is 89.8% accurate at detecting deceptive opinion spam.[19]

Surprisingly, models trained only on UNIGRAMS—the simplest n-gram feature set—outperform all non–text-categorization approaches, and models trained on BIGRAMS^{+} perform *even better* (one-tailed sign test $p = 0.07$). This suggests that a universal set of keyword-based deception cues (e.g., LIWC) is not the best approach to detecting deception, and a context-sensitive approach (e.g., BIGRAMS^{+}) might be necessary to achieve state-of-the-art deception detection performance.

To better understand the models learned by these automated approaches, we report in Table 5 the top 15 highest weighted features for each class (*truthful* and *deceptive*) as learned by $\text{LIWC+BIGRAMS}^{+}_{\text{SVM}}$ and LIWC_{SVM}. In agreement with theories of reality monitoring (Johnson and Raye, 1981), we observe that truthful opinions tend to include more sensorial and concrete language than deceptive opinions; in particular, truthful opinions are more specific about spatial configurations (e.g., small, bathroom, on, location). This finding is also supported by recent work by Vrij et al. (2009) suggesting that liars have considerable difficultly encoding spatial information into their lies. Accordingly, we observe an increased focus in deceptive opinions on aspects external to the hotel being reviewed (e.g., husband, business,

[19]The result is not significantly better than $\text{BIGRAMS}^{+}_{\text{SVM}}$.

Ambiguous features are subscripted to indicate the source of the feature. LIWC features correspond to groups of keywords as explained in Section 4.2; more details about LIWC and the LIWC categories are available at `http://liwc.net`.

vacation).

We also acknowledge several findings that, on the surface, are in contrast to previous psycholinguistic studies of deception (Hancock et al., 2008; Newman et al., 2003). For instance, while deception is often associated with negative emotion terms, our deceptive reviews have more positive and fewer negative emotion terms. This pattern makes sense when one considers the goal of our deceivers, namely to create a positive review (Buller and Burgoon, 1996).

Deception has also previously been associated with decreased usage of first person singular, an effect attributed to psychological distancing (Newman et al., 2003). In contrast, we find increased first person singular to be among the largest indicators of deception, which we speculate is due to our deceivers attempting to enhance the credibility of their reviews by emphasizing their own presence in the review. Additional work is required, but these findings further suggest the importance of moving beyond a universal set of deceptive language features (e.g., LIWC) by considering both the contextual (e.g., BIGRAMS$^+$) and motivational parameters underlying a deception as well.

6 Conclusion and Future Work

In this work we have developed the first large-scale dataset containing *gold-standard* deceptive opinion spam. With it, we have shown that the detection of deceptive opinion spam is well beyond the capabilities of human judges, most of whom perform roughly at-chance. Accordingly, we have introduced three *automated* approaches to deceptive opinion spam detection, based on insights coming from research in computational linguistics and psychology. We find that while standard n-gram–based text categorization is the best individual detection approach, a *combination* approach using psycholinguistically-motivated features and n-gram features can perform slightly better.

Finally, we have made several theoretical contributions. Specifically, our findings suggest the importance of considering both the context (e.g., BIGRAMS$^+$) and motivations underlying a deception, rather than strictly adhering to a universal set of deception cues (e.g., LIWC). We have also presented results based on the feature weights learned by our classifiers that illustrate the difficulties faced by liars in encoding spatial information. Lastly, we have discovered a plausible relationship between deceptive opinion spam and imaginative writing, based on POS distributional similarities.

Possible directions for future work include an extended evaluation of the methods proposed in this work to both negative opinions, as well as opinions coming from other domains. Many additional approaches to detecting deceptive opinion spam are also possible, and a focus on approaches with high deceptive precision might be useful for production environments.

Abstract

Most previous work on multilingual sentiment analysis has focused on methods to adapt sentiment resources from resource-rich languages to resource-poor languages. We present a novel approach for joint bilingual sentiment classification at the sentence level that augments available labeled data in each language with unlabeled parallel data. We rely on the intuition that the sentiment labels for parallel sentences should be similar and present a model that jointly learns improved monolingual sentiment classifiers for each language. Experiments on multiple data sets show that the proposed approach (1) outperforms the monolingual baselines, significantly improving the accuracy for both languages by 3.44%-8.12%; (2) outperforms two standard approaches for leveraging unlabeled data; and (3) produces (albeit smaller) performance gains when employing pseudo-parallel data from machine translation engines.

1 Introduction

The field of sentiment analysis has quickly attracted the attention of researchers and practitioners alike (e.g. Pang et al., 2002; Turney, 2002; Hu and Liu, 2004; Wiebe et al., 2005; Breck et al., 2007; Pang and Lee, 2008). Indeed, sentiment analysis systems, which mine opinions from textual sources (e.g. news, blogs, and reviews), can be used in a wide variety of applications, including interpreting product reviews, opinion retrieval and political polling.

Not surprisingly, most methods for sentiment classification are supervised learning techniques, which require training data annotated with the appropriate sentiment labels (e.g. document-level or sentence-level positive vs. negative polarity). This data is difficult and costly to obtain, and must be acquired separately for each language under consideration.

Previous work in multilingual sentiment analysis has therefore focused on methods to adapt sentiment resources (e.g. lexicons) from resource-rich languages (typically English) to other languages, with the goal of transferring sentiment or subjectivity analysis capabilities from English to other languages (e.g. Mihalcea et al. (2007); Banea et al. (2008; 2010); Wan (2008; 2009); Prettenhofer and Stein (2010)). In recent years, however, sentiment-labeled data is gradually becoming available for languages other than English (e.g. Seki et al. (2007; 2008); Nakagawa et al. (2010); Schulz et al. (2010)). In addition, there is still much room for improvement in existing monolingual (including English) sentiment classifiers, especially at the sentence level (Pang and Lee, 2008).

This paper tackles the task of bilingual sentiment analysis. In contrast to previous work, we (1) assume that some amount of sentiment-labeled data is available for the language pair under study, and (2) investigate methods to simultaneously improve sentiment classification for *both languages*. Given the labeled data in each language, we propose an approach that exploits an *unlabeled* parallel corpus with the following

[*] The work was conducted when the first author was visiting Cornell University.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 320–330,
Portland, Oregon, June 19-24, 2011.

intuition: *two sentences or documents that are parallel (i.e. translations of one another) should exhibit the same sentiment — their sentiment labels (e.g. polarity, subjectivity, intensity) should be similar*. The proposed maximum entropy-based EM approach jointly learns two monolingual sentiment classifiers by treating the sentiment labels in the unlabeled parallel text as unobserved latent variables, and maximizes the regularized joint likelihood of the language-specific labeled data together with the inferred sentiment labels of the parallel text. Although our approach should be applicable at the document-level and for additional sentiment tasks, we focus on sentence-level polarity classification in this work.

We evaluate our approach for English and Chinese on two dataset combinations (see Section 4) and find that the proposed approach outperforms the monolingual baselines (i.e. maximum entropy and SVM classifiers) as well as two alternative methods for leveraging unlabeled data (transductive SVMs (Joachims, 1999b) and co-training (Blum and Mitchell, 1998)). Accuracy is significantly improved for both languages, by 3.44%-8.12%. We furthermore find that improvements, albeit smaller, are obtained when the parallel data is replaced with a pseudo-parallel (i.e. automatically translated) corpus. To our knowledge, this is the first multilingual sentiment analysis study to focus on methods for simultaneously improving sentiment classification for a pair of languages based on unlabeled data rather than resource adaptation from one language to another.

The rest of the paper is organized as follows. Section 2 introduces related work. In Section 3, the proposed joint model is described. Sections 4 and 5, respectively, provide the experimental setup and results; the conclusion (Section 6) follows.

2 Related Work

Multilingual Sentiment Analysis. There is a growing body of work on multilingual sentiment analysis. Most approaches focus on resource adaptation from one language (usually English) to other languages with few sentiment resources. Mihalcea et al. (2007), for example, generate subjectivity analysis resources in a new language from English sentiment resources by leveraging a bilingual dictionary or a parallel corpus. Banea et al. (2008; 2010) instead automatically translate the English resources using automatic machine translation engines for subjectivity classification. Prettenhofer and Stein (2010) investigate cross-lingual sentiment classification from the perspective of domain adaptation based on structural correspondence learning (Blitzer et al., 2006).

Approaches that do not explicitly involve resource adaptation include Wan (2009), which uses co-training (Blum and Mitchell, 1998) with English vs. Chinese features comprising the two independent "views" to exploit unlabeled Chinese data and a labeled English corpus and thereby improves Chinese sentiment classification. Another notable approach is the work of Boyd-Graber and Resnik (2010), which presents a generative model --- supervised multilingual latent Dirichlet allocation --- that jointly models topics that are consistent across languages, and employs them to better predict sentiment ratings.

Unlike the methods described above, we focus on simultaneously improving the performance of sentiment classification in a pair of languages by developing a model that relies on sentiment-labeled data in each language as well as unlabeled parallel text for the language pair.

Semi-supervised Learning. Another line of related work is semi-supervised learning, which combines labeled and unlabeled data to improve the performance of the task of interest (Zhu and Goldberg, 2009). Among the popular semi-supervised methods (e.g. EM on Naïve Bayes (Nigam et al., 2000), co-training (Blum and Mitchell, 1998), transductive SVMs (Joachims, 1999b), and co-regularization (Sindhwani et al., 2005; Amini et al., 2010)), our approach employs the EM algorithm, extending it to the bilingual case based on maximum entropy. We compare to co-training and transductive SVMs in Section 5.

Multilingual NLP for Other Tasks. Finally, there exists related work using bilingual resources to help other NLP tasks, such as word sense disambiguation (e.g. Ido and Itai (1994)), parsing (e.g. Burkett and Klein (2008); Zhao et al. (2009); Burkett et al. (2010)), information retrieval (Gao et al., 2009), named entity detection (Burkett et al., 2010); topic extraction (e.g. Zhang et al., 2010), text classification (e.g. Amini et al., 2010), and hyponym-relation acquisition (e.g. Oh et al., 2009).

In these cases, multilingual models increase performance because different languages contain different ambiguities and therefore present complementary views on the shared underlying labels. Our work shares a similar motivation.

3 A Joint Model with Unlabeled Parallel Text

We propose a maximum entropy-based statistical model. Maximum entropy (MaxEnt) models[1] have been widely used in many NLP tasks (Berger et al., 1996; Ratnaparkhi, 1997; Smith, 2006). The models assign the conditional probability of the label y given the observation x as follows:

$$p(y|x;\vec{\theta}) = \frac{1}{Z}\exp\left(\vec{\theta}\cdot\vec{f}(x,y)\right) \quad (1)$$

where $\vec{\theta}$ is a real-valued vector of feature weights and $\vec{f}$ is a feature function that maps pairs (x, y) to a nonnegative real-valued feature vector. Each feature has an associated parameter, θ_i, which is called its weight; and Z is the corresponding normalization factor.

Maximum likelihood parameter estimation (training) for such a model, with a set of labeled examples $\{(x_i, y_i)_{i=1}^n\}$, amounts to solving the following optimization problem:

$$\vec{\theta}^* = \arg\max_{\vec{\theta}} \prod_{i=1}^n p(y_i|x_i;\vec{\theta}) \quad (2)$$

3.1 Problem Definition

Given two languages L_1 and L_2, suppose we have two distinct (i.e. not parallel) sets of sentiment-labeled data, D_1 and D_2, written in L_1 and L_2, respectively. In addition, we have unlabeled (w.r.t. sentiment) bilingual (in L_1 and L_2) parallel data U that are defined as follows.

$$D_1 = (X_1, Y_1) = \{(x_i^1, \mathrm{y_i^1})_{i=1}^{l_1}\}$$
$$D_2 = (X_2, Y_2) = \{(x_i^2, \mathrm{y_i^2})_{i=1}^{l_2}\}$$
$$U = (X_1', X_2') = \left\{\left(x_i^{1'}, x_i^{2'}\right)_{i=1}^{u}\right\}$$

where $y_i \in \mathcal{Y} = \{+1, -1\}$ denotes the polarity of the i-th instance x_i (positive or negative); l_1 and l_2 are respectively the numbers of labeled instances in L_1 and L_2; $x_i^{1'}$ and $x_i^{2'}$ are parallel instances in L_1 and L_2, respectively (i.e. they are supposed to be translations of one another), whose labels $y_i^{1'}$ and $y_i^{2'}$ are unobserved, but according to the intuition outlined in Section 1, should be similar.

Given the input data D_1, D_2 and U, our task is to jointly learn two monolingual sentiment classifiers — one for L_1 and one for L_2. With MaxEnt, we learn from the input data:

$$f\colon \{D_1, D_2, U\} \rightarrow (\vec{\theta}_1^*, \vec{\theta}_2^*)$$

where $\vec{\theta}_1^*$ and $\vec{\theta}_2^*$ are the vectors of feature weights for L_1 and L_2, respectively (for brevity we denote them as θ_1 and θ_2 in the remaining sections). In this study, we focus on sentence-level sentiment classification, i.e. each x_i is a sentence, and $x_i^{1'}$ and $x_i^{2'}$ are parallel sentences.

3.2 The Joint Model

Given the problem definition above, we now present a novel model to exploit the correspondence of parallel sentences in unlabeled bilingual text. The model maximizes the following joint likelihood with respect to θ_1 and θ_2:

$$\begin{aligned}\mathcal{L}(\theta_1, \theta_2|D_1, D_2, U) &= p(Y_1|X_1;\theta_1)p(Y_2|X_2;\theta_2)\\ &\quad p(Y_1', Y_2'|X_1', X_2';\theta_1, \theta_2)\\ &= \prod_{v=1}^{2}\prod_{i=1}^{l_v} p(y_i^v|x_i^v;\theta_v)\\ &\quad \prod_{i=1}^{u} p\left(y_i^{1'}, y_i^{2'}|x_i^{1'}, x_i^{2'};\theta_1, \theta_2\right)\end{aligned} \quad (3)$$

where $v \in \{1,2\}$ denotes L_1 or L_2; the first term on the right-hand side is the likelihood of labeled data for both D_1 and D_2; and the second term is the likelihood of the unlabeled parallel data U.

If we assume that parallel sentences are perfect translations, the two sentences in each pair should have the same polarity label, which gives us:

$$\begin{aligned}&p\left(y_i^{1'}, y_i^{2'}|x_i^{1'}, x_i^{2'};\theta_1, \theta_2\right) =\\ &\textstyle\sum_{y_i'} p\left(y_i'|x_i^{1'};\theta_1\right)p\left(y_i'|x_i^{2'};\theta_2\right)\end{aligned} \quad (4)$$

where y_i' is the unobserved class label for the i-th instance in the unlabeled data. This probability directly models the sentiment label agreement between $x_i^{1'}$ and $x_i^{2'}$.

However, there could be considerable noise in real-world parallel data, i.e. the sentence pairs may be noisily parallel (or even comparable) instead of fully parallel (Munteanu and Marcu, 2005). In such noisy cases, the labels (positive or negative) could be different for the two monolingual sentences in a sentence pair. Although we do not know the exact probability that a sentence pair exhibits the same label, we can approximate it using their translation

[1]They are sometimes referred to as log-linear models, but also known as exponential models, generalized linear models, or logistic regression.

probabilities, which can be computed using word alignment toolkits such as Giza++ (Och and Ney, 2003) or the Berkeley word aligner (Liang et al., 2006). *The intuition here is that if the translation probability of two sentences is high, the probability that they have the same sentiment label should be high as well*. Therefore, by considering the noise in parallel data, we get:

$$p(y_i^{1'}, y_i^{2'} | x_i^{1'}, x_i^{2'}; \theta_1, \theta_2) = \sum_{y'}\{p(a_i)p(y'|x_i^{1'};\theta_1)p(y'|x_i^{2'};\theta_2)\} + \sum_{y'}\{(1-p(a_i))p(y'|x_i^{1'};\theta_1)p(\bar{y'}|x_i^{2'};\theta_2)\} \quad (5)$$

where $p(a_i)$ is the translation probability of the i-th sentence pair in U;[2] $\bar{y'}$ is the opposite of y'; the first term models the probability that $x_i^{1'}$ and $x_i^{2'}$ have the same label; and the second term models the probability that they have different labels.

By further considering the weight to ascribe to the unlabeled data vs. the labeled data (and the weight for the L2-norm regularization), we get the following regularized joint log likelihood to be maximized:

$$\log \mathcal{L}(\theta_1, \theta_2 | D_1, D_2, U) = \sum_{v=1}^{2} \log p(Y_v | X_v; \theta_v) + \lambda_1 \log p(Y_1', Y_2' | X_1', X_2'; \theta_1, \theta_2) - \frac{\lambda_2}{2} \sum_{v=1}^{2} \| \theta_v \|_2^2 \quad (6)$$

where the first term on the right-hand side is the log likelihood of the labeled data from both D_1 and D_2; the second is the log likelihood of the unlabeled parallel data U, multiplied by $\lambda_1 \geq 0$, a constant that controls the contribution of the unlabeled data; and $\lambda_2 \geq 0$ is a regularization constant that penalizes model complexity or large feature weights. When λ_1 is 0, the algorithm ignores the unlabeled data and degenerates to two MaxEnt models trained on only the labeled data.

3.3 The EM Algorithm on MaxEnt

To solve the optimization problem for the model, we need to jointly estimate the optimal parameters for the two monolingual classifiers by finding:

$$(\theta_1^*, \theta_2^*) = \arg\max_{(\theta_1, \theta_2)} \log \mathcal{L}(\theta_1, \theta_2 | D_1, D_2, U) \quad (7)$$

This can be done with an EM algorithm, whose steps are summarized in Algorithm 1. First, the MaxEnt parameters, θ_1 and θ_2, are estimated from just the labeled data. Then, in the E-step, the classifiers, based on current values of θ_1 and θ_2, compute $p(y_i|x_i)$ for each labeled example and assign probabilistically-weighted class labels to each unlabeled example. Next, in the M-step, the parameters, θ_1 and θ_2, are updated using both the original labeled data (D_1 and D_2) and the newly labeled data U. These last two steps are iterated until convergence or a predefined iteration limit T.

Algorithm 1. The MaxEnt-based EM Algorithm for Multilingual Sentiment Classification

Input: Labeled data D_1 and D_2
Unlabeled parallel data U

Output: Two monolingual MaxEnt classifiers with parameters θ_1^* and θ_2^*, respectively

1. **Train two initial monolingual models**
   Train and initialize $\theta_1^{(0)}$ and $\theta_2^{(0)}$ on the labeled data
2. **Jointly optimize two monolingual models**
   for $t = 1$ **to** T **do** // T: number of iterations
   E-Step:
   Compute $p(y|x)$ for each example in D_1, D_2 and U based on $\theta_1^{(t-1)}$ and $\theta_2^{(t-1)}$;
   Compute the expectation of the log likelihood with respect to $p(y|x)$;
   M-Step:
   Find $\theta_1^{(t)}$ and $\theta_2^{(t)}$ by maximizing the regularized joint log likelihood;
   Convergence:
   If the increase of the joint log likelihood is sufficiently small, break;
   end for
3. Output θ_1^* as $\theta_1^{(t)}$s, and θ_2^* as $\theta_2^{(t)}$

In the M-step, we can optimize the regularized joint log likelihood using any gradient-based optimization technique (Malouf, 2002). The gradient for Equation 3 based on Equation 4 is shown in Appendix A; those for Equations 5 and 6 can be derived similarly. In our experiments, we use the L-BFGS algorithm (Liu et al., 1989) and run EM until the change in regularized joint log likelihood is less than 1e-5 or we reach 100 iterations.[3]

[2]The probability should be rescaled within the range of [0, 1], where 0.5 means that we are completely unsure if the sentences are translations of each other or not, and only those translation pairs with a probability larger than 0.5 are meaningful for our purpose.

[3]Since the EM-based algorithm may find a local maximum of the objective function, the initialization of the parameters is important. Our experiments show that an effective maximum can usually be found by initializing the parameters with those learned from the labeled data; performance would be much worse if we initialize all the parameters to 0 or 1.

3.4 Pseudo-Parallel Labeled and Unlabeled Data

We also consider the case where a parallel corpus is not available: to obtain a pseudo-parallel corpus U (i.e. sentences in one language with their corresponding automatic translations), we use an automatic machine translation system (e.g. Google machine translation[4]) to translate unlabeled in-domain data from L_1 to L_2 or vice versa.

Since previous work (Banea et al., 2008; 2010; Wan, 2009) has shown that it could be useful to automatically translate the labeled data from the source language into the target language, we can further incorporate such translated labeled data into the joint model by adding the following component into Equation 6:

$$\lambda_3 \sum_{v=1}^{2} \sum_{i=1}^{l_{\bar{v}}} \log p\left(y_i^{\bar{v}} \middle| x_i^{\bar{v}^*}; \theta_v\right) \quad (8)$$

where $\bar{v}$ is the alternative class of v, $x_i^{\bar{v}^*}$ is the automatically translated example from $x_i^{\bar{v}}$; and $\lambda_3 \geq 0$ is a constant that controls the weight of the translated labeled data.

4 Experimental Setup

4.1 Data Sets and Preprocessing

The following labeled datasets are used in our experiments.

MPQA (Labeled English Data): The Multi-Perspective Question Answering (MPQA) corpus (Wiebe et al., 2005) consists of newswire documents manually annotated with phrase-level subjectivity information. We extract all sentences containing strong (i.e. intensity is *medium* or higher), sentiment-bearing (i.e. polarity is *positive* or *negative*) expressions following Choi and Cardie (2008). Sentences with both positive and negative strong expressions are then discarded, and the polarity of each remaining sentence is set to that of its sentiment-bearing expression(s).

NTCIR-EN (Labeled English Data) and NTCIR-CH (Labeled Chinese Data): The NTCIR Opinion Analysis task (Seki et al., 2007; 2008) provides sentiment-labeled news data in Chinese, Japanese and English. Only those sentences with a polarity label (positive or negative) agreed to by at least two annotators are extracted. We use the Chinese data from NTCIR-6 as our Chinese labeled data. Since far fewer sentences in the English data pass the annotator agreement filter, we combine the English data from NTCIR-6 and NTCIR-7. The Chinese sentences are segmented using the Stanford Chinese word segmenter (Tseng et al., 2005).

The number of sentences in each of these datasets is shown in Table 1. In our experiments, we evaluate two settings of the data: (1) MPQA+NTCIR-CH, and (2) NTCIR-EN+NTCIR-CH. In each setting, the English labeled data constitutes D_1 and the Chinese labeled data, D_2.

	MPQA	NTCIR-EN	NTCIR-CH
Positive	1,471 (30%)	528 (30%)	2,378 (55%)
Negative	3,487 (70%)	1,209 (70%)	1,916 (45%)
Total	4,958	1,737	4,294

Table 1: Sentence Counts for the Labeled Data

Unlabeled Parallel Text and its Preprocessing. For the unlabeled parallel text, we use the ISI Chinese-English parallel corpus (Munteanu and Marcu, 2005), which was extracted automatically from news articles published by Xinhua News Agency in the Chinese Gigaword (2nd Edition) and English Gigaword (2nd Edition) collections. Because sentence pairs in the ISI corpus are quite noisy, we rely on Giza++ (Och and Ney, 2003) to obtain a new translation probability for each sentence pair, and select the 100,000 pairs with the highest translation probabilities.[5]

We also try to remove neutral sentences from the parallel data since they can introduce noise into our model, which deals only with positive and negative examples. To do this, we train a single classifier from the combined Chinese and English labeled data for each data setting above by concatenating the original English and Chinese feature sets. We then classify each unlabeled sentence pair by combining the two sentences in each pair into one. We choose the most confidently predicted 10,000 positive and 10,000 negative pairs to constitute the unlabeled parallel corpus U for each data setting.

[4]http://translate.google.com/

[5]We removed sentence pairs with an original confidence score (given in the corpus) smaller than 0.98, and also removed the pairs that are too long (more than 60 characters in one sentence) to facilitate Giza++. We first obtain translation probabilities for both directions (i.e. Chinese to English and English to Chinese) with Giza++, take the log of the product of those two probabilities, and then divide it by the sum of lengths of the two sentences in each pair.

4.2 Baseline Methods

In our experiments, the proposed joint model is compared with the following baseline methods.

MaxEnt: This method learns a MaxEnt classifier for each language given the monolingual labeled data; the unlabeled data is not used.

SVM: This method learns an SVM classifier for each language given the monolingual labeled data; the unlabeled data is not used. SVM-light (Joachims, 1999a) is used for all the SVM-related experiments.

Monolingual TSVM (TSVM-M): This method learns two transductive SVM (TSVM) classifiers given the monolingual labeled data and the monolingual unlabeled data for each language.

Bilingual TSVM (TSVM-B): This method learns one TSVM classifier given the labeled training data in two languages together with the unlabeled sentences by combining the two sentences in each unlabeled pair into one. We expect this method to perform better than TSVM-M since the combined (bilingual) unlabeled sentences could be more helpful than the unlabeled monolingual sentences.

Co-Training with SVMs (Co-SVM): This method applies SVM-based co-training given both the labeled training data and the unlabeled parallel data following Wan (2009). First, two monolingual SVM classifiers are built based on only the corresponding labeled data, and then they are bootstrapped by adding the most confident predicted examples from the unlabeled data into the training set. We run bootstrapping for 100 iterations. In each iteration, we select the most confidently predicted 50 positive and 50 negative sentences from each of the two classifiers, and take the union of the resulting 200 sentence pairs as the newly labeled training data. (Examples with conflicting labels within the pair are not included.)

5 Results and Analysis

In our experiments, the methods are tested in the two data settings with the corresponding unlabeled parallel corpus as mentioned in Section 4.[6] We use 5-fold cross-validation and report average accuracy (also MicroF1 in this case) and MacroF1 scores. Unigrams are used as binary features for all models, as Pang et al. (2002) showed that binary features perform better than frequency features for sentiment classification. The weights for unlabeled data and regularization, λ_1 and λ_2, are set to 1 unless otherwise stated. Later, we will show that the proposed approach performs well with a wide range of parameter values.[7]

5.1 Method Comparison

We first compare the proposed joint model (**Joint**) with the baselines in Table 2. As seen from the table, the proposed approach outperforms all five baseline methods in terms of both accuracy and MacroF1 for both English and Chinese and in both of the data settings.[8] By making use of the unlabeled parallel data, our proposed approach improves the accuracy, compared to MaxEnt, by 8.12% (or 33.27% error reduction) on English and 3.44% (or 16.92% error reduction) on Chinese in the first setting, and by 5.07% (or 19.67% error reduction) on English and 3.87% (or 19.4% error reduction) on Chinese in the second setting.

Among the baselines, the best is Co-SVM; TSVMs do not always improve performance using the unlabeled data compared to the standalone SVM; and TSVM-B outperforms TSVM-M except for Chinese in the second setting. The MPQA data is more difficult in general compared to the NTCIR data. Without unlabeled parallel data, the performance on the Chinese data is better than on the English data, which is consistent with results reported in NTCIR-6 (Seki et al., 2007).

Overall, the unlabeled parallel data improves classification accuracy for both languages when using our proposed joint model and Co-SVM. The joint model makes better use of the unlabeled parallel data than Co-SVM or TSVMs presumably because of its attempt to jointly optimize the two monolingual models via soft (probabilistic) assignments of the unlabeled instances to classes in each iteration, instead of the hard assignments in Co-SVM and TSVMs. Although English sentiment

[6] The results reported in this section employ Equation 4. Preliminary experiments showed that Equation 5 does not significantly improve the performance in our case, which is reasonable since we choose only sentence pairs with the highest translation probabilities to be our unlabeled data (see Section 4.1).

[7] The code is at http://sites.google.com/site/lubin2010.

[8] Significance is tested using paired t-tests with $p<0.05$: $^{\epsilon}$ denotes statistical significance compared to the corresponding performance of MaxEnt; * denotes statistical significance compared to SVM; and $^{\Gamma}$ denotes statistical significance compared to Co-SVM.

	Setting 1: NTCIR-EN+NTCIR-CH				**Setting 2**: MPQA+NTCIR-CH			
	Accuracy		MacroF1		Accuracy		MacroF1	
	English	Chinese	English	Chinese	English	Chinese	English	Chinese
MaxEnt	75.59	79.67	66.61*	79.34	74.22	79.67	65.09*	79.34
SVM	76.34	81.02	61.12	80.75$^{\epsilon}$	76.74$^{\epsilon}$	81.02	61.35	80.75$^{\epsilon}$
TSVM-M	73.46	80.21	55.33	79.99	72.89	81.14	52.82	79.99
TSVM-B	78.36	81.60$^{\epsilon}$	65.53	81.42	76.42$^{\epsilon}$	78.51	61.66	78.32
Co-SVM	82.44$^{\epsilon*}$	82.79$^{\epsilon}$	72.61$^{\epsilon*}$	82.67$^{\epsilon*}$	78.18$^{\epsilon*}$	82.63$^{\epsilon*}$	68.03$^{\epsilon*}$	82.51$^{\epsilon*}$
Joint	**83.71**$^{\epsilon*}$	**83.11**$^{\epsilon*}$	**75.89**$^{\epsilon*\Gamma}$	**82.97**$^{\epsilon*}$	**79.29**$^{\epsilon*\Gamma}$	**83.54**$^{\epsilon*}$	**72.58**$^{\epsilon*\Gamma}$	**83.37**$^{\epsilon*}$

Table 2: Comparison of Results

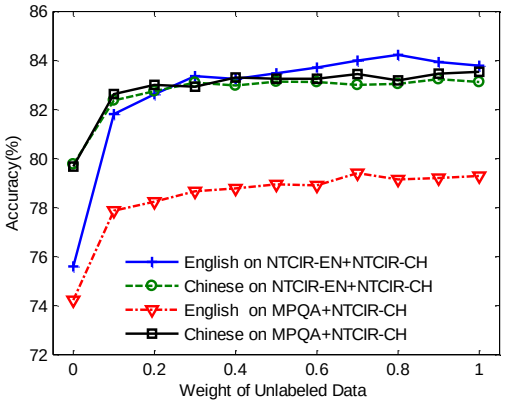

Figure 1. Accuracy vs. Weight of Unlabeled Data

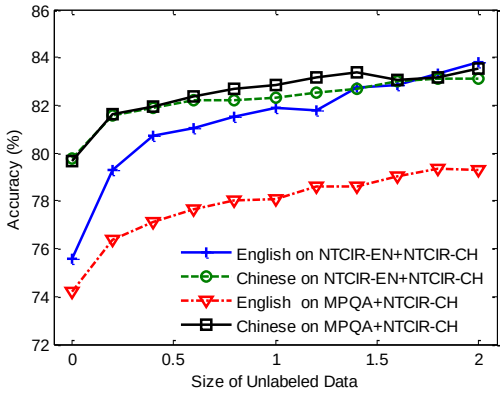

Figure 2. Accuracy vs. Amount of Unlabeled Data

classification alone is more difficult than Chinese for our datasets, we obtain greater performance gains for English by exploiting unlabeled parallel data as well as the Chinese labeled data.

5.2 Varying the Weight and Amount of Unlabeled Data

Figure 1 shows the accuracy curve of the proposed approach for the two data settings when varying the weight for the unlabeled data, λ_1, from 0 to 1. When λ_1 is set to 0, the joint model degenerates to two MaxEnt models trained with only the labeled data.

We can see that the performance gains for the proposed approach are quite remarkable even when λ_1 is set to 0.1; performance is largely stable after λ_1 reaches 0.4. Although MPQA is more difficult in general compared to the NTCIR data, we still see steady improvements in performance with unlabeled parallel data. Overall, the proposed approach performs quite well for a wide range of parameter values of λ_1.

Figure 2 shows the accuracy curve of the proposed approach for the two data settings when varying the amount of unlabeled data from 0 to 20,000 instances. We see that the performance of the proposed approach improves steadily by adding more and more unlabeled data. However, even with only 2,000 unlabeled sentence pairs, the proposed approach still produces large performance gains.

5.3 Results on Pseudo-Parallel Unlabeled Data

As discussed in Section 3.4, we generate pseudo-parallel data by translating the monolingual sentences in each setting using Google's machine translation system. Figures 3 and 4 show the performance of our model using the pseudo-parallel data versus the real parallel data, in the two settings, respectively. The EN->CH pseudo-parallel data consists of the English unlabeled data and its automatic Chinese translation, and vice versa.

Although not as significant as those with parallel data, we can still obtain improvements using the pseudo-parallel data, especially in the first setting. The difference between using parallel versus pseudo-parallel data is around 2-4% in Figures 3 and 4, which is reasonable since the quality of the pseudo-parallel data is not as good as that of the parallel data. Therefore, the performance using pseudo-parallel data is better with a small weight (e.g. λ_1= 0.1) in some cases.

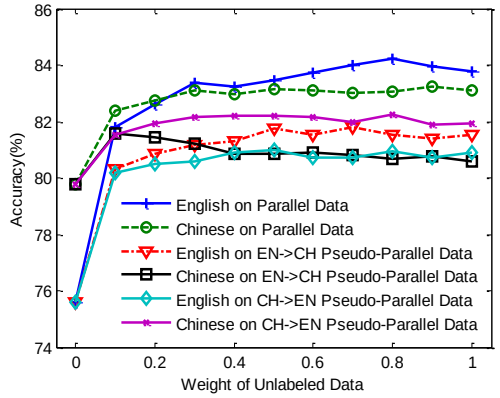

Figure 3. Accuracy with Pseudo-Parallel Unlabeled Data in **Setting 1**

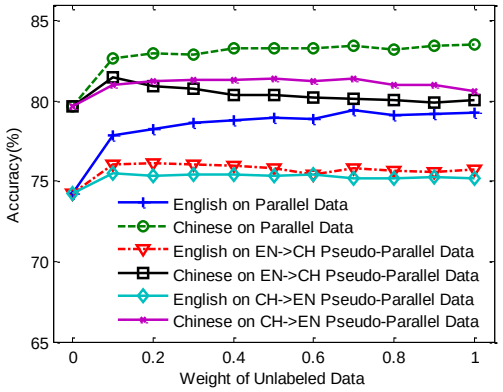

Figure 4. Accuracy with Pseudo-Parallel Unlabeled Data in **Setting 2**

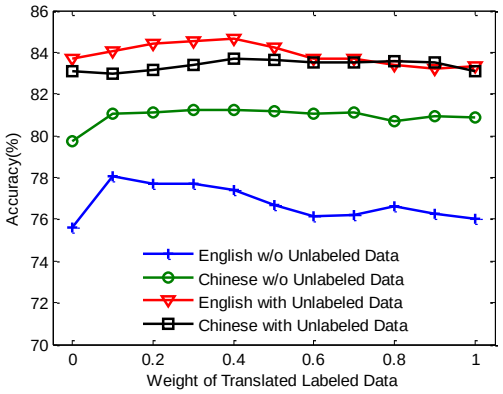

Figure 5. Accuracy with Pseudo-Parallel Labeled Data in **Setting 1**

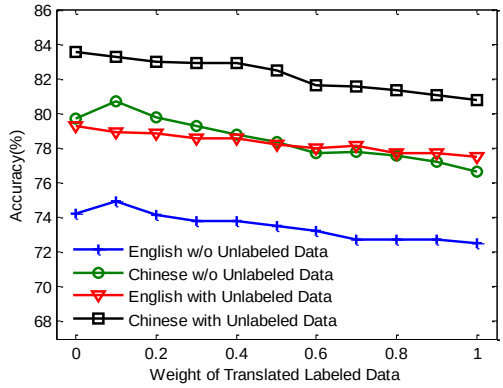

Figure 6. Accuracy with Pseudo-Parallel Labeled Data in **Setting 2**

5.4 Adding Pseudo-Parallel Labeled Data

In this section, we investigate how adding automatically translated labeled data might influence the performance as mentioned in Section 3.4. We use only the translated labeled data to train classifiers, and then directly classify the test data. The average accuracies in setting 1 are 66.61% and 63.11% on English and Chinese, respectively; while the accuracies in setting 2 are 58.43% and 54.07% on English and Chinese, respectively. This result is reasonable because of the language gap between the original language and the translated language. In addition, the class distributions of the English labeled data and the Chinese are quite different (30% vs. 55% for positive as shown in Table 1).

Figures 5 and 6 show the accuracies when varying the weight of the translated labeled data vs. the labeled data, with and without the unlabeled parallel data. From Figure 5 for setting 1, we can see that the translated data can be helpful given the labeled data and even the unlabeled data, as long as λ_3 is small; while in Figure 6, the translated data decreases the performance in most cases for setting 2. One possible reason is that in the first data setting, the NTCIR English data covers the same topics as the NTCIR Chinese data and thus direct translation is helpful, while the English and Chinese topics are quite different in the second data setting, and thus direct translation hurts the performance given the existing labeled data in each language.

5.5 Discussion

To further understand what contributions our proposed approach makes to the performance gain, we look inside the parameters in the MaxEnt models learned before and after adding the parallel unlabeled data. Table 3 shows the features in the model learned from the labeled data that have the largest weight change after adding the parallel data;

	Word	Weight		
		Before	After	Change
Positive	important	0.452	1.659	1.207
	cooperation	0.325	1.492	1.167
	support	0.533	1.483	0.950
	importance	0.450	1.193	0.742
	agreed	0.347	1.061	0.714
Negative	difficulties	0.018	0.663	0.645
	not	0.202	0.844	0.641
	never	0.245	0.879	0.634
	germany	0.035	0.664	0.629
	taiwan	0.590	1.216	0.626

Table 3. Original Features with Largest Weight Change

Positive		Negative	
Word	Weight	Word	Weight
friendly	0.701	german	0.783
principles	0.684	arduous	0.531
hopes	0.630	oppose	0.511
hoped	0.553	administrations	0.431
cooperative	0.552	oau[9]	0.408

Table 4. New Features Learned from Unlabeled Data

and Table 4 shows the newly learned features from the unlabeled data with the largest weights.

From Table 3[10] we can see that the weight changes of the original features are quite reasonable, e.g. the top words in the positive class are obviously positive and the proposed approach gives them higher weights. The new features also seem reasonable given the knowledge that the labeled and unlabeled data includes negative news about for specific topics (e.g. Germany, Taiwan),.

We also examine the process of joint training by checking the performance on test data and the agreement of the two monolingual models on the unlabeled parallel data in both settings. The average agreement across 5 folds is 85.06% and 73.87% in settings 1 and 2, respectively, before the joint training, and increases to 100% and 99.89%, respectively, after 100 iterations of joint training. Although the average agreement has already increased to 99.50% and 99.02% in settings 1 and 2, respectively, after 30 iterations, the performance on the test set steadily improves in both settings until around 50-60 iterations, and then becomes relatively stable after that.

Examination of those sentence pairs in setting 2 for which the two monolingual models still disagree after 100 iterations of joint training often produces sentences that are not quite parallel, e.g.:

English: The two sides attach great importance to international cooperation on protection and promotion of human rights.

Chinese: 双方认为,在人权问题上不能采取"双重标准",反对在国际关系中利用人权问题施压。(Both sides agree that double standards on the issue of human rights are to be avoided, and are opposed to using pressure on human rights issues in international relations.)

Since the two sentences discuss *human rights* from very different perspectives, it is reasonable that the two monolingual models will classify them with different polarities (i.e. positive for the English sentence and negative for the Chinese sentence) even after joint training.

6 Conclusion

In this paper, we study bilingual sentiment classification and propose a joint model to simultaneously learn better monolingual sentiment classifiers for each language by exploiting an unlabeled parallel corpus together with the labeled data available for each language. Our experiments show that the proposed approach can significantly improve sentiment classification for both languages. Moreover, the proposed approach continues to produce (albeit smaller) performance gains when employing pseudo-parallel data from machine translation engines.

In future work, we would like to apply the joint learning idea to other learning frameworks (e.g. SVMs), and to extend the proposed model to handle word-level parallel information, e.g. bilingual dictionaries or word alignment information. Another issue is to investigate how to improve multilingual sentiment analysis by exploiting comparable corpora.

Appendix A. Equation Deduction

In this appendix, we derive the gradient for the objective function in Equation 3, which is used in parameter estimation. As mentioned in Section 3.3, the parameters can be learned by finding:

$$\begin{aligned}(\theta_1^*, \theta_2^*) &= \underset{(\theta_1,\theta_2)}{\operatorname{argmax}} \mathcal{L}(\theta_1, \theta_2 | D_1, D_2, U) \\ &= \underset{(\theta_1,\theta_2)}{\operatorname{argmax}} \log \mathcal{L}(\theta_1, \theta_2 | D_1, D_2, U) \\ &= \underset{(\theta_1,\theta_2)}{\operatorname{argmax}} \{\log p(Y_1|X_1;\theta_1) p(Y_2|X_2;\theta_2) \\ &\quad + \textstyle\sum_{i=1}^{u} \log p(y_i^{1'}, y_i^{2'} | x_i^{1'}, x_i^{2'}; \theta_1, \theta_2)\}\end{aligned}$$

Since the first term on the right-hand side is just the expression for the standard MaxEnt problem, we will focus on the gradient for the second term, and denote $\log p(y_i^{1'}, y_i^{2'} | x_i^{1'}, x_i^{2'}; \theta_1, \theta_2)$ as $(*)$.

Let $v \in \{1,2\}$ denote L_1 or L_2, and θ_k^v be the kth weight in the vector θ_v. For brevity, we drop the $'$ in the above notation, and write x_i^v to denote $x_i^{v'}$. Then the partial derivative of (*) based on Equation 4 with respect to θ_k^v is as follows:

$$\frac{\partial(*)}{\partial \theta_k^v} = \frac{\sum_{y_i^*} p\left(y_i^* | x_i^{\bar{v}}; \theta_{\bar{v}}\right) \frac{\partial}{\partial \theta_k^v} p(y_i^* | x_i^v; \theta_v)}{\sum_{y_i'} p(y_i' | x_i^v; \theta_v) p(y_i' | x_i^{\bar{v}}; \theta_{\bar{v}})} \quad (1)$$

Further, we obtain:

$$\begin{aligned}&\frac{\partial}{\partial \theta_k^v} p(y_i^* | x_i^v; \theta_v) = \frac{\partial}{\partial \theta_k^v} \frac{\exp\left(\vec{\theta}_v \vec{f}(x_i^v, y_i^*)\right)}{\sum_{y_i'} \exp\left(\vec{\theta}_v \vec{f}(x_i^v, y_i')\right)} \\ &= \frac{\exp\left(\vec{\theta}_v \vec{f}(x_i^v, y_i^*)\right)}{\sum_{y_i'} \exp\left(\vec{\theta}_v \vec{f}(x_i^v, y_i')\right)} f_k^v(x_i^v, y_i^*) - \\ &\quad \frac{\exp\left(\vec{\theta}_v \vec{f}(x_i^v, y_i^*)\right)}{\left[\sum_{y_i'} \exp\left(\vec{\theta}_v \vec{f}(x_i^v, y_i')\right)\right]^2} \sum_{y_i'} \left\{\exp\left(\vec{\theta}_v \vec{f}(x_i^v, y_i')\right) f_k^v(x_i^v, y_i')\right\} \\ &= p(y_i^* | x_i^v; \theta_v) \left\{f_k^v(x_i^v, y_i^*) - \textstyle\sum_{y_i'} p(y_i' | x_i^v; \theta_v) f_k^v(x_i^v, y_i')\right\} \quad (2)\end{aligned}$$

Merge (2) into (1), we get:

$$\begin{aligned}\frac{\partial(*)}{\partial \theta_k^v} &= \frac{1}{\sum_{y_i'} p(y_i' | x_i^v; \theta_v) p(y_i' | x_i^{\bar{v}}; \theta_{\bar{v}})} \sum_{y_i^*} \{p\left(y_i^* | x_i^{\bar{v}}; \theta_{\bar{v}}\right) p(y_i^* | x_i^v; \theta_v) \\ &\quad [f_k^v(x_i^v, y_i^*) - \textstyle\sum_{y_i'} p(y_i' | x_i^v; \theta_v) f_k^v(x_i^v, y_i')]\} \\ &= \textstyle\sum_{y_i^*} p\left(y_i^* | x_i^1; \theta_1\right) p\left(y_i^* | x_i^2; \theta_2\right) f_k^v(x_i^v, y_i^*) - \\ &\quad \textstyle\sum_{y_i'} p(y_i' | x_i^v; \theta_v) f_k^v(x_i^v, y_i') \\ &= \textstyle\sum_{y_i^*} f_k^v(x_i^v, y_i^*) \{p(y_i^* | x_i^1; \theta_1) p(y_i^* | x_i^2; \theta_2) - p(y_i^* | x_i^v; \theta_v)\}\end{aligned}$$

A Pilot Study of Opinion Summarization in Conversations

Dong Wang **Yang Liu**
The University of Texas at Dallas
dongwang,yangl@hlt.utdallas.edu

Abstract

This paper presents a pilot study of opinion summarization on conversations. We create a corpus containing extractive and abstractive summaries of speaker's opinion towards a given topic using 88 telephone conversations. We adopt two methods to perform extractive summarization. The first one is a sentence-ranking method that linearly combines scores measured from different aspects including topic relevance, subjectivity, and sentence importance. The second one is a graph-based method, which incorporates topic and sentiment information, as well as additional information about sentence-to-sentence relations extracted based on dialogue structure. Our evaluation results show that both methods significantly outperform the baseline approach that extracts the longest utterances. In particular, we find that incorporating dialogue structure in the graph-based method contributes to the improved system performance.

1 Introduction

Both sentiment analysis (opinion recognition) and summarization have been well studied in recent years in the natural language processing (NLP) community. Most of the previous work on sentiment analysis has been conducted on reviews. Summarization has been applied to different genres, such as news articles, scientific articles, and speech domains including broadcast news, meetings, conversations and lectures. However, opinion summarization has not been explored much. This can be useful for many domains, especially for processing the increasing amount of conversation recordings (telephone conversations, customer service, round-table discussions or interviews in broadcast programs) where we often need to find a person's opinion or attitude, for example, "how does the speaker think about capital punishment and why?". This kind of questions can be treated as a topic-oriented opinion summarization task. Opinion summarization was run as a pilot task in Text Analysis Conference (TAC) in 2008. The task was to produce summaries of opinions on specified targets from a set of blog documents. In this study, we investigate this problem using spontaneous conversations. The problem is defined as, given a conversation and a topic, a summarization system needs to generate a summary of the speaker's opinion towards the topic.

This task is built upon opinion recognition and topic or query based summarization. However, this problem is challenging in that: (a) Summarization in spontaneous speech is more difficult than well structured text (Mckeown et al., 2005), because speech is always less organized and has recognition errors when using speech recognition output; (b) Sentiment analysis in dialogues is also much harder because of the genre difference compared to other domains like product reviews or news resources, as reported in (Raaijmakers et al., 2008); (c) In conversational speech, information density is low and there are often off topic discussions, therefore presenting a need to identify utterances that are relevant to the topic.

In this paper we perform an exploratory study on opinion summarization in conversations. We compare two unsupervised methods that have been

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 331–339,
Portland, Oregon, June 19-24, 2011.

widely used in extractive summarization: sentence-ranking and graph-based methods. Our system attempts to incorporate more information about topic relevancy and sentiment scores. Furthermore, in the graph-based method, we propose to better incorporate the dialogue structure information in the graph in order to select salient summary utterances. We have created a corpus of reasonable size in this study. Our experimental results show that both methods achieve better results compared to the baseline.

The rest of this paper is organized as follows. Section 2 briefly discusses related work. Section 3 describes the corpus and annotation scheme we used. We explain our opinion-oriented conversation summarization system in Section 4 and present experimental results and analysis in Section 5. Section 6 concludes the paper.

2 Related Work

Research in document summarization has been well established over the past decades. Many tasks have been defined such as single-document summarization, multi-document summarization, and query-based summarization. Previous studies have used various domains, including news articles, scientific articles, web documents, reviews. Recently there is an increasing research interest in speech summarization, such as conversational telephone speech (Zhu and Penn, 2006; Zechner, 2002), broadcast news (Maskey and Hirschberg, 2005; Lin et al., 2009), lectures (Zhang et al., 2007; Furui et al., 2004), meetings (Murray et al., 2005; Xie and Liu, 2010), voice mails (Koumpis and Renals, 2005). In general speech domains seem to be more difficult than well written text for summarization. In previous work, unsupervised methods like Maximal Marginal Relevance (MMR), Latent Semantic Analysis (LSA), and supervised methods that cast the extraction problem as a binary classification task have been adopted. Prior research has also explored using speech specific information, including prosodic features, dialog structure, and speech recognition confidence.

In order to provide a summary over opinions, we need to find out which utterances in the conversation contain opinion. Most previous work in sentiment analysis has focused on reviews (Pang and Lee, 2004; Popescu and Etzioni, 2005; Ng et al., 2006) and news resources (Wiebe and Riloff, 2005). Many kinds of features are explored, such as lexical features (unigram, bigram and trigram), part-of-speech tags, dependency relations. Most of prior work used classification methods such as naive Bayes or SVMs to perform the polarity classification or opinion detection. Only a handful studies have used conversational speech for opinion recognition (Murray and Carenini, 2009; Raaijmakers et al., 2008), in which some domain-specific features are utilized such as structural features and prosodic features.

Our work is also related to question answering (QA), especially opinion question answering. (Stoyanov et al., 2005) applies a subjectivity filter based on traditional QA systems to generate opinionated answers. (Balahur et al., 2010) answers some specific opinion questions like "Why do people criticize Richard Branson?" by retrieving candidate sentences using traditional QA methods and selecting the ones with the same polarity as the question. Our work is different in that we are not going to answer specific opinion questions, instead, we provide a summary on the speaker's opinion towards a given topic.

There exists some work on opinion summarization. For example, (Hu and Liu, 2004; Nishikawa et al., 2010) have explored opinion summarization in review domain, and (Paul et al., 2010) summarizes contrastive viewpoints in opinionated text. However, opinion summarization in spontaneous conversation is seldom studied.

3 Corpus Creation

Though there are many annotated data sets for the research of speech summarization and sentiment analysis, there is no corpus available for opinion summarization on spontaneous speech. Thus for this study, we create a new pilot data set using a subset of the Switchboard corpus (Godfrey and Holliman, 1997).[1] These are conversational telephone speech between two strangers that were assigned a topic to talk about for around 5 minutes. They were told to find the opinions of the other person. There are 70 topics in total. From the Switchboard cor-

[1] Please contact the authors to obtain the data.

pus, we selected 88 conversations from 6 topics for this study. Table 1 lists the number of conversations in each topic, their average length (measured in the unit of dialogue acts (DA)) and standard deviation of length.

topic	#Conv.	avg len	stdev
space flight and exploration	6	165.5	71.40
capital punishment	24		
gun control	15		
universal health insurance	9		
drug testing	12		
universal public service	22		

Table 1: Corpus statistics: topic description, number of conversations in each topic, average length (number of dialog acts), and standard deviation.

We recruited 3 annotators that are all undergraduate computer science students. From the 88 conversations, we selected 18 (3 from each topic) and let all three annotators label them in order to study inter-annotator agreement. The rest of the conversations has only one annotation.

The annotators have access to both conversation transcripts and audio files. For each conversation, the annotator writes an abstractive summary of up to 100 words for each speaker about his/her opinion or attitude on the given topic. They were told to use the words in the original transcripts if possible. Then the annotator selects up to 15 DAs (no minimum limit) in the transcripts for each speaker, from which their abstractive summary is derived. The selected DAs are used as the human generated extractive summary. In addition, the annotator is asked to select an overall opinion towards the topic for each speaker among five categories: strongly support, somewhat support, neutral, somewhat against, strongly against. Therefore for each conversation, we have an abstractive summary, an extractive summary, and an overall opinion for each speaker. The following shows an example of such annotation for speaker B in a dialogue about "capital punishment":

[**Extractive Summary**]

I think I've seen some statistics that say that, uh, it's more expensive to kill somebody than to keep them in prison for life.

committing them mostly is, you know, either crimes of passion or at the moment

or they think they're not going to get caught

but you also have to think whether it's worthwhile on the individual basis, for example, someone like, uh, jeffrey dahlmer,

by putting him in prison for life, there is still a possibility that he will get out again.

I don't think he could ever redeem himself,

but if you look at who gets accused and who are the ones who actually get executed, it's very racially related – and ethnically related

[**Abstractive Summary**]

B is against capital punishment except under certain circumstances. B finds that crimes deserving of capital punishment are "crimes of the moment" and as a result feels that capital punishment is not an effective deterrent. however, B also recognizes that on an individual basis some criminals can never "redeem" themselves.

[**Overall Opinion**]

Somewhat against

Table 2 shows the compression ratio of the extractive summaries and abstractive summaries as well as their standard deviation. Because in conversations, utterance length varies a lot, we use words as units when calculating the compression ratio.

	avg ratio	stdev
extractive summaries	0.26	0.13
abstractive summaries	0.13	0.06

Table 2: Compression ratio and standard deviation of extractive and abstractive summaries.

We measured the inter-annotator agreement among the three annotators for the 18 conversations (each has two speakers, thus 36 "documents" in total). Results are shown in Table 3. For the extractive or abstractive summaries, we use ROUGE scores (Lin, 2004), a metric used to evaluate automatic summarization performance, to measure the pairwise agreement of summaries from different annotators. ROUGE F-scores are shown in the table for different matches, unigram (R-1), bigram (R-2), and longest subsequence (R-L). For the overall opinion category, since it is a multiclass label (not binary decision), we use Krippendorff's α coefficient to measure human agreement, and the difference function for interval data: $\delta^2_{ck} = (c-k)^2$ (where c, k are the interval values, on a scale of 1 to 5 corresponding to the five categories for the overall opinion).

We notice that the inter-annotator agreement for extractive summaries is comparable to other speech

extractive summaries	R-1	0.61
	R-2	0.52
	R-L	0.61
abstractive summaries	R-1	0.32
	R-2	0.13
	R-L	0.25
overall opinion	$\alpha = 0.79$	

Table 3: Inter-annotator agreement for extractive and abstractive summaries, and overall opinion.

summary annotation (Liu and Liu, 2008). The agreement on abstractive summaries is much lower than extractive summaries, which is as expected. Even for the same opinion or sentence, annotators use different words in the abstractive summaries. The agreement for the overall opinion annotation is similar to other opinion/emotion studies (Wilson, 2008b), but slightly lower than the level recommended by Krippendorff for reliable data ($\alpha = 0.8$) (Hayes and Krippendorff, 2007), which shows it is even difficult for humans to determine what opinion a person holds (support or against something). Often human annotators have different interpretations about the same sentence, and a speaker's opinion/attitude is sometimes ambiguous. Therefore this also demonstrates that it is more appropriate to provide a summary rather than a simple opinion category to answer questions about a person's opinion towards something.

4 Opinion Summarization Methods

Automatic summarization can be divided into extractive summarization and abstractive summarization. Extractive summarization selects sentences from the original documents to form a summary; whereas abstractive summarization requires generation of new sentences that represent the most salient content in the original documents like humans do. Often extractive summarization is used as the first step to generate abstractive summary.

As a pilot study for the problem of opinion summarization in conversations, we treat this problem as an extractive summarization task. This section describes two approaches we have explored in generating extractive summaries. The first one is a sentence-ranking method, in which we measure the salience of each sentence according to a linear combination of scores from several dimensions. The second one is a graph-based method, which incorporates the dialogue structure in ranking. We choose to investigate these two methods since they have been widely used in text and speech summarization, and perform competitively. In addition, they do not require a large labeled data set for modeling training, as needed in some classification or feature based summarization approaches.

4.1 Sentence Ranking

In this method, we use Equation 1 to assign a score to each DA s, and select the most highly ranked ones until the length constriction is satisfied.

$$\begin{aligned} score(s) &= \lambda_{sim} sim(s, D) + \lambda_{rel} REL(s, topic) \\ &\quad + \lambda_{sent} sentiment(s) + \lambda_{len} length(s) \\ \sum_i \lambda_i &= 1 \end{aligned} \quad (1)$$

- $sim(s, D)$ is the cosine similarity between DA s and all the utterances in the dialogue from the same speaker, D. It measures the relevancy of s to the entire dialogue from the target speaker. This score is used to represent the salience of the DA. It has been shown to be an important indicator in summarization for various domains. For cosine similarity measure, we use TF*IDF (term frequency, inverse document frequency) term weighting. The IDF values are obtained using the entire Switchboard corpus, treating each conversation as a document.

- $REL(s, topic)$ measures the topic relevance of DA s. It is the sum of the topic relevance of all the words in the DA. We only consider the content words for this measure. They are identified using TreeTagger toolkit.[2] To measure the relevance of a word to a topic, we use Pairwise Mutual Information (PMI):

$$PMI(w, topic) = log_2 \frac{p(w\&topic)}{p(w)p(topic)} \quad (2)$$

[2] http://www.ims.uni-stuttgart.de/projekte/corplex/TreeTagger/DecisionTreeTagger.html

where all the statistics are collected from the Switchboard corpus: $p(w\&topic)$ denotes the probability that word w appears in a dialogue of topic t, and $p(w)$ is the probability of w appearing in a dialogue of any topic. Since our goal is to rank DAs in the same dialog, and the topic is the same for all the DAs, we drop $p(topic)$ when calculating PMI scores. Because the value of $PMI(w, topic)$ is negative, we transform it into a positive one (denoted by $PMI^+(w, topic)$) by adding the absolute value of the minimum value. The final relevance score of each sentence is normalized to $[0, 1]$ using linear normalization:

$$\begin{aligned} REL_{orig}(s, topic) &= \sum_{w \in s} PMI^+(w, topic) \\ REL(s, topic) &= \frac{REL_{orig}(s, topic) - Min}{Max - Min} \end{aligned}$$

- $sentiment(s)$ indicates the probability that utterance s contains opinion. To obtain this, we trained a maximum entropy classifier with a bag-of-words model using a combination of data sets from several domains, including movie data (Pang and Lee, 2004), news articles from MPQA corpus (Wilson and Wiebe, 2003), and meeting transcripts from AMI corpus (Wilson, 2008a). Each sentence (or DA) in these corpora is annotated as "subjective" or "objective". We use each utterance's probability of being "subjective" predicted by the classifier as its sentiment score.

- $length(s)$ is the length of the utterance. This score can effectively penalize the short sentences which typically do not contain much important content, especially the backchannels that appear frequently in dialogues. We also perform linear normalization such that the final value lies in $[0, 1]$.

4.2 Graph-based Summarization

Graph-based methods have been widely used in document summarization. In this approach, a document is modeled as an adjacency matrix, where each node represents a sentence, and the weight of the edge between each pair of sentences is their similarity (cosine similarity is typically used). An iterative process is used until the scores for the nodes converge. Previous studies (Erkan and Radev, 2004) showed that this method can effectively extract important sentences from documents. The basic framework we use in this study is similar to the query-based graph summarization system in (Zhao et al., 2009). We also consider sentiment and topic relevance information, and propose to incorporate information obtained from dialog structure in this framework. The score for a DA s is based on its content similarity with all other DAs in the dialogue, the connection with other DAs based on the dialogue structure, the topic relevance, and its subjectivity, that is:

$$\begin{aligned} score(s) &= \lambda_{sim} \sum_{v \in C} \frac{sim(s, v)}{\sum_{z \in C} sim(z, v)} score(v) \\ &\quad + \lambda_{rel} \frac{REL(s, topic)}{\sum_{z \in C} REL(z, topic)} \\ &\quad + \lambda_{sent} \frac{sentiment(s)}{\sum_{z \in C} sentiment(z)} \\ &\quad + \lambda_{adj} \sum_{v \in C} \frac{ADJ(s, v)}{\sum_{z \in C} ADJ(z, v)} score(v) \\ \sum_i \lambda_i &= 1 \end{aligned} \quad (3)$$

where C is the set of all DAs in the dialogue; $REL(s, topic)$ and $sentiment(s)$ are the same as those in the above sentence ranking method; $sim(s, v)$ is the cosine similarity between two DAs s and v. In addition to the standard connection between two DAs with an edge weight $sim(s, v)$, we introduce new connections $ADJ(s, v)$ to model dialog structure. It is a directed edge from s to v, defined as follows:

- If s and v are from the same speaker and within the same turn, there is an edge from s to v and an edge from v to s with weight $1/dis(s, v)$ ($ADJ(s, v) = ADJ(v, s) = 1/dis(s, v)$), where $dis(s, v)$ is the distance between s and v, measured based on their DA indices. This way the DAs in the same turn can reinforce each other. For example, if we consider that

one DA is important, then the other DAs in the same turn are also important.

- If s and v are from the same speaker, and separated only by one DA from another speaker with length less than 3 words (usually backchannel), there is an edge from s to v as well as an edge from v to s with weight 1 ($ADJ(s, v) = ADJ(v, s) = 1$).

- If s and v form a question-answer pair from two speakers, then there is an edge from question s to answer v with weight 1 ($ADJ(s, v) = 1$). We use a simple rule-based method to determine question-answer pairs — sentence s has question marks or contains "wh-word" (i.e., "what, how, why"), and sentence v is the immediately following one. The motivation for adding this connection is, if the score of a question sentence is high, then the answer's score is also boosted.

- If s and v form an agreement or disagreement pair, then there is an edge from v to s with weight 1 ($ADJ(v, s) = 1$). This is also determined by simple rules: sentence v contains the word "agree" or "disagree", s is the previous sentence, and from a different speaker. The reason for adding this is similar to the above question-answer pairs.

- If there are multiple edges generated from the above steps between two nodes, then we use the highest weight.

Since we are using a directed graph for the sentence connections to model dialog structure, the resulting adjacency matrix is asymmetric. This is different from the widely used graph methods for summarization. Also note that in the first sentence ranking method or the basic graph methods, summarization is conducted for each speaker separately. Utterances from one speaker have no influence on the summary decision for the other speaker. Here in our proposed graph-based method, we introduce connections between the two speakers, so that the adjacency pairs between them can be utilized to extract salient utterances.

5 Experiments

5.1 Experimental Setup

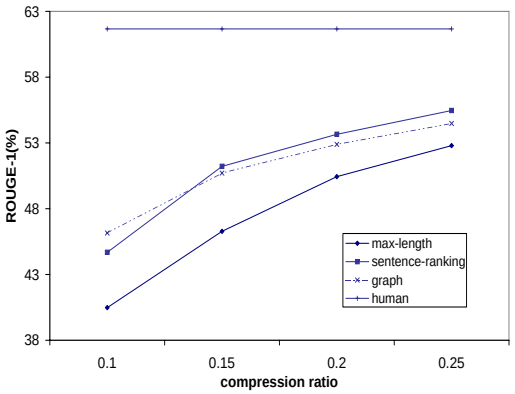
The 18 conversations annotated by all 3 annotators are used as test set, and the rest of 70 conversations are used as development set to tune the parameters (determining the best combination weights). In preprocessing we applied word stemming. We perform extractive summarization using different word compression ratios (ranging from 10% to 25%). We use human annotated dialogue acts (DA) as the extraction units. The system-generated summaries are compared to human annotated extractive and abstractive summaries. We use ROUGE as the evaluation metrics for summarization performance.

We compare our methods to two systems. The first one is a baseline system, where we select the longest utterances for each speaker. This has been shown to be a relatively strong baseline for speech summarization (Gillick et al., 2009). The second one is human performance. We treat each annotator's extractive summary as a system summary, and compare to the other two annotators' extractive and abstractive summaries. This can be considered as the upper bound of our system performance.

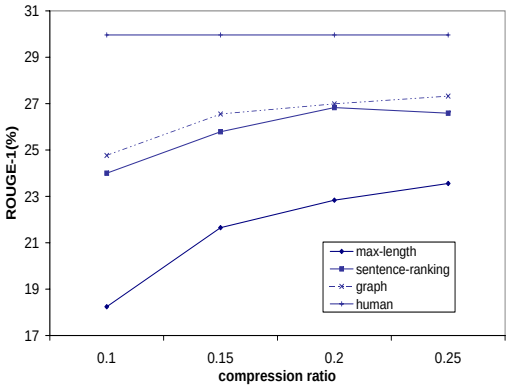
5.2 Results

From the development set, we used the grid search method to obtain the best combination weights for the two summarization methods. In the sentence-ranking method, the best parameters found on the development set are $\lambda_{sim} = 0, \lambda_{rel} = 0.3, \lambda_{sent} = 0.3, \lambda_{len} = 0.4$. It is surprising to see that the similarity score is not useful for this task. The possible reason is, in Switchboard conversations, what people talk about is diverse and in many cases only topic words (except stopwords) appear more than once. In addition, REL score is already able to catch the topic relevancy of the sentence. Thus, the similarity score is redundant here.

In the graph-based method, the best parameters are $\lambda_{sim} = 0, \lambda_{adj} = 0.3, \lambda_{rel} = 0.4, \lambda_{sent} = 0.3$. The similarity between each pair of utterances is also not useful, which can be explained with similar reasons as in the sentence-ranking method. This is different from graph-based summarization systems for text domains. A similar finding has also been shown in (Garg et al., 2009), where similarity be-



(a) compare to reference extractive summary



(b) compare to reference abstractive summary

Figure 1: ROUGE-1 F-scores compared to extractive and abstractive reference summaries for different systems: max-length, sentence-ranking method, graph-based method, and human performance.

tween utterances does not perform well in conversation summarization.

Figure 1 shows the ROUGE-1 F-scores comparing to human extractive and abstractive summaries for different compression ratios. Similar patterns are observed for other ROUGE scores such as ROUGE-2 or ROUGE-L, therefore they are not shown here. Both methods improve significantly over the baseline approach. There is relatively less improvement using a higher compression ratio, compared to a lower one. This is reasonable because when the compression ratio is low, the most salient utterances are not necessarily the longest ones, thus using more information sources helps better identify important sentences; but when the compression ratio is higher, longer utterances are more likely to be selected since they contain more content.

There is no significant difference between the two methods. When compared to extractive reference summaries, sentence-ranking is slightly better except for the compression ratio of 0.1. When compared to abstractive reference summaries, the graph-based method is slightly better. The two systems share the same topic relevance score (REL) and sentiment score, but the sentence-ranking method prefers longer DAs and the graph-based method prefers DAs that are emphasized by the ADJ matrix, such as the DA in the middle of a cluster of utterances from the same speaker, the answer to a question, etc.

5.3 Analysis

To analyze the effect of dialogue structure we introduce in the graph-based summarization method, we compare two configurations: $\lambda_{adj} = 0$ (only using REL score and sentiment score in ranking) and $\lambda_{adj} = 0.3$. We generate summaries using these two setups and compare with human selected sentences. Table 4 shows the number of false positive instances (selected by system but not by human) and false negative ones (selected by human but not by system). We use all three annotators' annotation as reference, and consider an utterance as positive if one annotator selects it. This results in a large number of reference summary DAs (because of low human agreement), and thus the number of false negatives in the system output is very high. As expected, a smaller compression ratio (fewer selected DAs in the system output) yields a higher false negative rate and a lower false positive rate. From the results, we can see that generally adding adjacency matrix information is able to reduce both types of errors except when the compression ratio is 0.15.

The following shows an example, where the third DA is selected by the system with $\lambda_{adj} = 0.3$, but not by $\lambda_{adj} = 0$. This is partly because the weight of the second DA is enhanced by the the question-

	$\lambda_{adj} = 0$		$\lambda_{adj} = 0.3$	
ratio	FP	FN	FP	FN
0.1	37	588	33	581
0.15	60	542	61	546
0.2	100	516	90	511
0.25	137	489	131	482

Table 4: The number of false positive (FP) and false negative (FN) instances using the graph-based method with $\lambda_{adj} = 0$ and $\lambda_{adj} = 0.3$ for different compression ratios.

answer pair (the first and the second DA), and thus subsequently boosting the score of the third DA.

A: Well what do you think?

B: Well, I don't know, I'm thinking about from one to ten what my no would be.

B: It would probably be somewhere closer to, uh, less control because I don't see, -

We also examined the system output and human annotation and found some reasons for the system errors:

(a) Topic relevance measure. We use the statistics from the Switchboard corpus to measure the relevance of each word to a given topic (PMI score), therefore only when people use the same word in different conversations of the topic, the PMI score of this word and the topic is high. However, since the size of the corpus is small, some topics only contain a few conversations, and some words only appear in one conversation even though they are topic-relevant. Therefore the current PMI measure cannot properly measure a word's and a sentence's topic relevance. This problem leads to many false negative errors (relevant sentences are not captured by our system).

(b) Extraction units. We used DA segments as units for extractive summarization, which can be problematic. In conversational speech, sometimes a DA segment is not a complete sentence because of overlaps and interruptions. We notice that annotators tend to select consecutive DAs that constitute a complete sentence, however, since each individual DA is not quite meaningful by itself, they are often not selected by the system. The following segment is extracted from a dialogue about "universal health insurance". The two DAs from speaker B are not selected by our system but selected by human annotators, causing false negative errors.

B: and it just can devastate –
A: and your constantly, -
B: – your budget, you know.

6 Conclusion and Future Work

This paper investigates two unsupervised methods in opinion summarization on spontaneous conversations by incorporating topic score and sentiment score in existing summarization techniques. In the sentence-ranking method, we linearly combine several scores in different aspects to select sentences with the highest scores. In the graph-based method, we use an adjacency matrix to model the dialogue structure and utilize it to find salient utterances in conversations. Our experiments show that both methods are able to improve the baseline approach, and we find that the cosine similarity between utterances or between an utterance and the whole document is not as useful as in other document summarization tasks.

In future work, we will address some issues identified from our error analysis. First, we will investigate ways to represent a sentence's topic relevance. Second, we will evaluate using other extraction units, such as applying preprocessing to remove disfluencies and concatenate incomplete sentence segments together. In addition, it would be interesting to test our system on speech recognition output and automatically generated DA boundaries to see how robust it is.

Abstract

We present disputant relation-based method for classifying news articles on contentious issues. We observe that the disputants of a contention are an important feature for understanding the discourse. It performs unsupervised classification on news articles based on disputant relations, and helps readers intuitively view the articles through the opponent-based frame. The readers can attain balanced understanding on the contention, free from a specific biased view. We applied a modified version of HITS algorithm and an SVM classifier trained with pseudo-relevant data for article analysis.

1 Introduction

The coverage of contentious issues of a community is an essential function of journalism. Contentious issues continuously arise in various domains, such as politics, economy, environment; each issue involves diverse participants and their different complex arguments. However, news articles are frequently biased and fail to fairly deliver conflicting arguments of the issue. It is difficult for ordinary readers to analyze the conflicting arguments and understand the contention; they mostly perceive the issue passively, often through a single article. Advanced news delivery models are required to increase awareness on conflicting views.

In this paper, we present *disputant relation-based method* for classifying news articles on contentious issues. We observe that the disputants of a contention, i.e., people who take a position and participate in the contention such as politicians, companies, stakeholders, civic groups, experts, commentators, etc., are an important feature for understanding the discourse. News producers primarily shape an article on a contention by selecting and covering specific disputants (Baker. 1994). Readers also intuitively understand the contention by identifying who the opposing disputants are.

The method helps readers intuitively view the news articles through the *opponent-based frame*. It performs classification in an unsupervised manner: it dynamically identifies opposing disputant groups and classifies the articles according to their positions. As such, it effectively helps readers contrast articles of a contention and attain balanced understanding, free from specific biased viewpoints.

The proposed method differs from those used in related tasks as it aims to perform classification under the opponent-based frame. Research on sentiment classification and debate stance recognition takes a topic-oriented view, and attempts to perform classification under the 'positive vs. negative' or 'for vs. against' frame for the given topic, e.g., positive vs. negative about iPhone.

However, such frames are often not appropriate for classifying news articles of a contention. The coverage of a contention often spans over different topics (Miller. 2001). For the contention on the health care bill, an article may discuss the enlarged coverage whereas another may discuss the increase of insurance premiums. In addition, we observe that opposing arguments of a contention are often complex to classify under these frames. For exam-

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 340–349,
Portland, Oregon, June 19-24, 2011.

ple, in a political contention on holding a referendum on the Sejong project[1], the opposition parties strongly opposed and criticized the president office. Meanwhile, the president office argued that they were not considering holding the referendum and the contention arose from a misunderstanding. In such a case, it is difficult to classify any argument to the "positive" category of the frame.

We demonstrate that the opponent-based frame is clear and effective for contrasting opposing views of contentious issues. For the contention on the referendum, 'president office vs. opposition parties' provides an intuitive frame to understand the contention. The frame does not require the documents to discuss common topics nor the opposing arguments to be positive vs. negative.

Under the proposed frame, it becomes important to analyze which side is more centrally covered in an article. Unlike debate posts or product reviews news articles, in general, do not take a position explicitly (except a few types such as editorials). They instead quote a specific side, elaborate them, and provide supportive facts. On the other hand, the opposing disputants compete for news coverage to influence more readers and gain support (Miller et al. 2001). Thus, the method focuses on identifying the disputants of each side and classifying the articles based on the side it covers.

We applied a modified version of HITS algorithm to identify the key opponents of an issue, and used disputant extraction techniques combined with an SVM classifier for article analysis. We observe that the method achieves acceptable performance for practical use with basic language resources and tools, i.e., Named Entity Recognizer (Lee et al. 2006), POS tagger (Shim et al. 2002), and a translated positive/negative lexicon. As we deal with non-English (Korean) news articles, it is difficult to obtain rich resources and tools, e.g., WordNet, dependency parser, annotated corpus such as MPQA. When applied to English, we believe the method could be further improved by adopting them.

2 Background and Related Work

Research has been made on sentiment classification in document-level (Turney et al., 2002, Pang et al., 2002, Seki et al. 2008, Ounis et al. 2006). It aims to automatically identify and classify the sentiment of documents into positive or negative. Opinion summarization aims a similar goal, to identify different opinions on a topic and generate summaries of them. Paul et al. (2010) developed an unsupervised method for generating summaries of contrastive opinions on a common topic. These works make a number of assumptions that are difficult to apply to the discourse of contentious news issues. They assume that the input documents have a common opinion target, e.g., a movie. Many of them primarily deal with documents which explicitly reveal opinions on the selected target, e.g., movie reviews. They usually apply one static classification frame, positive vs. negative, to the topic.

The discourse of contentious issues in news articles show different characteristics from that studied in the sentiment classification tasks. First, the opponents of a contentious issue often discuss different topics, as discussed in the example above. Research in mass communication has showed that opposing disputants talk across each other, not by dialogue, i.e., they martial different facts and interpretations rather than to give different answers to the same topics (Schon et al., 1994).

Second, the frame of argument is not fixed as 'positive vs. negative'. We frequently observed both sides of a contention articulating negative arguments attacking each other. The forms of arguments are also complex and diverse to classify them as positive or negative; for example, an argument may just neglect the opponent's argument without positive or negative expressions, or emphasize a different discussion point.

In addition, a position of a contention can be communicated without explicit expression of opinion or sentiment. It is often conveyed through objective sentences that include carefully selected facts. For example, a news article can cast a negative light on a government program simply by covering the increase of deficit caused by it.

A number of works deal with debate stance recognition, which is a closely related task. They attempt to identify a position of a debate, such as ideological (Somasundaran et al., 2010, Lin et al., 2006) or product comparison debate (Somasundaran et al., 2009). They assume a debate frame, which is similar to the frame of the sentiment classification task, i.e., for vs. against the debate topic. All articles of a debate in their corpus cover a coherent debate topic, e.g., iPhone vs. Blackberry, and explicitly express opinions for or

[1] http://www.koreatimes.co.kr/www/news/nation/2010/07/116_61649.html

against to the topic, e.g., for or against iPhone or Blackberry. The proposed methods assume that the debate frame is known apriori. This debate frame is often not appropriate for contentious issues for similar reasons as the positive/negative frame. In contrast, our method does not assume a fixed debate frame, and rather develops one based on the opponents of the contention at hand.

The news corpus is also different from the debate corpus. News articles of a contentious issue are more diverse than debate articles conveying explicit argument of a specific side. There are news articles which cover both sides, facts without explicit opinions, and different topics unrelated to the arguments of either side.

Several works have used the relation between speakers or authors for classifying their debate stance (Thomas et al., 2006, Agrawal et al., 2003). However, these works also assume the same debate frame and use the debate corpus, e.g., floor debates in the House of Representatives, online debate forums. Their approaches are also supervised, and require training data for relation analysis, e.g., voting records of congresspeople.

3 Argument Frame Comparison

Establishing an appropriate argument frame is important. It provides a framework which enable readers to intuitively understand the contention. It also determines how classification methods should classify articles of the issue.

We conducted a user study to compare the opponent-based frame and the positive (for) vs. negative (against) frame. In the experiment, multiple human annotators classified the same set of news articles under each of the two frames. We compared which frame is clearer for the classification, and more effective for exposing opposing views.

We selected 14 contentious issues from Naver News (a popular news portal in Korea) issue archive. We randomly sampled about 20 articles per each issue, for a total of 250 articles. The selected issues range over diverse domains such as politics, local, diplomacy, economy; to name a few for example, the contention on the 4 river project, of which the key opponents are the government vs. catholic church; the entrance of big retailers to the supermarket business, of which the key opponents are the small store owners vs. big retail companies; the refusal to approve an integrated civil servants' union, of which the key opponents are government vs. Korean government employees' union.

We use an internationally known contention, i.e., the dispute about the Cheonan sinking incident, as an example to give more details on the disputants. Our data set includes 25 articles that were published after the South Korea's announcement of their investigation result. Many disputants appear in the articles, e.g., South Korean Government, South Korea defense secretary, North Korean Government, United States officials, Chinese experts, political parties of South Korea, etc.

Three annotators performed the classification. All of them were students. For impartiality, two of them were recruited from outside the team, who were not aware of this research.

The annotators performed two subtasks for classification. As for the positive vs. negative frame, first, we asked them to designate the main topic of the contention. Second, they classified the articles which mainly deliver arguments for the topic to the "positive" category and those delivering arguments against the topic to the "negative" category. The articles are classified to the "Other" category if they do not deal with the main topic nor cover positive or negative arguments.

As for the opponent-based frame, first, we asked them to designate the competing opponents. Second, we asked to classify articles to a specific side if the articles cover only the positions, arguments, or information supportive of that side or if they cover information detrimental or criticism to its opposite side. Other articles were classified to the "Other" category. Examples of this category include articles covering both sides fairly, describing general background or implications of the issue.

Issue #	Free-marginal kappa		Issue #	Free-marginal kappa	
	Pos.-Neg.	Opponent		Pos.-Neg.	Opponent
1	0.83	0.67	**8**	0.26	0.58
2	0.57	0.48	**9**	0.07	1.00
3	0.44	0.95	**10**	0.48	0.84
4	0.75	0.87	**11**	0.71	0.86
5	0.36	0.64	**12**	0.71	0.71
6	0.30	0.70	**13**	0.63	0.79
7	0.18	0.96	**14**	0.48	0.87
			Avg.	0.50	0.78

Table 1. Inter-rater agreement result.

The agreement in classification was higher for the opponent-based frame in most issues. This indicates that the annotators could apply the frame more clearly, resulting in smaller difference between them. The kappa measure was 0.78 on aver-

age. The kappa measure near 0.8 indicates a substantial level of agreement, and the value can be achieved, for example, when 8 or 9 out of 10 items are annotated equally (Table 1).

In addition, fewer articles were classified to the "Other" category under the opponent-based frame. The annotators classified about half of the articles to this category under the positive vs. negative frame whereas they classified about 35% to the category under the opponent-based frame. This is because the frame is more flexible to classify diverse articles of an issue, such as those covering arguments on different points, and those covering detrimental facts to a specific side without explicit positive or negative arguments.

The kappa measure was less than 0.5 for near half of the issues under the positive-negative frame. The agreement was low especially when the main topic of the contention was interpreted differently among the annotators; the main topic was interpreted differently for issue 3, 7, 8, and 9. Even when the topic was interpreted identically, the annotators were confused in judging complex arguments either as positive or negative. One annotator commented that "it was confusing as the arguments were not clearly for or against the topic often. Even when a disputant was assumed to have a positive attitude towards the topic, the disputant's main argument was not about the topic but about attacking the opponent" The annotators all agreed that the opponent-based frame is more effective to understand the contention.

4 Disputant relation-based method

Disputant relation-based method adopts the opponent-based frame for classification. It attempts to identify the two opposing groups of the issue at hand, and analyzes whether an article more reflects the position of a specific side. The method is based on the observation that there exists two opposing groups of disputants, and the groups compete for news coverage. They strive to influence readers' interpretation, evaluation of the issue and gain support from them (Miller et al. 2001). In this competing process, news articles may give more chance of speaking to a specific side, explain or elaborate them, or provide supportive facts of that side (Baker 1994).

The proposed method is performed in three stages: the first stage, disputant extraction, extracts the disputants appearing in an article set; the second stage, disputant partition, partitions the extracted disputants into two opposing groups; lastly, the news classification stage classifies the articles into three categories, i.e., two for the articles biased to each group, and one for the others.

4.1 Disputant Extraction

In this stage, the disputants who participate in the contention have to be extracted. We utilize that many disputants appear as the subject of quotes in the news article set. The articles actively quote or cover their action in order to deliver the contention lively. We used straight forward methods for extraction of subjects. The methods were effective in practice as quotes of articles frequently had a regular pattern.

The subjects of direct and indirect quotes are extracted. The sentences including an utterance inside double quotes are considered as direct quotes.

The sentences which convey an utterance without double quotes, and those describing the action of a disputant are considered as indirect quotes (See the translated example 1 below). The indirect quotes are identified based on the morphology of the ending word. The ending word of the indirect quotes frequently has a verb as its root or includes a verbalization suffix. Other sentences, typically, those describing the reporter's interpretation or comments are not considered as quotes. (See example sentence 2. The ending word of the original sentence is written in boldface).

(1) The *government* **clarified** that there won't be any talks unless *North Korea* apologizes for the attack.

(2) The *government*'s **belief** is that a stern response is the only solution for the current crisis

A named entity combined with a topic particle or a subject particle is identified as the subject of these quotes. We detect the name of an organization, person, or country using the Korean Named Entity Recognizer (Lee et al. 2006). A simple anaphora resolution is conducted to identify subjects also from abbreviated references or pronouns in subsequent quotes.

4.2 Disputant Partitioning

We develop key opponent-based partitioning method for disputant partitioning. The method first identifies two key opponents, each representing

one side, and uses them as a pivot for partitioning other disputants. The other disputants are divided according to their relation with the key opponents, i.e., which key opponent they stand for or against.

The intuition behind the method is that there usually exists key opponents who represent the contention, and many participants argue about the key opponents whereas they seldom recognize and talk about minor disputants. For instance, in the contention on "investigation result of the Cheonan sinking incident", the government of North Korea and that of South Korea are the key opponents; other disputants, such as politicians, experts, civic group of South Korea, the government of U.S., and that of China, mostly speak about the key opponents. Thus, it is effective to analyze where the disputants stand regarding their attitude toward the key opponents.

Selecting key opponents: In order to identify the key opponents of the issue, we search for the disputants who frequently criticize, and are also criticized by other disputants. As the key opponents get more news coverage, they have more chance to articulate their argument, and also have more chance to face counter-arguments by other disputants.

This is done in two steps. First, for each disputant, we analyze whom he or she criticizes and by whom he or she is criticized. The method goes through each sentence of the article set and searches for both disputant's criticisms and the criticisms about the disputant. Based on the criticisms, it analyzes relationships among disputants.

A sentence is considered to express the disputant's criticism to another disputant if the following holds: 1) the sentence is a quote, 2) the disputant is the subject of the quote, 3) another disputant appears in the quote, and 4) a negative lexicon appears in the sentence.

On the other hand, if the disputant is not the subject but appears in the quote, the sentence is considered to express a criticism about the disputant made by another disputant (See example 3. The disputants are written in italic, and negative words are in boldface.).

(3) the *government* defined that "the **attack** of *North Korea* is an act of **invasion** and also a **violation** of North-South Basic Agreement"

The negative lexicon we use is carefully built from the Wilson lexicon (Wilson et al. 2005). We translated all the terms in it using the Google translation, and manually inspected the translated result to filter out inappropriate translations and the terms that are not negative in the Korean context.

Second, we apply an adapted version of HITS graph algorithm to find major disputants. For this, the criticizing relationships obtained in the first step are represented in a graph. Each disputant is modeled as a node, and a link is made from a criticizing disputant to a criticized disputant.

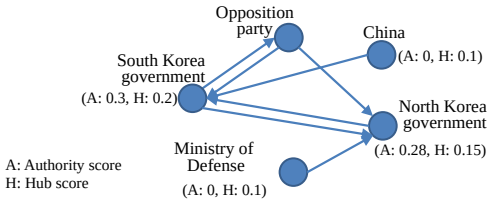

Figure 1. Example HITS graph illustration

Originally, the HITS algorithm (Kleinberg, 1999) is designed to rate Web pages regarding the link structure. The feature of the algorithm is that it separately models the value of outlinks and inlinks. Each node, i.e., a web page, has two scores: the authority score, which reflects the value of inlinks toward itself, and the hub score, which reflects the value of its outlinks to others. The hub score of a node increases if it links to nodes with high authority score, and the authority score increases if it is pointed by many nodes with high hub score.

We adopt the HITS algorithm due to above feature. It enables us to separately measure the significance of a disputant's criticism (using the hub score) and the criticism about the disputant (using the authority score). We aim to find the nodes which have both high hub score and high authority score; the key opponents will have many links to others and also be pointed by many nodes.

The modified HITS algorithm is shown in Figure 2. We make some adaptation to make the algorithm reflect the disputants' characteristics. The initial hub score of a node is set to the number of quotes in which the corresponding disputant is the subject. The initial authority score is set to the number of quotes in which the disputant appears but not as the subject. In addition, the weight of each link (from a criticizing disputant to a criticized disputant) is set to the number of sentences that express such criticism.

We select the nodes which show relatively high hub score and high authority score compared to other nodes. We rank the nodes according to the sum of hub and authority scores, and select from

the top ranking node. The node is not selected if its hub or authority score is zero. The selection is finished if more than two nodes are selected and the sum of hub and authority scores is less than half of the sum of the previously selected node.

Modified HITS(G,W,k)

$G = <V, E>$ where
V is a set of vertex, a vertex v_i represents a disputant
E is a set of edges, an edge e_{ij} represents a criticizing quote from disputant i to j
$W = \{w_{ij} |$ weight of edge $e_{ij}\}$

For all $v_i \in V$
$Auth^1(v_i)$ = # of quotes of which the subject is disputant i
$Hub^1(v_i)$ = # of quotes of which disputant i appears, but not as the subject

For $t = 1$ to k:
$Auth^{t+1}(v_i) = \sum_{j:\, e_{ji} \in E} Hub^t(v_j) \times w_{ji}$
$Hub^{t+1}(v_i) = \sum_{j:\, e_{ij} \in E} Auth^t(v_j) \times w_{ij}$
Normalize $Auth^{t+1}(v_i)$ and $Hub^{t+1}(v_i)$

Figure 2. Algorithm of the Modified HITS

More than two disputants can be selected if more than one disputant is active from a specific side. In such cases, we choose the two disputants whose criticizing relationship is the strongest among the selected ones, i.e., the two who show the highest ratio of criticism between them.

Partitioning minor disputants: Given the two key opponents, we partition the rest of disputants based on their relations with the key opponents. For this, we identify whether each disputant has positive or negative relations with the key opponents. The disputant is classified to the side of the key opponent who shows more positive relations. If the disputant shows more negative relations, the disputant is classified to the opposite side.

We analyze the relationship not only from the article set but also from the web news search results. The minor disputants may not be covered importantly in the article set; hence, it can be difficult to obtain sufficient data for analysis. The web news search results provide supplementary data for the analysis of relationships.

We develop four features to capture the positive and negative relationships between the disputants.

1) Positive Quote Rate (PQR_{ab}): Given two disputants (a key opponent *a*, and a minor disputant *b*), the feature measures the ratio of positive quotes between them. A sentence is considered as a positive quote if the following conditions hold: the sentence is a direct or indirect quote, the two disputants appear in the sentence, one is the subject of the quote, and a positive lexicon appears in the sentence. The number of such sentences is divided by the number of all quotes in which the two disputants appear and one appears as the subject.

2) Negative Quote Rate (NQR_{ab}): This feature is an opposite version of PQR. It measures the ratio of negative quotes between the two disputants. The same conditions are considered to detect negative quotes except that negative lexicon is used instead of positive lexicon.

3) Frequency of Standing Together (FST_{ab}): This feature attempts to capture whether the two disputants share a position, e.g., "*South Korea* and *U.S.* both criticized North Korea for…" It counts how many times they are co-located or connected with the conjunction "and" in the sentences.

4) Frequency of Division (FD_{ab}): This feature is an opposite version of the FST. It counts how many times they are not co-located in the sentences.

The same features are also calculated from the web news search results; we collect news articles of which the title includes the two disputants, i.e., a key opponent *a* and a minor disputant *b*.

The calculation method of PQR and NQR is slightly adapted since the titles are mostly not complete sentences. For PQR (NQR), it counts the titles which the two disputants appear with a positive (negative) lexicon. The counted number is divided by the number of total search results. The calculation method of FST and FD is the same except that they are calculated from the titles.

We combine the features obtained from web news search with the corresponding ones obtained from the article set by calculating a weighted sum. We currently give equal weights.

The disputants are partitioned by the following rule: given a minor disputant *a*, and the two key opponents *b* and *c*,

classify *a* to *b*'s side if,

$(PQR_{ab} - NQR_{ab}) > (PQR_{ac} - NQR_{ac})$ or $((FST_{ab} > FD_{ab})$ and $(FST_{ac} = 0))$;

classify *a* to *c*'s side if,

$(PQR_{ac} - NQR_{ac}) > (PQR_{ab} - NQR_{ab})$ or $((FST_{ac} > FD_{ac})$ and $(FST_{ab} = 0))$;

classify *a* to *other*, otherwise.

4.3 Article Classification

Each news article of the set is classified by analyzing which side is importantly covered. The method classifies the articles into three categories, either to one of the two sides or the category "other".

We observed that the major components which shape an article on a contention are quotes from disputants and journalists' commentary. Thus, our method considers two points for classification: first, from which side the article's quotes came; second, for the rest of the article's text, the similarity of the text to the arguments of each side.

As for the quotes of an article, the method calculates the proportion of the quotes from each side based on the disputant partitioning result. As for the rest of the sentences, a similarity analysis is conducted with an SVM classifier. The classifier takes a sentence as input, determines its class to one of the three categories, i.e., one of the two sides, or other. It is trained with the quotes from each side (tf.idf of unigram and bigram is used as features). The same number of quotes from each side is used for training. The training data is pseudo-relevant: it is automatically obtained based on the partitioning result of the previous stage.

An article is classified to a specific side if more of its quotes are from that side and more sentences are similar to that side: given an article *a*, and the two sides *b* and *c*,

classify *a* to *b* if $\frac{Q_b + S_b}{S_U} \geq \frac{\alpha \cdot Q_{bc} + \beta \cdot S_{bc}}{S_U}$

classify *a* to *c* if $\frac{Q_c + S_c}{S_U} \geq \frac{\alpha \cdot Q_{bc} + \beta \cdot S_{bc}}{S_U}$

classify *a* to *other*, otherwise.

where S_U: number of all sentences of the article
Q_i: number of quotes from the side *i*.
Q_{ij}: number of quotes from either side *i* or *j*.
S_i: number of sentences classified to *i* by SVM.
S_{ij}: number of sentences classified to either *i* or *j*.

We currently set the parameters heuristically. We set 0.7 and 0.6 for the two parameters α and β respectively. Thus, for an article written purely with quotes, the article is classified to a specific side if more than 70% of the quotes are from that side. On the other hand, for an article which does not include quotes from any side, more than 60% of the sentences have to be determined similar to a specific side's quotes. We set a lower value for β to classify articles with less number of biased sentences (Articles often include non-quote sentences unrelated to any side to give basic information).

5 Evaluation and Discussion

Our evaluation of the method is twofold: first, we evaluate the disputant partitioning results, second, the accuracy of classification. The method was evaluated using the same data set used for the classification frame comparison experiment.

A gold result was created through the three human annotators. To evaluate the disputant partitioning results, we had the annotators to extract the disputants of each issue, divide them into opposing two groups. We then created a gold partitioning result, by taking a union of the three annotators' results. A gold classification is also created from the classification of the annotators. We resolved the disagreements between the annotators' results by following the decision of the majority.

5.1 Evaluation of Disputant Partitioning

We evaluated the partitioning result of the two opposing groups, denoted as G1 and G2. The performance is measured using precision and recall. Table 2 presents the results. The precision of the partitioning was about 70% on average. The false positives were mostly the disputants who appear only a few times both in the article set and the news search results. As they appeared rarely, there was not enough data to infer their position. The effect of these false positives in article classification was limited.

The recall was slightly lower than precision. This was mainly because some disputants were omitted in the disputant extraction stage. The NER we used occasionally missed the names of unpopular organizations, e.g., civic groups, and the extraction rule failed to capture the subject in some complex sentences. However, most disputants who frequently appear in the article set were extracted and partitioned appropriately.

Issue #	G1		G2		Issue #	G1		G2	
	Pr.	Re.	Pr.	Re.		Pr.	Re.	Pr.	Re.
1	0.45	0.63	0.63	0.47	**8**	0.80	1.00	1.00	0.40
2	0.75	0.36	0.82	0.70	**9**	1.00	1.00	1.00	0.67

*N/A: The metric could not be calculated in some cases. This happened when no articles were classified to a category.

Table 3. Number of articles of each issue and group (left), and classification performance (right)

ty. It uses tf.idf of unigram and bigram as features, and cosine similarity as the similarity measure. We used the K-means clustering algorithm.

Quote-based classification (QbC.): The method is a partial implementation of our method. The disputant extraction and disputant partitioning is performed identically; however, it classifies news articles merely based on quotes. An article is classified to one of the two opposing sides if more than 70% of the quotes are from that side, or to the "other" category otherwise.

Results: We evaluated the classification result of the three categories, the two groups G1 and G2, and the category Other. The performance is measured using precision, recall, and f-measure. We additionally used the weighted f-measure (wF) to aggregate the f-measure of the three categories. It is the weighted average of the three f-measures. The weight is proportional to the number of articles in each category of the gold result.

The disputant relation-based method (DrC) performed better than the two comparison methods. The overall average of the weighted f-measure among issues was 0.68, 0.59, and 0.48 for the DrC, QbC, and Sim. method, respectively (See Table 3). The performance of the similarity-based clustering was lower than that of the other two in most issues.

A number of works have reported that text similarity is reliable in stance classification in political domains. These experiments were conducted in political debate corpus (Lin et al. 2006). However, news article set includes a number of articles covering different topics irrelevant to the arguments of the disputants. For example, there can be an article describing general background of the contention. Similarity-based clustering approach reacted sensitively to such articles and failed to capture the difference of the covered side.

Quote-based classification performs better than similarity-based approach as it classifies articles primarily based on the quoted disputants. The performance is comparable to DrC in many issues. The method performs similarly to DrC if most articles of an issue include many qutes. DrC performs better for other issues which include a number of articles with only a few quotes.

Error analysis: As for our method, we observed three main reasons of misclassification.

1) Articles with few quotes: Although the proposed method better classifies such articles than the quote-based classification, there were some misclassifications. There are sentences that are not directly related to the argument of any side, e.g., plain description of an event, summarizing the development of the issue, etc. The method made errors while trying to decide to which side these sentences are close to. Detecting such sentences and avoiding decisions for them would be one way of improvement. Research on classification

of subjective and objective sentences would be helpful (Wiebe et al. 99).
2) Article criticizing the quoted disputants: There were some articles criticizing the quoted disputants. For example, an article quoted the president frequently but occasionally criticized him between the quotes. The method misclassified such articles as it interpreted that the article is mainly delivering the president's argument.
3) Errors in disputant partitioning: Some misclassifications were made due to the errors in the disputant partitioning stage, specifically, those who were classified to a wrong side. Articles which refer to such disputants many times were misclassified.

6 Conclusion

We study the problem of classifying news articles on contentious issues. It involves new challenges as the discourse of contentious issues is complex, and news articles show different characteristics from commonly studied corpus, such as product reviews. We propose opponent-based frame, and demonstrate that it is a clear and effective classification frame to contrast arguments of contentious issues. We develop disputant relation-based classification and show that the method outperforms a text similarity-based approach.

Our method assumes polarization for contentious issues. This assumption was valid for most of the tested issues. For a few issues, there were some participants who do not belong to either side; however, they usually did not take a particular position nor make strong arguments. Thus, the effect on classification performance was limited. Discovering and developing methods for issues which involve more than two disputants groups is a future work.

Abstract

We present a probabilistic topic model for jointly identifying properties and attributes of social media review snippets. Our model simultaneously learns a set of properties of a product and captures aggregate user sentiments towards these properties. This approach directly enables discovery of highly rated or inconsistent properties of a product. Our model admits an efficient variational mean-field inference algorithm which can be parallelized and run on large snippet collections. We evaluate our model on a large corpus of snippets from Yelp reviews to assess property and attribute prediction. We demonstrate that it outperforms applicable baselines by a considerable margin.

Coherent property cluster

+	The **martinis** were very good.
	The **drinks** - both **wine** and **martinis** - were tasty.
-	The **wine list** was pricey.
	Their **wine selection** is horrible.

Incoherent property cluster

+	The sushi is the **best I've ever had**.
	Best paella **I'd ever had**.
	The fillet was the **best steak we'd ever had**.
	It's the **best soup I've ever had**.

Table 1: Example clusters of restaurant review snippets. The first cluster represents a coherent *property* of the underlying product, namely the *cocktail* property, and assesses distinctions in user sentiment. The latter cluster simply shares a common attribute expression and does not represent snippets discussing the same product property. In this work, we aim to produce the first type of property cluster with correct sentiment labeling.

1 Introduction

Online product reviews have become an increasingly valuable and influential source of information for consumers. Different reviewers may choose to comment on different properties or aspects of a product; therefore their reviews focus on different qualities of the product. Even when they discuss the same properties, their experiences and, subsequently, evaluations of the product can differ dramatically. Thus, information in any single review may not provide a complete and balanced view representative of the product as a whole. To address this need, online retailers often use simple aggregation mechanisms to represent the spectrum of user sentiment. For instance, product pages on Amazon prominently display the distribution of numerical scores across reviews, providing access to reviews at different levels of satisfaction.

The goal of our work is to provide a mechanism for review content aggregation that goes beyond numerical scores. Specifically, we are interested in identifying fine-grained product properties across reviews (e.g., *battery life* for electronics or *pizza* for restaurants) as well as capturing attributes of these properties, namely aggregate user sentiment.

For this task, we assume as input a set of product review snippets (i.e., standalone phrases such as "battery life is the best I've found") rather than complete reviews. There are many techniques for extracting this type of snippet in existing work; we use the Sauper et al. (2010) system.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 350–358,
Portland, Oregon, June 19-24, 2011.

At first glance, this task can be solved using existing methods for review analysis. These methods can effectively extract product properties from individual snippets along with their corresponding sentiment. While the resulting property-attribute pairs form a useful abstraction for cross-review analysis, in practice direct comparison of these pairs is challenging.

Consider, for instance, the two clusters of restaurant review snippets shown in Figure 1. While both clusters have many words in common among their members, only the first describes a coherent property cluster, namely the *cocktail* property. The snippets of the latter cluster do not discuss a single product property, but instead share similar expressions of sentiment. To solve this issue, we need a method which can correctly identify both property and sentiment words.

In this work, we propose an approach that jointly analyzes the whole collection of product review snippets, induces a set of learned properties, and models the aggregate user sentiment towards these properties. We capture this idea using a Bayesian topic model where a set of properties and corresponding attribute tendencies are represented as hidden variables. The model takes product review snippets as input and explains how the observed text arises from the latent variables, thereby connecting text fragments with corresponding properties and attributes.

The advantages of this formulation are twofold. First, this encoding provides a common ground for comparing and aggregating review content in the presence of varied lexical realizations. For instance, this representation allows us to directly compare how many reviewers liked a given property of a product. Second, our model yields an efficient mean-field variational inference procedure which can be parallelized and run on a large number of review snippets.

We evaluate our approach in the domain of snippets taken from restaurant reviews on Yelp. In this collection, each restaurant has on average 29.8 snippets representing a wide spectrum of opinions about a restaurant. The evaluation we present demonstrates that the model can accurately retrieve clusters of review fragments that describe the same property, yielding 20% error reduction over a standalone clustering baseline. We also show that the model can effectively identify binary snippet attributes with 9.2% error reduction over applicable baselines, demonstrating that learning to identify attributes in the context of other product reviews yields significant gains. Finally, we evaluate our model on its ability to identify product properties for which there is significant sentiment disagreement amongst user snippets. This tests our model's capacity to jointly identify properties and assess attributes.

2 Related Work

Our work on review aggregation has connections to three lines of work in text analysis.

First, our work relates to research on extraction of product properties with associated sentiment from review text (Hu and Liu, 2004; Liu et al., 2005a; Popescu et al., 2005). These methods identify relevant information in a document using a wide range of methods such as association mining (Hu and Liu, 2004), relaxation labeling (Popescu et al., 2005) and supervised learning (Kim and Hovy, 2006). While our method also extracts product properties and sentiment, our focus is on multi-review aggregation. This task introduces new challenges which were not addressed in prior research that focused on per-document analysis.

A second related line of research is multi-document review summarization. Some of these methods directly apply existing domain-independent summarization methods (Seki et al., 2006), while others propose new methods targeted for opinion text (Liu et al., 2005b; Carenini et al., 2006; Hu and Liu, 2006; Kim and Zhai, 2009). For instance, these summaries may present contrastive view points (Kim and Zhai, 2009) or relay average sentiment (Carenini et al., 2006). The focus of this line of work is on how to select suitable sentences, assuming that relevant review features (such as numerical scores) are given. Since our emphasis is on multi-review analysis, we believe that the information we extract can benefit existing summarization systems.

Finally, a number of approaches analyze review documents using probabilistic topic models (Lu and Zhai, 2008; Titov and McDonald, 2008; Mei et al., 2007). While some of these methods focus primar-

ily on modeling ratable aspects (Titov and McDonald, 2008), others explicitly capture the mixture of topics and sentiments (Mei et al., 2007). These approaches are capable of identifying latent topics in the collection in opinion text (e.g., weblogs) as well as associated sentiment. While our model captures similar high-level intuition, it analyzes fine-grained properties expressed at the snippet level, rather than document-level sentiment. Delivering analysis at such a fine granularity requires a new technique.

3 Problem Formulation

In this section, we discuss the core random variables and abstractions of our model. We describe the generative models over these elements in Section 4.

Product: A product represents a reviewable object. For the experiments in this paper, we use restaurants as products.

Snippets: A snippet is a user-generated short sequence of tokens describing a product. Input snippets are deterministically taken from the output of the Sauper et al. (2010) system.

Property: A property corresponds to some fine-grained aspect of a product. For instance, the snippet "the pad thai was great" describes the *pad thai* property. We assume that each snippet has a single property associated with it. We assume a fixed number of possible properties K for each product.

For the corpus of restaurant reviews, we assume that the set of properties are specific to a given product, in order to capture fine-grained, relevant properties for each restaurant. For example, reviews from a sandwich shop may contrast the club sandwich with the turkey wrap, while for a more general restaurant, the snippets refer to sandwiches in general. For other domains where the properties are more consistent, it is straightforward to alter our model so that properties are shared across products.

Attribute: An attribute is a description of a property. There are multiple attribute *types*, which may correspond to semantic differences. We assume a fixed, pre-specified number of attributes N. For example, in the case of product reviews, we select $N = 2$ attributes corresponding to positive and negative sentiment. In the case of information extraction, it may be beneficial to use numeric and alphabetic types.

One of the goals of this work in the review domain is to improve sentiment prediction by exploiting correlations within a single property cluster. For example, if there are already many snippets with the attribute representing positive sentiment in a given property cluster, additional snippets are biased towards positive sentiment as well; however, data can always override this bias.

Snippets themselves are always observed; the goal of this work is to induce the latent property and attribute underlying each snippet.

4 Model

Our model generates the words of all snippets for each product in a collection of products. We use $s^{i,j,w}$ to represent the wth word of the jth snippet of the ith product. We use $\mathbf{s}$ to denote the collection of all snippet words. We also assume a fixed vocabulary of words V.

We present an overview of our generative model in Figure 1 and describe each component in turn:

Global Distributions: At the global level, we draw several unigram distributions: a global background distribution θ_B and attribute distributions θ_A^a for each attribute. The background distribution is meant to encode stop-words and domain white-noise, e.g., `food` in the restaurants domain. In this domain, the positive and negative attribute distributions encode words with positive and negative sentiments (e.g., *delicious* or *terrible*).

Each of these distributions are drawn from Dirichlet priors. The background distribution is drawn from a symmetric Dirichlet with concentration $\lambda_B = 0.2$. The positive and negative attribute distributions are initialized using seed words (V_{seed_a} in Figure 1). These seeds are incorporated into the attribute priors: a non-seed word gets ϵ hyperparameter and a seed word gets $\epsilon + \lambda_A$, where $\epsilon = 0.25$ and $\lambda_A = 1.0$.

Product Level: For the ith product, we draw property unigram distributions $\theta_P^{i,1}, \ldots, \theta_P^{i,K}$ for each of the possible K product properties. The property distribution represents product-specific content distributions over properties discussed in reviews of the product; for instance in the restaurant domains, properties may correspond to distinct menu items. Each $\theta_P^{i,k}$ is drawn from a symmetric Dirichlet prior

Global Level:

- Draw background distribution $\theta_B \sim \text{DIRICHLET}(\lambda_B V)$
- For each attribute type a,
  - Draw attribute distribution $\theta_A^a \sim \text{DIRICHLET}(\epsilon V + \lambda_A V_{seed_a})$

Product Level:

- For each product i,
  - Draw property distributions $\theta_P^k \sim \text{DIRICHLET}(\lambda_P V)$ for $k = 1, \ldots, K$
  - Draw property attribute binomial $\phi^{i,k} \sim \text{BETA}(\alpha_A, \beta_A)$ for $k = 1, \ldots, K$
  - Draw property multinomial $\psi^i \sim \text{DIRICHLET}(\lambda_M K)$

Snippet Level:

- For each snippet j in ith product,
  - Draw snippet property $Z_P^{i,j} \sim \psi^i$
  - Draw snippet attribute $Z_A^{i,j} \sim \phi^{Z_P^{ij}}$
  - Draw sequence of word topic indicators $Z_W^{i,j,w} \sim \Lambda | Z_W^{i,j,w-1}$
  - Draw snippet word given property $Z_P^{i,j}$ and attribute $Z_A^{i,j}$

$$s_{i,j,w} \sim \begin{cases} \theta_P^{i,Z_P^{i,j}}, & \text{when } Z_W^{i,j,w} = P \\ \theta_A^{Z_A^{i,j}}, & \text{when } Z_W^{i,j,w} = A \\ \theta_B, & \text{when } Z_W^{i,j,w} = B \end{cases}$$

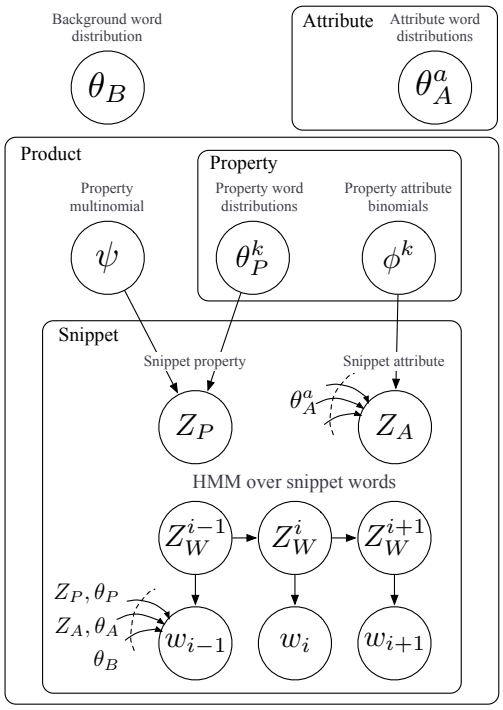

Figure 1: A high-level verbal and graphical description for our model in Section 4. We use $\text{DIRICHLET}(\lambda V)$ to denote a finite Dirichlet prior where the hyper-parameter counts are a scalar times the unit vector of vocabulary items. For the global attribute distribution, the prior hyper-parameter counts are ϵ for all vocabulary items and λ_A for V_{seed_a}, the vector of vocabulary items in the set of seed words for attribute a.

with hyper-parameter $\lambda_P = 0.2$.

For each property $k = 1, \ldots, K$. $\phi_{i,k}$, we draw a binomial distribution $\phi_{i,k}$. This represents the distribution over positive and negative attributes for that property; it is drawn from a beta prior using hyper-parameters $\alpha_A = 2$ and $\beta_A = 2$. We also draw a multinomial ψ^i over K possible properties from a symmetric Dirichlet distribution with hyper-parameter $\lambda_M = 1,000$. This distribution is used to draw snippet properties.

Snippet Level: For the jth snippet of the ith product, a property random variable $Z_P^{i,j}$ is drawn according to the multinomial ψ^i. Conditioned on this choice, we draw an attribute $Z_A^{i,j}$ (positive or negative) from the property attribute distribution $\phi^{i,Z_P^{j,j}}$.

Once the property $Z_P^{i,j}$ and attribute $Z_A^{i,j}$ have been selected, the tokens of the snippet are generated using a simple HMM. The latent state underlying a token, $Z_W^{i,j,w}$, indicates whether the wth word comes from the property distribution, attribute distribution, or background distribution; we use P, A, or B to denote these respective values of $Z_W^{i,j,w}$.

The sequence $Z_W^{i,j,1}, \ldots, Z_W^{i,j,m}$ is generated using a first-order Markov model. The full transition parameter matrix Λ parametrizes these decisions. Conditioned on the underlying $Z_W^{i,j,w}$, a word, $s^{i,j,w}$ is drawn from $\theta_P^{i,j}$, $\theta_A^{i,Z_P^{i,j}}$, or θ_B for the values P,A, or B respectively.

5 Inference

The goal of inference is to predict the snippet property and attribute distributions over each snippet given all the observed snippets $P(Z_P^{i,j}, Z_A^{i,j} | \mathbf{s})$ for all products i and snippets j. Ideally, we would like to marginalize out nuisance random variables and distributions. Specifically, we approximate the full

model posterior using variational inference:[1]

$$P(\psi, \boldsymbol{\theta_P}, \theta_B, \boldsymbol{\theta_A}, \phi, |\mathbf{s}) \approx Q(\psi, \boldsymbol{\theta_P}, \theta_B, \boldsymbol{\theta_A}, \phi)$$

where ψ, $\boldsymbol{\theta_P}$, ϕ denote the collection of latent distributions in our model. Here, we assume a full mean-field factorization of the variational distribution; see Figure 2 for the decomposition. Each variational factor $q(\cdot)$ represents an approximation of that variable's posterior given observed random variables. The variational distribution $Q(\cdot)$ makes the (incorrect) assumption that the posteriors amongst factors are independent. The goal of variational inference is to set factors $q(\cdot)$ so that it minimizes the KL divergence to the true model posterior:

$$\min_{Q(\cdot)} KL(P(\psi, \boldsymbol{\theta_P}, \theta_B, \boldsymbol{\theta_A}, \phi, |\mathbf{s}) \| Q(\psi, \boldsymbol{\theta_P}, \theta_B, \boldsymbol{\theta_A}, \phi)$$

We optimize this objective using coordinate descent on the $q(\cdot)$ factors. Concretely, we update each factor by optimizing the above criterion with all other factors fixed to current values. For instance, the update for the factor $q(Z_W^{i,j,w})$ takes the form:

$$q(Z_W^{i,j,w}) \leftarrow \mathbb{E}_{Q/q(Z_W^{i,j,w})} \lg P(\psi, \boldsymbol{\theta_P}, \theta_B, \boldsymbol{\theta_A}, \phi, \mathbf{s})$$

The full factorization of $Q(\cdot)$ and updates for all random variable factors are given in Figure 2. Updates of parameter factors are omitted; however these are derived through simple counts of the Z_A, Z_P, and Z_W latent variables. For related discussion, see Blei et al. (2003).

6 Experiments

In this section, we describe in detail our data set and present three experiments and their results.

Data Set Our data set consists of snippets from Yelp reviews generated by the system described in Sauper et al. (2010). This system is trained to extract snippets containing short descriptions of user sentiment towards some aspect of a restaurant.[2] We select only the snippets labeled by that system as referencing *food*, and we ignore restaurants with fewer than 20 snippets. There are 13,879 snippets in total, taken from 328 restaurants in and around the Boston/Cambridge area. The average snippet length is 7.8 words, and there are an average of 42.1 snippets per restaurant, although there is high variance in number of snippets for each restaurant. Figure 3 shows some example snippets.

The [P noodles] and the [P meat] were actually [+ pretty good].
I [+ recommend] the [P chicken noodle pho].
The [P noodles] were [- soggy].
The [P chicken pho] was also [+ good].

The [P spring rolls] and [P coffee] were [+ good] though.
The [P spring roll wrappers] were a [- little dry tasting].
My [+ favorites] were the [P crispy spring rolls].
The [P Crispy Tuna Spring Rolls] are [+ fantastic]!

The [P lobster roll] my mother ordered was [- dry] and [- scant].
The [P portabella mushroom] is my [+ go-to] [P sandwich].
The [P bread] on the [P sandwich] was [- stale].
The slice of [P tomato] was [- rather measly].

The [P shumai] and [P California maki sushi] were [+ decent].
The [P spicy tuna roll] and [P eel roll] were [+ perfect].
The [P rolls] with [P spicy mayo] were [- not so great].
I [+ love] [P Thai rolls].

Figure 3: Example snippets from our data set, grouped according to property. Property words are labeled **P** and colored blue, NEGATIVE attribute words are labeled **-** and colored red, and POSITIVE attribute words are labeled **+** and colored green. The grouping and labeling are *not* given in the data set and must be learned by the model.

For sentiment attribute seed words, we use 42 and 33 words for the positive and negative distributions respectively. These are hand-selected based on the restaurant review domain; therefore, they include domain-specific words such as *delicious* and *gross*.

Tasks We perform three experiments to evaluate our model's effectiveness. First, a cluster prediction task is designed to test the quality of the learned property clusters. Second, an attribute analysis task will evaluate the sentiment analysis portion of the model. Third, we present a task designed to test whether the system can correctly identify properties which have conflicting attributes, which tests both clustering and sentiment analysis.

[1] See Liang and Klein (2007) for an overview of variational techniques.

[2] For exact training procedures, please reference that paper.

Mean-field Factorization

$$Q(\boldsymbol{\psi}, \boldsymbol{\theta_P}, \theta_B, \boldsymbol{\theta_A}, \boldsymbol{\phi}) = q(\theta_B) \left(\prod_{a=1}^{N} q(\theta_A^a) \right) \left(\prod_{i}^{n} \left(\prod_{k=1}^{K} q(\theta_P^{i,k}) q(\phi^{i,k}) \right) \left(\prod_{j} q(Z_A^{i,j}) q(Z_P^{i,j}) \prod_{w} q(Z_W^{i,j,w}) \right) \right)$$

Snippet Property Indicator

$$\lg q(Z_P^{i,j} = k) \propto \mathbb{E}_{q(\psi^i)} \lg \psi^i(p) + \sum_{w} q(Z_W^{i,j,w} = P) \mathbb{E}_{q(\theta_P^{i,k})} \lg \theta_P^{i,k}(s^{i,j,w}) + \sum_{a=1}^{N} q(Z_A^{i,j} = a) \mathbb{E}_{q(\phi^{i,k})} \lg \phi^{i,k}(a)$$

Snippet Attribute Indicator

$$\lg q(Z_A^{i,j} = a) = \sum_{k} q(Z_P^{i,j} = k) \mathbb{E}_{q(\phi^{i,k})} \lg \phi^{i,k}(a) + \sum_{w} q(Z_W^{i,j,w} = A) \mathbb{E}_{q(\theta_A^a)} \lg \theta_A^a(s^{i,j,w})$$

Word Topic Indicator

$$\lg q(Z_W^{i,j,w} = P) \propto \lg P(Z_W = P) + \sum_{k} q(Z_P^{i,j} = k) \mathbb{E}_{q(\theta_P^{i,k})} \lg \theta_P^{i,j}(s^{i,j,w})$$

$$\lg q(Z_W^{i,j,w} = A) \propto \lg P(Z_W = A) + \sum_{a \in \{+,-\}} q(Z_A^{i,j} = a) \mathbb{E}_{q(\theta_A^a)} \lg \theta_A^a(s^{i,j,w})$$

$$\lg q(Z_W^{i,j,w} = B) \propto \lg P(Z_W = B) + \mathbb{E}_{q(\theta_B)} \lg \theta_B(s^{i,j,w})$$

Figure 2: The mean-field variational algorithm used during learning and inference to obtain posterior predictions over snippet properties and attributes, as described in Section 5. Mean-field inference consists of updating each of the latent variable factors as well as a straightforward update of latent parameters in round robin fashion.

6.1 Cluster prediction

The goal of this task is to evaluate the quality of property clusters; specifically the $Z_P^{i,j}$ variable in Section 4. In an ideal clustering, the predicted clusters will be cohesive (i.e., all snippets predicted for a given property are related to each other) and comprehensive (i.e., all snippets which are related to a property are predicted for it). For example, a snippet will be assigned the property *pad thai* if and only if that snippet mentions some aspect of the pad thai.

Annotation For this task, we use a set of gold clusters over 3,250 snippets across 75 restaurants collected through Mechanical Turk. In each task, a worker was given a set of 25 snippets from a single restaurant and asked to cluster them into as many clusters as they desired, with the option of leaving any number unclustered. This yields a set of gold clusters and a set of unclustered snippets. For verification purposes, each task was provided to two different workers. The intersection of both workers' judgments was accepted as the gold standard, so the model is not evaluated on judgments which disagree. In total, there were 130 unique tasks, each of which were provided to two workers, for a total output of 210 generated clusters.

Baseline The baseline for this task is a clustering algorithm weighted by TF*IDF over the data set as implemented by the publicly available CLUTO package.[3] This baseline will put a strong connection between things which are lexically similar. Because our model only uses property words to tie together clusters, it may miss correlations between words which are not correctly identified as property words. The baseline is allowed 10 property clusters per restaurant.

We use the MUC cluster evaluation metric for this task (Vilain et al., 1995). This metric measures the number of cluster merges and splits required to recreate the gold clusters given the model's output.

[3] Available at http://glaros.dtc.umn.edu/gkhome/cluto/cluto/overview with agglomerative clustering, using the cosine similarity distance metric.

	Precision	Recall	F1
Baseline	80.2	61.1	69.3
Our model	72.2	79.1	75.5

Table 2: Results using the MUC metric on the cluster prediction task. Note that while the precision of the baseline is higher, the recall and overall F1 of our model outweighs that. While MUC has a deficiency in that putting everything into a single cluster will artificially inflate the score, parameters on our model are set so that the model uses the same number of clusters as the baseline system.

Therefore, it can concisely show how accurate our clusters are as a whole. While it would be possible to artificially inflate the score by putting everything into a single cluster, the parameters on our model and the likelihood objective are such that the model prefers to use all available clusters, the same number as the baseline system.

Results Results for our cluster prediction task are in Table 2. While our system does suffer on precision in comparison to the baseline system, the recall gains far outweigh this loss, for a total error reduction of 20% on the MUC measure.

The most common cause of poor cluster choices in the baseline system is its inability to distinguish property words from attribute words. For example, if many snippets in a given restaurant use the word *delicious*, there may end up being a cluster based on that alone. Because our system is capable of distinguishing which words are property words (i.e., words relevant to clustering), it can choose clusters which make more sense overall. We show an example of this in Table 3.

6.2 Attribute analysis

We also evaluate the system's predictions of snippet attribute using the predicted posterior over the attribute distribution for the snippet (i.e., $Z_A^{i,j}$). For this task, we consider the binary judgment to be simply the one with higher value in $q(Z_A^{i,j})$ (see Section 5). The goal of this task is to evaluate whether our model correctly distinguishes attribute words.

Annotation For this task, we use a set of 260 total snippets from the Yelp reviews for 30 restaurants, evenly split into a training and test sets of 130 snippets each. These snippets are manually labeled POSITIVE or NEGATIVE. Neutral snippets are ignored for the purpose of this experiment.

The martini selection looked delicious The s'mores martini sounded excellent
The martinis were good The martinis are very good
The mozzarella was very fresh The fish and various meets were very well made

The best carrot cake I've ever eaten Carrot cake was deliciously moist
The carrot cake was delicious.
It was rich, creamy and delicious. The pasta Bolognese was rich and robust.

Table 3: Example phrases from clusters in both the baseline and our model. For each pair of clusters, the dashed line indicates separation by the baseline model, while the solid line indicates separation by our model. In the first example, the baseline mistakenly clusters some snippets about *martinis* with those containing the word *very*. In the second example, the same occurs with the word *delicious*.

Baseline We use two baselines for this task, one based on a standard discriminative classifier and one based on the seed words from our model.

The DISCRIMINATIVE baseline for this task is a standard maximum entropy discriminative binary classifier over unigrams. Given enough snippets from enough unrelated properties, the classifier should be able to identify that words like *great* indicate positive sentiment and those like *bad* indicate negative sentiment, while words like *chicken* are neutral and have no effect.

The SEED baseline simply counts the number of words from the positive and negative seed lists used by the model, V_{seed_+} and V_{seed_-}. If there are more words from V_{seed_+}, the snippet is labeled positive, and if there are more words from V_{seed_-}, the snippet is labeled negative. If there is a tie or there are no seed words, we split the prediction. Because the seed word lists are specifically slanted toward restaurant reviews (i.e., they contain words such as *delicious*), this baseline should perform well.

Results For this experiment, we measure the overall classification accuracy of each system (see Table

	Accuracy
DISCRIMINATIVE baseline	75.9
SEED baseline	78.2
Our model	80.2

Table 4: Attribute prediction accuracy of the full system compared to the DISCRIMINATIVE and SEED baselines. The advantage of our system is its ability to distinguish property words from attribute words in order to restrict judgment to only the relevant terms.

The naan was **hot** and **fresh**
All the veggies were really **fresh** and **crisp**.
Perfect mix of **fresh flavors** and **comfort** food
The lo main smelled and tasted **rancid**
My grilled cheese sandwich was a little **gross**

Table 5: Examples of sentences correctly labeled by our system but incorrectly labeled by the DISCRIMINATIVE baseline; the key sentiment words are highlighted. Notice that these words are not the most common sentiment words; therefore, it is difficult for the classifier to make a correct generalization. Only two of these words are seed words for our model (*fresh* and *gross*).

4). Our system outperforms both supervised baselines.

As in the cluster prediction case, the main flaw with the DISCRIMINATIVE baseline system is its inability to recognize which words are relevant for the task at hand, in this case the attribute words. By learning to separate attribute words from the other words in the snippets, our full system is able to more accurately judge their sentiment. Examples of these cases are found in Table 5.

The obvious flaw in the SEED baseline is the inability to pre-specify every possible sentiment word; our model's performance indicates that it is learning something beyond just these basic words.

6.3 Conflict identification

Our final task requires both correct cluster prediction and correct sentiment judgments. In many domains, it is interesting to know not only whether a product is rated highly, but also whether there is conflicting sentiment or debate. In the case of restaurant reviews, it is relevant to know whether the dishes are consistently good or whether there is some variation in quality.

Judgment P	Judgment A		Attribute / Snippet
Yes	Yes	-	The salsa isn't great
		+	Chips and salsa are sublime
		-	The grits were good, but not great.
		+	Grits were the perfect consistency
		-	The tom yum kha was bland
		+	It's the best Thai soup I ever had
		-	The naan is a bit doughy and undercooked
		+	The naan was pretty tasty
		-	My reuben was a little dry.
		+	The reuben was a good reuben.
Yes	No	-	Belgian frites are crave-able
		+	The frites are very, very good.
No	Yes	-	The blackened chicken was meh
		+	Chicken enchiladas are yummy!
		-	The taste overall was mediocre
		+	The oysters are tremendous
No	No	-	The cream cheese wasn't bad
		+	Ice cream was just delicious

Table 6: Example property-attribute correctness for the conflict identification task, over both property and attribute. Property judgment (P) indicates whether the snippets are discussing the same item; attribute judgment (A) indicates whether there is a correct difference in attribute (sentiment), regardless of properties.

To evaluate this, we examine the output clusters which contain predictions of both positive and negative snippets. The goal is to identify whether these are true conflicts of sentiment or there was a failure in either property clustering or attribute classification.

For this task, the output clusters are manually annotated for correctness of both property and attribute judgments, as in Table 6. As there is no obvious baseline for this experiment, we treat it simply as an analysis of errors.

Results For this task, we examine the accuracy of conflict prediction, both with and without the correctly identified properties. The results by property-attribute correctness are shown in Table 7. From these numbers, we can see that 50% of the clusters are correct in both property (cohesiveness) and attribute (difference in sentiment) dimensions.

Overall, the properties are correctly identified (subject of NEG matches the subject of POS) 68% of the time and a correct difference in attribute is identified 67% of the time. Of the clusters which are correct in property, 74% show a correctly labeled

Judgment		
P	A	# Clusters
Yes	Yes	52
Yes	No	18
No	Yes	17
No	No	15

Table 7: Results of conflict analysis by correctness of property label (P) and attribute conflict (A). Examples of each type of correctness pair are show in in Table 6. 50% of the clusters are correct in both labels, and there are approximately the same number of errors toward both property and attribute.

difference in attribute.

7 Conclusion

We have presented a probabilistic topic model for identifying properties and attitudes of product review snippets. The model is relatively simple and admits an efficient variational mean-field inference procedure which is parallelized and can be run on a large number of snippets. We have demonstrated on multiple evaluation tasks that our model outperforms applicable baselines by a considerable margin.

Abstract

The challenges of Named Entities Recognition (NER) for tweets lie in the insufficient information in a tweet and the unavailability of training data. We propose to combine a K-Nearest Neighbors (KNN) classifier with a linear Conditional Random Fields (CRF) model under a semi-supervised learning framework to tackle these challenges. The KNN based classifier conducts pre-labeling to collect global coarse evidence across tweets while the CRF model conducts sequential labeling to capture fine-grained information encoded in a tweet. The semi-supervised learning plus the gazetteers alleviate the lack of training data. Extensive experiments show the advantages of our method over the baselines as well as the effectiveness of KNN and semi-supervised learning.

1 Introduction

Named Entities Recognition (NER) is generally understood as the task of identifying mentions of rigid designators from text belonging to named-entity types such as persons, organizations and locations (Nadeau and Sekine, 2007). Proposed solutions to NER fall into three categories: 1) The rule-based (Krupka and Hausman, 1998); 2) the machine learning based (Finkel and Manning, 2009; Singh et al., 2010) ; and 3) hybrid methods (Jansche and Abney, 2002). With the availability of annotated corpora, such as ACE05, Enron (Minkov et al., 2005) and CoNLL03 (Tjong Kim Sang and De Meulder, 2003), the data driven methods now become the dominating methods.

However, current NER mainly focuses on formal text such as news articles (Mccallum and Li, 2003; Etzioni et al., 2005). Exceptions include studies on informal text such as emails, blogs, clinical notes (Wang, 2009). Because of the domain mismatch, current systems trained on non-tweets perform poorly on tweets, a new genre of text, which are short, informal, ungrammatical and noise prone. For example, the average F1 of the Stanford NER (Finkel et al., 2005) , which is trained on the CoNLL03 shared task data set and achieves state-of-the-art performance on that task, drops from 90.8% (Ratinov and Roth, 2009) to 45.8% on tweets.

Thus, building a domain specific NER for tweets is necessary, which requires a lot of annotated tweets or rules. However, manually creating them is tedious and prohibitively unaffordable. Proposed solutions to alleviate this issue include: 1) Domain adaption, which aims to reuse the knowledge of the source domain in a target domain. Two recent examples are Wu et al. (2009), which uses data that is informative about the target domain and also easy to be labeled to bridge the two domains, and Chiticariu et al. (2010), which introduces a high-level rule language, called NERL, to build the general and domain specific NER systems; and 2) semi-supervised learning, which aims to use the abundant unlabeled data to compensate for the lack of annotated data. Suzuki and Isozaki (2008) is one such example.

Another challenge is the limited information in tweet. Two factors contribute to this difficulty. One

[*] This work has been done while the author was visiting Microsoft Research Asia.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 359–367,
Portland, Oregon, June 19-24, 2011.

is the tweet's informal nature, making conventional features such as part-of-speech (POS) and capitalization not reliable. The performance of current NLP tools drops sharply on tweets. For example, OpenNLP [1], the state-of-the-art POS tagger, gets only an accuracy of 74.0% on our test data set. The other is the tweet's short nature, leading to the excessive abbreviations or shorthand in tweets, and the availability of very limited context information. Tackling this challenge, ideally, requires adapting related NLP tools to fit tweets, or normalizing tweets to accommodate existing tools, both of which are hard tasks.

We propose a novel NER system to address these challenges. Firstly, a K-Nearest Neighbors (KNN) based classifier is adopted to conduct word level classification, leveraging the similar and recently labeled tweets. Following the two-stage prediction aggregation methods (Krishnan and Manning, 2006), such pre-labeled results, together with other conventional features used by the state-of-the-art NER systems, are fed into a linear Conditional Random Fields (CRF) (Lafferty et al., 2001) model, which conducts fine-grained tweet level NER. Furthermore, the KNN and CRF model are repeatedly retrained with an incrementally augmented training set, into which high confidently labeled tweets are added. Indeed, it is the combination of KNN and CRF under a semi-supervised learning framework that differentiates ours from the existing. Finally, following Lev Ratinov and Dan Roth (2009), 30 gazetteers are used, which cover common names, countries, locations, temporal expressions, etc. These gazetteers represent general knowledge across domains. The underlying idea of our method is to combine global evidence from KNN and the gazetteers with local contextual information, and to use common knowledge and unlabeled tweets to make up for the lack of training data.

12,245 tweets are manually annotated as the test data set. Experimental results show that our method outperforms the baselines. It is also demonstrated that integrating KNN classified results into the CRF model and semi-supervised learning considerably boost the performance.

Our contributions are summarized as follows.

1. We propose to a novel method that combines a KNN classifier with a conventional CRF based labeler under a semi-supervised learning framework to combat the lack of information in tweet and the unavailability of training data.

2. We evaluate our method on a human annotated data set, and show that our method outperforms the baselines and that both the combination with KNN and the semi-supervised learning strategy are effective.

The rest of our paper is organized as follows. In the next section, we introduce related work. In Section 3, we formally define the task and present the challenges. In Section 4, we detail our method. In Section 5, we evaluate our method. Finally, Section 6 concludes our work.

2 Related Work

Related work can be roughly divided into three categories: NER on tweets, NER on non-tweets (e.g., news, bio-logical medicine, and clinical notes), and semi-supervised learning for NER.

2.1 NER on Tweets

Finin et al. (2010) use Amazons Mechanical Turk service [2] and CrowdFlower [3] to annotate named entities in tweets and train a CRF model to evaluate the effectiveness of human labeling. In contrast, our work aims to build a system that can automatically identify named entities in tweets. To achieve this, a KNN classifier with a CRF model is combined to leverage cross tweets information, and the semi-supervised learning is adopted to leverage unlabeled tweets.

2.2 NER on Non-Tweets

NER has been extensively studied on formal text, such as news, and various approaches have been proposed. For example, Krupka and Hausman (1998) use manual rules to extract entities of predefined types; Zhou and Ju (2002) adopt Hidden Markov Models (HMM) while Finkel et al. (2005) use CRF to train a sequential NE labeler, in which the BIO (meaning Beginning, the Inside and the Outside of

[1] http://sourceforge.net/projects/opennlp/

[2] https://www.mturk.com/mturk/

[3] http://crowdflower.com/

an entity, respectively) schema is applied. Other methods, such as classification based on Maximum Entropy models and sequential application of Perceptron or Winnow (Collins, 2002), are also practiced. The state-of-the-art system, e.g., the Stanford NER, can achieve an F1 score of over 92.0% on its test set.

Biomedical NER represents another line of active research. Machine learning based systems are commonly used and outperform the rule based systems. A state-of-the-art biomedical NER system (Yoshida and Tsujii, 2007) uses lexical features, orthographic features, semantic features and syntactic features, such as part-of-speech (POS) and shallow parsing.

A handful of work on other domains exists. For example, Wang (2009) introduces NER on clinical notes. A data set is manually annotated and a linear CRF model is trained, which achieves an F-score of 81.48% on their test data set; Downey et al. (2007) employ capitalization cues and n-gram statistics to locate names of a variety of classes in web text; most recently, Chiticariu et al. (2010) design and implement a high-level language NERL that is tuned to simplify the process of building, understanding, and customizing complex rule-based named-entity annotators for different domains.

Ratinov and Roth (2009) systematically study the challenges in NER, compare several solutions and report some interesting findings. For example, they show that a conditional model that does not consider interactions at the output level performs comparably to beam search or Viterbi, and that the BILOU (Beginning, the Inside and the Last tokens of multi-token chunks as well as Unit-length chunks) encoding scheme significantly outperforms the BIO schema (Beginning, the Inside and Outside of a chunk).

In contrast to the above work, our study focuses on NER for tweets, a new genre of texts, which are short, noise prone and ungrammatical.

2.3 Semi-supervised Learning for NER

Semi-supervised learning exploits both labeled and un-labeled data. It proves useful when labeled data is scarce and hard to construct while unlabeled data is abundant and easy to access.

Bootstrapping is a typical semi-supervised learning method. It iteratively adds data that has been confidently labeled but is also informative to its training set, which is used to re-train its model. Jiang and Zhai (2007) propose a balanced bootstrapping algorithm and successfully apply it to NER. Their method is based on instance re-weighting, which allows the small amount of the bootstrapped training sets to have an equal weight to the large source domain training set. Wu et al. (2009) propose another bootstrapping algorithm that selects bridging instances from an unlabeled target domain, which are informative about the target domain and are also easy to be correctly labeled. We adopt bootstrapping as well, but use human labeled tweets as seeds.

Another representative of semi-supervised learning is learning a robust representation of the input from unlabeled data. Miller et al. (2004) use word clusters (Brown et al., 1992) learned from unlabeled text, resulting in a performance improvement of NER. Guo et al. (2009) introduce Latent Semantic Association (LSA) for NER. In our pilot study of NER for tweets, we adopt bag-of-words models to represent a word in tweet, to concentrate our efforts on combining global evidence with local information and semi-supervised learning. We leave it to our future work to explore which is the best input representation for our task.

3 Task Definition

We first introduce some background about tweets, then give a formal definition of the task.

3.1 The Tweets

A tweet is a short text message containing no more than 140 characters in Twitter, the biggest micro-blog service. Here is an example of tweets: “mycraftingworld: #Win Microsoft Office 2010 Home and Student *2Winners* #Contest from @office and @momtobedby8 #Giveaway http://bit.ly/bCsLOr ends 11/14”, where ”mycraftingworld” is the name of the user who published this tweet. Words beginning with the “#” character, like “”#Win”, “#Contest” and “#Giveaway”, are hash tags, usually indicating the topics of the tweet; words starting with “@”, like “@office” and “@momtobedby8”, represent user names, and “http://bit.ly/bCsLOr” is a shortened link.

Twitter users are interested in named entities, such

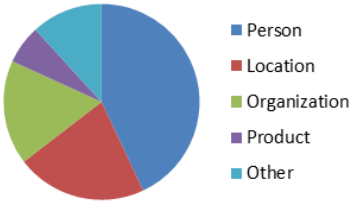

Figure 1: Portion of different types of named entities in tweets. This is based on an investigation of 12,245 randomly sampled tweets, which are manually labeled.

as person names, organization names and product names, as evidenced by the abundant named entities in tweets. According to our investigation on 12,245 randomly sampled tweets that are manually labeled, about 46.8% have at least one named entity. Figure 1 shows the portion of named entities of different types.

3.2 The Task

Given a tweet as input, our task is to identify both the boundary and the class of each mention of entities of predefined types. We focus on four types of entities in our study, i.e., persons, organizations, products, and locations, which, according to our investigation as shown in Figure 1, account for 89.0% of all the named entities.

Here is an example illustrating our task. The input is "...Me without you is like an iphone without apps, Justin Bieber without his hair, Lady gaga without her telephone, it just wouldn..." The expected output is as follows:"...Me without you is like an <PRODUCT >iphone</PRODUCT>without apps, <PERSON>Justin Bieber</PERSON>without his hair,<PERSON>Lady gaga</PERSON> without her telephone, it just wouldn...", meaning that "iphone" is a product, while "Justin Bieber" and "Lady gaga" are persons.

4 Our Method

Now we present our solution to the challenging task of NER for tweets. An overview of our method is first given, followed by detailed discussion of its core components.

4.1 Method Overview

NER task can be naturally divided into two sub-tasks, i.e., boundary detection and type classification. Following the common practice , we adopt a sequential labeling approach to jointly resolve these sub-tasks, i.e., for each word in the input tweet, a label is assigned to it, indicating both the boundary and entity type. Inspired by Ratinov and Roth (2009), we use the BILOU schema.

Algorithm 1 outlines our method, where: $train_s$ and $train_k$ denote two machine learning processes to get the CRF labeler and the KNN classifier, respectively; $repr_w$ converts a word in a tweet into a bag-of-words vector; the $repr_t$ function transforms a tweet into a feature matrix that is later fed into the CRF model; the knn function predicts the class of a word; the $update$ function applies the predicted class by KNN to the inputted tweet; the crf function conducts word level NE labeling;τ and γ represent the minimum labeling confidence of KNN and CRF, respectively, which are experimentally set to 0.1 and 0.001; N (1,000 in our work) denotes the maximum number of new accumulated training data.

Our method, as illustrated in Algorithm 1, repeatedly adds the new confidently labeled tweets to the training set [4] and retrains itself once the number of new accumulated training data goes above the threshold N. Algorithm 1 also demonstrates one striking characteristic of our method: A KNN classifier is applied to determine the label of the current word before the CRF model. The labels of the words that confidently assigned by the KNN classifier are treated as visible variables for the CRF model.

4.2 Model

Our model is hybrid in the sense that a KNN classifier and a CRF model are sequentially applied to the target tweet, with the goal that the KNN classifier captures global coarse evidence while the CRF model fine-grained information encoded in a single tweet and in the gazetteers. Algorithm 2 outlines the training process of KNN, which records the labeled word vector for every type of label.

Algorithm 3 describes how the KNN classifier

[4]The training set ts has a maximum allowable number of items, which is 10,000 in our work. Adding an item into it will cause the oldest one being removed if it is full.

Algorithm 1 NER for Tweets.

Require: Tweet stream i; output stream o.
Require: Training tweets ts; gazetteers ga.

Initialize l_s, the CRF labeler: $l_s = train_s(ts)$.
Initialize l_k, the KNN classifier: $l_k = train_k(ts)$.
Initialize n, the # of new training tweets: $n = 0$.
while Pop a tweet t from i and $t \neq null$ **do**
    for Each word $w \in t$ **do**
        Get the feature vector $\vec{w}$: $\vec{w} = repr_w(w, t)$.
        Classify $\vec{w}$ with knn: $(c, cf) = knn(l_k, \vec{w})$.
        if $cf > \tau$ **then**
            Pre-label: $t = update(t, w, c)$.
        end if
    end for
    Get the feature vector $\vec{t}$: $\vec{t} = repr_t(t, ga)$.
    Label $\vec{t}$ with crf: $(t, cf) = crf(l_s, \vec{t})$.
    Put labeled result (t, cf) into o.
    if $cf > \gamma$ **then**
        Add labeled result t to ts , $n = n + 1$.
    end if
    if $n > N$ **then**
        Retrain l_s: $l_s = train_s(ts)$.
        Retrain l_k: $l_k = train_k(ts)$.
        $n = 0$.
    end if
end while
return o.

Algorithm 2 KNN Training.

Require: Training tweets ts.

Initialize the classifier l_k:$l_k = \varnothing$.
for Each tweet $t \in ts$ **do**
    for Each word,label pair $(w, c) \in t$ **do**
        Get the feature vector $\vec{w}$: $\vec{w} = repr_w(w, t)$.
        Add the $\vec{w}$ and c pair to the classifier: $l_k = l_k \cup \{(\vec{w}, c)\}$.
    end for
end for
return KNN classifier l_k.

predicts the label of the word. In our work, K is experimentally set to 20, which yields the best performance.

Two desirable properties of KNN make it stand out from its alternatives: 1) It can straightforwardly incorporate evidence from new labeled tweets and retraining is fast; and 2) combining with a CRF model, which is good at encoding the subtle interactions between words and their labels, compensates for KNN's incapability to capture fine-grained evidence involving multiple decision points.

Algorithm 3 KNN predication.

Require: KNN classifier l_k ;word vector $\vec{w}$.

Initialize nb, the neighbors of $\vec{w}$: $nb = neigbors(l_k, \vec{w})$.
Calculate the predicted class c^*: $c^* = argmax_c \sum_{(\vec{w}', c') \in nb} \delta(c, c') \cdot cos(\vec{w}, \vec{w}')$.
Calculate the labeling confidence cf: $cf = \frac{\sum_{(\vec{w}', c') \in nb} \delta(c, c') \cdot cos(\vec{w}, \vec{w}')}{\sum_{(\vec{w}', c') \in nb} cos(\vec{w}, \vec{w}')}$.
return The predicted label c^* and its confidence cf.

The Linear CRF model is used as the fine model, with the following considerations: 1) It is well-studied and has been successfully used in state-of-the-art NER systems (Finkel et al., 2005; Wang, 2009); 2) it can output the probability of a label sequence, which can be used as the labeling confidence that is necessary for the semi-supervised learning framework.

In our experiments, the CRF++ [5] toolkit is used to train a linear CRF model. We have written a Viterbi decoder that can incorporate partially observed labels to implement the crf function in Algorithm 1.

4.3 Features

Given a word in a tweet, the KNN classifier considers a text window of size 5 with the word in the middle (Zhang and Johnson, 2003), and extracts bag-of-word features from the window as features. For each word, our CRF model extracts similar features as Wang (2009) and Ratinov and Roth (2009), namely, orthographic features, lexical features and gazetteers related features. In our work, we use the gazetteers provided by Ratinov and Roth (2009).

Two points are worth noting here. One is that before feature extraction for either the KNN or the CRF, stop words are removed. The stop words used here are mainly from a set of frequently-used words [6]. The other is that tweet meta data is normalized, that is, every link becomes *LINK* and every

[5] http://crfpp.sourceforge.net/

[6] http://www.textfixer.com/resources/common-english-words.txt

account name becomes *ACCOUNT*. Hash tags are treated as common words.

4.4 Discussion

We now discuss several design considerations related to the performance of our method, i.e., additional features, gazetteers and alternative models.

Additional Features. Features related to chunking and parsing are not adopted in our final system, because they give only a slight performance improvement while a lot of computing resources are required to extract such features. The ineffectiveness of these features is linked to the noisy and informal nature of tweets. Word class (Brown et al., 1992) features are not used either, which prove to be unhelpful for our system. We are interested in exploring other tweet representations, which may fit our NER task, for example the LSA models (Guo et al., 2009).

Gazetteers. In our work, gazetteers prove to be substantially useful, which is consistent with the observation of Ratinov and Roth (2009). However, the gazetteers used in our work contain noise, which hurts the performance. Moreover, they are static, directly from Ratinov and Roth (2009), thus with a relatively lower coverage, especially for person names and product names in tweets. We are developing tools to clean the gazetteers. In future, we plan to feed the fresh entities correctly identified from tweets back into the gazetteers. The correctness of an entity can rely on its frequency or other evidence.

Alternative Models. We have replaced KNN by other classifiers, such as those based on Maximum Entropy and Support Vector Machines, respectively. KNN consistently yields comparable performance, while enjoying a faster retraining speed. Similarly, to study the effectiveness of the CRF model, it is replaced by its alternations, such as the HMM labeler and a beam search plus a maximum entropy based classifier. In contrast to what is reported by Ratinov and Roth (2009), it turns out that the CRF model gives remarkably better results than its competitors. Note that all these evaluations are on the same training and testing data sets as described in Section 5.1.

5 Experiments

In this section, we evaluate our method on a manually annotated data set and show that our system outperforms the baselines. The contributions of the combination of KNN and CRF as well as the semi-supervised learning are studied, respectively.

5.1 Data Preparation

We use the Twigg SDK [7] to crawl all tweets from April 20^{th} 2010 to April 25^{th} 2010, then drop non-English tweets and get about 11,371,389, from which 15,800 tweets are randomly sampled, and are then labeled by two independent annotators, so that the beginning and the end of each named entity are marked with <TYPE> and </TYPE>, respectively. Here TYPE is PERSON, PRODUCT, ORGANIZATION or LOCATION. 3555 tweets are dropped because of inconsistent annotation. Finally we get 12,245 tweets, forming the gold-standard data set. Figure 1 shows the portion of named entities of different types. On average, a named entity has 1.2 words. The gold-standard data set is evenly split into two parts: One for training and the other for testing.

5.2 Evaluation Metrics

For every type of named entity, Precision (Pre.), recall (Rec.) and F1 are used as the evaluation metrics. Precision is a measure of what percentage the output labels are correct, and recall tells us to what percentage the labels in the gold-standard data set are correctly labeled, while F1 is the harmonic mean of precision and recall. For the overall performance, we use the average Precision, Recall and F1, where the weight of each name entity type is proportional to the number of entities of that type. These metrics are widely used by existing NER systems to evaluate their performance.

5.3 Baselines

Two systems are used as baselines: One is the dictionary look-up system based on the gazetteers; the other is the modified version of our system without KNN and semi-supervised learning. Hereafter these two baselines are called NER_{DIC} and NER_{BA}, respectively. The OpenNLP and the Stanford parser (Klein and Manning, 2003) are used to extract linguistic features for the baselines and our method.

[7] It is developed by the Bing social search team, and currently is only internally available.

System	Pre.(%)	Rec.(%)	F1(%)
NER_{CB}	81.6	78.8	80.2
NER_{BA}	83.6	68.6	75.4
NER_{DIC}	32.6	25.4	28.6

Table 1: Overall experimental results.

System	Pre.(%)	Rec.(%)	F1(%)
NER_{CB}	78.4	74.5	76.4
NER_{BA}	83.6	68.4	75.2
NER_{DIC}	37.1	29.7	33.0

Table 2: Experimental results on PERSON.

NER_{CB}	83.2	60.4	70.0
NER_{BA}	87.6	52.5	65.7
NER_{DIC}	54.5	11.8	19.4

Table 5: Experimental results on ORGANIZATION.

5.4 Basic Results

Table 1 shows the overall results for the baselines and ours with the name NER_{CB}. Here our system is trained as described in Algorithm 1, combining a KNN classifier and a CRF labeler, with semi-supervised learning enabled. As can be seen from Table 1, on the whole, our method significantly outperforms (with $p < 0.001$) the baselines. Tables 2-5 report the results on each entity type, indicating that our method consistently yields better results on all entity types.

5.5 Effects of KNN Classifier

Table 6 shows the performance of our method without combining the KNN classifier, denoted by NER_{CB-KNN}. A drop in performance is observed then. We further check the confidently predicted labels of the KNN classifier, which account for about 22.2% of all predications, and find that its F1 is as high as 80.2% while the baseline system based on the CRF model achieves only an F1 of 75.4%. This largely explains why the KNN classifier helps the CRF labeler. The KNN classifier is replaced with its competitors, and only a slight difference in performance is observed. We do observe that retraining KNN is obviously faster.

5.6 Effects of the CRF Labeler

Similarly, the CRF model is replaced by its alternatives. As is opposite to the finding of Ratinov and Roth (2009), the CRF model gives remarkably better results, i.e., 2.1% higher in F1 than its best followers (with $p < 0.001$). Table 7 shows the overall performance of the CRF labeler with various feature set combinations, where F_o, F_l and F_g denote the orthographic features, the lexical features and the gazetteers related features, respectively. It can be seen from Table 7 that the lexical and gazetteer related features are helpful. Other advanced features such as chunking are also explored but with no significant improvement.

5.7 Effects of Semi-supervised Learning

Table 8 compares our method with its modified version without semi-supervised learning, suggesting that semi-supervised learning considerably boosts the performance. To get more details about self-training, we evenly divide the test data into 10 parts and feed them into our method sequentially; we record the average F1 score on each part, as shown in Figure 2.

5.8 Error Analysis

Errors made by our system on the test set fall into three categories. The first kind of error, accounting for 35.5% of all errors, is largely related to slang expressions and informal abbreviations. For example, our method identifies "Cali", which actually means "California", as a PERSON in the tweet "i love Cali so much". In future, we can design a normalization

System	Pre.(%)	Rec.(%)	F1(%)
NER_{CB}	81.6	78.8	80.2
NER_{CB-KNN}	82.6	74.8	78.5

Table 6: Overall performance of our system with and without the KNN classifier, respectively.

Features	Pre.(%)	Rec.(%)	F1(%)
F_o	71.3	42.8	53.5
$F_o + F_l$	76.2	44.2	55.9
$F_o + F_g$	80.5	66.2	72.7
$F_o + F_l + F_g$	82.6	74.8	78.5

Table 7: Overview performance of the CRF labeler (combined with KNN) with different feature sets.

component to handle such slang expressions and informal abbreviations.

The second kind of error, accounting for 37.2% of all errors, is mainly attributed to the data sparseness. For example, for this tweet "come to see jaxon someday", our method mistakenly labels "jaxon" as a LOCATION, which actually denotes a PERSON. This error is understandable somehow, since this tweet is one of the earliest tweets that mention "jaxon", and at that time there was no strong evidence supporting that it represents a person. Possible solutions to these errors include continually enriching the gazetteers and aggregating additional external knowledge from other channels such as traditional news.

The last kind of error, which represents 27.3% of all errors, somehow links to the noise prone nature of tweets. Consider this tweet "wesley snipes ws cought 4 nt payin tax coz ths celebz dnt take it cirus.", in which "wesley snipes" is not identified as a PERSON but simply ignored by our method, because this tweet is too noisy to provide effective features. Tweet normalization technology seems a possible solution to alleviate this kind of error.

Features	Pre.(%)	Rec.(%)	F1(%)
NER_{CB}	81.6	78.8	80.2
NER'_{CB}	82.1	71.9	76.7

Table 8: Performance of our system with and without semi-supervised learning, respectively.

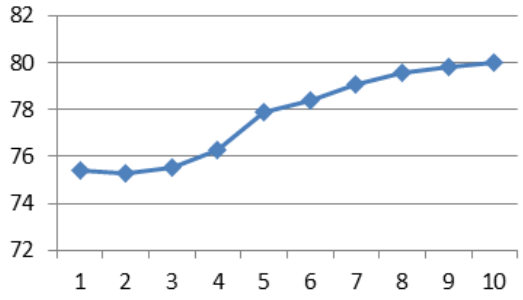

Figure 2: F1 score on 10 test data sets sequentially fed into the system, each with 600 instances. Horizontal and vertical axes represent the sequential number of the test data set and the averaged F1 score (%), respectively.

6 Conclusions and Future work

We propose a novel NER system for tweets, which combines a KNN classifier with a CRF labeler under a semi-supervised learning framework. The KNN classifier collects global information across recently labeled tweets while the CRF labeler exploits information from a single tweet and from the gazetteers. A serials of experiments show the effectiveness of our method, and particularly, show the positive effects of KNN and semi-supervised learning.

In future, we plan to further improve the performance of our method through two directions. Firstly, we hope to develop tweet normalization technology to make tweets friendlier to the NER task. Secondly, we are interested in integrating new entities from tweets or other channels into the gazetteers.

Acknowledgments

Lexical Normalisation of Short Text Messages: Makn Sens a #twitter

Bo Han and **Timothy Baldwin**
NICTA Victoria Research Laboratory

hanb@student.unimelb.edu.au tb@ldwin.net

Abstract

Twitter provides access to large volumes of data in real time, but is notoriously noisy, hampering its utility for NLP. In this paper, we target out-of-vocabulary words in short text messages and propose a method for identifying and normalising ill-formed words. Our method uses a classifier to detect ill-formed words, and generates correction candidates based on morphophonemic similarity. Both word similarity and context are then exploited to select the most probable correction candidate for the word. The proposed method doesn't require any annotations, and achieves state-of-the-art performance over an SMS corpus and a novel dataset based on Twitter.

1 Introduction

Twitter and other micro-blogging services are highly attractive for information extraction and text mining purposes, as they offer large volumes of real-time data, with around 65 millions tweets posted on Twitter per day in June 2010 (Twitter, 2010). The quality of messages varies significantly, however, ranging from high quality newswire-like text to meaningless strings. Typos, ad hoc abbreviations, phonetic substitutions, ungrammatical structures and emoticons abound in short text messages, causing grief for text processing tools (Sproat et al., 2001; Ritter et al., 2010). For instance, presented with the input *u must be talkin bout the paper but I was thinkin movies* ("You must be talking about the paper but I was thinking movies"),[1] the Stanford parser (Klein and Manning, 2003; de Marneffe et al., 2006) analyses *bout the paper* and *thinkin movies* as a clause and noun phrase, respectively, rather than a prepositional phrase and verb phrase. If there were some way of preprocessing the message to produce a more canonical lexical rendering, we would expect the quality of the parser to improve appreciably. Our aim in this paper is this task of lexical normalisation of noisy English text, with a particular focus on Twitter and SMS messages. In this paper, we will collectively refer to individual instances of typos, ad hoc abbreviations, unconventional spellings, phonetic substitutions and other causes of lexical deviation as "ill-formed words".

The message normalisation task is challenging. It has similarities with spell checking (Peterson, 1980), but differs in that ill-formedness in text messages is often intentional, whether due to the desire to save characters/keystrokes, for social identity, or due to convention in this text sub-genre. We propose to go beyond spell checkers, in performing deabbreviation when appropriate, and recovering the canonical word form of commonplace shorthands like *b4* "before", which tend to be considered beyond the remit of spell checking (Aw et al., 2006). The free writing style of text messages makes the task even more complex, e.g. with word lengthening such as *goooood* being commonplace for emphasis. In addition, the detection of ill-formed words is difficult due to noisy context.

Our objective is to restore ill-formed words to their canonical lexical forms in standard English. Through a pilot study, we compared OOV words in Twitter and SMS data with other domain corpora,

[1] Throughout the paper, we will provide a normalised version of examples as a gloss in double quotes.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 368–378,
Portland, Oregon, June 19-24, 2011.

revealing their characteristics in OOV word distribution. We found Twitter data to have an unsurprisingly long tail of OOV words, suggesting that conventional supervised learning will not perform well due to data sparsity. Additionally, many ill-formed words are ambiguous, and require context to disambiguate. For example, *Gooood* may refer to *Good* or *God* depending on context. This provides the motivation to develop a method which does not require annotated training data, but is able to leverage context for lexical normalisation. Our approach first generates a list of candidate canonical lexical forms, based on morphological and phonetic variation. Then, all candidates are ranked according to a list of features generated from noisy context and similarity between ill-formed words and candidates. Our proposed cascaded method is shown to achieve state-of-the-art results on both SMS and Twitter data.

Our contributions in this paper are as follows: (1) we conduct a pilot study on the OOV word distribution of Twitter and other text genres, and analyse different sources of non-standard orthography in Twitter; (2) we generate a text normalisation dataset based on Twitter data; (3) we propose a novel normalisation approach that exploits dictionary lookup, word similarity and word context, without requiring annotated data; and (4) we demonstrate that our method achieves state-of-the-art accuracy over both SMS and Twitter data.

2 Related work

The noisy channel model (Shannon, 1948) has traditionally been the primary approach to tackling text normalisation. Suppose the ill-formed text is T and its corresponding standard form is S, the approach aims to find $\arg\max P(S|T)$ by computing $\arg\max P(T|S)P(S)$, in which $P(S)$ is usually a language model and $P(T|S)$ is an error model. Brill and Moore (2000) characterise the error model by computing the product of operation probabilities on slice-by-slice string edits. Toutanova and Moore (2002) improve the model by incorporating pronunciation information. Choudhury et al. (2007) model the word-level text generation process for SMS messages, by considering graphemic/phonetic abbreviations and unintentional typos as hidden Markov model (HMM) state transitions and emissions, respectively (Rabiner, 1989). Cook and Stevenson (2009) expand the error model by introducing inference from different erroneous formation processes, according to the sampled error distribution. While the noisy channel model is appropriate for text normalisation, $P(T|S)$, which encodes the underlying error production process, is hard to approximate accurately. Additionally, these methods make the strong assumption that a token $t_i \in T$ only depends on $s_i \in S$, ignoring the context around the token, which could be utilised to help in resolving ambiguity.

Statistical machine translation (SMT) has been proposed as a means of context-sensitive text normalisation, by treating the ill-formed text as the source language, and the standard form as the target language. For example, Aw et al. (2006) propose a phrase-level SMT SMS normalisation method with bootstrapped phrase alignments. SMT approaches tend to suffer from a critical lack of training data, however. It is labor intensive to construct an annotated corpus to sufficiently cover ill-formed words and context-appropriate corrections. Furthermore, it is hard to harness SMT for the lexical normalisation problem, as even if phrase-level re-ordering is suppressed by constraints on phrase segmentation, word-level re-orderings within a phrase are still prevalent.

Some researchers have also formulated text normalisation as a speech recognition problem. For example, Kobus et al. (2008) firstly convert input text tokens into phonetic tokens and then restore them to words by phonetic dictionary lookup. Beaufort et al. (2010) use finite state methods to perform French SMS normalisation, combining the advantages of SMT and the noisy channel model. Kaufmann and Kalita (2010) exploit a machine translation approach with a preprocessor for syntactic (rather than lexical) normalisation.

Predominantly, however, these methods require large-scale annotated training data, limiting their adaptability to new domains or languages. In contrast, our proposed method doesn't require annotated data. It builds on the work on SMS text normalisation, and adapts it to Twitter data, exploiting multiple data sources for normalisation.

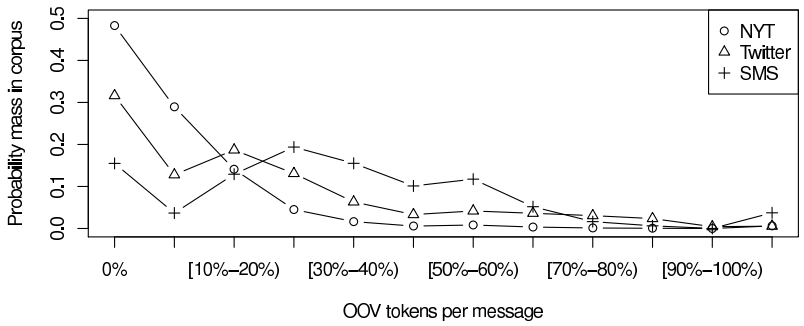

Figure 1: Out-of-vocabulary word distribution in English Gigaword (NYT), Twitter and SMS data

3 Scoping Text Normalisation

3.1 Task Definition of Lexical Normalisation

We define the task of text normalisation to be a mapping from "ill-formed" OOV lexical items to their standard lexical forms, focusing exclusively on English for the purposes of this paper. We define the task as follows:

- only OOV words are considered for normalisation;
- normalisation must be to a single-token word, meaning that we would normalise *smokin* to *smoking*, but not *imo* to *in my opinion*; a side-effect of this is to permit lower-register contractions such as *gonna* as the canonical form of *gunna* (given that *going to* is out of scope as a normalisation candidate, on the grounds of being multi-token).

Given this definition, our first step is to identify candidate tokens for lexical normalisation, where we examine all tokens that consist of alphanumeric characters, and categorise them into in-vocabulary (IV) and out-of-vocabulary (OOV) words, relative to a dictionary. The OOV word definition is somewhat rough, because it includes neologisms and proper nouns like *hopeable* or *WikiLeaks* which have not made their way into the dictionary. However, it greatly simplifies the candidate identification task, at the cost of pushing complexity downstream to the word detection task, in that we need to explicitly distinguish between correct OOV words and ill-formed OOV words such as typos (e.g. *earthquak* "earthquake"), register-specific single-word abbreviations (e.g. *lv* "love"), and phonetic substitutions (e.g. *2morrow* "tomorrow").

An immediate implication of our task definition is that ill-formed words which happen to coincide with an IV word (e.g. the misspelling of *can't* as *cant*) are outside the scope of this research. We also consider that deabbreviation largely falls outside the scope of text normalisation, as abbreviations can be formed freely in standard English. Note that single-word abbreviations such as *govt* "government" are very much within the scope of lexical normalisation, as they are OOV and match to a single token in their standard lexical form.

Throughout this paper, we use the GNU aspell dictionary (v0.60.6)[2] to determine whether a token is OOV. In tokenising the text, hyphenanted tokens and tokens containing apostrophes (e.g. *take-off* and *won't*, resp.) are treated as a single token. Twitter mentions (e.g. *@twitter*), hashtags (e.g. *#twitter*) and urls (e.g. *twitter.com*) are excluded from consideration for normalisation, but left in situ for context modelling purposes. Dictionary lookup of Internet slang is performed relative to a dictionary of 5021 items collected from the Internet.[3]

3.2 OOV Word Distribution and Types

To get a sense of the relative need for lexical normalisation, we perform analysis of the distribution of OOV words in different text types. In particular, we calculate the proportion of OOV tokens per message (or sentence, in the case of edited text), bin the messages according to the OOV token proportion, and plot the probability mass contained in each bin for a given text type. The three corpora we compare

[2]We remove all one character tokens, except *a* and *I*, and treat *RT* as an IV word.

[3]`http://www.noslang.com`

are the New York Times (NYT),[4] SMS,[5] and Twitter.[6] The results are presented in Figure 1.

Both SMS and Twitter have a relatively flat distribution, with Twitter having a particularly large tail: around 15% of tweets have 50% or more OOV tokens. This has implications for any context modelling, as we cannot rely on having only isolated occurrences of OOV words. In contrast, NYT shows a more Zipfian distribution, despite the large number of proper names it contains.

While this analysis confirms that Twitter and SMS are similar in being heavily laden with OOV tokens, it does not shed any light on the relative similarity in the makeup of OOV tokens in each case. To further analyse the two data sources, we extracted the set of OOV terms found exclusively in SMS and Twitter, and analysed each. Manual analysis of the two sets revealed that most OOV words found only in SMS were personal names. The Twitter-specific set, on the other hand, contained a heterogeneous collection of ill-formed words and proper nouns. This suggests that Twitter is a richer/noisier data source, and that text normalisation for Twitter needs to be more nuanced than for SMS.

To further analyse the ill-formed words in Twitter, we randomly selected 449 tweets and manually analysed the sources of lexical variation, to determine the phenomena that lexical normalisation needs to deal with. We identified 254 token instances of lexical normalisation, and broke them down into categories, as listed in Table 1. "Letter" refers to instances where letters are missing or there are extraneous letters, but the lexical correspondence to the target word form is trivially accessible (e.g. *shuld* "should"). "Number Substitution" refers to instances of letter–number substitution, where numbers have been substituted for phonetically-similar sequences of letters (e.g. *4* "for"). "Letter&Number" refers to instances which have both extra/missing letters and number substitution (e.g. *b4* "before"). "Slang" refers to instances of Internet slang (e.g. *lol* "laugh out loud"), as found in a slang dictionary (see Section 3.1). "Other" is the remainder of the instances, which is predominantly made up of occurrences of spaces having being deleted between words (e.g. *sucha* "such a"). If a given instance belongs to multiple error categories (e.g. "Letter&Number" and it is also found in a slang dictionary), we classify it into the higher-occurring category in Table 1.

Category	Ratio
Letter&Number	2.36%
Letter	72.44%
Number Substitution	2.76%
Slang	12.20%
Other	10.24%

Table 1: Ill-formed word distribution

From Table 1, it is clear that "Letter" accounts for the majority of ill-formed words in Twitter, and that most ill-formed words are based on morphophonemic variations. This empirical finding assists in shaping our strategy for lexical normalisation.

4 Lexical normalisation

Our proposed lexical normalisation strategy involves three general steps: (1) confusion set generation, where we identify normalisation candidates for a given word; (2) ill-formed word identification, where we classify a word as being ill-formed or not, relative to its confusion set; and (3) candidate selection, where we select the standard form for tokens which have been classified as being ill formed. In confusion set generation, we generate a set of IV normalisation candidates for each OOV word type based on morphophonemic variation. We call this set the confusion set of that OOV word, and aim to include all feasible normalisation candidates for the word type in the confusion set. The confusion candidates are then filtered for each token occurrence of a given OOV word, based on their local context fit with a language model.

4.1 Confusion Set Generation

Revisiting our manual analysis from Section 3.2, most ill-formed tokens in Twitter are morphophonemically derived. First, inspired by Kaufmann and Kalita (2010), any repititions of more than 3 letters are reduced back to 3 letters (e.g. *cooool* is re-

[4]Based on 44 million sentences from English Gigaword.

[5]Based on 12.6 thousand SMS messages from How and Kan (2005) and Choudhury et al. (2007).

[6]Based on 1.37 million tweets collected from the Twitter streaming API from Aug to Oct 2010, and filtered for monolingual English messages; see Section 5.1 for details of the language filtering methodology.

Criterion	Recall	Average Candidates
$T_c \leq 1$	40.4%	24
$T_c \leq 2$	76.6%	240
$T_p = 0$	55.4%	65
$T_p \leq 1$	83.4%	1248
$T_p \leq 2$	91.0%	9694
$T_c \leq 2 \vee T_p \leq 1$	88.8%	1269
$T_c \leq 2 \vee T_p \leq 2$	92.7%	9515

Table 2: Recall and average number of candidates for different confusion set generation strategies

duced to *coool*). Second, IV words within a threshold T_c character edit distance of the given OOV word are calculated, as is widely used in spell checkers. Third, the double metaphone algorithm (Philips, 2000) is used to decode the pronunciation of all IV words, and IV words within a threshold T_p edit distance of the given OOV word under phonemic transcription, are included in the confusion set; this allows us to capture OOV words such as *earthquick* "earthquake". In Table 2, we list the recall and average size of the confusion set generated by the final two strategies with different threshold settings, based on our evaluation dataset (see Section 5.1).

The recall for lexical edit distance with $T_c \leq 2$ is moderately high, but it is unable to detect the correct candidate for about one quarter of words. The combination of the lexical and phonemic strategies with $T_c \leq 2 \vee T_p \leq 2$ is more impressive, but the number of candidates has also soared. Note that increasing the edit distance further in both cases leads to an explosion in the average number of candidates, with serious computational implications for downstream processing. Thankfully, $T_c \leq 2 \vee T_p \leq 1$ leads to an extra increment in recall to 88.8%, with only a slight increase in the average number of candidates. Based on these results, we use $T_c \leq 2 \vee T_p \leq 1$ as the basis for confusion set generation.

Examples of ill-formed words where we are unable to generate the standard lexical form are clippings such as *fav* "favourite" and *convo* "conversation".

In addition to generating the confusion set, we rank the candidates based on a trigram language model trained over 1.5GB of clean Twitter data, i.e. tweets which consist of all IV words: despite the prevalence of OOV words in Twitter, the sheer volume of the data means that it is relatively easy to collect large amounts of all-IV messages. To train the language model, we used SRILM (Stolcke, 2002) with the `-<unk>` option. If we truncate the ranking to the top 10% of candidates, the recall drops back to 84% with a 90% reduction in candidates.

4.2 Ill-formed Word Detection

The next step is to detect whether a given OOV word in context is actually an ill-formed word or not, relative to its confusion set. To the best of our knowledge, we are the first to target the task of ill-formed word detection in the context of short text messages, although related work exists for text with lower relative occurrences of OOV words (Izumi et al., 2003; Sun et al., 2007). Due to the noisiness of the data, it is impractical to use full-blown syntactic or semantic features. The most direct source of evidence is IV words around an OOV word. Inspired by work on labelled sequential pattern extraction (Sun et al., 2007), we exploit large-scale edited corpus data to construct dependency-based features.

First, we use the Stanford parser (Klein and Manning, 2003; de Marneffe et al., 2006) to extract dependencies from the NYT corpus (see Section 3.2). For example, from a sentence such as *One obvious difference is the way they look*, we would extract dependencies such as `rcmod(way-6,look-8)` and `nsubj(look-8,they-7)`. We then transform the dependencies into relational features for each OOV word. Assuming that *way* were an OOV word, e.g., we would extract dependencies of the form `(look,way,+2)`, indicating that *look* occurs 2 words after *way*. We choose dependencies to represent context because they are an effective way of capturing key relationships between words, and similar features can easily be extracted from tweets. Note that we don't record the dependency type here, because we have no intention of dependency parsing text messages, due to their noisiness and the volume of the data. The counts of dependency forms are combined together to derive a confidence score, and the scored dependencies are stored in a dependency bank.

Given the dependency-based features, a linear kernel SVM classifier (Fan et al., 2008) is trained on clean Twitter data, i.e. the subset of Twitter messages without OOV words. Each word is repre-

sented by its IV words within a context window of three words to either side of the target word, together with their relative positions in the form of `(word1,word2,position)` tuples, and their score in the dependency bank. These form the positive training exemplars. Negative exemplars are automatically constructed by replacing target words with highly-ranked candidates from their confusion set. Note that the classifier does not require any hand annotation, as all training exemplars are constructed automatically.

To predict whether a given OOV word is ill-formed, we form an exemplar for each of its confusion candidates, and extract `(word1,word2,position)` features. If all its candidates are predicted to be negative by the model, we mark it as correct; otherwise, we treat it as ill-formed, and pass all candidates (not just positively-classified candidates) on to the candidate selection step. For example, given the message *way yu lookin shuld be a sin* and the OOV word *lookin*, we would generate context features for each candidate word such as `(way,looking,-2)`, and classify each such candidate.

In training, it is possible for the exact same feature vector to occur as both positive and negative exemplars. To prevent positive exemplars being contaminated from the automatic generation, we remove all negative instances in such cases. The `(word1,word2,position)` features are sparse and sometimes lead to conservative results in ill-formed word detection. That is, without valid features, the SVM classifier tends to label uncertain cases as correct rather than ill-formed words. This is arguably the right approach to normalisation, in choosing to under- rather than over-normalise in cases of uncertainty.

As the context for a target word often contains OOV words which don't occur in the dependency bank, we expand the dependency features to include context tokens up to a phonemic edit distance of 1 from context tokens in the dependency bank. In this way, we generate dependency-based features for context words such as *seee* "see" in `(seee, flm, +2)` (based on the target word *flm* in the context of *flm to seee*). However, expanded dependency features may introduce noise, and we therefore introduce expanded dependency weights $w_d \in \{0.0, 0.5, 1.0\}$ to ameliorate the effects of noise: a weight of $w_d = 0.0$ means no expansion, while 1.0 means expanded dependencies are indistinguishable from non-expanded (strict match) dependencies.

We separately introduce a threshold $t_d \in \{1, 2, ..., 10\}$ on the number of positive predictions returned by the detection classifier over the set of normalisation candidates for a given OOV token: the token is considered to be ill-formed iff t_d or more candidates are positively classified, i.e. predicted to be correct candidates.

4.3 Candidate Selection

For OOV words which are predicted to be ill-formed, we select the most likely candidate from the confusion set as the basis of normalisation. The final selection is based on the following features, in line with previous work (Wong et al., 2006; Cook and Stevenson, 2009).

Lexical edit distance, phonemic edit distance, prefix substring, suffix substring, and the longest common subsequence (LCS) are exploited to capture morphophonemic similarity. Both lexical and phonemic edit distance (ED) are normalised by the reciprocal of $exp(ED)$. The prefix and suffix features are intended to capture the fact that leading and trailing characters are frequently dropped from words, e.g. in cases such as *ish* and *talkin*. We calculate the ratio of the LCS over the maximum string length between ill-formed word and the candidate, since the ill-formed word can be either longer or shorter than (or the same size as) the standard form. For example, *mve* can be restored to either *me* or *move*, depending on context. We normalise these ratios following Cook and Stevenson (2009).

For context inference, we employ both language model- and dependency-based frequency features. Ranking by language model score is intuitively appealing for candidate selection, but our trigram model is trained only on clean Twitter data and ill-formed words often don't have sufficient context for the language model to operate effectively, as in *bt* "but" in *say 2 sum1 bt nt gonna say* "say to someone but not going to say". To consolidate the context modelling, we obtain dependencies from the dependency bank used in ill-formed word detection. Although text messages are of a different genre to edited newswire text, we assume they form similar

dependencies based on the common goal of getting across the message effectively. The dependency features can be used in noisy contexts and are robust to the effects of other ill-formed words, as they do not rely on contiguity. For example, *uz* "use" in *i did #tt uz me and yu*, dependencies can capture relationships like `aux(use-4, do-2)`, which is beyond the capabilities of the language model due to the hashtag being treated as a correct OOV word.

5 Experiments

5.1 Dataset and baselines

The aim of our experiments is to compare the effectiveness of different methodologies over text messages, based on two datasets: (1) an SMS corpus (Choudhury et al., 2007); and (2) a novel Twitter dataset developed as part of this research, based on a random sampling of 549 English tweets. The English tweets were annotated by three independent annotators. All OOV words were pre-identified, and the annotators were requested to determine: (a) whether each OOV word was ill-formed or not; and (b) what the standard form was for ill-formed words, subject to the task definition outlined in Section 3.1. The total number of ill-formed words contained in the SMS and Twitter datasets were 3849 and 1184, respectively.[7]

The language filtering of Twitter to automatically identify English tweets was based on the language identification method of Baldwin and Lui (2010), using the EuroGOV dataset as training data, a mixed unigram/bigram/trigram byte feature representation, and a skew divergence nearest prototype classifier.

We reimplemented the state-of-art noisy channel model of Cook and Stevenson (2009) and SMT approach of Aw et al. (2006) as benchmark methods. We implement the SMT approach in Moses (Koehn et al., 2007), with synthetic training and tuning data of 90,000 and 1000 sentence pairs, respectively. This data is randomly sampled from the 1.5GB of clean Twitter data, and errors are generated according to distribution of SMS corpus. The 10-fold cross-validated BLEU score (Papineni et al., 2002) over this data is 0.81.

[7]The Twitter dataset is available at `http://www.csse.unimelb.edu.au/research/lt/resources/lexnorm/`.

In addition to comparing our method with competitor methods, we also study the contribution of different feature groups. We separately compare dictionary lookup over our Internet slang dictionary, the contextual feature model, and the word similarity feature model, as well as combinations of these three.

5.2 Evaluation metrics

The evaluation of lexical normalisation consists of two stages (Hirst and Budanitsky, 2005): (1) ill-formed word detection, and (2) candidate selection. In terms of detection, we want to make sense of how well the system can identify ill-formed words and leave correct OOV words untouched. This step is crucial to further normalisation, because if correct OOV words are identified as ill-formed, the candidate selection step can never be correct. Conversely, if an ill-formed word is predicted to be correct, the candidate selection will have no chance to normalise it.

We evaluate detection performance by token-level precision, recall and F-score ($\beta = 1$). Previous work over the SMS corpus has assumed perfect ill-formed word detection and focused only on the candidate selection step, so we evaluate ill-formed word detection for the Twitter data only.

For candidate selection, we once again evaluate using token-level precision, recall and F-score. Additionally, we evaluate using the BLEU score over the normalised form of each message, as the SMT method can lead to perturbations of the token stream, vexing standard precision, recall and F-score evaluation.

5.3 Results and Analysis

First, we test the impact of the w_d and t_d values on ill-formed word detection effectiveness, based on dependencies from either the Spinn3r blog corpus (Blog: Burton et al. (2009)) or NYT. The results for precision, recall and F-score are presented in Figure 2.

Some conclusions can be drawn from the graphs. First, higher detection threshold values (t_d) give better precision but lower recall. Generally, as t_d is raised from 1 to 10, the precision improves slightly but recall drops dramatically, with the net effect that the F-score decreases monotonically. Thus, we use a

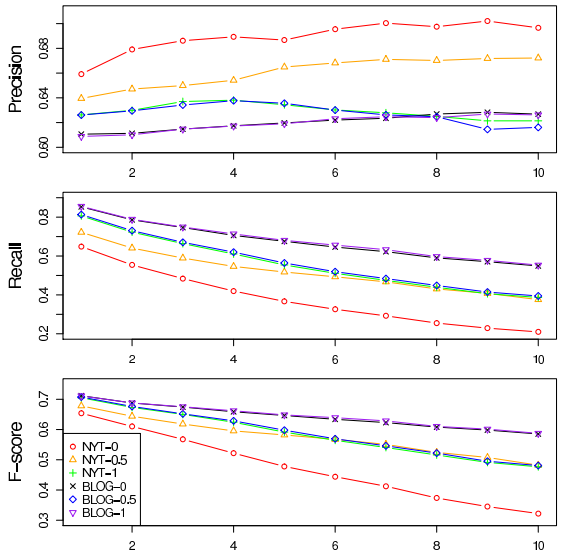

Figure 2: Ill-formed word detection precision, recall and F-score

smaller threshold, i.e. $t_d = 1$. Second, there are differences between the two corpora, with dependencies from the Blog corpus producing slightly lower precision but higher recall, compared with the NYT corpus. The lower precision for the Blog corpus appears to be due to the text not being as clean as NYT, introducing parser errors. Nevertheless, the difference in F-score between the two corpora is insignificant. Third, we obtain the best results, especially in terms of precision, for $w_d = 0.5$, i.e. with expanded dependencies, but penalised relative to non-expanded dependencies.

Overall, the best F-score is 71.2%, with a precision of 61.1% and recall of 85.3%, obtained over the Blog corpus with $t_d = 1$ and $w_d = 0.5$. Clearly there is significant room for immprovements in these results. We leave the improvement of ill-formed word detection for future work, and perform evaluation of candidate selection for Twitter assuming perfect ill-formed word detection, as for the SMS data.

From Table 3, we see that the general performance of our proposed method on Twitter is better than that on SMS. To better understand this trend, we examined the annotations in the SMS corpus, and found them to be looser than ours, because they have different task specifications than our lexical normalisation. In our annotation, the annotators only normalised ill-formed word if they had high confidence of how to normalise, as with *talkin* "talking". For ill-formed words where they couldn't be certain of the standard form, the tokens were left untouched. However, in the SMS corpus, annotations such as *sammis* "same" are also included. This leads to a performance drop for our method over the SMS corpus.

The noisy channel method of Cook and Stevenson (2009) shares similar features with word similarity ("WS"), However, when word similarity and context support are combined ("WS+CS"), our method outperforms the noisy channel method by about 7% and 12% in F-score over SMS and Twitter corpora, respectively. This can be explained as follows. First, the Cook and Stevenson (2009) method is type-based, so all token instances of a given ill-formed word will be normalised identically. In the Twitter data, however, the same word can be normalised differently depending on context, e.g. *hw* "how" in *so hw many time remaining so I can calculate it?* vs. *hw* "homework" in *I need to finish my hw first*. Second, the noisy channel method was developed specifically for SMS normalisation, in which clipping is the most prevalent form of lexical variation, while in the Twitter data, we commonly have instances of word lengthening for emphasis, such as *moviiie* "movie". Having said this, our method is superior to the noisy channel method over both the SMS and Twitter data.

The SMT approach is relatively stable on the two datasets, but well below the performance of our method. This is due to the limitations of the training data: we obtain the ill-formed words and their standard forms from the SMS corpus, but the ill-formed words in the SMS corpus are not sufficient to cover those in the Twitter data (and we don't have sufficient Twitter data to train the SMT method directly). Thus, novel ill-formed words are missed in normalisation. This shows the shortcoming of supervised data-driven approaches that require annotated data to cover all possibilities of ill-formed words in Twitter.

The dictionary lookup method ("DL") unsurprisingly achieves the best precision, but the recall on Twitter is not competitive. Consequently, the Twitter normalisation cannot be tackled with dictionary lookup alone, although it is an effective preprocessing strategy when combined with more ro-

Dataset	*Evaluation*	*NC*	*MT*	*DL*	*WS*	*CS*	*WS+CS*	*DL+WS+CS*

	Recall	0.464	—	0.597	0.520	0.116	0.531	**0.754**
	F-score	0.464	—	0.726	0.520	0.116	0.531	**0.755**
	BLEU	0.746	0.700	0.801	0.764	0.612	0.772	**0.876**
Twitter	Precision	0.452	—	**0.961**	0.551	0.194	0.571	0.753
	Recall	0.452	—	0.460	0.551	0.194	0.571	**0.753**
	F-score	0.452	—	0.622	0.551	0.194	0.571	**0.753**
	BLEU	0.857	0.728	0.861	0.878	0.797	0.884	**0.934**

Table 3: Candidate selection effectiveness on different datasets (*NC* = noisy channel model (Cook and Stevenson, 2009); *MT* = SMT (Aw et al., 2006); *DL* = dictionary lookup; *WS* = word similarity; *CS* = context support)

bust techniques such as our proposed method, and effective at capturing common abbreviations such as *gf* "girlfriend".

Of the component methods proposed in this research, word similarity ("WS") achieves higher precision and recall than context support ("CS"), signifying that many of the ill-formed words emanate from morphophonemic variations. However, when combined with word similarity features, context support improves over the basic method at a level of statistical significance (based on randomised estimation, $p < 0.05$: Yeh (2000)), indicating the complementarity of the two methods, especially on Twitter data. The best F-score is achieved when combining dictionary lookup, word similarity and context support ("DL+WS+CS"), in which ill-formed words are first looked up in the slang dictionary, and only if no match is found do we apply our normalisation method.

We found several limitations in our proposed approach by analysing the output of our method. First, not all ill-formed words offer useful context. Some highly noisy tweets contain almost all misspellings and unique symbols, and thus no context features can be extracted. This also explains why "CS" features often fail. For such cases, the method falls back to context-independent normalisation. We found that only 32.6% ill-formed words have all IV words in their context windows. Moreover, the IV words may not occur in the dependency bank, further decreasing the effectiveness of context support features. Second, the different features are linearly combined, where a weighted combination is likely to give better results, although it also requires a certain amount of well-sampled annotations for tuning.

6 Conclusion and Future Work

In this paper, we have proposed the task of lexical normalisation for short text messages, as found in Twitter and SMS data. We found that most ill-formed words are based on morphophonemic variation and proposed a cascaded method to detect and normalise ill-formed words. Our ill-formed word detector requires no explicit annotations, and the dependency-based features were shown to be somewhat effective, however, there was still a lot of room for improvement at ill-formed word detection. In normalisation, we compared our method with two benchmark methods from the literature, and achieved that highest F-score and BLEU score by integrating dictionary lookup, word similarity and context support modelling.

In future work, we propose to pursue a number of directions. First, we plan to improve our ill-formed word detection classifier by introducing an OOV word whitelist. Furthermore, we intend to alleviate noisy contexts with a bootstrapping approach, in which ill-formed words with high confidence and no ambiguity will be replaced by their standard forms, and fed into the normalisation model as new training data.

Abstract

Summarizing and analyzing Twitter content is an important and challenging task. In this paper, we propose to extract topical keyphrases as one way to summarize Twitter. We propose a context-sensitive topical PageRank method for keyword ranking and a probabilistic scoring function that considers both relevance and interestingness of keyphrases for keyphrase ranking. We evaluate our proposed methods on a large Twitter data set. Experiments show that these methods are very effective for topical keyphrase extraction.

1 Introduction

Twitter, a new microblogging website, has attracted hundreds of millions of users who publish short messages (a.k.a. *tweets*) on it. They either publish original tweets or *retweet* (i.e. forward) others' tweets if they find them interesting. Twitter has been shown to be useful in a number of applications, including tweets as social sensors of real-time events (Sakaki et al., 2010), the sentiment prediction power of Twitter (Tumasjan et al., 2010), etc. However, current explorations are still in an early stage and our understanding of Twitter content still remains limited. How to automatically understand, extract and summarize useful Twitter content has therefore become an important and emergent research topic.

In this paper, we propose to extract keyphrases as a way to summarize Twitter content. Traditionally, keyphrases are defined as a short list of terms to summarize the topics of a document (Turney, 2000). It can be used for various tasks such as document summarization (Litvak and Last, 2008) and indexing (Li et al., 2004). While it appears natural to use keyphrases to summarize Twitter content, compared with traditional text collections, keyphrase extraction from Twitter is more challenging in at least two aspects: 1) Tweets are much shorter than traditional articles and not all tweets contain useful information; 2) Topics tend to be more diverse in Twitter than in formal articles such as news reports.

So far there is little work on keyword or keyphrase extraction from Twitter. Wu et al. (2010) proposed to automatically generate personalized tags for Twitter users. However, user-level tags may not be suitable to summarize the overall Twitter content within a certain period and/or from a certain group of people such as people in the same region. Existing work on keyphrase extraction identifies keyphrases from either individual documents or an entire text collection (Turney, 2000; Tomokiyo and Hurst, 2003). These approaches are not immediately applicable to Twitter because it does not make sense to extract keyphrases from a single tweet, and if we extract keyphrases from a whole tweet collection we will mix a diverse range of topics together, which makes it difficult for users to follow the extracted keyphrases.

Therefore, in this paper, we propose to study the novel problem of extracting *topical keyphrases* for summarizing and analyzing Twitter content. In other words, we extract and organize keyphrases by topics learnt from Twitter. In our work, we follow the standard three steps of keyphrase extraction, namely, keyword ranking, candidate keyphrase generation

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 379–388,
Portland, Oregon, June 19-24, 2011.

and keyphrase ranking. For keyword ranking, we modify the Topical PageRank method proposed by Liu et al. (2010) by introducing topic-sensitive score propagation. We find that topic-sensitive propagation can largely help boost the performance. For keyphrase ranking, we propose a principled probabilistic phrase ranking method, which can be flexibly combined with any keyword ranking method and candidate keyphrase generation method. Experiments on a large Twitter data set show that our proposed methods are very effective in topical keyphrase extraction from Twitter. Interestingly, our proposed keyphrase ranking method can incorporate users' interests by modeling the *retweet* behavior. We further examine what topics are suitable for incorporating users' interests for topical keyphrase extraction.

To the best of our knowledge, our work is the first to study how to extract keyphrases from microblogs. We perform a thorough analysis of the proposed methods, which can be useful for future work in this direction.

2 Related Work

Our work is related to unsupervised keyphrase extraction. Graph-based ranking methods are the state of the art in unsupervised keyphrase extraction. Mihalcea and Tarau (2004) proposed to use TextRank, a modified PageRank algorithm to extract keyphrases. Based on the study by Mihalcea and Tarau (2004), Liu et al. (2010) proposed to decompose a traditional random walk into multiple random walks specific to various topics. Language modeling methods (Tomokiyo and Hurst, 2003) and natural language processing techniques (Barker and Cornacchia, 2000) have also been used for unsupervised keyphrase extraction. Our keyword extraction method is mainly based on the study by Liu et al. (2010). The difference is that we model the score propagation with topic context, which can lower the effect of noise, especially in microblogs.

Our work is also related to automatic topic labeling (Mei et al., 2007). We focus on extracting topical keyphrases in microblogs, which has its own challenges. Our method can also be used to label topics in other text collections.

Another line of relevant research is Twitter-related text mining. The most relevant work is by Wu et al. (2010), who directly applied TextRank (Mihalcea and Tarau, 2004) to extract keywords from tweets to tag users. Topic discovery from Twitter is also related to our work (Ramage et al., 2010), but we further extract keyphrases from each topic for summarizing and analyzing Twitter content.

3 Method

3.1 Preliminaries

Let $\mathcal{U}$ be a set of Twitter users. Let $\mathcal{C} = \{\{d_{u,m}\}_{m=1}^{M_u}\}_{u \in \mathcal{U}}$ be a collection of tweets generated by $\mathcal{U}$, where M_u is the total number of tweets generated by user u and $d_{u,m}$ is the m-th tweet of u. Let $\mathcal{V}$ be the vocabulary. $d_{u,m}$ consists of a sequence of words $(w_{u,m,1}, w_{u,m,2}, \ldots, w_{u,m,N_{u,m}})$ where $N_{u,m}$ is the number of words in $d_{u,m}$ and $w_{u,m,n} \in \mathcal{V}$ $(1 \leq n \leq N_{u,m})$. We also assume that there is a set of topics $\mathcal{T}$ over the collection $\mathcal{C}$.

Given $\mathcal{T}$ and $\mathcal{C}$, topical keyphrase extraction is to discover a list of keyphrases for each topic $t \in \mathcal{T}$. Here each keyphrase is a sequence of words.

To extract keyphrases, we first identify topics from the Twitter collection using topic models (Section 3.2). Next for each topic, we run a topical PageRank algorithm to rank keywords and then generate candidate keyphrases using the top ranked keywords (Section 3.3). Finally, we use a probabilistic model to rank the candidate keyphrases (Section 3.4).

3.2 Topic discovery

We first describe how we discover the set of topics $\mathcal{T}$. Author-topic models have been shown to be effective for topic modeling of microblogs (Weng et al., 2010; Hong and Davison, 2010). In Twitter, we observe an important characteristic of tweets: tweets are short and a single tweet tends to be about a single topic. So we apply a modified author-topic model called Twitter-LDA introduced by Zhao et al. (2011), which assumes a single topic assignment for an entire tweet.

The model is based on the following assumptions. There is a set of topics $\mathcal{T}$ in Twitter, each represented by a word distribution. Each user has her topic interests modeled by a distribution over the topics. When a user wants to write a tweet, she first chooses a topic based on her topic distribution. Then she chooses a

1. Draw $\phi^{\mathcal{B}} \sim \text{Dir}(\beta), \pi \sim \text{Dir}(\gamma)$
2. For each topic $t \in \mathcal{T}$,
   (a) draw $\phi^t \sim \text{Dir}(\beta)$
3. For each user $u \in \mathcal{U}$,
   (a) draw $\theta^u \sim \text{Dir}(\alpha)$
   (b) for each tweet $d_{u,m}$
      i. draw $z_{u,m} \sim \text{Multi}(\theta^u)$
      ii. for each word $w_{u,m,n}$
         A. draw $y_{u,m,n} \sim \text{Bernoulli}(\pi)$
         B. draw $w_{u,m,n} \sim \text{Multi}(\phi^{\mathcal{B}})$ if $y_{u,m,n} = 0$ and $w_{u,m,n} \sim \text{Multi}(\phi^{z_{u,m}})$ if $y_{u,m,n} = 1$

Figure 1: The generation process of tweets.

bag of words one by one based on the chosen topic. However, not all words in a tweet are closely related to the topic of that tweet; some are background words commonly used in tweets on different topics. Therefore, for each word in a tweet, the user first decides whether it is a background word or a topic word and then chooses the word from its respective word distribution.

Formally, let ϕ^t denote the word distribution for topic t and $\phi^{\mathcal{B}}$ the word distribution for background words. Let θ^u denote the topic distribution of user u. Let π denote a Bernoulli distribution that governs the choice between background words and topic words. The generation process of tweets is described in Figure 1. Each multinomial distribution is governed by some symmetric Dirichlet distribution parameterized by α, β or γ.

3.3 Topical PageRank for Keyword Ranking

Topical PageRank was introduced by Liu et al. (2010) to identify keywords for future keyphrase extraction. It runs topic-biased PageRank for each topic separately and boosts those words with high relevance to the corresponding topic. Formally, the topic-specific PageRank scores can be defined as follows:

$$R_t(w_i) = \lambda \sum_{j:w_j \to w_i} \frac{e(w_j, w_i)}{O(w_j)} R_t(w_j) + (1-\lambda) P_t(w_i), \quad (1)$$

where $R_t(w)$ is the topic-specific PageRank score of word w in topic t, $e(w_j, w_i)$ is the weight for the edge $(w_j \to w_i)$, $O(w_j) = \sum_{w'} e(w_j, w')$ and λ is a damping factor ranging from 0 to 1. The topic-specific preference value $P_t(w)$ for each word w is its random jumping probability with the constraint that $\sum_{w \in \mathcal{V}} P_t(w) = 1$ given topic t. A large $R_t(\cdot)$ indicates a word is a good candidate keyword in topic t. We denote this original version of the Topical PageRank as *TPR*.

However, the original *TPR* ignores the topic context when setting the edge weights; the edge weight is set by counting the number of co-occurrences of the two words within a certain window size. Taking the topic of "electronic products" as an example, the word "juice" may co-occur frequently with a good keyword "apple" for this topic because of Apple electronic products, so "juice" may be ranked high by this context-free co-occurrence edge weight although it is not related to electronic products. In other words, context-free propagation may cause the scores to be off-topic.

So in this paper, we propose to use a topic context sensitive PageRank method. Formally, we have

$$R_t(w_i) = \lambda \sum_{j:w_j \to w_i} \frac{e_t(w_j, w_i)}{O_t(w_j)} R_t(w_j) + (1-\lambda) P_t(w_i). \quad (2)$$

Here we compute the propagation from w_j to w_i in the context of topic t, namely, the edge weight from w_j to w_i is parameterized by t. In this paper, we compute edge weight $e_t(w_j, w_i)$ between two words by counting the number of co-occurrences of these two words in tweets *assigned to topic* t. We denote this context-sensitive topical PageRank as *cTPR*.

After keyword ranking using *cTPR* or any other method, we adopt a common candidate keyphrase generation method proposed by Mihalcea and Tarau (2004) as follows. We first select the top S keywords for each topic, and then look for combinations of these keywords that occur as frequent phrases in the text collection. More details are given in Section 4.

3.4 Probabilistic Models for Topical Keyphrase Ranking

With the candidate keyphrases, our next step is to rank them. While a standard method is to simply aggregate the scores of keywords inside a candidate keyphrase as the score for the keyphrase, here we propose a different probabilistic scoring function. Our method is based on the following hypotheses about good keyphrases given a topic:

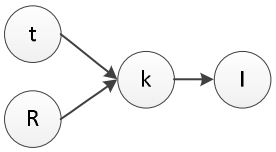

Figure 2: Assumptions of variable dependencies.

Relevance: A good keyphrase should be closely related to the given topic and also discriminative. For example, for the topic "news," "*president obama*" is a good keyphrase while "*math class*" is not.

Interestingness: A good keyphrase should be interesting and can attract users' attention. For example, for the topic "music," "*justin bieber*" is more interesting than "*song player*."

Sometimes, there is a trade-off between these two properties and a good keyphrase has to balance both.

Let R be a binary variable to denote relevance where 1 is relevant and 0 is irrelevant. Let I be another binary variable to denote interestingness where 1 is interesting and 0 is non-interesting. Let k denote a candidate keyphrase. Following the probabilistic relevance models in information retrieval (Lafferty and Zhai, 2003), we propose to use $P(R=1, I=1|t,k)$ to rank candidate keyphrases for topic t. We have

$$\begin{aligned}
& P(R=1, I=1|t,k) \\
= \; & P(R=1|t,k)P(I=1|t,k,R=1) \\
= \; & P(I=1|t,k,R=1)P(R=1|t,k) \\
= \; & P(I=1|k)P(R=1|t,k) \\
= \; & P(I=1|k) \times \frac{P(R=1|t,k)}{P(R=1|t,k)+P(R=0|t,k)} \\
= \; & P(I=1|k) \times \frac{1}{1+\frac{P(R=0|t,k)}{P(R=1|t,k)}} \\
= \; & P(I=1|k) \times \frac{1}{1+\frac{P(R=0,k|t)}{P(R=1,k|t)}} \\
= \; & P(I=1|k) \times \frac{1}{1+\frac{P(R=0|t)}{P(R=1|t)} \times \frac{P(k|t,R=0)}{P(k|t,R=1)}} \\
= \; & P(I=1|k) \times \frac{1}{1+\frac{P(R=0)}{P(R=1)} \times \frac{P(k|t,R=0)}{P(k|t,R=1)}}.
\end{aligned}$$

Here we have assumed that I is independent of t and R given k, i.e. the interestingness of a keyphrase is independent of the topic or whether the keyphrase is relevant to the topic. We have also assumed that R is independent of t when k is unknown, i.e. without knowing the keyphrase, the relevance is independent of the topic. Our assumptions can be depicted by Figure 2.

We further define $\delta = \frac{P(R=0)}{P(R=1)}$. In general we can assume that $P(R=0) \gg P(R=1)$ because there are much more non-relevant keyphrases than relevant ones, that is, $\delta \gg 1$. In this case, we have

$$\begin{aligned}
& \log P(R=1, I=1|t,k) \qquad (3) \\
= \; & \log\Big(P(I=1|k) \times \frac{1}{1+\delta \times \frac{P(k|t,R=0)}{P(k|t,R=1)}}\Big) \\
\approx \; & \log\Big(P(I=1|k) \times \frac{P(k|t,R=1)}{P(k|t,R=0)} \times \frac{1}{\delta}\Big) \\
= \; & \log P(I=1|k) + \log \frac{P(k|t,R=1)}{P(k|t,R=0)} - \log\delta.
\end{aligned}$$

We can see that the ranking score $\log P(R=1, I=1|t,k)$ can be decomposed into two components, a relevance score $\log \frac{P(k|t,R=1)}{P(k|t,R=0)}$ and an interestingness score $\log P(I=1|k)$. The last term $\log\delta$ is a constant and thus not relevant.

Estimating the relevance score

Let a keyphrase candidate k be a sequence of words $(w_1, w_2, \ldots, w_N)$. Based on an independent assumption of words given R and t, we have

$$\begin{aligned}
\log \frac{P(k|t,R=1)}{P(k|t,R=0)} &= \log \frac{P(w_1 w_2 \ldots w_N|t,R=1)}{P(w_1 w_2 \ldots w_N|t,R=0)} \\
&= \sum_{n=1}^{N} \log \frac{P(w_n|t,R=1)}{P(w_n|t,R=0)}. \qquad (4)
\end{aligned}$$

Given the topic model ϕ^t previously learned for topic t, we can set $P(w|t,R=1)$ to ϕ_w^t, i.e. the probability of w under ϕ^t. Following Griffiths and Steyvers (2004), we estimate ϕ_w^t as

$$\phi_w^t = \frac{\#(\mathcal{C}_t, w) + \beta}{\#(\mathcal{C}_t, \cdot) + \beta|\mathcal{V}|}. \qquad (5)$$

Here $\mathcal{C}_t$ denotes the collection of tweets assigned to topic t, $\#(\mathcal{C}_t, w)$ is the number of times w appears in $\mathcal{C}_t$, and $\#(\mathcal{C}_t, \cdot)$ is the total number of words in $\mathcal{C}_t$.

$P(w|t,R=0)$ can be estimated using a smoothed background model.

$$P(w|R=0,t) = \frac{\#(\mathcal{C}, w) + \mu}{\#(\mathcal{C}, \cdot) + \mu|\mathcal{V}|}. \qquad (6)$$

Here $\#(\mathcal{C},\cdot)$ denotes the number of words in the whole collection $\mathcal{C}$, and $\#(\mathcal{C},w)$ denotes the number of times w appears in the whole collection.

After plugging Equation (5) and Equation (6) into Equation (4), we get the following formula for the relevance score:

$$\begin{aligned}
&\log\frac{P(k|t,R=1)}{P(k|t,R=0)}\\
=&\sum_{w\in k}\Big(\log\frac{\#(\mathcal{C}_t,w)+\beta}{\#(\mathcal{C},w)+\mu}+\log\frac{\#(\mathcal{C},\cdot)+\mu|\mathcal{V}|}{\#(\mathcal{C}_t,\cdot)+\beta|\mathcal{V}|}\Big)\\
=&\Big(\sum_{w\in k}\log\frac{\#(\mathcal{C}_t,w)+\beta}{\#(\mathcal{C},w)+\mu}\Big)+|k|\eta, \qquad (7)
\end{aligned}$$

where $\eta=\frac{\#(\mathcal{C},\cdot)+\mu|\mathcal{V}|}{\#(\mathcal{C}_t,\cdot)+\beta|\mathcal{V}|}$ and $|k|$ denotes the number of words in k.

Estimating the interestingness score

To capture the interestingness of keyphrases, we make use of the retweeting behavior in Twitter. We use string matching with `RT` to determine whether a tweet is an original posting or a retweet. If a tweet is interesting, it tends to get retweeted multiple times. Retweeting is therefore a stronger indicator of user interests than tweeting. We use retweet ratio $\frac{|\text{ReTweets}_k|}{|\text{Tweets}_k|}$ to estimate $P(I=1|k)$. To prevent zero frequency, we use a modified add-one smoothing method. Finally, we get

$$\log P(I=1|k)=\log\frac{|\text{ReTweets}_k|+1.0}{|\text{Tweets}_k|+l_{avg}}. \qquad (8)$$

Here $|\text{ReTweets}_k|$ and $|\text{Tweets}_k|$ denote the numbers of retweets and tweets containing the keyphrase k, respectively, and l_{avg} is the average number of tweets that a candidate keyphrase appears in.

Finally, we can plug Equation (7) and Equation (8) into Equation (3) and obtain the following scoring function for ranking:

$$\begin{aligned}
\text{Score}_t(k)=&\log\frac{|\text{ReTweets}_k|+1.0}{|\text{Tweets}_k|+l_{avg}} \qquad (9)\\
&+\left(\sum_{w\in k}\log\frac{\#(\mathcal{C}_t,w)+\beta}{\#(\mathcal{C},w)+\mu}\right)+|k|\eta.
\end{aligned}$$

#user	#tweet	#term	#token
13,307	1,300,300	50,506	11,868,910

Table 1: Some statistics of the data set.

Incorporating length preference

Our preliminary experiments with Equation (9) show that this scoring function usually ranks longer keyphrases higher than shorter ones. However, because our candidate keyphrase are extracted without using any linguistic knowledge such as noun phrase boundaries, longer candidate keyphrases tend to be less meaningful as a phrase. Moreover, for our task of using keyphrases to summarize Twitter, we hypothesize that shorter keyphrases are preferred by users as they are more compact. We would therefore like to incorporate some length preference.

Recall that Equation (9) is derived from $P(R=1,I=1|t,k)$, but this probability does not allow us to directly incorporate any length preference. We further observe that Equation (9) tends to give longer keyphrases higher scores mainly due to the term $|k|\eta$. So here we heuristically incorporate our length preference by removing $|k|\eta$ from Equation (9), resulting in the following final scoring function:

$$\begin{aligned}
\text{Score}_t(k)=&\log\frac{|\text{ReTweets}_k|+1.0}{|\text{Tweets}_k|+l_{avg}} \qquad (10)\\
&+\left(\sum_{w\in k}\log\frac{\#(\mathcal{C}_t,w)+\beta}{\#(\mathcal{C},w)+\mu}\right).
\end{aligned}$$

4 Experiments

4.1 Data Set and Preprocessing

We use a Twitter data set collected from Singapore users for evaluation. We used *Twitter REST API*[1] to facilitate the data collection. The majority of the tweets collected were published in a 20-week period from December 1, 2009 through April 18, 2010. We removed common stopwords and words which appeared in fewer than 10 tweets. We also removed all users who had fewer than 5 tweets. Some statistics of this data set after cleaning are shown in Table 1.

We ran Twitter-LDA with 500 iterations of Gibbs sampling. After trying a few different numbers of

[1] http://apiwiki.twitter.com/w/page/22554663/REST-API-Documentation

topics, we empirically set the number of topics to 30. We set α to $50.0/|\mathcal{T}|$ as Griffiths and Steyvers (2004) suggested, but set β to a smaller value of 0.01 and γ to 20. We chose these parameter settings because they generally gave coherent and meaningful topics for our data set. We selected 10 topics that cover a diverse range of content in Twitter for evaluation of topical keyphrase extraction. The top 10 words of these topics are shown in Table 2.

We also tried the standard LDA model and the author-topic model on our data set and found that our proposed topic model was better or at least comparable in terms of finding meaningful topics. In addition to generating meaningful topics, Twitter-LDA is much more convenient in supporting the computation of tweet-level statistics (e.g. the number of co-occurrences of two words in a specific topic) than the standard LDA or the author-topic model because Twitter-LDA assumes a single topic assignment for an entire tweet.

4.2 Methods for Comparison

As we have described in Section 3.1, there are three steps to generate keyphrases, namely, keyword ranking, candidate keyphrase generation, and keyphrase ranking. We have proposed a context-sensitive topical PageRank method (*cTPR*) for the first step of keyword ranking, and a probabilistic scoring function for the third step of keyphrase ranking. We now describe the baseline methods we use to compare with our proposed methods.

Keyword Ranking

We compare our *cTPR* method with the original topical PageRank method (Equation (1)), which represents the state of the art. We refer to this baseline as *TPR*.

For both *TPR* and *cTPR*, the damping factor is empirically set to 0.1, which always gives the best performance based on our preliminary experiments. We use normalized $P(t|w)$ to set $P_t(w)$ because our preliminary experiments showed that this was the best among the three choices discussed by Liu et al. (2010). This finding is also consistent with what Liu et al. (2010) found.

In addition, we also use two other baselines for comparison: (1) *kwBL1*: ranking by $P(w|t) = \phi_w^t$. (2) *kwBL2*: ranking by $P(t|w) = \frac{P(t)\phi_w^t}{\sum_{t'} P(t')\phi_w^{t'}}$.

Keyphrase Ranking

We use *kpRelInt* to denote our relevance and interestingness based keyphrase ranking function $P(R = 1, I = 1|t, k)$, i.e. Equation (10). β and μ are empirically set to 0.01 and 500. Usually μ can be set to zero, but in our experiments we find that our ranking method needs a more uniform estimation of the background model. We use the following ranking functions for comparison:

- *kpBL1*: Similar to what is used by Liu et al. (2010), we can rank candidate keyphrases by $\sum_{w \in k} f(w)$, where $f(w)$ is the score assigned to word w by a keyword ranking method.
- *kpBL2*: We consider another baseline ranking method by $\sum_{w \in k} \log f(w)$.
- *kpRel*: If we consider only relevance but not interestingness, we can rank candidate keyphrases by $\sum_{w \in k} \log \frac{\#(\mathcal{C}_t, w)+\beta}{\#(\mathcal{C}, w)+\mu}$.

4.3 Gold Standard Generation

Since there is no existing test collection for topical keyphrase extraction from Twitter, we manually constructed our test collection. For each of the 10 selected topics, we ran all the methods to rank keywords. For each method we selected the top 3000 keywords and searched all the combinations of these words as phrases which have a frequency larger than 30. In order to achieve high phraseness, we first computed the minimum value of pointwise mutual information for all bigrams in one combination, and we removed combinations having a value below a threshold, which was empirically set to 2.135. Then we merged all these candidate phrases. We did not consider single-word phrases because we found that it would include too many frequent words that might not be useful for summaries.

We asked two judges to judge the quality of the candidate keyphrases. The judges live in Singapore and had used Twitter before. For each topic, the judges were given the top topic words and a short topic description. Web search was also available. For each candidate keyphrase, we asked the judges to score it as follows: 2 (relevant, meaningful and informative), 1 (relevant but either too general or too specific, or informal) and 0 (irrelevant or meaningless). Here in addition to relevance, the other two criteria, namely, whether a phrase is meaningful and informative, were studied by Tomokiyo and Hurst

Table 2: Top 10 Words of Sample Topics on our Singapore Twitter Dateset.

(2003). We then averaged the scores of the two judges as the final scores. The Cohen's Kappa coefficients of the 10 topics range from 0.45 to 0.80, showing fair to good agreement[2]. We further discarded all candidates with an average score less than 1. The number of the remaining keyphrases for each topic ranges from 56 to 282.

4.4 Evaluation Metrics

Traditionally keyphrase extraction is evaluated using precision and recall on all the extracted keyphrases. We choose not to use these measures for the following reasons: (1) Traditional keyphrase extraction works on single documents while we study topical keyphrase extraction. The gold standard keyphrase list for a single document is usually short and clean, while for each Twitter topic there can be many keyphrases, some are more relevant and interesting than others. (2) Our extracted topical keyphrases are meant for summarizing Twitter content, and they are likely to be directly shown to the users. It is therefore more meaningful to focus on the quality of the top-ranked keyphrases.

Inspired by the popular *nDCG* metric in information retrieval (Järvelin and Kekäläinen, 2002), we define the following normalized keyphrase quality measure (*nKQM*) for a method $\mathcal{M}$:

$$nKQM@K = \frac{1}{|\mathcal{T}|}\sum_{t\in\mathcal{T}}\frac{\sum_{j=1}^{K}\frac{1}{\log_2(j+1)}score(\mathcal{M}_{t,j})}{IdealScore_{(K,t)}},$$

where $\mathcal{T}$ is the set of topics, $\mathcal{M}_{t,j}$ is the j-th keyphrase generated by method $\mathcal{M}$ for topic t, $score(\cdot)$ is the average score from the two human judges, and $IdealScore_{(K,t)}$ is the normalization factor—score of the top K keyphrases of topic t under the ideal ranking. Intuitively, if $\mathcal{M}$ returns more good keyphrases in top ranks, its *nKQM* value will be higher.

We also use mean average precision (MAP) to measure the overall performance of keyphrase ranking:

$$MAP = \frac{1}{|\mathcal{T}|}\sum_{t\in\mathcal{T}}\frac{1}{N_{\mathcal{M},t}}\sum_{j=1}^{|\mathcal{M}_t|}\frac{N_{\mathcal{M},t,j}}{j}\mathbb{1}(score(\mathcal{M}_{t,j})\geq 1),$$

where $\mathbb{1}(\mathcal{S})$ is an indicator function which returns 1 when $\mathcal{S}$ is true and 0 otherwise, $N_{\mathcal{M},t,j}$ denotes the number of correct keyphrases among the top j keyphrases returned by $\mathcal{M}$ for topic t, and $N_{\mathcal{M},t}$ denotes the total number of correct keyphrases of topic t returned by $\mathcal{M}$.

4.5 Experiment Results

Evaluation of keyword ranking methods

Since keyword ranking is the first step for keyphrase extraction, we first compare our keyword ranking method *cTPR* with other methods. For each topic, we pooled the top 20 keywords ranked by all four methods. We manually examined whether a word is a good keyword or a noisy word based on topic context. Then we computed the average number of noisy words in the 10 topics for each method. As shown in Table 5, we can observe that *cTPR* performed the best among the four methods.

Since our final goal is to extract topical keyphrases, we further compare the performance of *cTPR* and *TPR* when they are combined with a keyphrase ranking algorithm. Here we use the two

[2]We find that judgments on topics related to social media (e.g. T_4) and daily life (e.g. T_{13}) tend to have a higher degree of disagreement.

	Method	nKQM@5	nKQM@10	nKQM@25	nKQM@50	MAP

baseline keyphrase ranking algorithms *kpBL1* and *kpBL2*. The comparison is shown in Table 3. We can see that *cTPR* is consistently better than the three other methods for both *kpBL1* and *kpBL2*.

Evaluation of keyphrase ranking methods

In this section we compare keypharse ranking methods. Previously we have shown that *cTPR* is better than *TPR*, *kwBL1* and *kwBL2* for keyword ranking. Therefore we use *cTPR* as the keyword ranking method and examine the keyphrase ranking method *kpRelInt* with *kpBL1*, *kpBL2* and *kpRel* when they are combined with *cTPR*. The results are shown in Table 4. From the results we can see the following: (1) Keyphrase ranking methods *kpRelInt* and *kpRel* are more effective than *kpBL1* and *kpBL2*, especially when using the *nKQM* metric. (2) *kpRelInt* is better than *kpRel*, especially for the *nKQM* metric. Interestingly, we also see that for the *nKQM* metric, *kpBL1*, which is the most commonly used keyphrase ranking method, did not perform as well as *kpBL2*, a modified version of *kpBL1*.

We also tested *kpRelInt* and *kpRel* on *TPR*, *kwBL1* and *kwBL2* and found that *kpRelInt* and *kpRel* are consistently better than *kpBL2* and *kpBL1*. Due to space limit, we do not report all the results here. These findings support our assumption that our proposed keyphrase ranking method is effective.

The comparison between *kpBL2* with *kpBL1* shows that taking the product of keyword scores is more effective than taking their sum. *kpRel* and *kpRelInt* also use the product of keyword scores. This may be because there is more noise in Twitter than traditional documents. Common words (e.g. "good") and domain background words (e.g. "Singapore") tend to gain higher weights during keyword ranking due to their high frequency, especially in graph-based method, but we do not want such words to contribute too much to keyphrase scores. Taking the product of keyword scores is therefore more suitable here than taking their sum.

Further analysis of interestingness

As shown in Table 4, *kpRelInt* performs better in terms of *nKQM* compared with *kpRel*. Here we study why it worked better for keyphrase ranking. The only difference between *kpRel* and *kpRelInt* is that *kpRelInt* includes the factor of user interests. By manually examining the top keyphrases, we find that the topics "Movie-TV" (T_5), "News" (T_{12}), "Music" (T_{20}) and "Sports" (T_{25}) particularly benefited from *kpRelInt* compared with other topics. We find that well-known named entities (e.g. celebrities, political leaders, football clubs and big companies) and significant events tend to be ranked higher by *kpRelInt* than *kpRel*.

We then counted the numbers of *entity and event keyphrases* for these four topics retrieved by different methods, shown in Table 6 . We can see that in these four topics, *kpRelInt* is consistently better than *kpRel* in terms of the number of *entity and event keyphrases* retrieved.

T_2	T_5	T_{10}	T_{12}	T_{20}	T_{25}

instant noodles	andrew garcia	marina bay	#singapore #business	joe jonas	manchester derby

Table 7: Top 10 keyphrases of 6 topics from *cTPR+kpRelInt*.

Methods	T_5	T_{12}	T_{20}	T_{25}
cTPR+kpRel	8	9	16	11
cTPR+kpRelInt	10	12	17	14

Table 6: Numbers of entity and event keyphrases retrieved by different methods within top 20.

On the other hand, we also find that for some topics interestingness helped little or even hurt the performance a little, e.g. for the topics "Food" and "Traffic." We find that the keyphrases in these topics are stable and change less over time. This may suggest that we can modify our formula to handle different topics different. We will explore this direction in our future work.

Parameter settings

We also examine how the parameters in our model affect the performance.

λ: We performed a search from 0.1 to 0.9 with a step size of 0.1. We found $\lambda = 0.1$ was the optimal parameter for *cTPR* and *TPR*. However, *TPR* is more sensitive to λ. The performance went down quickly with λ increasing.

μ: We checked the overall performance with $\mu \in \{400, 450, 500, 550, 600\}$. We found that $\mu = 500 \approx 0.01|\mathcal{V}|$ gave the best performance generally for *cTPR*. The performance difference is not very significant between these different values of μ, which indicates that the our method is robust.

4.6 Qualitative evaluation of *cTPR+kpRelInt*

We show the top 10 keyphrases discovered by *cTPR+kRelInt* in Table 7. We can observe that these keyphrases are clear, interesting and informative for summarizing Twitter topics.

We hypothesize that the following applications can benefit from the extracted keyphrases:

Automatic generation of realtime trendy phrases: For exampoe, keyphrases in the topic "Food" (T_2) can be used to help online restaurant reviews.

Event detection and topic tracking: In the topic "News" top keyphrases can be used as candidate trendy topics for event detection and topic tracking.

Automatic discovery of important named entities: As discussed previously, our methods tend to rank important named entities such as celebrities in high ranks.

5 Conclusion

In this paper, we studied the novel problem of topical keyphrase extraction for summarizing and analyzing Twitter content. We proposed the context-sensitive topical PageRank (cTPR) method for keyword ranking. Experiments showed that *cTPR* is consistently better than the original *TPR* and other baseline methods in terms of top keyword and keyphrase extraction. For keyphrase ranking, we proposed a probabilistic ranking method, which models both relevance and interestingness of keyphrases. In our experiments, this method is shown to be very effective to boost the performance of keyphrase extraction for different kinds of keyword ranking methods. In the future, we may consider how to incorporate keyword scores into our keyphrase ranking method. Note that we propose to rank keyphrases by a general formula $P(R = 1, I = 1|t, k)$ and we have made some approximations based on reasonable assumptions. There should be other potential ways to estimate $P(R = 1, I = 1|t, k)$.

Abstract

We present a novel method for record extraction from social streams such as Twitter. Unlike typical extraction setups, these environments are characterized by short, one sentence messages with heavily colloquial speech. To further complicate matters, individual messages may not express the full relation to be uncovered, as is often assumed in extraction tasks. We develop a graphical model that addresses these problems by learning a latent set of records and a record-message alignment simultaneously; the output of our model is a set of canonical records, the values of which are consistent with aligned messages. We demonstrate that our approach is able to accurately induce event records from Twitter messages, evaluated against events from a local city guide. Our method achieves significant error reduction over baseline methods.[1]

1 Introduction

We propose a method for discovering event records from social media feeds such as Twitter. The task of extracting event properties has been well studied in the context of formal media (e.g., newswire), but data sources such as Twitter pose new challenges. Social media messages are often short, make heavy use of colloquial language, and require situational context for interpretation (see examples in Figure 1). Not all properties of an event may be expressed in a single message, and the mapping between messages and canonical event records is not obvious.

Twitter Messages

Craig, nice seeing you at #noelnight this weekend @becksdavis!

Records

Artist	Venue
Craig Ferguson	Carnegie Hall
DJ Pauly D	Terminal 5

Figure 1: Examples of Twitter messages, along with automatically extracted records.

These properties of social media streams make existing extraction techniques significantly less effective. Despite these challenges, this data exhibits an important property that makes learning amenable: the multitude of messages referencing the same event.

Our goal is to induce a comprehensive set of event records given a seed set of example records, such as a city event calendar table. While such resources are widely available online, they are typically high precision, but low recall. Social media is a natural place to discover new events missed by curation, but mentioned online by someone planning to attend.

We formulate our approach as a structured graphical model which simultaneously analyzes individual messages, clusters them according to event, and induces a canonical value for each event property. At the message level, the model relies on a conditional random field component to extract field values such

[1]Data and code available at `http://groups.csail.mit.edu/rbg/code/twitter`

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 389–398,
Portland, Oregon, June 19-24, 2011.

as location of the event and artist name. We bias local decisions made by the CRF to be consistent with canonical record values, thereby facilitating consistency within an event cluster. We employ a factor-graph model to capture the interaction between each of these decisions. Variational inference techniques allow us to effectively and efficiently make predictions on a large body of messages.

A seed set of example records constitutes our only source of supervision; we do not observe alignment between these seed records and individual messages, nor any message-level field annotation. The output of our model consists of an event-based clustering of messages, where each cluster is represented by a single multi-field record with a canonical value chosen for each field.

We apply our technique to construct entertainment event records for the city calendar section of `NYC.com` using a stream of Twitter messages. Our method yields up to a 63% recall against the city table and up to 85% precision evaluated manually, significantly outperforming several baselines.

2 Related Work

A large number of information extraction approaches exploit redundancy in text collections to improve their accuracy and reduce the need for manually annotated data (Agichtein and Gravano, 2000; Yangarber et al., 2000; Zhu et al., 2009; Mintz et al., 2009a; Yao et al., 2010b; Hasegawa et al., 2004; Shinyama and Sekine, 2006). Our work most closely relates to methods for multi-document information extraction which utilize redundancy in input data to increase the accuracy of the extraction process. For instance, Mann and Yarowsky (2005) explore methods for fusing extracted information across multiple documents by performing extraction on each document independently and then merging extracted relations by majority vote. This idea of consensus-based extraction is also central to our method. However, we incorporate this idea into our model by simultaneously clustering output and labeling documents rather than performing the two tasks in serial fashion. Another important difference is inherent in the input data we are processing: it is not clear a priori which extraction decisions should agree with each other. Identifying messages that refer to the same event is a large part of our challenge.

Our work also relates to recent approaches for relation extraction with *distant supervision* (Mintz et al., 2009b; Bunescu and Mooney, 2007; Yao et al., 2010a). These approaches assume a database and a collection of documents that verbalize some of the database relations. In contrast to traditional supervised IE approaches, these methods do not assume that relation instantiations are annotated in the input documents. For instance, the method of Mintz et al. (2009b) induces the mapping automatically by bootstrapping from sentences that directly match record entries. These mappings are used to learn a classifier for relation extraction. Yao et al. (2010a) further refine this approach by constraining predicted relations to be consistent with entity types assignment. To capture the complex dependencies among assignments, Yao et al. (2010a) use a factor graph representation. Despite the apparent similarity in model structure, the two approaches deal with various types of uncertainties. The key challenge for our method is modeling message to record alignment which is not an issue in the previous set up.

Finally, our work fits into a broader area of text processing methods designed for social-media streams. Examples of such approaches include methods for conversation structure analysis (Ritter et al., 2010) and exploration of geographic language variation (Eisenstein et al., 2010) from Twitter messages. To our knowledge no work has yet addressed record extraction from this growing corpus.

3 Problem Formulation

Here we describe the key latent and observed random variables of our problem. A depiction of all random variables is given in Figure 2.

Message (x): Each message x is a single posting to Twitter. We use x^j to represent the j^{th} token of x, and we use $\mathbf{x}$ to denote the entire collection of messages. Messages are always observed during training and testing.

Record (R): A record is a representation of the canonical properties of an event. We use R_i to denote the i^{th} record and R_i^ℓ to denote the value of the ℓ^{th} property of that record. In our experiments, each record R_i is a tuple $\langle R_i^1, R_i^2 \rangle$ which represents that

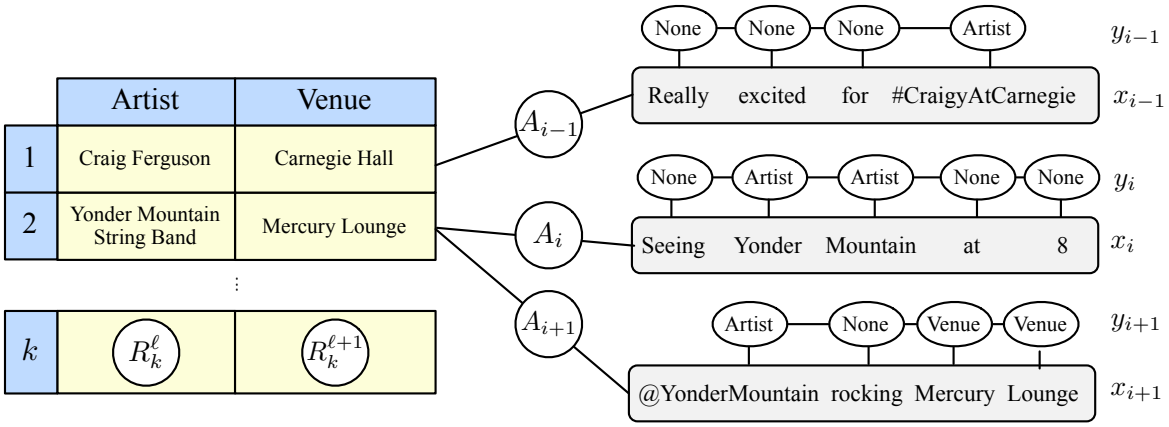

Figure 2: The key variables of our model. A collection of K latent records R_k, each consisting of a set of L properties. In the figure above, R_1^1 ="Craig Ferguson" and R_1^2 ="Carnegie Hall." Each tweet x_i is associated with a labeling over tokens y_i and is aligned to a record via the A_i variable. See Section 3 for further details.

record's values for the schema ⟨ARTIST, VENUE⟩. Throughout, we assume a known fixed number K of records $R_1, \ldots, R_K$, and we use $\mathbf{R}$ to denote this collection of records. For tractability, we consider a finite number of possibilities for each R_k^ℓ which are computed from the input $\mathbf{x}$ (see Section 5.1 for details). Records are observed during training and latent during testing.

Message Labels (y): We assume that each message has a sequence labeling, where the labels consist of the record fields (e.g., ARTIST and VENUE) as well as a NONE label denoting the token does not correspond to any domain field. Each token x^j in a message has an associated label y^j. Message labels are always latent during training and testing.

Message to Record Alignment (A): We assume that each message is aligned to some record such that the event described in the message is the one represented by that record. Each message x_i is associated with an alignment variable A_i that takes a value in $\{1, \ldots, K\}$. We use $\mathbf{A}$ to denote the set of alignments across all x_i. Multiple messages can and do align to the same record. As discussed in Section 4, our model will encourage tokens associated with message labels to be "similar" to corresponding aligned record values. Alignments are always latent during training and testing.

4 Model

Our model can be represented as a factor graph which takes the form,

$$P(R, A, y|x) \propto$$
$$\left(\prod_i \phi_{SEQ}(x_i, y_i)\right) \quad \text{(Seq. Labeling)}$$
$$\left(\prod_\ell \phi_{UNQ}(R^\ell)\right) \quad \text{(Rec. Uniqueness)}$$
$$\left(\prod_{i,\ell} \phi_{POP}(x_i, y_i, R^\ell_{A_i})\right) \quad \text{(Term Popularity)}$$
$$\left(\prod_i \phi_{CON}(x_i, y_i, R_{A_i})\right) \quad \text{(Rec. Consistency)}$$

where $\mathbf{R}^\ell$ denotes the sequence $R_1^\ell, \ldots, R_K^\ell$ of record values for a particular domain field ℓ. Each of the potentials takes a standard log-linear form:

$$\phi(z) = \theta^T f(z)$$

where θ are potential-specific parameters and $f(\cdot)$ is a potential-specific feature function. We describe each potential separately below.

4.1 Sequence Labeling Factor

The sequence labeling factor is similar to a standard sequence CRF (Lafferty et al., 2001), where the potential over a message label sequence decomposes

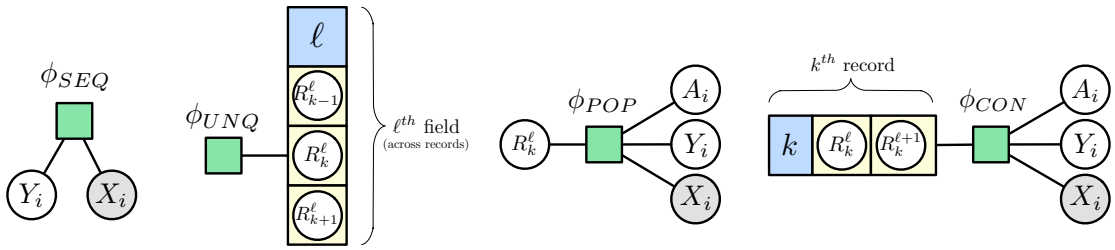

Figure 3: Factor graph representation of our model. Circles represent variables and squares represent factors. For readability, we depict the graph broken out as a set of templates; the full graph is the combination of these factor templates applied to each variable. See Section 4 for further details.

over pairwise cliques:

$$\phi_{SEQ}(x,y) = \exp\{\theta^T_{SEQ} f_{SEQ}(x,y)\}$$
$$= \exp\left\{\theta^T_{SEQ} \sum_j f_{SEQ}(x, y^j, y^{j+1})\right\}$$

This factor is meant to encode the typical message contexts in which fields are evoked (e.g. *going to see X tonight*). Many of the features characterize how likely a given token label, such as ARTIST, is for a given position in the message sequence conditioning arbitrarily on message text context.

The feature function $f_{SEQ}(x,y)$ for this component encodes each token's identity; word shape[2]; whether that token matches a set of regular expressions encoding common emoticons, time references, and venue types; and whether the token matches a bag of words observed in artist names (scraped from Wikipedia; 21,475 distinct tokens from 22,833 distinct names) or a bag of words observed in New York City venue names (scraped from `NYC.com`; 304 distinct tokens from 169 distinct names).[3] The only edge feature is label-to-label.

4.2 Record Uniqueness Factor

One challenge with Twitter is the so-called echo chamber effect: when a topic becomes popular, or "trends," it quickly dominates the conversation online. As a result some events may have only a few referent messages while other more popular events may have thousands or more. In such a circumstance, the messages for a popular event may collect to form multiple identical record clusters. Since we fix the number of records learned, such behavior inhibits the discovery of less talked-about events. Instead, we would rather have just two records: one with two aligned messages and another with thousands. To encourage this outcome, we introduce a potential that rewards fields for being unique across records.

The uniqueness potential $\phi_{UNQ}(\mathbf{R}^\ell)$ encodes the preference that each of the values $R^\ell, \ldots, R^\ell_K$ for each field ℓ do not overlap textually. This factor factorizes over pairs of records:

$$\phi_{UNQ}(\mathbf{R}^\ell) = \prod_{k \neq k'} \phi_{UNQ}(R^\ell_k, R^\ell_{k'})$$

where R^ℓ_k and $R^\ell_{k'}$ are the values of field ℓ for two records R_k and $R_{k'}$. The potential over this pair of values is given by:

$$\phi_{UNQ}(R^\ell_k, R^\ell_{k'}) = \exp\{-\theta^T_{SIM} f_{SIM}(R^\ell_k, R^\ell_{k'})\}$$

where f_{SIM} is computes the likeness of the two values at the token level:

$$f_{SIM}(R^\ell_k, R^\ell_{k'}) = \frac{|R^\ell_k \cap R^\ell_{k'}|}{\max(|R^\ell_k|, |R^\ell_{k'}|)}$$

This uniqueness potential does not encode any preference for record values; it simply encourages each field ℓ to be distinct across records.

4.3 Term Popularity Factor

The term popularity factor ϕ_{POP} is the first of two factors that guide the clustering of messages. Because speech on Twitter is colloquial, we would like these clusters to be amenable to many variations of the canonical record properties that are ultimately learned. The ϕ_{POP} factor accomplishes this by representing a lenient compatibility score between a

[2] e.g.: xxx, XXX, Xxx, or other

[3] These are just features, not a filter; we are free to extract any artist or venue regardless of their inclusion in this list.

message x, its labels y, and some candidate value v for a record field (e.g., *Dave Matthews Band*).

This factor decomposes over tokens, and we align each token x^j with the best matching token v^k in v (e.g., *Dave*). The token level sum is scaled by the length of the record value being matched to avoid a preference for long field values.

$$\phi_{POP}(x, y, R^\ell_A = v) = \sum_j \max_k \frac{\phi_{POP}(x^j, y^j, R^\ell_A = v^k)}{|v|}$$

This token-level component may be thought of as a compatibility score between the labeled token x^j and the record field assignment $R^\ell_A = v$. Given that token x^j aligns with the token v^k, the token-level component returns the sum of three parts, subject to the constraint that $y^j = \ell$:

- $IDF(x^j)\mathbb{I}[x^j = v^k]$, an equality indicator between tokens x^j and v^k, scaled by the inverse document frequency of x^j
- $\alpha IDF(x^j)\left(\mathbb{I}[x^{j-1} = v^{k-1}] + \mathbb{I}[x^{j+1} = v^{k+1}]\right)$, a small bonus of $\alpha = 0.3$ for matches on adjacent tokens, scaled by the IDF of x^j
- $\mathbb{I}[x^j = v^k$ and x contains $v]/|v|$, a bonus for a complete string match, scaled by the size of the value. This is equivalent to this token's contribution to a complete-match bonus.

4.4 Record Consistency Factor

While the uniqueness factor discourages a flood of messages for a single event from clustering into multiple event records, we also wish to discourage messages from multiple events from clustering into the same record. When such a situation occurs, the model may either resolve it by changing inconsistent token labelings to the NONE label or by reassigning some of the messages to a new cluster. We encourage the latter solution with a record consistency factor ϕ_{CON}.

The record consistency factor is an indicator function on the field values of a record being present and labeled correctly in a message. While the popularity factor encourages agreement on a per-label basis, this factor influences the joint behavior of message labels to agree with the aligned record. For a given record, message, and labeling, $\phi_{CON}(x, y, R_A) = 1$ if $\phi_{POP}(x, y, R^\ell_A) > 0$ for all ℓ, and 0 otherwise.

4.5 Parameter Learning

The weights of the CRF component of our model, θ_{SEQ}, are the only weights learned at training time, using a distant supervision process described in Section 6. The weights of the remaining three factors were hand-tuned[4] using our training data set.

5 Inference

Our goal is to predict a set of records $\mathbf{R}$. Ideally we would like to compute $P(\mathbf{R}|\mathbf{x})$, marginalizing out the nuisance variables $\mathbf{A}$ and $\mathbf{y}$. We approximate this posterior using variational inference.[5] Concretely, we approximate the full posterior over latent variables using a mean-field factorization:

$$P(\mathbf{R}, \mathbf{A}, \mathbf{y}|\mathbf{x}) \approx Q(\mathbf{R}, \mathbf{A}, \mathbf{y}) = \left(\prod_{k=1}^{K}\prod_{\ell} q(R^\ell_k)\right)\left(\prod_{i=1}^{n} q(A_i)q(y_i)\right)$$

where each variational factor $q(\cdot)$ represents an approximation of that variable's posterior given observed random variables. The variational distribution $Q(\cdot)$ makes the (incorrect) assumption that the posteriors amongst factors are independent. The goal of variational inference is to set factors $q(\cdot)$ to optimize the variational objective:

$$\min_{Q(\cdot)} KL(Q(\mathbf{R}, \mathbf{A}, \mathbf{y}) \| P(\mathbf{R}, \mathbf{A}, \mathbf{y}|\mathbf{x}))$$

We optimize this objective using coordinate descent on the $q(\cdot)$ factors. For instance, for the case of $q(y_i)$ the update takes the form:

$$q(y_i) \leftarrow \mathbb{E}_{Q/q(y_i)} \log P(\mathbf{R}, \mathbf{A}, \mathbf{y}|\mathbf{x})$$

where $Q/q(y_i)$ denotes the expectation under all variables except y_i. When computing a mean field update, we only need to consider the potentials involving that variable. The complete updates for each of the kinds of variables (y, A, and R^ℓ) can be found in Figure 4. We briefly describe the computations involved with each update.

$q(y)$ **update**: The $q(y)$ update for a single message yields an implicit expression in terms of pairwise cliques in y. We can compute arbitrary

[4] Their values are: $\theta_{UNQ} = -10$, $\theta^{\text{Phrase}}_{POP} = 5$, $\theta^{\text{Token}}_{POP} = 10$, $\theta_{CON} = 2e8$

[5] See Liang and Klein (2007) for an overview of variational techniques.

Message labeling update:

$$\begin{aligned}\ln q(y) &\propto \left\{\mathbb{E}_{Q/q(y)} \ln \phi_{SEQ}(x,y) + \ln\left[\phi_{POP}(x,y,R^\ell_A)\phi_{CON}(x,y,R_A)\right]\right\} \\ &= \ln \phi_{SEQ}(x,y) + \mathbb{E}_{Q/q(y)} \ln\left[\phi_{POP}(x,y,R^\ell_A)\phi_{CON}(x,y,R_A)\right] \\ &= \ln \phi_{SEQ}(x,y) + \sum_{z,v,\ell} q(A=z)q(y^j=\ell)q(R^\ell_z=v)\ln\left[\phi_{POP}(x,y,R^\ell_z=v)\phi_{CON}(x,y,R^\ell_z=v)\right]\end{aligned}$$

Mention record alignment update:

$$\begin{aligned}\ln q(A=z) &\propto \mathbb{E}_{Q/q(A)}\left\{\ln \phi_{SEQ}(x,y) + \ln\left[\phi_{POP}(x,y,R^\ell_A)\phi_{CON}(x,y,R_A)\right]\right\} \\ &\propto \mathbb{E}_{Q/q(A)}\left\{\ln\left[\phi_{POP}(x,y,R^\ell_A)\phi_{CON}(x,y,R_A)\right]\right\} \\ &= \sum_{z,v,\ell} q(R^\ell_z=v)\left\{\ln\left[\phi_{POP}(x,y,R^\ell_z=v)\phi_{CON}(x,y,R^\ell_z=v)\right]\right\} \\ &= \sum_{z,v,\ell} q(R^\ell_z=v)q(y^j_i=\ell)\ln\left[\phi_{POP}(x,y,R^\ell_z=v)\phi_{CON}(x,y,R^\ell_z=v)\right]\end{aligned}$$

Record Field update:

$$\begin{aligned}\ln q(R^\ell_k=v) &\propto \mathbb{E}_{Q/q(R^\ell_k)}\left\{\sum_{k'}\ln\phi_{UNQ}(R^\ell_{k'},v) + \sum_i \ln\left[\phi_{POP}(x_i,y_i,v)\phi_{CON}(x_i,y_i,v)\right]\right\} \\ &= \sum_{k'\neq k,v'}\Bigg(q(R^\ell_{k'}=v')\ln\phi_{UNQ}(v,v') \\ &+ \sum_i q(A_i=k)\sum_j q(y^j_i=\ell)\ln\left[\phi_{POP}(x,y,R^\ell_z=v,j)\phi_{CON}(x,y,R^\ell_z=v,j)\right]\Bigg)\end{aligned}$$

Figure 4: The variational mean-field updates used during inference (see Section 5). Inference consists of performing updates for each of the three kinds of latent variables: message labels (y), record alignments (A), and record field values (R^ℓ). All are relatively cheap to compute except for the record field update $q(R^\ell_k)$ which requires looping potentially over all messages. Note that at inference time all parameters are fixed and so we only need to perform updates for latent variable factors.

marginals for this distribution by using the forwards-backwards algorithm on the potentials defined in the update. Therefore computing the $q(y)$ update amounts to re-running forward backwards on the message where there is an expected potential term which involves the belief over other variables. Note that the popularity and consensus potentials (ϕ_{POP} and ϕ_{CON}) decompose over individual message tokens so this can be tractably computed.

$q(A)$ **update:** The update for individual record alignment reduces to being log-proportional to the expected popularity and consensus potentials.

$q(R^\ell_k)$ **update:** The update for the record field distribution is the most complex factor of the three. It requires computing expected similarity with other record field values (the ϕ_{UNQ} potential) and looping over all messages to accumulate a contribution from each, weighted by the probability that it is aligned to the target record.

5.1 Initializing Factors

Since a uniform initialization of all factors is a saddle-point of the objective, we opt to initialize the $q(y)$ factors with the marginals obtained using just the CRF parameters, accomplished by running forwards-backwards on all messages using only the

ϕ_{SEQ} potentials. The $q(R)$ factors are initialized randomly and then biased with the output of our baseline model. The $q(A)$ factor is initialized to uniform plus a small amount of noise.

To simplify inference, we pre-compute a finite set of values that each R_k^ℓ is allowed to take, conditioned on the corpus. To do so, we run the CRF component of our model (ϕ_{SEQ}) over the corpus and extract, for each ℓ, all spans that have a token-level probability of being labeled ℓ greater than $\lambda = 0.1$. We further filter this set down to only values that occur at least twice in the corpus.

This simplification introduces sparsity that we take advantage of during inference to speed performance. Because each term in ϕ_{POP} and ϕ_{CON} includes an indicator function based on a token match between a field-value and a message, knowing the possible values $\mathbf{v}$ of each R_k^ℓ enables us to precompute the combinations of (x, ℓ, v) for which nonzero factor values are possible. For each such tuple, we can also precompute the best alignment position k for each token x^j.

6 Evaluation Setup

Data We apply our approach to construct a database of concerts in New York City. We used Twitter's public API to collect roughly 4.7 Million tweets across three weekends that we subsequently filter down to 5,800 messages. The messages have an average length of 18 tokens, and the corpus vocabulary comprises 468,000 unique words[6]. We obtain labeled gold records using data scraped from the `NYC.com` music event guide; totaling 110 extracted records. Each gold record had two fields of interest: ARTIST and VENUE.

The first weekend of data (messages and events) was used for training and the second two weekends were used for testing.

Preprocessing Only a small fraction of Twitter messages are relevant to the target extraction task. Directly processing the raw unfiltered stream would prohibitively increase computational costs and make learning more difficult due to the noise inherent in the data. To focus our efforts on the promising portion of the stream, we perform two types of filtering. First, we only retain tweets whose authors list some variant of New York as their location in their profile. Second, we employ a MIRA-based binary classifier (Ritter et al., 2010) to predict whether a message mentions a concert event. After training on 2,000 hand-annotated tweets, this classifier achieves an F_1 of 46.9 (precision of 35.0 and recall of 71.0) when tested on 300 messages. While the two-stage filtering does not fully eliminate noise in the input stream, it greatly reduces the presence of irrelevant messages to a manageable 5,800 messages without filtering too many 'signal' tweets.

We also filter our gold record set to include only records in which each field value occurs at least once somewhere in the corpus, as these are the records which are possible to learn given the input. This yields 11 training and 31 testing records.

Training The first weekend of data (2,184 messages and 11 records after preprocessing) is used for training. As mentioned in Section 4, the only learned parameters in our model are those associated with the sequence labeling factor ϕ_{SEQ}. While it is possible to train these parameters via direct annotation of messages with label sequences, we opted instead to use a simple approach where message tokens from the training weekend are labeled via their intersection with gold records, often called "distant supervision" (Mintz et al., 2009b). Concretely, we automatically label message tokens in the training corpus with either the ARTIST or VENUE label if they belonged to a sequence that matched a gold record field, and with NONE otherwise. This is the only use that is made of the gold records throughout training. θ_{SEQ} parameters are trained using this labeling with a standard conditional likelihood objective.

Testing The two weekends of data used for testing totaled 3,662 tweets after preprocessing and 31 gold records for evaluation. The two weekends were tested separately and their results were aggregated across weekends.

Our model assumes a fixed number of records $K = 130$.[7] We rank these records according to a heuristic ranking function that favors the uniqueness of a record's field values across the set and the number of messages in the testing corpus that have

[6] Only considering English tweets and not counting user names (so-called -mentions.)

[7] Chosen based on the training set

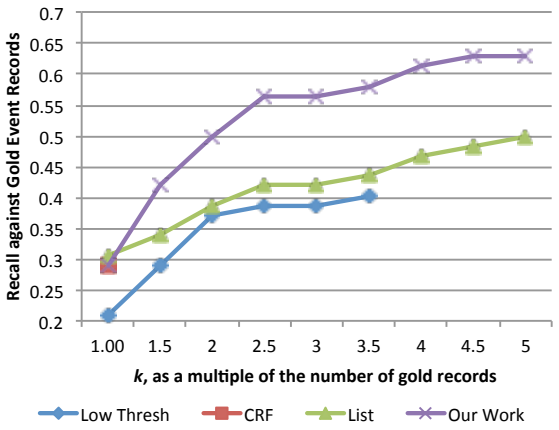

Figure 5: Recall against the gold records. The horizontal axis is the number of records kept from the ranked model output, as a multiple of the number of golds. The CRF lines terminate because of low record yield.

token overlap with these values. This ranking function is intended to push garbage collection records to the bottom of the list. Finally, we retain the top k records, throwing away the rest. Results in Section 7 are reported as a function of this k.

Baseline We compare our system against three baselines that employ a voting methodology similar to Mann and Yarowsky (2005). The baselines label each message and then extract one record for each combination of labeled phrases. Each extraction is considered a vote for that record's existence, and these votes are aggregated across all messages.

Our *List Baseline* labels messages by finding string overlaps against a list of musical artists and venues scraped from web data (the same lists used as features in our CRF component). The *CRF Baseline* is most similar to Mann and Yarowsky (2005)'s CRF Voting method and uses the maximum likelihood CRF labeling of each message. The *Low Threshold Baseline* generates all possible records from labelings with a token-level likelihood greater than $\lambda = 0.1$. The output of these baselines is a set of records ranked by the number of votes cast for each, and we perform our evaluation against the top k of these records.

7 Evaluation

The evaluation of record construction is challenging because many induced music events discussed in Twitter messages are not in our gold data set; our gold records are precise but incomplete. Because of this, we evaluate recall and precision separately. Both evaluations are performed using hard zero-one loss at record level. This is a harsh evaluation criterion, but it is realistic for real-world use.

Recall We evaluate recall, shown in Figure 5, against the gold event records for each weekend. This shows how well our model could do at replacing the a city event guide, providing Twitter users chat about events taking place.

We perform our evaluation by taking the top k records induced, performing a stable marriage matching against the gold records, and then evaluating the resulting matched pairs. Stable marriage matching is a widely used approach that finds a bipartite matching between two groups such that no pairing exists in which both participants would prefer some other pairing (Irving et al., 1987). With our hard loss function and no duplicate gold records, this amounts to the standard recall calculation. We choose this bipartite matching technique because it generalizes nicely to allow for other forms of loss calculation (such as token-level loss).

Precision To evaluate precision we assembled a list of the distinct records produced by all models and then manually determined if each record was correct. This determination was made blind to which model produced the record. We then used this aggregate list of correct records to measure precision for each individual model, shown in Figure 6.

By construction, our baselines incorporate a hard constraint that each relation learned must be expressed in entirety in at least one message. Our model only incorporates a soft version of this constraint via the ϕ_{CON} factor, but this constraint clearly has the ability to boost precision. To show it's effect, we additionally evaluate our model, labeled *Our Work + Con*, with this constraint applied in hard form as an output filter.

The downward trend in precision that can be seen in Figure 6 is the effect of our ranking algorithm, which attempts to push garbage collection records towards the bottom of the record list. As we incorporate these records, precision drops. These lines trend up for two of the baselines because the rank-

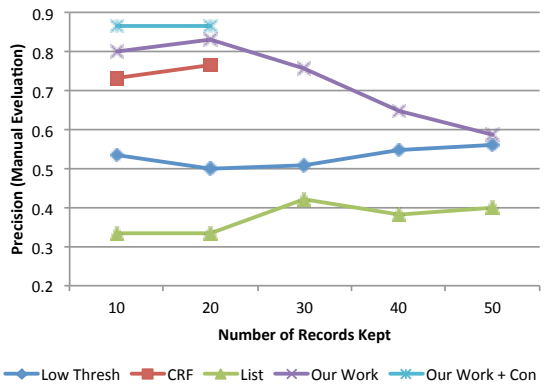

Figure 6: Precision, evaluated manually by cross-referencing model output with event mentions in the input data. The CRF and hard-constrained consensus lines terminate because of low record yield.

ing heuristic is not as effective for them.

These graphs confirm our hypothesis that we gain significant benefit by intertwining constraints on extraction consistency in the learning process, rather than only using this constraint to filter output.

7.1 Analysis

One persistent problem is a popular phrase appearing in many records, such as the value "New York" filling many ARTIST slots. The uniqueness factor θ_{UNQ} helps control this behavior, but it is a relatively blunt instrument. Ideally, our model would learn, for each field ℓ, the degree to which duplicate values are permitted. It is also possible that by learning, rather than hand-tuning, the θ_{CON}, θ_{POP}, and θ_{UNQ} parameters, our model could find a balance that permits the proper level of duplication for a particular domain.

Other errors can be explained by the lack of constituent features in our model, such as the selection of VENUE values that do not correspond to noun phrases. Further, semantic features could help avoid learning syntactically plausible artists like "Screw the Rain" because of the message:

Screw the rain$_{Artist}$! Grab an umbrella and head down to **Webster Hall**$_{Venue}$ for some American rock and roll.

Our model's soft string comparison-based clustering can be seen at work when our model uncovers records that would have been impossible without this approach. One such example is correcting the misspelling of venue names (e.g. *Terminal Five* → *Terminal 5*) even when no message about the event spells the venue correctly.

Still, the clustering can introduce errors by combining messages that provide orthogonal field contributions yet have overlapping tokens (thus escaping the penalty of the consistency factor). An example of two messages participating in this scenario is shown below; the shared term "holiday" in the second message gets relabeled as ARTIST:

Come check out the **holiday cheer**$_{Artist}$ parkside is bursting..
Pls tune in to TV **Guide Network**$_{Venue}$ TONIGHT at 8 pm for 25 Most Hilarious *Holiday* TV Moments...

While our experiments utilized binary relations, we believe our general approach should be useful for n-ary relation recovery in the social media domain. Because short messages are unlikely to express high arity relations completely, tying extraction and clustering seems an intuitive solution. In such a scenario, the record consistency constraints imposed by our model would have to be relaxed, perhaps examining pairwise argument consistency instead.

8 Conclusion

We presented a novel model for record extraction from social media streams such as Twitter. Our model operates on a noisy feed of data and extracts canonical records of events by aggregating information across multiple messages. Despite the noise of irrelevant messages and the relatively colloquial nature of message language, we are able to extract records with relatively high accuracy. There is still much room for improvement using a broader array of features on factors.

How do you pronounce your name? Improving G2P with transliterations

Aditya Bhargava and Grzegorz Kondrak
Department of Computing Science
University of Alberta
Edmonton, Alberta, Canada, T6G 2E8
{abhargava,kondrak}@cs.ualberta.ca

Abstract

Grapheme-to-phoneme conversion (G2P) of names is an important and challenging problem. The correct pronunciation of a name is often reflected in its transliterations, which are expressed within a different phonological inventory. We investigate the problem of using transliterations to correct errors produced by state-of-the-art G2P systems. We present a novel re-ranking approach that incorporates a variety of score and n-gram features, in order to leverage transliterations from multiple languages. Our experiments demonstrate significant accuracy improvements when re-ranking is applied to n-best lists generated by three different G2P programs.

1 Introduction

Grapheme-to-phoneme conversion (G2P), in which the aim is to convert the orthography of a word to its pronunciation (phonetic transcription), plays an important role in speech synthesis and understanding. Names, which comprise over 75% of unseen words (Black et al., 1998), present a particular challenge to G2P systems because of their high pronunciation variability. Guessing the correct pronunciation of a name is often difficult, especially if they are of foreign origin; this is attested by the *ad hoc* transcriptions which sometimes accompany new names introduced in news articles, especially for international stories with many foreign names.

Transliterations provide a way of disambiguating the pronunciation of names. They are more abundant than phonetic transcriptions, for example when news items of international or global significance are reported in multiple languages. In addition, writing scripts such as Arabic, Korean, or Hindi are more consistent and easier to identify than various phonetic transcription schemes. The process of transliteration, also called *phonetic translation* (Li et al., 2009b), involves "sounding out" a name and then finding the closest possible representation of the sounds in another writing script. Thus, the correct pronunciation of a name is partially encoded in the form of the transliteration. For example, given the ambiguous letter-to-phoneme mapping of the English letter *g*, the initial phoneme of the name *Gershwin* may be predicted by a G2P system to be either /ɡ/ (as in *Gertrude*) or /ʤ/ (as in *Gerald*). The transliterations of the name in other scripts provide support for the former (correct) alternative.

Although it seems evident that transliterations should be helpful in determining the correct pronunciation of a name, designing a system that takes advantage of this insight is not trivial. The main source of the difficulty stems from the differences between the phonologies of distinct languages. The mappings between phonemic inventories are often complex and context-dependent. For example, because Hindi has no /w/ sound, the transliteration of *Gershwin* instead uses a symbol that represents the phoneme /ʋ/, similar to the /v/ phoneme in English. In addition, converting transliterations into phonemes is often non-trivial; although few orthographies are as inconsistent as that of English, this is effectively the G2P task for the particular language in question.

In this paper, we demonstrate that leveraging transliterations can, in fact, improve the grapheme-to-phoneme conversion of names. We propose a novel system based on discriminative re-ranking that is capable of incorporating multiple transliterations. We show that simplistic approaches to the problem

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 399–408,
Portland, Oregon, June 19-24, 2011.

fail to achieve the same goal, and that transliterations from multiple languages are more helpful than from a single language. Our approach can be combined with any G2P system that produces n-best lists instead of single outputs. The experiments that we perform demonstrate significant error reduction for three very different G2P base systems.

2 Improving G2P with transliterations

2.1 Problem definition

In both G2P and machine transliteration, we are interested in learning a function that, given an input sequence x, produces an output sequence y. In the G2P task, x is composed of graphemes and y is composed of phonemes; in transliteration, both sequences consist of graphemes but they represent different writing scripts. Unlike in machine translation, the monotonicity constraint is enforced; i.e., we assume that x and y can be aligned without the alignment links crossing each other (Jiampojamarn and Kondrak, 2010). We assume that we have available a base G2P system that produces an n-best list of outputs with a corresponding list of confidence scores. The goal is to improve the base system's performance by applying existing transliterations of the input x to re-rank the system's n-best output list.

2.2 Similarity-based methods

A simple and intuitive approach to improving G2P with transliterations is to select from the n-best list the output sequence that is most similar to the corresponding transliteration. For example, the Hindi transliteration in Figure 1 is arguably closest in perceptual terms to the phonetic transcription of the second output in the n-best list, as compared to the other outputs. One obvious problem with this method is that it ignores the relative ordering of the n-best lists and their corresponding scores produced by the base system.

A better approach is to combine the similarity score with the output score from the base system, allowing it to contribute an estimate of confidence in its output. For this purpose, we apply a linear combination of the two scores, where a single parameter λ, ranging between zero and one, determines the relative weight of the scores. The exact value of λ can be optimized on a training set. This approach is similar to the method used by Finch and Sumita (2010) to combine the scores of two different machine transliteration systems.

2.3 Measuring similarity

The approaches presented in the previous section crucially depend on a method for computing the similarity between various symbol sequences that represent the same word. If we have a method of converting transliterations to phonetic representations, the similarity between two sequences of phonemes can be computed with a simple method such as normalized edit distance or the longest common subsequence ratio, which take into account the number and position of identical phonemes. Alternatively, we could apply a more complex approach, such as ALINE (Kondrak, 2000), which computes the distance between pairs of phonemes. However, the implementation of a conversion program would require ample training data or language-specific expertise.

A more general approach is to skip the transcription step and compute the similarity between phonemes and graphemes directly. For example, the edit distance function can be learned from a training set of transliterations and their phonetic transcriptions (Ristad and Yianilos, 1998). In this paper, we apply M2M-ALIGNER (Jiampojamarn et al., 2007), an unsupervised aligner, which is a many-to-many generalization of the learned edit distance algorithm. M2M-ALIGNER was originally designed to align graphemes and phonemes, but can be applied to discover the alignment between any sets of symbols (given training data). The logarithm of the probability assigned to the optimal alignment can then be interpreted as a similarity measure between the two sequences.

2.4 Discriminative re-ranking

The methods described in Section 2.2, which are based on the similarity between outputs and transliterations, are difficult to generalize when multiple transliterations of a single name are available. A linear combination is still possible but in this case optimizing the parameters would no longer be straightforward. Also, we are interested in utilizing other features besides sequence similarity.

The SVM re-ranking paradigm offers a solution

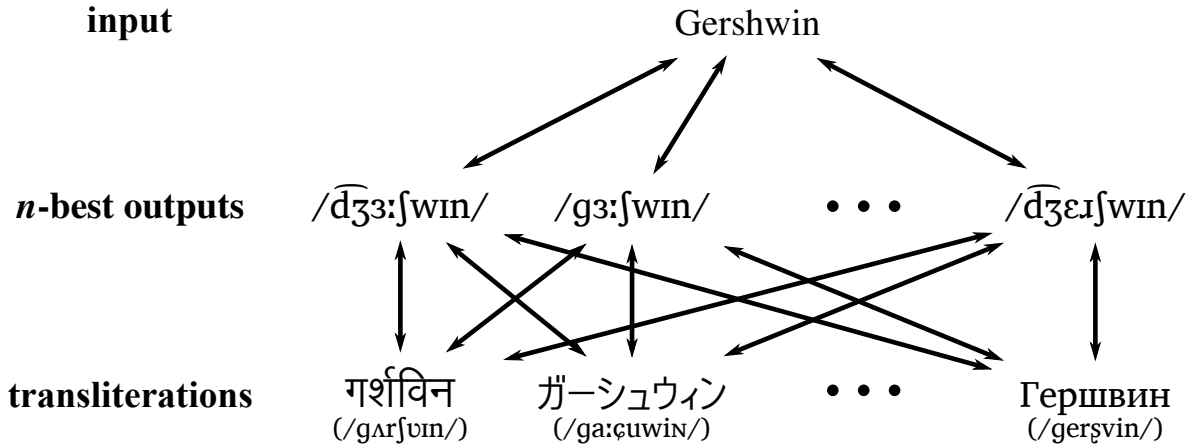

Figure 1: An example name showing the data used for feature construction. Each arrow links a pair used to generate features, including n-gram and score features. The score features use similarity scores for transliteration-transcription pairs and system output scores for input-output pairs. One feature vector is constructed for each system output.

to the problem. Our re-ranking system is informed by a large number of features, which are based on scores and n-grams. The scores are of three types:

1. The scores produced by the base system for each output in the n-best list.
2. The similarity scores between the outputs and each available transliteration.
3. The differences between scores in the n-best lists for both (1) and (2).

Our set of binary n-gram features includes those used for DIRECTL+ (Jiampojamarn et al., 2010). They can be divided into four types:

1. The context features combine output symbols (phonemes) with n-grams of varying sizes in a window of size c centred around a corresponding position on the input side.
2. The transition features are bigrams on the output (phoneme) side.
3. The linear chain features combine the context features with the bigram transition features.
4. The joint n-gram features are n-grams containing both input and output symbols.

We apply the features in a new way: instead of being applied strictly to a given input-output set, we expand their use across many languages and use all of them simultaneously. We apply the n-gram features across all transliteration-transcription pairs in addition to the usual input-output pairs corresponding to the n-best lists. Figure 1 illustrates the set of pairs used for feature generation.

In this paper, we augment the n-gram features by a set of *reverse* features. Unlike a traditional G2P generator, our re-ranker has access to the outputs produced by the base system. By swapping the input and the output side, we can add reverse context and linear-chain features. Since the n-gram features are also applied to transliteration-transcription pairs, the reverse features enable us to include features which bind a variety of n-grams in the transliteration string with a single corresponding phoneme.

The construction of n-gram features presupposes a fixed alignment between the input and output sequences. If the base G2P system does not provide input-output alignments, we use M2M-ALIGNER for this purpose. The transliteration-transcription pairs are also aligned by M2M-ALIGNER, which at the same time produces the corresponding similarity scores. (We set a lower limit of -100 on the M2M-ALIGNER scores.) If M2M-ALIGNER is unable to produce an alignment, we indicate this with a binary feature that is included with the n-gram features.

3 Experiments

We perform several experiments to evaluate our transliteration-informed approaches. We test simple

similarity-based approaches on single-transliteration data, and evaluate our SVM re-ranking approach against this as well. We then test our approach using all available transliterations. Relevant code and scripts required to reproduce our experimental results are available online[1].

3.1 Data & setup

For pronunciation data, we extracted all names from the Combilex corpus (Richmond et al., 2009). We discarded all diacritics, duplicates and multi-word names, which yielded 10,084 unique names. Both the similarity and SVM methods require transliterations for identifying the best candidates in the n-best lists. They are therefore trained and evaluated on the subset of the G2P corpus for which transliterations available. Naturally, allowing transliterations from all languages results in a larger corpus than the one obtained by the intersection with transliterations from a single language.

For our experiments, we split the data into 10% for testing, 10% for development, and 80% for training. The development set was used for initial tests and experiments, and then for our final results the training and development sets were combined into one set for final system training. For SVM re-ranking, during both development and testing we split the training set into 10 folds; this is necessary when training the re-ranker as it must have system output scores that are representative of the scores on unseen data. We ensured that there was never any overlap between the training and testing data for all trained systems.

Our transliteration data come from the shared tasks on transliteration at the 2009 and 2010 Named Entities Workshops (Li et al., 2009a; Li et al., 2010). We use all of the 2010 English-source data plus the English-to-Russian data from 2009, which makes nine languages in total. In cases where the data provide alternative transliterations for a given input, we keep only one; our preliminary experiments indicated that including alternative transliterations did not improve performance. It should be noted that these transliteration corpora are noisy: Jiampojamarn et al. (2009) note a significant increase in English-to-Hindi transliteration performance with a simple cleaning of the data.

Language	Corpus size	Overlap
Bengali	12,785	1,840
Chinese	37,753	4,713
Hindi	12,383	2,179
Japanese	26,206	4,773
Kannada	10,543	1,918
Korean	6,761	3,015
Russian	6,447	487
Tamil	10,646	1,922
Thai	27,023	5,436

Table 1: The number of unique single-word entries in the transliteration corpora for each language and the amount of common data (overlap) with the pronunciation data.

Our tests involving transliterations from multiple languages are performed on the set of names for which we have both the pronunciation and transliteration data. There are 7,423 names in the G2P corpus for which at least one transliteration is available. Table 1 lists the total size of the transliteration corpora as well as the amount of overlap with the G2P data. Note that the base G2P systems are trained using all 10,084 names in the corpus as opposed to only the 7,423 names for which there are transliterations available. This ensures that the G2P systems have more training data to provide the best possible base performance.

For our single-language experiments, we normalize the various scores when tuning the linear combination parameter λ so that we can compare values across different experimental conditions. For SVM re-ranking, we directly implement the method of Joachims (2002) to convert the re-ranking problem into a classification problem, and then use the very fast LIBLINEAR (Fan et al., 2008) to build the SVM models. Optimal hyperparameter values were determined during development.

We evaluate using word accuracy, the percentage of words for which the pronunciations are correctly predicted. This measure marks pronunciations that are even slightly different from the correct one as incorrect, so even a small change in pronunciation that might be acceptable or even unnoticeable to humans would count against the system's performance.

[1] http://www.cs.ualberta.ca/~ab31/g2p-tl-rr

3.2 Base systems

It is important to test multiple base systems in order to ensure that any gain in performance applies to the task in general and not just to a particular system. We use three G2P systems in our tests:

1. FESTIVAL (FEST), a popular speech synthesis package, which implements G2P conversion with CARTs (decision trees) (Black et al., 1998).

2. SEQUITUR (SEQ), a generative system based on the joint n-gram approach (Bisani and Ney, 2008).

3. DIRECTL+ (DTL), the discriminative system on which our n-gram features are based (Jiampojamarn et al., 2010).

All systems are capable of providing n-best output lists along with scores for each output, although for FESTIVAL they had to be constructed from the list of output probabilities for each input character.

We run DIRECTL+ with all of the features described in (Jiampojamarn et al., 2010) (i.e., context features, transition features, linear chain features, and joint n-gram features). System parameters, such as maximum number of iterations, were determined during development. For SEQUITUR, we keep default options except for the enabling of the 10 best outputs and we convert the probabilities assigned to the outputs to log-probabilities. We set SEQUITUR's joint n-gram order to 6 (this was also determined during development).

Note that the three base systems differ slightly in terms of the alignment information that they provide in their outputs. FESTIVAL operates letter-by-letter, so we use the single-letter inputs with the phoneme outputs as the aligned units. DIRECTL+ specifies many-to-many alignments in its output. For SEQUITUR, however, since it provides no information regarding the output structure, we use M2M-ALIGNER to induce alignments for n-gram feature generation.

3.3 Transliterations from a single language

The goal of the first experiment is to compare several similarity-based methods, and to determine how they compare to our re-ranking approach. In order to find the similarity between phonetic transcriptions, we use the two different methods described in Section 2.2: ALINE and M2M-ALIGNER. We further test the use of a linear combination of the similarity scores with the base system's score so that its confidence information can be taken into account; the linear combination weight is determined from the training set. These methods are referred to as ALINE+BASE and M2M+BASE. For these experiments, our training and testing sets are obtained by intersecting our G2P training and testing sets respectively with the Hindi transliteration corpus, yielding 1,950 names for training and 229 names for testing.

Since the similarity-based methods are designed to incorporate homogeneous same-script transliterations, we can only run this experiment on one language at a time. Furthermore, ALINE operates on phoneme sequences, so we first need to convert the transliterations to phonemes. An alternative would be to train a proper G2P system, but this would require a large set of word-pronunciation pairs. For this experiment, we choose Hindi, for which we constructed a rule-based G2P converter. Aside from simple one-to-one mapping (romanization) rules, the converter has about ten rules to adjust for context.

For these experiments, we apply our SVM reranking method in two ways:

1. Using only Hindi transliterations (referred to as SVM-HINDI).

2. Using all available languages (referred to as SVM-ALL).

In both cases, the test set is restricted to the same 229 names, in order to provide a valid comparison.

Table 2 presents the results. Regardless of the choice of the similarity function, the simplest approaches fail in a spectacular manner, significantly reducing the accuracy with respect to the base system. The linear combination methods give mixed results, improving the accuracy for FESTIVAL but not for SEQUITUR or DIRECTL+ (although the differences are not statistically significant). However, they perform much better than the methods based on similarity scores alone as they are able to take advantage of the base system's output scores. If we look at the values of λ that provide the best performance

	Base system		
	FEST	SEQ	DTL
Base	58.1	67.3	71.6
ALINE	28.0	26.6	27.5
M2M	39.3	36.2	36.2
ALINE+BASE	58.5	65.9	71.2
M2M+BASE	58.5	66.4	70.3
SVM-HINDI	63.3	69.0	69.9
SVM-ALL	68.6	72.5	75.6

Table 2: Word accuracy (in percentages) of various methods when only Hindi transliterations are used.

on the training set, we find that they are higher for the stronger base systems, indicating more reliance on the base system output scores. For example, for ALINE+BASE the FESTIVAL-based system has $\lambda = 0.58$ whereas the DIRECTL+-based system has $\lambda = 0.81$. Counter-intuitively, the ALINE+BASE and M2M+BASE methods are unable to improve upon SEQUITUR or DIRECTL+. We would expect to achieve at least the base system's performance, but disparities between the training and testing sets prevent this.

The two SVM-based methods achieve much better results. SVM-ALL produces impressive accuracy gains for all three base systems, while SVM-HINDI yields smaller (but still statistically significant) improvements for FESTIVAL and SEQUITUR. These results suggest that our re-ranking method provides a bigger boost to systems built with different design principles than to DIRECTL+ which utilizes a similar set of features. On the other hand, the results also show that the information obtained by consulting a single transliteration may be insufficient to improve an already high-performing G2P converter.

3.4 Transliterations from multiple languages

Our second experiment expands upon the first; we use all available transliterations instead of being restricted to one language. This rules out the simple similarity-based approaches, but allows us to test our re-ranking approach in a way that fully utilizes the available data. We test three variants of our transliteration-informed SVM re-ranking approach,

	Base system		
	FEST	SEQ	DTL
Base	55.3	66.5	70.8
SVM-SCORE	62.1	68.4	71.0
SVM-N-GRAM	66.2	72.5	73.8
SVM-ALL	67.2	73.4	74.3

Table 3: Word accuracy of the base system versus the re-ranking variants with transliterations from multiple languages.

which differ with respect to the set of included features:

1. SVM-SCORE includes only the three types of score features described in Section 2.4.
2. SVM-N-GRAM uses only the n-gram features.
3. SVM-ALL is the full system that combines the score and n-gram features.

The objective is to determine the degree to which each of the feature classes contributes to the overall results. Because we are using all available transliterations, we achieve much greater coverage over our G2P data than in the previous experiment; in this case, our training set consists of 6,660 names while the test set has 763 names.

Table 3 presents the results. Note that the baseline accuracies are somewhat lower than in Table 2 because of the different test set. We find that, when using all features, the SVM re-ranker can provide a very impressive error reduction over FESTIVAL (26.7%) and SEQUITUR (20.7%) and a smaller but still significant ($p < 0.01$ with the McNemar test) error reduction over DIRECTL+ (12.1%).

When we consider our results using only the score and n-gram features, we can see that, interestingly, the n-gram features are most important. We draw a further conclusion from our results: consider the large disparity in improvements over the base systems. This indicates that FESTIVAL and SEQUITUR are benefiting from the DIRECTL+-style features used in the re-ranking. Without the n-gram features, however, there is still a significant improvement over FESTIVAL, demonstrating that the scores *do* provide useful information. In this case there is

no way for DIRECTL+-style information to make its way into the re-ranking; the process is based purely on the transliterations and their similarities with the transcriptions in the output lists, indicating that the system is capable of extracting useful information directly from transliterations. In the case of DIRECTL+, the transliterations help through the n-gram features rather than the score features; this is probably because the crucial feature that signals the inability of M2M-ALIGNER to align a given transliteration-transcription pair belongs to the set of the n-gram features. Both the n-gram features and score features are dependent on the alignments, but they differ in that the n-gram features allow weights to be learned for local n-gram pairs whereas the score features are based on global information, providing only a single feature for a given transliteration-transcription pair. The two therefore overlap to some degree, although the score features still provide useful information via probabilities learned during the alignment training process.

A closer look at the results provides additional insight into the operation of our re-ranking system. For example, consider the name *Bacchus*, which DIRECTL+ incorrectly converts into /bæktʃəs/. The most likely reason why our re-ranker selects instead the correct pronunciation /bækəs/ is that M2M-ALIGNER fails to align three of the five available transliterations with /bæktʃəs/. Such alignment failures are caused by a lack of evidence for the mapping of the grapheme representing the sound /k/ in the transliteration training data with the phoneme /tʃ/. In addition, the lack of alignments prevents any n-gram features from being enabled.

Considering the difficulty of the task, the top accuracy of almost 75% is quite impressive. In fact, many instances of human transliterations in our corpora are clearly incorrect. For example, the Hindi transliteration of *Bacchus* contains the /tʃ/ consonant instead of the correct /k/. Moreover, our strict evaluation based on word accuracy counts all system outputs that fail to exactly match the dictionary data as errors. The differences are often very minor and may reflect an alternative pronunciation. The *phoneme* accuracy[2] of our best result is 93.1%, which provides some idea of how similar the predicted pronunciation is to the correct one.

[2]The phoneme accuracy is calculated from the minimum edit distance between the predicted and correct pronunciations.

# TL	# Entries	Improvement
≤ 1	111	0.9
≤ 2	266	3.0
≤ 3	398	3.8
≤ 4	536	3.2
≤ 5	619	2.8
≤ 6	685	3.4
≤ 7	732	3.7
≤ 8	762	3.5
≤ 9	763	3.5

Table 4: Absolute improvement in word accuracy (%) over the base system (DIRECTL+) of the SVM re-ranker for various numbers of available transliterations.

3.5 Effect of multiple transliterations

One motivating factor for the use of SVM re-ranking was the ability to incorporate multiple transliteration languages. But how important is it to use more than one language? To examine this question, we look particularly at the sets of names having at most k transliterations available. Table 4 shows the results with DIRECTL+ as the base system. Note that the number of names with more than five transliterations was small. Importantly, we see that the increase in performance when only one transliteration is available is so small as to be insignificant. From this, we can conclude that obtaining improvement on the basis of a single transliteration is difficult in general. This corroborates the results of the experiment described in Section 3.3, where we used only Hindi transliterations.

4 Previous work

There are three lines of research that are relevant to our work: (1) G2P in general; (2) G2P on names; and (3) combining diverse data sources and/or systems.

The two leading approaches to G2P are represented by SEQUITUR (Bisani and Ney, 2008) and DIRECTL+ (Jiampojamarn et al., 2010). Recent comparisons suggests that the former obtains somewhat higher accuracy, especially when it includes joint n-gram features (Jiampojamarn et al., 2010). Systems based on decision trees are far behind. Our

results confirm this ranking.

Names can present a particular challenge to G2P systems. Kienappel and Kneser (2001) reported a higher error rate for German names than for general words, while on the other hand Black et al. (1998) report similar accuracy on names as for other types of English words. Yang et al. (2006) and van den Heuvel et al. (2007) post-process the output of a general G2P system with name-specific phoneme-to-phoneme (P2P) systems. They find significant improvement using this method on data sets consisting of Dutch first names, family names, and geographical names. However, it is unclear whether such an approach would be able to improve the performance of the current state-of-the-art G2P systems. In addition, the P2P approach works only on single outputs, whereas our re-ranking approach is designed to handle n-best output lists.

Although our approach is (to the best of our knowledge) the first to use different *tasks* (G2P and transliteration) to inform each other, this is conceptually similar to model and system combination approaches. In statistical machine translation (SMT), methods that incorporate translations from other languages (Cohn and Lapata, 2007) have proven effective in low-resource situations: when phrase translations are unavailable for a certain language, one can look at other languages where the translation *is* available and then translate from that language. A similar pivoting approach has also been applied to machine transliteration (Zhang et al., 2010). Notably, the focus of these works have been on cases in which there are less data available; they also modify the generation process directly, rather than operating on existing outputs as we do. Ultimately, a combination of the two approaches is likely to give the best results.

Finch and Sumita (2010) combine two very different approaches to transliteration using simple linear interpolation: they use SEQUITUR's n-best outputs and re-rank them using a linear combination of the original SEQUITUR score and the score for that output of a phrased-based SMT system. The linear weights are hand-tuned. We similarly use linear combinations, but with many more scores and other features, necessitating the use of SVMs to determine the weights. Importantly, we combine different *data types* where they combine different *systems*.

5 Conclusions & future work

In this paper, we explored the application of transliterations to G2P. We demonstrated that transliterations have the potential for helping choose between n-best output lists provided by standard G2P systems. Simple approaches based solely on similarity do not work when tested using a single transliteration language (Hindi), necessitating the use of smarter methods that can incorporate multiple transliteration languages. We apply SVM re-ranking to this task, enabling us to use a variety of features based not only on similarity scores but on n-grams as well. Our method shows impressive error reductions over the popular FESTIVAL system and the generative joint n-gram SEQUITUR system. We also find significant error reduction using the state-of-the-art DIRECTL+ system. Our analysis demonstrated that it is essential to provide the re-ranking system with transliterations from multiple languages in order to mitigate the differences between phonological inventories and smooth out noise in the transliterations.

In the future, we plan to generalize our approach so that it can be applied to the task of generating transliterations, and to combine data from distinct G2P dictionaries. The latter task is related to the notion of domain adaptation. We would also like to apply our approach to web data; we have shown that it is possible to use noisy transliteration data, so it may be possible to leverage the noisy *ad hoc* pronunciation data as well. Finally, we plan to investigate earlier integration of such external information into the G2P process for single systems; while we noted that re-ranking provides a general approach applicable to any system that can generate n-best lists, there is a limit as to what re-ranking can do, as it relies on the correct output existing in the n-best list. Modifying existing systems would provide greater potential for improving results even though the changes would be necessarily system-specific.

Unsupervised Word Alignment with Arbitrary Features

Abstract

We introduce a discriminatively trained, globally normalized, log-linear variant of the lexical translation models proposed by Brown et al. (1993). In our model, arbitrary, non-independent features may be freely incorporated, thereby overcoming the inherent limitation of generative models, which require that features be sensitive to the conditional independencies of the generative process. However, unlike previous work on discriminative modeling of word alignment (which also permits the use of arbitrary features), the parameters in our models are learned from unannotated parallel sentences, rather than from supervised word alignments. Using a variety of intrinsic and extrinsic measures, including translation performance, we show our model yields better alignments than generative baselines in a number of language pairs.

1 Introduction

Word alignment is an important subtask in statistical machine translation which is typically solved in one of two ways. The more common approach uses a generative translation model that relates bilingual string pairs using a latent alignment variable to designate which source words (or phrases) generate which target words. The parameters in these models can be learned straightforwardly from parallel sentences using EM, and standard inference techniques can recover most probable alignments (Brown et al., 1993). This approach is attractive because it only requires parallel training data. An alternative to the generative approach uses a discriminatively trained alignment model to predict word alignments in the parallel corpus. Discriminative models are attractive because they can incorporate arbitrary, overlapping features, meaning that errors observed in the predictions made by the model can be addressed by engineering new and better features. Unfortunately, *both* approaches are problematic, but in different ways.

In the case of discriminative alignment models, manual alignment data is required for training, which is problematic for at least three reasons. Manual alignments are notoriously difficult to create and are available only for a handful of language pairs. Second, manual alignments impose a commitment to a particular preprocessing regime; this can be problematic since the optimal segmentation for translation often depends on characteristics of the test set or size of the available training data (Habash and Sadat, 2006) or may be constrained by requirements of other processing components, such parsers. Third, the "correct" alignment annotation for different tasks may vary: for example, relatively denser or sparser alignments may be optimal for different approaches to (downstream) translation model induction (Lopez, 2008; Fraser, 2007).

Generative models have a different limitation: the joint probability of a particular setting of the random variables must factorize according to steps in a process that successively "generates" the values of the variables. At each step, the probability of some value being generated may depend only on the generation history (or a subset thereof), and the possible values a variable will take must form a locally normalized conditional probability distribution (CPD). While these locally normalized CPDs may be pa-

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 409–419,
Portland, Oregon, June 19-24, 2011.

rameterized so as to make use of multiple, overlapping features (Berg-Kirkpatrick et al., 2010), the requirement that models factorize according to a particular generative process imposes a considerable restriction on the *kinds* of features that can be incorporated. When Brown et al. (1993) wanted to incorporate a fertility model to create their Models 3 through 5, the generative process used in Models 1 and 2 (where target words were generated one by one from source words independently of each other) had to be abandoned in favor of one in which each source word had to first decide how many targets it would generate.[1]

In this paper, we introduce a discriminatively trained, globally normalized log-linear model of lexical translation that can incorporate arbitrary, overlapping features, and use it to infer word alignments. Our model enjoys the usual benefits of discriminative modeling (e.g., parameter regularization, well-understood learning algorithms), but is trained entirely from parallel sentences without gold-standard word alignments. Thus, it addresses the two limitations of current word alignment approaches.

This paper is structured as follows. We begin by introducing our model (§2), and follow this with a discussion of tractability, parameter estimation, and inference using finite-state techniques (§3). We then describe the specific features we used (§4) and provide experimental evaluation of the model, showing substantial improvements in three diverse language pairs (§5). We conclude with an analysis of related prior work (§6) and a general discussion (§8).

2 Model

In this section, we develop a conditional model $p(\mathbf{t} \mid \mathbf{s})$ that, given a source language sentence $\mathbf{s}$ with length $m = |\mathbf{s}|$, assigns probabilities to a target sentence $\mathbf{t}$ with length n, where each word t_j is an element in the finite target vocabulary Ω. We begin by using the chain rule to factor this probability into two components, a translation model and a length model.

$$p(\mathbf{t} \mid \mathbf{s}) = p(\mathbf{t}, n \mid \mathbf{s}) = \underbrace{p(\mathbf{t} \mid \mathbf{s}, n)}_{\text{translation model}} \times \underbrace{p(n \mid \mathbf{s})}_{\text{length model}}$$

[1] Moore (2005) likewise uses this example to motivate the need for models that support arbitrary, overlapping features.

In the translation model, we then assume that each word t_j is a translation of one source word, or a special null token. We therefore introduce a latent *alignment* variable $\mathbf{a} = \langle a_1, a_2, \ldots, a_n \rangle \in [0, m]^n$, where $a_j = 0$ represents a special null token.

$$p(\mathbf{t} \mid \mathbf{s}, n) = \sum_{\mathbf{a}} p(\mathbf{t}, \mathbf{a} \mid \mathbf{s}, n)$$

So far, our model is identical to that of (Brown et al., 1993); however, we part ways here. Rather than using the chain rule to further decompose this probability and motivate opportunities to make independence assumptions, we use a log-linear model with parameters $\boldsymbol{\theta} \in \mathbb{R}^k$ and feature vector function $\mathbf{H}$ that maps each tuple $\langle \mathbf{a}, \mathbf{s}, \mathbf{t}, n \rangle$ into $\mathbb{R}^k$ to model $p(\mathbf{t}, \mathbf{a} \mid \mathbf{s}, n)$ directly:

$$p_{\boldsymbol{\theta}}(\mathbf{t}, \mathbf{a} \mid \mathbf{s}, n) = \frac{\exp \boldsymbol{\theta}^\top \mathbf{H}(\mathbf{t}, \mathbf{a}, \mathbf{s}, n)}{Z_{\boldsymbol{\theta}}(\mathbf{s}, n)}, \quad \text{where}$$

$$Z_{\boldsymbol{\theta}}(\mathbf{s}, n) = \sum_{\mathbf{t}' \in \Omega^n} \sum_{\mathbf{a}'} \exp \boldsymbol{\theta}^\top \mathbf{H}(\mathbf{t}', \mathbf{a}', \mathbf{s}, n)$$

Under some reasonable assumptions (a finite target vocabulary Ω and that all $\theta_k < \infty$), the partition function $Z_{\boldsymbol{\theta}}(\mathbf{s}, n)$ will always take on finite values, guaranteeing that $p(\mathbf{t}, \mathbf{a} \mid \mathbf{s}, n)$ is a proper probability distribution.

So far, we have said little about the length model. Since our intent here is to use the model for alignment, where both the target length and target string are observed, it will not be necessary to commit to any length model, even during training.

3 Tractability, Learning, and Inference

The model introduced in the previous section is extremely general, and it can incorporate features sensitive to any imaginable aspects of a sentence pair and their alignment, from linguistically inspired (e.g., an indicator feature for whether both the source and target sentences contain a verb), to the mundane (e.g., the probability of the sentence pair and alignment under Model 1), to the absurd (e.g., an indicator if $\mathbf{s}$ and $\mathbf{t}$ are palindromes of each other).

However, while our model can make use of arbitrary, overlapping features, when designing feature functions it is necessary to balance expressiveness and the computational complexity of the inference

algorithms used to reason under models that incorporate these features.[2] To understand this tradeoff, we assume that the random variables being modeled $(\mathbf{t}, \mathbf{a})$ are arranged into an undirected graph $\mathcal{G}$ such that the vertices represent the variables and the edges are specified so that the feature function $\mathbf{H}$ decomposes linearly over all the cliques C in $\mathcal{G}$,

$$\mathbf{H}(\mathbf{t}, \mathbf{a}, \mathbf{s}, n) = \sum_{C} \mathbf{h}(\mathbf{t}_C, \mathbf{a}_C, \mathbf{s}, n) \quad ,$$

where $\mathbf{t}_C$ and $\mathbf{a}_C$ are the components associated with subgraph C and $\mathbf{h}(\cdot)$ is a *local* feature vector function. In general, exact inference is exponential in the width of tree-decomposition of $\mathcal{G}$, but, given a fixed width, they can be solved in polynomial time using dynamic programming. For example, when the graph has a sequential structure, exact inference can be carried out using the familiar forward-backward algorithm (Lafferty et al., 2001). Although our features look at more structure than this, they are designed to keep treewidth low, meaning exact inference is still possible with dynamic programming. Figure 1 gives a graphical representation of our model as well as the more familiar generative (directed) variants. The edge set in the depicted graph is determined by the features that we use (§4).

3.1 Parameter Learning

To learn the parameters of our model, we select the $\boldsymbol{\theta}^*$ that minimizes the ℓ_1 regularized conditional log-likelihood of a set of training data $\mathcal{T}$:

$$\mathcal{L}(\boldsymbol{\theta}) = -\sum_{\langle \mathbf{s}, \mathbf{t} \rangle \in \mathcal{T}} \log \sum_{\mathbf{a}} p_{\boldsymbol{\theta}}(\mathbf{t}, \mathbf{a} \mid \mathbf{s}, n) + \beta \sum_{k} |\theta_k| \quad .$$

Because of the ℓ_1 penalty, this objective is not everywhere differentiable, but the gradient with respect to the parameters of the log-likelihood term is as follows.

$$\frac{\partial \mathcal{L}}{\partial \boldsymbol{\theta}} = \sum_{\langle \mathbf{s}, \mathbf{t} \rangle \in \mathcal{T}} \mathbb{E}_{p_{\boldsymbol{\theta}}(\mathbf{a} | \mathbf{s}, \mathbf{t}, n)}[\mathbf{H}(\cdot)] - \mathbb{E}_{p_{\boldsymbol{\theta}}(\mathbf{t}, \mathbf{a} | \mathbf{s}, n)}[\mathbf{H}(\cdot)] \tag{1}$$

To optimize $\mathcal{L}$, we employ an online method that approximates ℓ_1 regularization and only depends on the gradient of the unregularized objective (Tsuruoka et al., 2009). This method is quite attractive since it is only necessary to represent the active features, meaning impractically large feature spaces can be searched provided the regularization strength is sufficiently high. Additionally, not only has this technique been shown to be very effective for optimizing convex objectives, but evidence suggests that the stochasticity of online algorithms often results in better solutions than batch optimizers for non-convex objectives (Liang and Klein, 2009). On account of the latent alignment variable in our model, $\mathcal{L}$ is non-convex (as is the likelihood objective of the generative variant).

To choose the regularization strength β and the initial learning rate η_0,[3] we trained several models on a 10,000-sentence-pair subset of the French-English Hansards, and chose values that minimized the alignment error rate, as evaluated on a 447 sentence set of manually created alignments (Mihalcea and Pedersen, 2003). For the remainder of the experiments, we use the values we obtained, $\beta = 0.4$ and $\eta_0 = 0.3$.

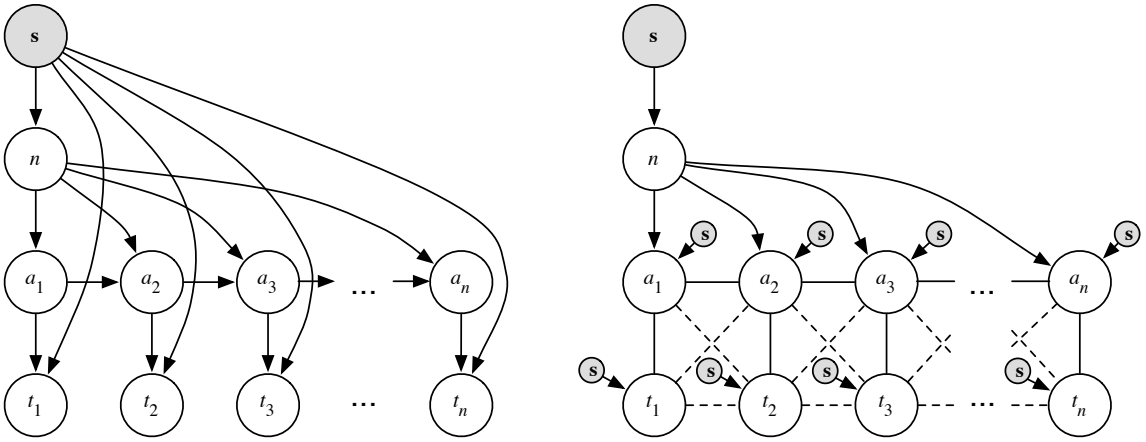
3.2 Inference with WFSAs

We now describe how to use weighted finite-state automata (WFSAs) to compute the quantities necessary for training. We begin by describing the ideal WFSA representing the full translation search space, which we call the *discriminative neighborhood*, and then discuss strategies for reducing its size in the next section, since the full model is prohibitively large, even with small data sets.

For each training instance $\langle \mathbf{s}, \mathbf{t} \rangle$, the contribution to the gradient (Equation 1) is the difference in two vectors of expectations. The first term is the expected value of $\mathbf{H}(\cdot)$ when observing $\langle \mathbf{s}, n, \mathbf{t} \rangle$ and letting $\mathbf{a}$ range over all possible alignments. The second is the expectation of the same function, but observing only $\langle \mathbf{s}, n \rangle$ and letting $\mathbf{t}'$ and $\mathbf{a}$ take on any possible values (i.e., all possible translations of length n and all their possible alignments to $\mathbf{s}$). To compute these expectations, we can construct a WFSA representing the discriminative neighborhood, the set $\Omega^n \times [0, m]^n$, such that every path from the start state to goal yields a pair $\langle \mathbf{t}', \mathbf{a} \rangle$ with weight

[2] One way to understand expressiveness is in terms of independence assumptions, of course. Research in graphical models has done much to relate independence assumptions to the complexity of inference algorithms (Koller and Friedman, 2009).

[3] For the other free parameters of the algorithm, we use the default values recommended by Tsuruoka et al. (2009).



Fully directed model (Brown et al., 1993; Vogel et al., 1996; Berg-Kirkpatrick et al., 2010)

Our model

Figure 1: A graphical representation of a conventional generative lexical translation model (left) and our model with an undirected translation model. For clarity, the observed node **s** (representing the full source sentence) is drawn in multiple locations. The dashed lines indicate a dependency on a deterministic mapping of t_j (not its complete value).

$\mathbf{H}(\mathbf{t}', \mathbf{a}, \mathbf{s}, n)$. With our feature set (§4), number of states in this WFSA is $O(m \times n)$ since at each target index j, there is a different state for each possible index of the source word translated at position $j - 1$.[4]

Once the WFSA representing the discriminative neighborhood is built, we use the forward-backward algorithm to compute the *second* expectation term. We then intersect the WFSA with an unweighted FSA representing the target sentence **t** (because of the restricted structure of our WFSA, this amounts to removing edges), and finally run the forward-backward algorithm on the resulting WFSA to compute the first expectation.

3.3 Shrinking the Discriminative Neighborhood

The WFSA we constructed requires $m \times |\Omega|$ transitions between all adjacent states, which is impractically large. We can reduce the number of edges by restricting the set of words that each source word can translate into. Thus, the model will not discriminate among all candidate target strings in Ω^n, but rather in $\Omega^n_{\mathbf{s}}$, where $\Omega_{\mathbf{s}} = \bigcup_{i=1}^{m} \Omega_{s_i}$, and where Ω_s is the set of target words that s may translate into.[5]

We consider four different definitions of Ω_s: (1) the baseline of the full target vocabulary, (2) the set of all target words that co-occur in sentence pairs containing s, (3) the most probable words under IBM Model 1 that are above a threshold, and (4) the same Model 1, except we add a sparse symmetric Dirichlet prior ($\alpha = 0.01$) on the translation distributions and use the empirical Bayes (EB) method to infer a point estimate, using variational inference.

Table 1: Comparison of alternative definitions Ω_s (arrows indicate whether higher or lower is better).

Ω_s	time (s) ↓	$\sum_s \lvert\Omega_s\rvert$ ↓	AER ↓
$= \Omega$	22.4	86.0M	**0.0**
co-occ.	8.9	0.68M	**0.0**
Model 1	**0.2**	0.38M	6.2
EB-Model 1	1.0	**0.15M**	2.9

Table 1 compares the average per-sentence time required to run the inference algorithm described

[4] States contain a bit more information than the index of the previous source word, for example, there is some additional information about the previous translation decision that is passed forward. However, the concept of splitting states to guarantee distinct paths for different values of non-local features is well understood by NLP and machine translation researchers, and the necessary state structure should be obvious from the feature description.

[5] Future work will explore alternative formulations of the discriminative neighborhood with the goal of further improving inference efficiency. Smith and Eisner (2005) show that good performance on unsupervised syntax learning is possible even when learning from very small discriminative neighborhoods, and we posit that the same holds here.

above under these four different definitions of Ω_s on a 10,000 sentence subset of the Hansards French-English corpus that includes manual word alignments. While our constructions guarantee that all references are reachable even in the reduced neighborhoods, not all *alignments* between source and target are possible. The last column is the *oracle* AER. Although EB variant of Model 1 neighborhood is slightly more expensive to do inference with than regular Model 1, we use it because it has a lower oracle AER.[6]

During alignment prediction (rather than during training) for a sentence pair $\langle \mathbf{s}, \mathbf{t} \rangle$, it is possible to further restrict $\Omega_\mathbf{s}$ to be just the set of words occurring in $\mathbf{t}$, making extremely fast inference possible (comparable to that of the generative HMM alignment model).

4 Features

Feature engineering lets us encode knowledge about what aspects of a translation derivation are useful in predicting whether it is good or not. In this section we discuss the features we used in our model. Many of these were taken from the discriminative alignment modeling literature, but we also note that our features can be much more fine-grained than those used in supervised alignment modeling, since we learn our models from a large amount of parallel data, rather than a small number of manual alignments.

Word association features. Word association features are at the heart of all lexical translation models, whether generative or discriminative. In addition to fine-grained boolean indicator features $\langle s_{a_j}, t_j \rangle$ for pair types, we have several orthographic features: identity, prefix identity, and an orthographic similarity measure designed to be informative for predicting the translation of named entities in languages that use similar alphabets.[7] It has the property that source-target pairs of *long* words that are similar are given a higher score than word pairs that are *short* and similar (dissimilar pairs have a score near zero, regardless of length). We also include "global" association scores that are precomputed by looking at the full training data: Dice's coefficient (discretized), which we use to measure association strength between pairs of source and target word types across sentence pairs (Dice, 1945), IBM Model 1 forward and reverse probabilities, and the geometric mean of the Model 1 forward and reverse probabilities. Finally, we also cluster the source and target vocabularies (Och, 1999) and include class pair indicator features, which can learn generalizations that, e.g., "nouns tend to translate into nouns but not modal verbs."

Positional features. Following Blunsom and Cohn (2006), we include features indicating closeness to the alignment matrix diagonal, $h(a_j, j, m, n) = \left| \frac{a_j}{m} - \frac{j}{n} \right|$. We also conjoin this feature with the source word class type indicator to enable the model to learn that certain word types are more or less likely to favor a location on the diagonal (e.g. Urdu's sentence-final verbs).

Source features. Some words are functional elements that fulfill purely grammatical roles and should not be the "source" of a translation. For example, Romance languages require a preposition in the formation of what could be a noun-noun compound in English, thus, it may be useful to learn *not* to translate certain words (i.e. they should not participate in alignment links), or to have a bias to translate others. To capture this intuition we include an indicator feature that fires each time a source vocabulary item (and source word class) participates in an alignment link.

Source path features. One class of particularly useful features assesses the goodness of the alignment 'path' through the source sentence (Vogel et al., 1996). Although assessing the predicted path requires using nonlocal features, since each $a_j \in [0, m]$ and m is relatively small, features can be sensitive to a wider context than is often practical.

We use many overlapping source path features, some of which are sensitive to the distance and direction of the jump between a_{j-1} and a_j, and others which are sensitive to the word pair these two points define, and others that combine all three elements. The features we use include a discretized

[6] We included all translations whose probability was within a factor of 10^{-4} of the highest probability translation.

[7] In experiments with Urdu, which uses an Arabic-derived script, the orthographic feature was computed after first applying a heuristic Romanization, which made the orthographic forms somewhat comparable.

jump distance, the discretized jump conjoined with an indicator feature for the target length n, the discretized jump feature conjoined with the class of s_{a_j}, and the discretized jump feature conjoined with the class of s_{a_j} and $s_{a_{j-1}}$. To discretize the features we take a log transform (base 1.3) of the jump width and let an indicator feature fire for the closest integer. In addition to these distance-dependent features, we also include indicator features that fire on bigrams $\langle s_{a_{j-1}}, s_{a_j} \rangle$ and their word classes. Thus, this feature can capture our intuition that, e.g., adjectives are more likely to come before or after a noun in different languages.

Target string features. Features sensitive to multiple values in the predicted target string or latent alignment variable must be handled carefully for the sake of computational tractability. While features that look at multiple source words can be computed linearly in the number of source words considered (since the source string is always observable), features that look at multiple target words require exponential time and space![8] However, by grouping the t_j's into coarse equivalence classes and looking at small numbers of variables, it is possible to incorporate such features. We include a feature that fires when a word translates as itself (for example, a name or a date, which occurs in languages that share the same alphabet) in position j, but then is translated again (as something else) in position $j-1$ or $j+1$.

5 Experiments

We now turn to an empirical assessment of our model. Using various datasets, we evaluate the performance of the models' intrinsic quality and theirtheir alignments' contribution to a standard machine translation system. We make use of parallel corpora from languages with very different typologies: a small (0.8M words) Chinese-English corpus from the tourism and travel domain (Takezawa et al., 2002), a corpus of Czech-English news commentary (3.1M words),[9] and an Urdu-English corpus (2M words) provided by NIST for the 2009 Open MT Evaluation. These pairs were selected since each poses different alignment challenges (word order in Chinese and Urdu, morphological complexity in Czech, and a non-alphabetic writing system in Chinese), and confining ourselves to these relatively small corpora reduced the engineering overhead of getting an implementation up and running. Future work will explore the scalability characteristics and limits of the model.

5.1 Methodology

For each language pair, we train two log-linear translation models as described above (§3), once with English as the source and once with English as the target language. For a baseline, we use the Giza++ toolkit (Och and Ney, 2003) to learn Model 4, again in both directions. We symmetrize the alignments from both model types using the `grow-diag-final-and` heuristic (Koehn et al., 2003) producing, in total, six alignment sets. We evaluate them both intrinsically and in terms of their performance in a translation system.

Since we only have gold alignments for Czech-English (Bojar and Prokopová, 2006), we can report alignment error rate (AER; Och and Ney, 2003) only for this pair. However, we offer two further measures that we believe are suggestive and that do not require gold alignments. One is the average alignment "fertility" of source words that occur only a single time in the training data (so-called *hapax legomena*). This assesses the impact of a typical alignment problem observed in generative models trained to maximize likelihood: infrequent source words act as "garbage collectors", with many target words aligned to them (the word *dislike* in the Model 4 alignment in Figure 2 is an example). Thus, we expect lower values of this measure to correlate with better alignments. The second measure is the number of rule types learned in the grammar induction process used for translation that match the translation test sets.[10] While neither a decrease in the average singleton fertility nor an increase in the number of rules induced guarantees better alignment quality, we believe it is reasonable to assume that they are positively correlated.

For the translation experiments in each language pair, we make use of the `cdec` decoder (Dyer et al.,

[8] This is of course what makes history-based language model integration an inference challenge in translation.

[9] `http://statmt.org/wmt10`

[10] This measure does not assess whether the rule types are good or bad, but it does suggest that the system's coverage is greater.

2010), inducing a hierarchical phrase based translation grammar from two sets of symmetrized alignments using the method described by Chiang (2007). Additionally, recent work that has demonstrated that extracting rules from n-best alignments has value (Liu et al., 2009; Venugopal et al., 2008). We therefore define a third condition where rules are extracted from the corpus under *both* the Model 4 and discriminative alignments and merged to form a single grammar. We incorporate a 3-gram language model learned from the target side of the training data as well as 50M supplemental words of monolingual training data consisting of sentences randomly sampled from the English Gigaword, version 4. In the small Chinese-English travel domain experiment, we just use the LM estimated from the bitext. The parameters of the translation model were tuned using "hypergraph" minimum error rate training (MERT) to maximize BLEU on a held-out development set (Kumar et al., 2009). Results are reported using case-insensitive BLEU (Papineni et al., 2002), METEOR[11] (Lavie and Denkowski, 2009), and TER (Snover et al., 2006), with the number of references varying by task. Since MERT is a non-deterministic optimization algorithm and results can vary considerably between runs, we follow Clark et al. (2011) and report the *average* score and standard deviation of 5 independent runs, 30 in the case of Chinese-English, since observed variance was higher.

5.2 Experimental Results

Czech-English. Czech-English poses problems for word alignment models since, unlike English, Czech words have a complex inflectional morphology, and the syntax permits relatively free word order. For this language pair, we evaluate alignment error rate using the manual alignment corpus described by Bojar and Prokopová (2006). Table 2 summarizes the results.

Chinese-English. Chinese-English poses a different set of problems for alignment. While Chinese words have rather simple morphology, the Chinese writing system renders our orthographic features useless. Despite these challenges, the Chinese results in Table 3 show the same pattern of results as seen in Czech-English.

Table 2: Czech-English experimental results. $\tilde{\phi}_{sing.}$ is the average fertility of singleton source words.

Urdu-English. Urdu-English is a more challenging language pair for word alignment than the previous two we have considered. The parallel data is drawn from numerous genres, and much of it was acquired automatically, making it quite noisy. So our models must not only predict good translations, they must cope with bad ones as well. Second, there has been no previous work on discriminative modeling of Urdu, since, to our knowledge, no manual alignments have been created. Finally, unlike English, Urdu is a head-final language: not only does it have SOV word order, but rather than prepositions, it has post-positions, which follow the nouns they modify, meaning its large scale word order is substantially

[11] Meteor 1.0 with exact, stem, synonymy, and paraphrase modules and HTER parameters.

different from that of English. Table 4 demonstrates the same pattern of improving results with our alignment model.

5.3 Analysis

The quantitative results presented in this section strongly suggest that our modeling approach produces better alignments. In this section, we try to characterize how the model is doing what it does and what it has learned. Because of the ℓ_1 regularization, the number of active (non-zero) features in the inferred models is small, relative to the number of features considered during training. The number of active features ranged from about 300k for the small Chinese-English corpus to 800k for Urdu-English, which is less than one tenth of the available features in both cases. In all models, the coarse features (Model 1 probabilities, Dice coefficient, coarse positional features, etc.) typically received weights with large magnitudes, but finer features also played an important role.

Language pair differences manifested themselves in many ways in the models that were learned. For example, orthographic features were (unsurprisingly) more valuable in Czech-English, with their largely overlapping alphabets, than in Chinese or Urdu. Examining the more fine-grained features is also illuminating. Table 5 shows the most highly weighted source path bigram features on the three models where English was the source language, and in each, we may observe some interesting characteristics of the target language. Left-most is English-Czech. At first it may be surprising that words like *since* and *that* have a highly weighted feature for transitioning to themselves. However, Czech punctuation rules require that relative clauses and subordinating conjunctions be preceded by a comma (which is only optional or outright forbidden in English), therefore our model translates these words twice, once to produce the comma, and a second time to produce the lexical item. The middle column is the English-Chinese model. In the training data, many of the sentences are questions directed to a second person, *you*. However, Chinese questions do not invert and the subject remains in the canonical first position, thus the transition from the start of sentence to *you* is highly weighted. Finally, Figure 2 illustrates how Model 4 (left) and our discriminative model (right) align an English-Urdu sentence pair (the English side is being conditioned on in both models). A reflex of Urdu's head-final word order is seen in the list of most highly weighted bigrams, where a path through the English source where verbs that transition to end-of-sentence periods are predictive of good translations into Urdu.

Table 5: The most highly weighted source path bigram features in the English-Czech, -Chinese, and -Urdu models.

6 Related Work

The literature contains numerous descriptions of discriminative approaches to word alignment motivated by the desire to be able to incorporate multiple, overlapping knowledge sources (Ayan et al., 2005; Moore, 2005; Taskar et al., 2005; Blunsom and Cohn, 2006; Haghighi et al., 2009; Liu et al., 2010; DeNero and Klein, 2010; Setiawan et al., 2010). This body of work has been an invaluable source of useful features. Several authors have dealt with the problem training log-linear models in an unsu-

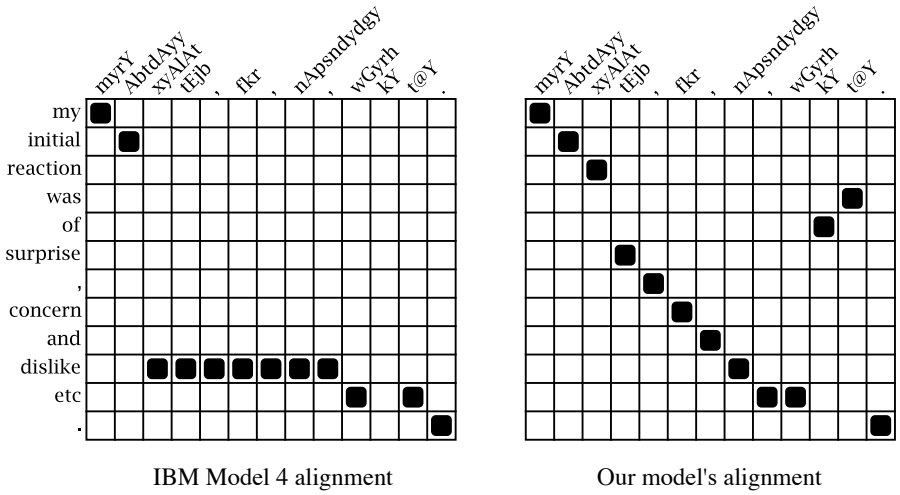

Figure 2: Example English-Urdu alignment under IBM Model 4 (left) and our discriminative model (right). Model 4 displays two characteristic errors: garbage collection and an overly-strong monotonicity bias. Whereas our model does not exhibit these problems, and in fact, makes no mistakes in the alignment.

pervised setting. The contrastive estimation technique proposed by Smith and Eisner (2005) is globally normalized (and thus capable of dealing with arbitrary features), and closely related to the model we developed; however, they do not discuss the problem of word alignment. Berg-Kirkpatrick et al. (2010) learn locally normalized log-linear models in a generative setting. Globally normalized discriminative models with latent variables (Quattoni et al., 2004) have been used for a number of language processing problems, including MT (Dyer and Resnik, 2010; Blunsom et al., 2008a). However, this previous work relied on translation grammars constructed using standard generative word alignment processes.

7 Future Work

While we have demonstrated that this model can be substantially useful, it is limited in some important ways which are being addressed in ongoing work. First, training is expensive, and we are exploring alternatives to the conditional likelihood objective that is currently used, such as contrastive neighborhoods advocated by (Smith and Eisner, 2005). Additionally, there is much evidence that non-local features like the source word fertility are (*cf.* IBM Model 3) useful for translation and alignment modeling. To be truly general, it must be possible to utilize such features. Unfortunately, features like this that depend on global properties of the alignment vector, **a**, make the inference problem NP-hard, and approximations are necessary. Fortunately, there is much recent work on approximate inference techniques for incorporating nonlocal features (Blunsom et al., 2008b; Gimpel and Smith, 2009; Cromières and Kurohashi, 2009; Weiss and Taskar, 2010), suggesting that this problem too can be solved using established techniques.

8 Conclusion

We have introduced a globally normalized, log-linear lexical translation model that can be trained discriminatively using only parallel sentences, which we apply to the problem of word alignment. Our approach addresses two important shortcomings of previous work: (1) that local normalization of generative models constrains the features that can be used, and (2) that previous discriminatively trained word alignment models required supervised alignments. According to a variety of measures in a variety of translation tasks, this model produces superior alignments to generative approaches. Furthermore, the features learned by our model reveal interesting characteristics of the language pairs being modeled.

Model-Based Aligner Combination Using Dual Decomposition

Abstract

Unsupervised word alignment is most often modeled as a Markov process that generates a sentence $\boldsymbol{f}$ conditioned on its translation $\boldsymbol{e}$. A similar model generating $\boldsymbol{e}$ from $\boldsymbol{f}$ will make different alignment predictions. Statistical machine translation systems combine the predictions of two directional models, typically using heuristic combination procedures like *grow-diag-final*. This paper presents a graphical model that embeds two directional aligners into a single model. Inference can be performed via dual decomposition, which reuses the efficient inference algorithms of the directional models. Our bidirectional model enforces a one-to-one phrase constraint while accounting for the uncertainty in the underlying directional models. The resulting alignments improve upon baseline combination heuristics in word-level and phrase-level evaluations.

1 Introduction

Word alignment is the task of identifying corresponding words in sentence pairs. The standard approach to word alignment employs directional Markov models that align the words of a sentence $\boldsymbol{f}$ to those of its translation $\boldsymbol{e}$, such as IBM Model 4 (Brown et al., 1993) or the HMM-based alignment model (Vogel et al., 1996).

Machine translation systems typically combine the predictions of two directional models, one which aligns $\boldsymbol{f}$ to $\boldsymbol{e}$ and the other $\boldsymbol{e}$ to $\boldsymbol{f}$ (Och et al., 1999). Combination can reduce errors and relax the one-to-many structural restriction of directional models. Common combination methods include the union or intersection of directional alignments, as well as heuristic interpolations between the union and intersection like *grow-diag-final* (Koehn et al., 2003). This paper presents a model-based alternative to aligner combination. Inference in a probabilistic model resolves the conflicting predictions of two directional models, while taking into account each model's uncertainty over its output.

This result is achieved by embedding two directional HMM-based alignment models into a larger bidirectional graphical model. The full model structure and potentials allow the two embedded directional models to disagree to some extent, but reward agreement. Moreover, the bidirectional model enforces a one-to-one phrase alignment structure, similar to the output of phrase alignment models (Marcu and Wong, 2002; DeNero et al., 2008), unsupervised inversion transduction grammar (ITG) models (Blunsom et al., 2009), and supervised ITG models (Haghighi et al., 2009; DeNero and Klein, 2010).

Inference in our combined model is not tractable because of numerous edge cycles in the model graph. However, we can employ dual decomposition as an approximate inference technique (Rush et al., 2010). In this approach, we iteratively apply the same efficient sequence algorithms for the underlying directional models, and thereby optimize a dual bound on the model objective. In cases where our algorithm converges, we have a certificate of optimality under the full model. Early stopping before convergence still yields useful outputs.

Our model-based approach to aligner combination yields improvements in alignment quality and phrase extraction quality in Chinese-English experiments, relative to typical heuristic combinations methods applied to the predictions of independent directional models.

2 Model Definition

Our bidirectional model $\mathcal{G} = (\mathcal{V}, \mathcal{D})$ is a globally normalized, undirected graphical model of the word alignment for a fixed sentence pair $(\boldsymbol{e}, \boldsymbol{f})$. Each vertex in the vertex set $\mathcal{V}$ corresponds to a model variable V_i, and each undirected edge in the edge set $\mathcal{D}$ corresponds to a pair of variables (V_i, V_j). Each vertex has an associated potential function $\omega_i(v_i)$ that assigns a real-valued potential to each possible value v_i of V_i.[1] Likewise, each edge has an associated potential function $\mu_{ij}(v_i, v_j)$ that scores pairs of values. The probability under the model of any full assignment $\boldsymbol{v}$ to the model variables, indexed by $\mathcal{V}$, factors over vertex and edge potentials.

$$\mathrm{P}(\boldsymbol{v}) \propto \prod_{v_i \in \mathcal{V}} \omega_i(v_i) \cdot \prod_{(v_i, v_j) \in \mathcal{D}} \mu_{ij}(v_i, v_j)$$

Our model contains two directional hidden Markov alignment models, which we review in Section 2.1, along with additional structure that that we introduce in Section 2.2.

2.1 HMM-Based Alignment Model

This section describes the classic hidden Markov model (HMM) based alignment model (Vogel et al., 1996). The model generates a sequence of words $\boldsymbol{f}$ conditioned on a word sequence $\boldsymbol{e}$. We conventionally index the words of $\boldsymbol{e}$ by i and $\boldsymbol{f}$ by j. $\mathrm{P}(\boldsymbol{f}|\boldsymbol{e})$ is defined in terms of a latent alignment vector $\mathbf{a}$, where $a_j = i$ indicates that word position i of $\boldsymbol{e}$ aligns to word position j of $\boldsymbol{f}$.

$$\mathrm{P}(\boldsymbol{f}|\boldsymbol{e}) = \sum_{\mathbf{a}} \mathrm{P}(\boldsymbol{f}, \mathbf{a}|\boldsymbol{e})$$

$$\mathrm{P}(\boldsymbol{f}, \mathbf{a}|\boldsymbol{e}) = \prod_{j=1}^{|\boldsymbol{f}|} \mathrm{D}(a_j|a_{j-1}) \mathrm{M}(f_j|e_{a_j}) \; . \quad (1)$$

In Equation 1 above, the emission model M is a learned multinomial distribution over word types. The transition model D is a multinomial over transition distances, which treats null alignments as a special case.

$$\mathrm{D}(a_j = 0|a_{j-1} = i) = \mathrm{p}_o$$
$$\mathrm{D}(a_j = i' \neq 0|a_{j-1} = i) = (1 - \mathrm{p}_o) \cdot c(i' - i) \; ,$$

where $c(i' - i)$ is a learned distribution over signed distances, normalized over the possible transitions from i. The parameters of the conditional multinomial M and the transition model c can be learned from a sentence aligned corpus via the expectation maximization algorithm. The null parameter p_o is typically fixed.[2]

The highest probability word alignment vector under the model for a given sentence pair $(\boldsymbol{e}, \boldsymbol{f})$ can be computed exactly using the standard Viterbi algorithm for HMMs in $O(|\boldsymbol{e}|^2 \cdot |\boldsymbol{f}|)$ time.

An alignment vector $\mathbf{a}$ can be converted trivially into a set of word alignment links $\mathcal{A}$:

$$\mathcal{A}_{\mathbf{a}} = \{(i, j) : a_j = i, i \neq 0\} \; .$$

$\mathcal{A}_{\mathbf{a}}$ is constrained to be many-to-one from $\boldsymbol{f}$ to $\boldsymbol{e}$; many positions j can align to the same i, but each j appears at most once.

We have defined a directional model that generates $\boldsymbol{f}$ from $\boldsymbol{e}$. An identically structured model can be defined that generates $\boldsymbol{e}$ from $\boldsymbol{f}$. Let $\mathbf{b}$ be a vector of alignments where $b_i = j$ indicates that word position j of $\boldsymbol{f}$ aligns to word position i of $\boldsymbol{e}$. Then, $\mathrm{P}(\boldsymbol{e}, \mathbf{b}|\boldsymbol{f})$ is defined similarly to Equation 1, but with $\boldsymbol{e}$ and $\boldsymbol{f}$ swapped. We can distinguish the transition and emission distributions of the two models by subscripting them with their generative direction.

$$\mathrm{P}(\boldsymbol{e}, \mathbf{b}|\boldsymbol{f}) = \prod_{j=1}^{|\boldsymbol{e}|} \mathrm{D}_{\boldsymbol{f} \to \boldsymbol{e}}(b_i|b_{i-1}) \mathrm{M}_{\boldsymbol{f} \to \boldsymbol{e}}(e_i|f_{b_i}) \; .$$

The vector $\mathbf{b}$ can be interpreted as a set of alignment links that is one-to-many: each value i appears at most once in the set.

$$\mathcal{A}_{\mathbf{b}} = \{(i, j) : b_i = j, j \neq 0\} \; .$$

2.2 A Bidirectional Alignment Model

We can combine two HMM-based directional alignment models by embedding them in a larger model

[1] Potentials in an undirected model play the same role as conditional probabilities in a directed model, but do not need to be locally normalized.

[2] In experiments, we set $\mathrm{p}_o = 10^{-6}$. Transitions from a null-aligned state $a_{j-1} = 0$ are also drawn from a fixed distribution, where $\mathrm{D}(a_j = 0|a_{j-1} = 0) = 10^{-4}$ and for $i' \geq 1$,

$$\mathrm{D}(a_j = i'|a_{j-1} = 0) \propto 0.8^{\left(-\left|i' \cdot \frac{|\boldsymbol{f}|}{|\boldsymbol{e}|} - j\right|\right)} \; .$$

With small p_o, the shape of this distribution has little effect on the alignment outcome.

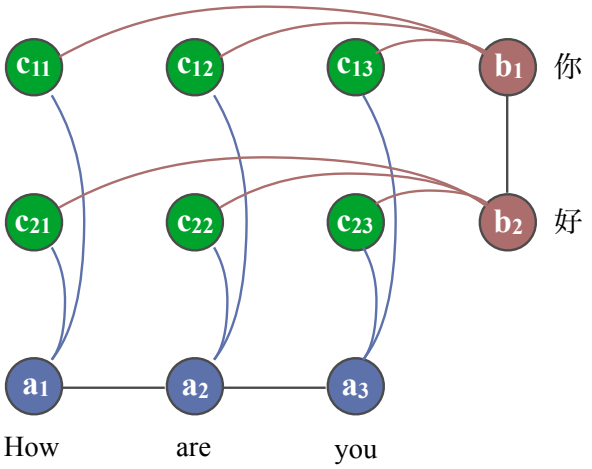

Figure 1: The structure of our graphical model for a simple sentence pair. The variables $\mathbf{a}$ are blue, $\mathbf{b}$ are red, and $\mathbf{c}$ are green.

that includes all of the random variables of two directional models, along with additional structure that promotes agreement and resolves discrepancies.

The original directional models include observed word sequences $\boldsymbol{e}$ and $\boldsymbol{f}$, along with the two latent alignment vectors $\mathbf{a}$ and $\mathbf{b}$ defined in Section 2.1. Because the word types and lengths of $\boldsymbol{e}$ and $\boldsymbol{f}$ are always fixed by the observed sentence pair, we can define our model only over $\mathbf{a}$ and $\mathbf{b}$, where the edge potentials between any a_j, f_j, and $\boldsymbol{e}$ are compiled into a vertex potential function $\omega_j^{(\mathbf{a})}$ on a_j, defined in terms of $\boldsymbol{f}$ and $\boldsymbol{e}$, and likewise for any b_i.

$$\omega_j^{(\mathbf{a})}(i) = \mathrm{M}_{\boldsymbol{e}\to\boldsymbol{f}}(f_j|e_i)$$
$$\omega_i^{(\mathbf{b})}(j) = \mathrm{M}_{\boldsymbol{f}\to\boldsymbol{e}}(e_i|f_j)$$

The edge potentials between $\mathbf{a}$ and $\mathbf{b}$ encode the transition model in Equation 1.

$$\mu_{j-1,j}^{(\mathbf{a})}(i,i') = \mathrm{D}_{\boldsymbol{e}\to\boldsymbol{f}}(a_j = i'|a_{j-1} = i)$$
$$\mu_{i-1,i}^{(\mathbf{b})}(j,j') = \mathrm{D}_{\boldsymbol{f}\to\boldsymbol{e}}(b_i = j'|b_{i-1} = j)$$

In addition, we include in our model a latent boolean matrix $\mathbf{c}$ that encodes the output of the combined aligners:

$$\mathbf{c} \in \{0,1\}^{|\boldsymbol{e}|\times|\boldsymbol{f}|} .$$

This matrix encodes the alignment links proposed by the bidirectional model:

$$\mathcal{A}_{\mathbf{c}} = \{(i,j) : c_{ij} = 1\} .$$

Each model node for an element $c_{ij} \in \{0,1\}$ is connected to a_j and b_i via *coherence edges*. These edges allow the model to ensure that the three sets of variables, $\mathbf{a}$, $\mathbf{b}$, and $\mathbf{c}$, together encode a coherent alignment analysis of the sentence pair. Figure 1 depicts the graph structure of the model.

2.3 Coherence Potentials

The potentials on coherence edges are not learned and do not express any patterns in the data. Instead, they are fixed functions that promote consistency between the integer-valued directional alignment vectors $\mathbf{a}$ and $\mathbf{b}$ and the boolean-valued matrix $\mathbf{c}$.

Consider the assignment $a_j = i$, where $i = 0$ indicates that word f_j is null-aligned, and $i \geq 1$ indicates that f_j aligns to e_i. The coherence potential ensures the following relationship between the variable assignment $a_j = i$ and the variables $c_{i'j}$, for any $i' \in [1, |\boldsymbol{e}|]$.

- If $i = 0$ (null-aligned), then all $c_{i'j} = 0$.
- If $i > 0$, then $c_{ij} = 1$.
- $c_{i'j} = 1$ only if $i' \in \{i-1,\ i,\ i+1\}$.
- Assigning $c_{i'j} = 1$ for $i' \neq i$ incurs a cost $e^{-\alpha}$.

Collectively, the list of cases above enforce an intuitive correspondence: an alignment $a_j = i$ ensures that c_{ij} must be 1, adjacent neighbors may be 1 but incur a cost, and all other elements are 0.

This pattern of effects can be encoded in a potential function $\mu^{(\mathbf{c})}$ for each coherence edge. These edge potential functions takes an integer value i for some variable a_j and a binary value k for some $c_{i'j}$.

$$\mu_{(a_j,c_{i'j})}^{(\mathbf{c})}(i,k) = \begin{cases} 1 & i = 0 \wedge k = 0 \\ 0 & i = 0 \wedge k = 1 \\ \hline 1 & i = i' \wedge k = 1 \\ 0 & i = i' \wedge k = 0 \\ \hline 1 & i \neq i' \wedge k = 0 \\ e^{-\alpha} & |i - i'| = 1 \wedge k = 1 \\ 0 & |i - i'| > 1 \wedge k = 1 \end{cases} \quad (2)$$

Above, potentials of 0 effectively disallow certain cases because a full assignment to $(\mathbf{a}, \mathbf{b}, \mathbf{c})$ is scored by the product of all model potentials. The potential function $\mu_{(b_i,c_{ij'})}^{(\mathbf{c})}(j,k)$ for a coherence edge between $\mathbf{b}$ and $\mathbf{c}$ is defined similarly.

2.4 Model Properties

We interpret $\mathbf{c}$ as the final alignment produced by the model, ignoring $\mathbf{a}$ and $\mathbf{b}$. In this way, we relax the one-to-many constraints of the directional models. However, all of the information about how words align is expressed by the vertex and edge potentials on $\mathbf{a}$ and $\mathbf{b}$. The coherence edges and the link matrix $\mathbf{c}$ only serve to resolve conflicts between the directional models and communicate information between them.

Because directional alignments are preserved intact as components of our model, extensions or refinements to the underlying directional Markov alignment model could be integrated cleanly into our model as well, including lexicalized transition models (He, 2007), extended conditioning contexts (Brunning et al., 2009), and external information (Shindo et al., 2010).

For any assignment to $(\mathbf{a}, \mathbf{b}, \mathbf{c})$ with non-zero probability, $\mathbf{c}$ must encode a one-to-one phrase alignment with a maximum phrase length of 3. That is, any word in either sentence can align to at most three words in the opposite sentence, and those words must be contiguous. This restriction is directly enforced by the edge potential in Equation 2.

3 Model Inference

In general, graphical models admit efficient, exact inference algorithms if they do not contain cycles. Unfortunately, our model contains numerous cycles. For every pair of indices (i, j) and (i', j'), the following cycle exists in the graph:

$$c_{ij} \rightarrow b_i \rightarrow c_{ij'} \rightarrow a_{j'} \rightarrow c_{i'j'} \rightarrow b_{i'} \rightarrow c_{i'j} \rightarrow a_j \rightarrow c_{ij}$$

Additional cycles also exist in the graph through the edges between a_{j-1} and a_j and between b_{i-1} and b_i. The general phrase alignment problem under an arbitrary model is known to be NP-hard (DeNero and Klein, 2008).

3.1 Dual Decomposition

While the entire graphical model has loops, there are two overlapping subgraphs that are cycle-free. One subgraph $\mathcal{G}_\mathbf{a}$ includes all of the vertices corresponding to variables $\mathbf{a}$ and $\mathbf{c}$. The other subgraph $\mathcal{G}_\mathbf{b}$ includes vertices for variables $\mathbf{b}$ and $\mathbf{c}$. Every edge in the graph belongs to exactly one of these two subgraphs.

The dual decomposition inference approach allows us to exploit this sub-graph structure (Rush et al., 2010). In particular, we can iteratively apply exact inference to the subgraph problems, adjusting their potentials to reflect the constraints of the full problem. The technique of dual decomposition has recently been shown to yield state-of-the-art performance in dependency parsing (Koo et al., 2010).

3.2 Dual Problem Formulation

To describe a dual decomposition inference procedure for our model, we first restate the inference problem under our graphical model in terms of the two overlapping subgraphs that admit tractable inference. Let $\mathbf{c}^{(\mathbf{a})}$ be a copy of $\mathbf{c}$ associated with $\mathcal{G}_\mathbf{a}$, and $\mathbf{c}^{(\mathbf{b})}$ with $\mathcal{G}_\mathbf{b}$. Also, let $f(\mathbf{a}, \mathbf{c}^{(\mathbf{a})})$ be the unnormalized log-probability of an assignment to $\mathcal{G}_\mathbf{a}$ and $g(\mathbf{b}, \mathbf{c}^{(\mathbf{b})})$ be the unnormalized log-probability of an assignment to $\mathcal{G}_\mathbf{b}$. Finally, let $\mathcal{I}$ be the index set of all (i, j) for $\mathbf{c}$. Then, the maximum likelihood assignment to our original model can be found by optimizing

$$\max_{\mathbf{a},\mathbf{b},\mathbf{c}^{(\mathbf{a})},\mathbf{c}^{(\mathbf{b})}} f(\mathbf{a}, \mathbf{c}^{(\mathbf{a})}) + g(\mathbf{b}, \mathbf{c}^{(\mathbf{b})}) \qquad (3)$$

$$\textit{such that: } c^{(\mathbf{a})}_{ij} = c^{(\mathbf{b})}_{ij} \;\; \forall\, (i,j) \in \mathcal{I}\,.$$

The Lagrangian relaxation of this optimization problem is $L(\mathbf{a}, \mathbf{b}, \mathbf{c}^{(\mathbf{a})}, \mathbf{c}^{(\mathbf{b})}, \mathbf{u}) =$

$$f(\mathbf{a}, \mathbf{c}^{(\mathbf{a})}) + g(\mathbf{b}, \mathbf{c}^{(\mathbf{b})}) + \sum_{(i,j)\in\mathcal{I}} u(i,j)(\mathbf{c}^{(\mathbf{a})}_{i,j} - \mathbf{c}^{(\mathbf{b})}_{i,j})\,.$$

Hence, we can rewrite the original problem as

$$\max_{\mathbf{a},\mathbf{b},\mathbf{c}^{(\mathbf{a})},\mathbf{c}^{(\mathbf{b})}} \min_{\mathbf{u}} L(\mathbf{a}, \mathbf{b}, \mathbf{c}^{(\mathbf{a})}, \mathbf{c}^{(\mathbf{b})}, \mathbf{u})\,.$$

We can form a dual problem that is an upper bound on the original optimization problem by swapping the order of $\min$ and $\max$. In this case, the dual problem decomposes into two terms that are each local to an acyclic subgraph.

$$\min_{\mathbf{u}} \left(\max_{\mathbf{a},\mathbf{c}^{(\mathbf{a})}} \left[f(\mathbf{a}, \mathbf{c}^{(\mathbf{a})}) + \sum_{i,j} u(i,j) c^{(\mathbf{a})}_{ij} \right] + \max_{\mathbf{b},\mathbf{c}^{(\mathbf{b})}} \left[g(\mathbf{b}, \mathbf{c}^{(\mathbf{b})}) - \sum_{i,j} u(i,j) c^{(\mathbf{b})}_{ij} \right] \right) \qquad (4)$$

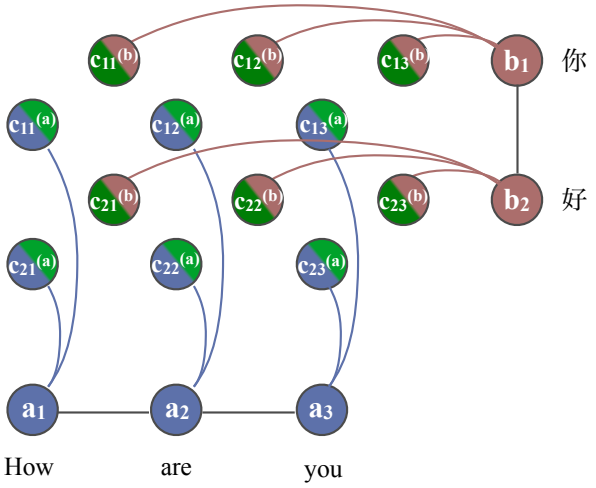

Figure 2: Our combined model decomposes into two acyclic models that each contain a copy of $\mathbf{c}$.

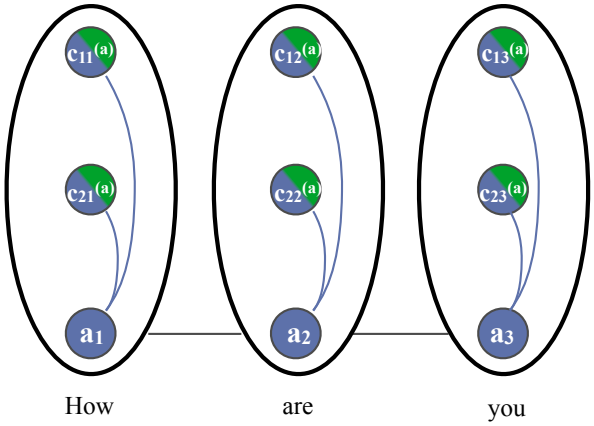

Figure 3: The tree-structured subgraph $\mathcal{G}_{\mathbf{a}}$ can be mapped to an equivalent chain-structured model by optimizing over $c_{i'j}$ for $a_j = i$.

The decomposed model is depicted in Figure 2. As in previous work, we solve for the dual variable $\mathbf{u}$ by repeatedly performing inference in the two decoupled maximization problems.

3.3 Sub-Graph Inference

We now address the problem of evaluating Equation 4 for fixed $\mathbf{u}$. Consider the first line of Equation 4, which includes variables $\mathbf{a}$ and $\mathbf{c}^{(\mathbf{a})}$.

$$\max_{\mathbf{a},\mathbf{c}^{(\mathbf{a})}} \left[f(\mathbf{a}, \mathbf{c}^{(\mathbf{a})}) + \sum_{i,j} u(i,j) c_{ij}^{(\mathbf{a})} \right] \quad (5)$$

Because the graph $\mathcal{G}_{\mathbf{a}}$ is tree-structured, Equation 5 can be evaluated in polynomial time. In fact, we can make a stronger claim: we can reuse the Viterbi inference algorithm for linear chain graphical models that applies to the embedded directional HMM models. That is, we can cast the optimization of Equation 5 as

$$\max_{\mathbf{a}} \left[\prod_{j=1}^{|\boldsymbol{f}|} \mathrm{D}_{\boldsymbol{e} \rightarrow \boldsymbol{f}}(a_j | a_{j-1}) \cdot \mathrm{M}'_j(a_j = i) \right] .$$

In the original HMM-based aligner, the vertex potentials correspond to bilexical probabilities. Those quantities appear in $f(\mathbf{a}, \mathbf{c}^{(\mathbf{a})})$, and therefore will be a part of $\mathrm{M}'_j(\cdot)$ above. The additional terms of Equation 5 can also be factored into the vertex potentials of this linear chain model, because the optimal choice of each c_{ij} can be determined from a_j and the model parameters. If $a_j = i$, then $c_{ij} = 1$ according to our edge potential defined in Equation 2. Hence, setting $a_j = i$ requires the inclusion of the corresponding vertex potential $\omega_j^{(\mathbf{a})}(i)$, as well as $u(i,j)$. For $i' \neq i$, either $c_{i'j} = 0$, which contributes nothing to Equation 5, or $c_{i'j} = 1$, which contributes $u(i',j) - \alpha$, according to our edge potential between a_j and $c_{i'j}$.

Thus, we can capture the net effect of assigning a_j and then optimally assigning all $c_{i'j}$ in a single potential $\mathrm{M}'_j(a_j = i) =$

$$\omega_j^{(\mathbf{a})}(i) + \exp \left[u(i,j) + \sum_{j' : |j'-j|=1} \max(0, u(i,j') - \alpha) \right]$$

Note that Equation 5 and f are sums of terms in log space, while Viterbi inference for linear chains assumes a product of terms in probability space, which introduces the exponentiation above.

Defining this potential allows us to collapse the source-side sub-graph inference problem defined by Equation 5, into a simple linear chain model that only includes potential functions M'_j and $\mu^{(\mathbf{a})}$. Hence, we can use a highly optimized linear chain inference implementation rather than a solver for general tree-structured graphical models. Figure 3 depicts this transformation.

An equivalent approach allows us to evaluate the

  if $\mathbf{c}^{(\mathbf{a})} = \mathbf{c}^{(\mathbf{b})}$ **then**
    return $\mathbf{c}^{(\mathbf{a})}$ ▷ *Converged*
  $\mathbf{u} \leftarrow \mathbf{u} + r \cdot (\mathbf{c}^{(\mathbf{b})} - \mathbf{c}^{(\mathbf{a})})$ ▷ *Dual update*
return combine$(\mathbf{c}^{(\mathbf{a})}, \mathbf{c}^{(\mathbf{b})})$ ▷ *Stop early*

second line of Equation 4 for fixed $\mathbf{u}$:

$$\max_{\mathbf{b}, \mathbf{c}^{(\mathbf{b})}} \left[g(\mathbf{b}, \mathbf{c}^{(\mathbf{b})}) + \sum_{i,j} u(i,j) c_{ij}^{(\mathbf{b})} \right] . \quad (6)$$

3.4 Dual Decomposition Algorithm

Now that we have the means to efficiently evaluate Equation 4 for fixed $\mathbf{u}$, we can define the full dual decomposition algorithm for our model, which searches for a $\mathbf{u}$ that optimizes Equation 4. We can iteratively search for such a $\mathbf{u}$ via sub-gradient descent. We use a learning rate $\frac{1}{t}$ that decays with the number of iterations t. The full dual decomposition optimization procedure appears in Algorithm 1.

If Algorithm 1 converges, then we have found a $\mathbf{u}$ such that the value of $\mathbf{c}^{(\mathbf{a})}$ that optimizes Equation 5 is identical to the value of $\mathbf{c}^{(\mathbf{b})}$ that optimizes Equation 6. Hence, it is also a solution to our original optimization problem: Equation 3. Since the dual problem is an upper bound on the original problem, this solution must be optimal for Equation 3.

3.5 Convergence and Early Stopping

Our dual decomposition algorithm provides an inference method that is exact upon convergence.[3] When Algorithm 1 does not converge, the two alignments $\mathbf{c}^{(\mathbf{a})}$ and $\mathbf{c}^{(\mathbf{b})}$ can still be used. While these alignments may differ, they will likely be more similar than the alignments of independent aligners.

These alignments will still need to be combined procedurally (e.g., taking their union), but because they are more similar, the importance of the combination procedure is reduced. We analyze the behavior of early stopping experimentally in Section 5.

[3]This certificate of optimality is not provided by other approximate inference algorithms, such as belief propagation, sampling, or simulated annealing.

3.6 Inference Properties

Because we set a maximum number of iterations n in the dual decomposition algorithm, and each iteration only involves optimization in a sequence model, our entire inference procedure is only a constant multiple n more computationally expensive than evaluating the original directional aligners.

Moreover, the value of $\mathbf{u}$ is specific to a sentence pair. Therefore, our approach does not require any additional communication overhead relative to the independent directional models in a distributed aligner implementation. Memory requirements are virtually identical to the baseline: only $\mathbf{u}$ must be stored for each sentence pair as it is being processed, but can then be immediately discarded once alignments are inferred.

Other approaches to generating one-to-one phrase alignments are generally more expensive. In particular, an ITG model requires $O(|\boldsymbol{e}|^3 \cdot |\boldsymbol{f}|^3)$ time, whereas our algorithm requires only

$$O(n \cdot (|\boldsymbol{f}||\boldsymbol{e}|^2 + |\boldsymbol{e}||\boldsymbol{f}|^2)) .$$

Moreover, our approach allows Markov distortion potentials, while standard ITG models are restricted to only hierarchical distortion.

4 Related Work

Alignment combination normally involves selecting some $\mathcal{A}$ from the output of two directional models. Common approaches include forming the union or intersection of the directional sets.

$$\mathcal{A}_{\cup} = \mathcal{A}_{\mathbf{a}} \cup \mathcal{A}_{\mathbf{b}}$$
$$\mathcal{A}_{\cap} = \mathcal{A}_{\mathbf{a}} \cap \mathcal{A}_{\mathbf{b}} .$$

More complex combiners, such as the *grow-diag-final* heuristic (Koehn et al., 2003), produce alignment link sets that include all of $\mathcal{A}_{\cap}$ and some subset of $\mathcal{A}_{\cup}$ based on the relationship of multiple links (Och et al., 1999).

In addition, supervised word alignment models often use the output of directional unsupervised aligners as features or pruning signals. In the case

that a supervised model is restricted to proposing alignment links that appear in the output of a directional aligner, these models can be interpreted as a combination technique (Deng and Zhou, 2009). Such a model-based approach differs from ours in that it requires a supervised dataset and treats the directional aligners' output as fixed.

Combination is also related to agreement-based learning (Liang et al., 2006). This approach to jointly learning two directional alignment models yields state-of-the-art unsupervised performance. Our method is complementary to agreement-based learning, as it applies to Viterbi inference under the model rather than computing expectations. In fact, we employ agreement-based training to estimate the parameters of the directional aligners in our experiments.

A parallel idea that closely relates to our bidirectional model is posterior regularization, which has also been applied to the word alignment problem (Graça et al., 2008). One form of posterior regularization stipulates that the posterior probability of alignments from two models must agree, and enforces this agreement through an iterative procedure similar to Algorithm 1. This approach also yields state-of-the-art unsupervised alignment performance on some datasets, along with improvements in end-to-end translation quality (Ganchev et al., 2008).

Our method differs from this posterior regularization work in two ways. First, we iterate over Viterbi predictions rather than posteriors. More importantly, we have changed the output space of the model to be a one-to-one phrase alignment via the coherence edge potential functions.

Another similar line of work applies belief propagation to factor graphs that enforce a one-to-one word alignment (Cromières and Kurohashi, 2009). The details of our models differ: we employ distance-based distortion, while they add structural correspondence terms based on syntactic parse trees. Also, our model training is identical to the HMM-based baseline training, while they employ belief propagation for both training and Viterbi inference. Although differing in both model and inference, our work and theirs both find improvements from defining graphical models for alignment that do not admit exact polynomial-time inference algorithms.

Aligner Model	Intersection $\lvert\mathcal{A}_{\cap}\rvert$	Union $\lvert\mathcal{A}_{\cup}\rvert$	Agreement $\lvert\mathcal{A}_{\cap}\rvert/\lvert\mathcal{A}_{\cup}\rvert$
Baseline	5,554	10,998	50.5%
Bidirectional	7,620	10,262	74.3%

Table 1: The bidirectional model's dual decomposition algorithm substantially increases the overlap between the predictions of the directional models, measured by the number of links in their intersection.

5 Experimental Results

We evaluated our bidirectional model by comparing its output to the annotations of a hand-aligned corpus. In this way, we can show that the bidirectional model improves alignment quality and enables the extraction of more correct phrase pairs.

5.1 Data Conditions

We evaluated alignment quality on a hand-aligned portion of the NIST 2002 Chinese-English test set (Ayan and Dorr, 2006). We trained the model on a portion of FBIS data that has been used previously for alignment model evaluation (Ayan and Dorr, 2006; Haghighi et al., 2009; DeNero and Klein, 2010). We conducted our evaluation on the first 150 sentences of the dataset, following previous work. This portion of the dataset is commonly used to train supervised models.

We trained the parameters of the directional models using the agreement training variant of the expectation maximization algorithm (Liang et al., 2006). Agreement-trained IBM Model 1 was used to initialize the parameters of the HMM-based alignment models (Brown et al., 1993). Both IBM Model 1 and the HMM alignment models were trained for 5 iterations on a 6.2 million word parallel corpus of FBIS newswire. This training regimen on this data set has provided state-of-the-art unsupervised results that outperform IBM Model 4 (Haghighi et al., 2009).

5.2 Convergence Analysis

With $n = 250$ maximum iterations, our dual decomposition inference algorithm only converges 6.2% of the time, perhaps largely due to the fact that the two directional models have different one-to-many structural constraints. However, the dual decompo-

Model	Combiner	Prec	Rec	AER
Baseline	union	57.6	80.0	33.4
	intersect	**86.2**	62.7	27.2
	grow-diag	60.1	78.8	32.1
Bidirectional	union	63.3	**81.5**	29.1
	intersect	77.5	75.1	**23.6**
	grow-diag	65.6	80.6	28.0

Table 2: Alignment error rate results for the bidirectional model versus the baseline directional models. "grow-diag" denotes the grow-diag-final heuristic.

Model	Combiner	Prec	Rec	F1
Baseline	union	**75.1**	33.5	46.3
	intersect	64.3	43.4	51.8
	grow-diag	68.3	37.5	48.4
Bidirectional	union	63.2	44.9	52.5
	intersect	57.1	**53.6**	**55.3**
	grow-diag	60.2	47.4	53.0

Table 3: Phrase pair extraction accuracy for phrase pairs up to length 5. "grow-diag" denotes the grow-diag-final heuristic.

sition algorithm does promote agreement between the two models. We can measure the agreement between models as the fraction of alignment links in the union $\mathcal{A}_\cup$ that also appear in the intersection $\mathcal{A}_\cap$ of the two directional models. Table 1 shows a 47% relative increase in the fraction of links that both models agree on by running dual decomposition (bidirectional), relative to independent directional inference (baseline). Improving convergence rates represents an important area of future work.

5.3 Alignment Error Evaluation

To evaluate alignment error of the baseline directional aligners, we must apply a combination procedure such as union or intersection to $\mathcal{A}_\mathbf{a}$ and $\mathcal{A}_\mathbf{b}$. Likewise, in order to evaluate alignment error for our combined model in cases where the inference algorithm does not converge, we must apply combination to $\mathbf{c}^{(\mathbf{a})}$ and $\mathbf{c}^{(\mathbf{b})}$. In cases where the algorithm does converge, $\mathbf{c}^{(\mathbf{a})} = \mathbf{c}^{(\mathbf{b})}$ and so no further combination is necessary.

We evaluate alignments relative to hand-aligned data using two metrics. First, we measure alignment error rate (AER), which compares the proposed alignment set $\mathcal{A}$ to the sure set $\mathcal{S}$ and possible set $\mathcal{P}$ in the annotation, where $\mathcal{S} \subseteq \mathcal{P}$.

$$\text{Prec}(\mathcal{A}, \mathcal{P}) = \frac{|\mathcal{A} \cap \mathcal{P}|}{|\mathcal{A}|}$$

$$\text{Rec}(\mathcal{A}, \mathcal{S}) = \frac{|\mathcal{A} \cap \mathcal{S}|}{|\mathcal{S}|}$$

$$\text{AER}(\mathcal{A}, \mathcal{S}, \mathcal{P}) = 1 - \frac{|\mathcal{A} \cap \mathcal{S}| + |\mathcal{A} \cap \mathcal{P}|}{|\mathcal{A}| + |\mathcal{S}|}$$

AER results for Chinese-English are reported in Table 2. The bidirectional model improves both precision and recall relative to all heuristic combination techniques, including *grow-diag-final* (Koehn et al., 2003). Intersected alignments, which are one-to-one phrase alignments, achieve the best AER.

Second, we measure phrase extraction accuracy. Extraction-based evaluations of alignment better coincide with the role of word aligners in machine translation systems (Ayan and Dorr, 2006). Let $\text{R}_5(\mathcal{S}, \mathcal{P})$ be the set of phrases up to length 5 extracted from the sure link set $\mathcal{S}$ and possible link set $\mathcal{P}$. Possible links are both included and excluded from phrase pairs during extraction, as in DeNero and Klein (2010). Null aligned words are never included in phrase pairs for evaluation. Phrase extraction precision, recall, and F1 for $\text{R}_5(\mathcal{A}, \mathcal{A})$ are reported in Table 3. Correct phrase pair recall increases from 43.4% to 53.6% (a 23.5% relative increase) for the bidirectional model, relative to the best baseline.

Finally, we evaluated our bidirectional model in a large-scale end-to-end phrase-based machine translation system from Chinese to English, based on the alignment template approach (Och and Ney, 2004). The translation model weights were tuned for both the baseline and bidirectional alignments using lattice-based minimum error rate training (Kumar et al., 2009). In both cases, *union* alignments outperformed other combination heuristics. Bidirectional alignments yielded a modest improvement of 0.2% BLEU[4] on a single-reference evaluation set of sentences sampled from the web (Papineni et al., 2002).

[4]BLEU improved from 29.59% to 29.82% after training IBM Model 1 for 3 iterations and training the HMM-based alignment model for 3 iterations. During training, link posteriors were symmetrized by pointwise linear interpolation.

As our model only provides small improvements in alignment precision and recall for the *union* combiner, the magnitude of the BLEU improvement is not surprising.

6 Conclusion

We have presented a graphical model that combines two classical HMM-based alignment models. Our bidirectional model, which requires no additional learning and no supervised data, can be applied using dual decomposition with only a constant factor additional computation relative to independent directional inference. The resulting predictions improve the precision and recall of both alignment links and extraced phrase pairs in Chinese-English experiments. The best results follow from combination via *intersection*.

Because our technique is defined declaratively in terms of a graphical model, it can be extended in a straightforward manner, for instance with additional potentials on $\mathbf{c}$ or improvements to the component directional models. We also look forward to discovering the best way to take advantage of these new alignments in downstream applications like machine translation, supervised word alignment, bilingual parsing (Burkett et al., 2010), part-of-speech tag induction (Naseem et al., 2009), or cross-lingual model projection (Smith and Eisner, 2009; Das and Petrov, 2011).

An Algorithm for Unsupervised Transliteration Mining with an Application to Word Alignment

Hassan Sajjad **Alexander Fraser** **Helmut Schmid**
Institute for Natural Language Processing
University of Stuttgart
{sajjad,fraser,schmid}@ims.uni-stuttgart.de

Abstract

We propose a language-independent method for the automatic extraction of transliteration pairs from parallel corpora. In contrast to previous work, our method uses no form of supervision, and does not require linguistically informed preprocessing. We conduct experiments on data sets from the NEWS 2010 shared task on transliteration mining and achieve an F-measure of up to 92%, outperforming most of the semi-supervised systems that were submitted. We also apply our method to English/Hindi and English/Arabic parallel corpora and compare the results with manually built gold standards which mark transliterated word pairs. Finally, we integrate the transliteration module into the GIZA++ word aligner and evaluate it on two word alignment tasks achieving improvements in both precision and recall measured against gold standard word alignments.

1 Introduction

Most previous methods for building transliteration systems were supervised, requiring either handcrafted rules or a clean list of transliteration pairs, both of which are expensive to create. Such resources are also not applicable to other language pairs.

In this paper, we show that it is possible to extract transliteration pairs from a parallel corpus using an unsupervised method. We first align a bilingual corpus at the word level using GIZA++ and create a list of word pairs containing a mix of non-transliterations and transliterations. We train a statistical transliterator on the list of word pairs. We then filter out a few word pairs (those which have the lowest transliteration probabilities according to the trained transliteration system) which are likely to be non-transliterations. We retrain the transliterator on the filtered data set. This process is iterated, filtering out more and more non-transliteration pairs until a nearly clean list of transliteration word pairs is left. The optimal number of iterations is automatically determined by a novel stopping criterion.

We compare our unsupervised transliteration mining method with the semi-supervised systems presented at the NEWS 2010 shared task on transliteration mining (Kumaran et al., 2010) using four language pairs. We refer to this task as NEWS10. These systems used a manually labelled set of data for initial supervised training, which means that they are semi-supervised systems. In contrast, our system is fully unsupervised. We achieve an F-measure of up to 92% outperforming most of the semi-supervised systems.

The NEWS10 data sets are extracted Wikipedia InterLanguage Links (WIL) which consist of parallel phrases, whereas a parallel corpus consists of parallel sentences. Transliteration mining on the WIL data sets is easier due to a higher percentage of transliterations than in parallel corpora. We also do experiments on parallel corpora for two language pairs. To this end, we created gold standards in which sampled word pairs are annotated as either transliterations or non-transliterations. These gold standards have been submitted with the paper as supplementary material as they are available to the research community.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 430–439,
Portland, Oregon, June 19-24, 2011.

Finally we integrate a transliteration module into the GIZA++ word aligner and show that it improves word alignment quality. The transliteration module is trained on the transliteration pairs which our mining method extracts from the parallel corpora. We evaluate our word alignment system on two language pairs using gold standard word alignments and achieve improvements of 10% and 13.5% in precision and 3.5% and 13.5% in recall.

The rest of the paper is organized as follows. In section 2, we describe the filtering model and the transliteration model. In section 3, we present our iterative transliteration mining algorithm and an algorithm which computes a stopping criterion for the mining algorithm. Section 4 describes the evaluation of our mining method through both gold standard evaluation and through using it to improve word alignment quality. In section 5, we present previous work and we conclude in section 6.

2 Models

Our algorithms use two different models. The first model is a joint character sequence model which we apply to transliteration mining. We use the grapheme-to-phoneme converter g2p to implement this model. The other model is a standard phrase-based MT model which we apply to transliteration (as opposed to transliteration mining). We build it using the Moses toolkit.

2.1 Joint Sequence Model Using g2p

Here, we briefly describe g2p using notation from Bisani and Ney (2008). The details of the model, its parameters and the utilized smoothing techniques can be found in Bisani and Ney (2008).

The training data is a list of word pairs (a source word and its presumed transliteration) extracted from a word-aligned parallel corpus. g2p builds a joint sequence model on the character sequences of the word pairs and infers m-to-n alignments between source and target characters with Expectation Maximization (EM) training. The m-to-n character alignment units are referred to as "multigrams".

The model built on multigrams consisting of source and target character sequences greater than one learns too much noise (non-transliteration information) from the training data and performs poorly. In our experiments, we use multigrams with a maximum of one character on the source and one character on the target side (i.e., 0,1-to-0,1 character alignment units).

The N-gram approximation of the joint probability can be defined in terms of multigrams q_i as:

$$p(q_1^k) \approx \prod_{j=1}^{k+1} p(q_j | q_{j-N+1}^{j-1}) \quad (1)$$

where q_0, q_{k+1} are set to a special boundary symbol.

N-gram models of order > 1 did not work well because these models tended to learn noise (information from non-transliteration pairs) in the training data. For our experiments, we only trained g2p with the unigram model.

In test mode, we look for the best sequence of multigrams given a fixed source and target string and return the probability of this sequence.

For the mining process, we trained g2p on lists containing both transliteration pairs and non-transliteration pairs.

2.2 Statistical Machine Transliteration System

We build a phrase-based MT system for transliteration using the Moses toolkit (Koehn et al., 2003). We also tried using g2p for implementing the transliteration decoder but found Moses to perform better. Moses has the advantage of using Minimum Error Rate Training (MERT) which optimizes transliteration accuracy rather than the likelihood of the training data as g2p does. The training data contains more non-transliteration pairs than transliteration pairs. We don't want to maximize the likelihood of the non-transliteration pairs. Instead we want to optimize the transliteration performance for test data. Secondly, it is easy to use a large language model (LM) with Moses. We build the LM on the target word types in the data to be filtered.

For training Moses as a transliteration system, we treat each word pair as if it were a parallel sentence, by putting spaces between the characters of each word. The model is built with the default settings of the Moses toolkit. The distortion limit "d" is set to zero (no reordering). The LM is implemented as a five-gram model using the SRILM-Toolkit (Stolcke, 2002), with Add-1 smoothing for unigrams and Kneser-Ney smoothing for higher n-grams.

3 Extraction of Transliteration Pairs

Training of a supervised transliteration system requires a list of transliteration pairs which is expensive to create. Such lists are usually either built manually or extracted using a classifier trained on manually labelled data and using other language dependent information. In this section, we present an iterative method for the extraction of transliteration pairs from parallel corpora which is fully unsupervised and language pair independent.

Initially, we extract a list of word pairs from a word-aligned parallel corpus using GIZA++. The extracted word pairs are either transliterations, other kinds of translations, or misalignments. In each iteration, we first train g2p on the list of word pairs. Then we delete those 5% of the (remaining) training data which are least likely to be transliterations according to g2p.[1] We determine the best iteration according to our stopping criterion and return the filtered data set from this iteration. The stopping criterion uses unlabelled held-out data to predict the optimal stopping point. The following sections describe the transliteration mining method in detail.

3.1 Methodology

We will first describe the iterative filtering algorithm (Algorithm 1) and then the algorithm for the stopping criterion (Algorithm 2). In practice, we first run Algorithm 2 for 100 iterations to determine the best number of iterations. Then, we run Algorithm 1 for that many iterations.

Initially, the parallel corpus is word-aligned using GIZA++ (Och and Ney, 2003), and the alignments are refined using the grow-diag-final-and heuristic (Koehn et al., 2003). We extract all word pairs which occur as 1-to-1 alignments in the word-aligned corpus. We ignore non-1-to-1 alignments because they are less likely to be transliterations for most language pairs. The extracted set of word pairs will be called "*list of word pairs*" later on. We use the list of word pairs as the training data for Algorithm 1.

Algorithm 1 builds a joint sequence model using g2p on the training data and computes the joint probability of all word pairs according to g2p. We normalize the probabilities by taking the nth square root where n is the average length of the source and the target string. The training data contains mostly non-transliteration pairs and a few transliteration pairs. Therefore the training data is initially very noisy and the joint sequence model is not very accurate. However it can successfully be used to eliminate a few word pairs which are very unlikely to be transliterations.

Algorithm 1 Mining of transliteration pairs

1: training data ←list of word pairs
2: I ← 0
3: **repeat**
4: Build a joint source channel model on the training data using g2p and compute the joint probability of every word pair.
5: Remove the 5% word pairs with the lowest length-normalized probability from the training data. {and repeat the process with the filtered training data}
6: I ← I+1
7: **until** I = Stopping iteration from Algorithm 2

On the filtered training data, we can train a model which is slightly better than the previous model. Using this improved model, we can eliminate further non-transliterations.

Our results show that at the iteration determined by our stopping criterion, the filtered set mostly contains transliterations and only a small number of transliterations have been mistakenly eliminated (see section 4.2).

Algorithm 2 automatically determines the best stopping point of the iterative transliteration mining process. It is an extension of Algorithm 1. It runs the iterative process of Algorithm 1 on half of the list of word pairs (training data) for 100 iterations. For every iteration, it builds a transliteration system on the filtered data. The transliteration system is tested on the source side of the other half of the list of word pairs (held-out). The output of the transliteration system is matched against the target side of the held-out data. (These target words are either transliterations, translations or misalignments.) We match the target side of the held-out data under the assumption that all matches are transliterations. The iteration where the output of the transliteration system best matches the held-out data is chosen as the stopping iteration of Algorithm 1.

[1] Since we delete 5% from the filtered data, the number of deleted data items decreases in each iteration.

Algorithm 2 Selection of the stopping iteration for the transliteration mining algorithm

1: Create clusters of word pairs from the list of word pairs which have a common prefix of length 2 both on the source and target language side.
2: Randomly add each cluster either to the training data or to the held-out data.
3: I $\leftarrow$ 0
4: **while** I $<$ 100 **do**
5: Build a joint sequence model on the training data using g2p and compute the length-normalized joint probability of every word pair in the training data.
6: Remove the 5% word pairs with the lowest probability from the training data. {The training data will be reduced by 5% of the rest in each iteration}
7: Build a transliteration system on the filtered training data and test it using the source side of the held-out and match the output against the target side of the held-out.
8: I $\leftarrow$ I+1
9: **end while**
10: Collect statistics of the matching results and take the median from 9 consecutive iterations (median9).
11: Choose the iteration with the best median9 score for the transliteration mining process.

We will now describe Algorithm 2 in detail. Algorithm 2 initially splits the word pairs into training and held-out data. This could be done randomly, but it turns out that this does not work well for some tasks. The reason is that the parallel corpus contains inflectional variants of the same word. If two variants are distributed over training and held-out data, then the one in the training data may cause the transliteration system to produce a correct translation (but not transliteration) of its variant in the held-out data. This problem is further discussed in section 4.2.2. Instead of randomly splitting the data, we first create clusters of word pairs which have a common prefix of length 2 both on the source and target language side. We randomly add each cluster either to the training data or to the held-out data.

We repeat the mining process (described in Algorithm 1) to eliminate non-transliteration pairs from the training data. For each iteration of Algorithm 2, i.e., steps 4 to 9, we build a transliteration system on the filtered training data and test it on the source side of the held-out. We collect statistics on how well the output of the system matches the target side of the held-out. The matching scores on the held-out data often make large jumps from iteration to iteration. We take the median of the results from 9 consecutive iterations (the 4 iterations before, the current and the 4 iterations after the current iteration) to smooth the scores. We call this median9. We choose the iteration with the best smoothed score as the stopping point for the filtering process. In our tests, the median9 heuristic indicated an iteration close to the optimal iteration.

Sometimes several nearby iterations have the same maximal smoothed score. In that case, we choose the one with the highest unsmoothed score. Section 4.2 explains the median9 heuristic in more detail and presents experimental results showing that it works well.

4 Experiments

We evaluate our transliteration mining algorithm on three tasks: transliteration mining from Wikipedia InterLanguage Links, transliteration mining from parallel corpora, and word alignment using a word aligner with a transliteration component. On the WIL data sets, we compare our fully unsupervised system with the semi-supervised systems presented at the NEWS10 (Kumaran et al., 2010). In the evaluation on parallel corpora, we compare our mining results with a manually built gold standard in which each word pair is either marked as a transliteration or as a non-transliteration. In the word alignment experiment, we integrate a transliteration module which is trained on the transliterations pairs extracted by our method into a word aligner and show a significant improvement. The following sections describe the experiments in detail.

4.1 Experiments Using Parallel Phrases of Wikipedia InterLanguage Links

We conduct transliteration mining experiments on the English/Arabic, English/Hindi, English/Tamil and English/Russian Wikipedia InterLanguage Links (WIL) used in the NEWS10.[2] All data sets

[2]We do not evaluate on the English/Chinese data because the Chinese data requires word segmentation which is beyond the scope of our work. Another problem is that our extraction method was developed for alphabetic languages and probably needs to be adapted before it is applicable to logographic languages such as Chinese.

	Our	S-Best	S-Worst	Systems	Rank
EA	87.4	91.5	70.2	16	3
ET	90.1	91.4	57.5	14	3
EH	92.2	94.4	71.4	14	3

Table 1: Summary of results on NEWS10 data sets where "EA" is English/Arabic, "ET" is English/Tamil and "EH" is English/Hindi. "Our" shows the F-measure of our filtered data against the gold standard using the supplied evaluation tool, "Systems" is the total number of participants in the subtask, and "Rank" is the rank we would have obtained if our system had participated.

contain training data, seed data and reference data. We make no use of the seed data since our system is fully unsupervised. We calculate the F-measure of our filtered transliteration pairs against the supplied gold standard using the supplied evaluation tool.

For English/Arabic, English/Hindi and English/Tamil, our system is better than most of the semi-supervised systems presented at the NEWS 2010 shared task for transliteration mining. Table 1 summarizes the F-scores on these data sets.

On the English/Russian data set, our system achieves 76% F-measure which is not good compared with the systems that participated in the shared task. The English/Russian corpus contains many cognates which – according to the NEWS10 definition – are not transliterations of each other. Our system learns the cognates in the training data and extracts them as transliterations (see Table 2).

The two best teams on the English/Russian task presented various extraction methods (Jiampojamarn et al., 2010; Darwish, 2010). Their systems behave differently on English/Russian than on other language pairs. Their best systems for English/Russian are only trained on the seed data and the use of unlabelled data does not help the performance. Since our system is fully unsupervised, and the unlabelled data is not useful, we perform badly.

4.2 Experiments Using Parallel Corpora

The Wikipedia InterLanguage Links shared task data contains a much larger proportion of transliterations than a parallel corpus. In order to examine how well our method performs on parallel corpora, we apply it to parallel corpora of English/Hindi and English/Arabic, and compare the transliteration mining results with a gold standard.

English	Russian	English	Russian
Studio	Студия/Studiya	Catalonia	Каталонии/Katalonii
Estonia	Эстонии/Estonii	Monastery	Монастырь/Monastyr
Tartary	Тартария/Tartariya	Geography	География/Geografiya

Table 2: Cognates from English/Russian corpus extracted by our system as transliteration pairs. None of them are correct transliteration pairs according to the gold standard.

We use the English/Hindi corpus from the shared task on word alignment, organized as part of the ACL 2005 Workshop on Building and Using Parallel Texts (WA05) (Martin et al., 2005). For English/Arabic, we use a freely available parallel corpus from the United Nations (UN) (Eisele and Chen, 2010). We randomly take 200,000 parallel sentences from the UN corpus of the year 2000. We create gold standards for both language pairs by randomly selecting a few thousand word pairs from the lists of word pairs extracted from the two corpora. We manually tag them as either transliterations or non-transliterations. The English/Hindi gold standard contains 180 transliteration pairs and 2084 non-transliteration pairs and the English/Arabic gold standard contains 288 transliteration pairs and 6639 non-transliteration pairs. We have submitted these gold standards with the paper. They are available to the research community.

In the following sections, we describe the median9 heuristic and the splitting method of Algorithm 2. The splitting method is used to avoid early peaks in the held-out statistics, and the median9 heuristic smooths the held-out statistics in order to obtain a single peak.[3]

4.2.1 Motivation for Median9 Heuristic

Algorithm 2 collects statistics from the held-out data (step 10) and selects the stopping iteration. Due to the noise in the held-out data, the transliteration accuracy on the held-out data often jumps from iteration to iteration. The dotted line in figure 1 (right) shows the held-out prediction accuracy for the En-

[3]We do not use the seed data in our system. However, to check the correctness of the stopping point, we tested the transliteration system on the seed data (available with NEWS10) for every iteration of Algorithm 2. We verified that the median9 held-out statistics and accuracy on the seed data have their peaks at the same iteration.

glish/Hindi parallel corpus. The curve is very noisy and has two peaks. It is difficult to see the effect of the filtering. We take the median of the results from 9 consecutive iterations to smooth the scores. The solid line in figure 1 (right) shows a smoothed curve built using the median9 held-out scores. A comparison with the gold standard (section 4.2.3) shows that the stopping point (peak) reached using the median9 heuristic is better than the stopping point obtained with unsmoothed scores.

4.2.2 Motivation for Splitting Method

Algorithm 2 initially splits the list of word pairs into training and held-out data. A random split worked well for the WIL data, but failed on the parallel corpora. The reason is that parallel corpora contain inflectional variants of the same word. If these variants are randomly distributed over training and held-out data, then a non-transliteration word pair such as the English-Hindi pair "change – badlao" may end up in the training data and the related pair "changes – badlao" in the held-out data. The Moses system used for transliteration will learn to "transliterate" (or actually translate) "change" to "badlao". From other examples, it will learn that a final "s" can be dropped. As a consequence, the Moses transliterator may produce the non-transliteration "badlao" for the English word "changes" in the held-out data. Such matching predictions of the transliterator which are actually translations lead to an overestimate of the transliteration accuracy and may cause Algorithm 2 to predict a stopping iteration which is too early.

By splitting the list of word pairs in such a way that inflectional variants of a word are placed either in the training data, or in the held-out, but not in both, this problem can be solved.[4]

The left graph in Figure 1 shows that the median9 held-out statistics obtained after a random data split of a Hindi/English corpus contains two peaks which occur too early. These peaks disappear in the right graph of Figure 1 which shows the results obtained after a split with the clustering method.

The overall trend of the smoothed curve in figure 1 (right) is very clear. We start by filtering out non-transliteration pairs from the data, so the results

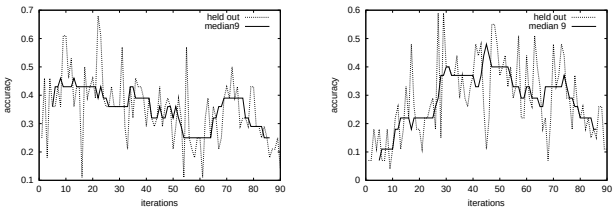

Figure 1: Statistics of held-out prediction of English/Hindi data using modified Algorithm 2 with random division of the list of word pairs (left) and using Algorithm 2 (right). The dotted line shows unsmoothed held-out scores and solid line shows median9 held-out scores

of the transliteration system go up. When no more non-transliteration pairs are left, we start filtering out transliteration pairs and the results of the system go down. We use this stopping criterion for all language pairs and achieve consistently good results.

4.2.3 Results on Parallel Corpora

According to the gold standard, the English/Hindi and English/Arabic data sets contain 8% and 4% transliteration pairs respectively. We repeat the same mining procedure – run Algorithm 2 up to 100 iterations and return the stopping iteration. Then, we run Algorithm 1 up to the stopping iteration returned by Algorithm 2 and obtain the filtered data.

	TP	FN	TN	FP
EH Filtered	170	10	2039	45
EA Filtered	197	91	6580	59

Table 3: Transliteration mining results using the parallel corpus of English/Hindi (EH) and English/Arabic (EA) against the gold standard

Table 3 shows the mining results on the English/Hindi and English/Arabic corpora. The gold standard is a subset of the data sets. The English/Hindi gold standard contains 180 transliteration pairs and 2084 non-transliteration pairs. The English/Arabic gold standard contains 288 transliteration pairs and 6639 non-transliteration pairs. From the English/Hindi data, the mining system has mined 170 transliteration pairs out of 180 transliteration pairs. The English/Arabic mined data contains 197 transliteration pairs out of 288 transliteration pairs. The mining system has wrongly identified a few non-transliteration pairs as transliterations (see

[4]This solution is appropriate for all of the language pairs used in our experiments, but should be revisited if there is inflection realized as prefixes, etc.

table 3, last column). Most of these word pairs are close transliterations and differ by only one or two characters from perfect transliteration pairs. The close transliteration pairs provide many valid multigrams which may be helpful for the mining system.

4.3 Integration into Word Alignment Model

In the previous section, we presented a method for the extraction of transliteration pairs from a parallel corpus. In this section, we will explain how to build a transliteration module on the extracted transliteration pairs and how to integrate it into MGIZA++ (Gao and Vogel, 2008) by interpolating it with the t-table probabilities of the IBM models and the HMM model. MGIZA++ is an extension of GIZA++. It has the ability to resume training from any model rather than starting with Model1.

4.3.1 Modified EM Training of the Word Alignment Models

GIZA++ applies the IBM models (Brown et al., 1993) and the HMM model (Vogel et al., 1996) in both directions, i.e., source to target and target to source. The alignments are refined using the grow-diag-final-and heuristic (Koehn et al., 2003). GIZA++ generates a list of translation pairs with alignment probabilities, which is called the t-table. In this section, we propose a method to modify the translation probabilities of the t-table by interpolating the translation counts with transliteration counts. The interpolation is done in both directions. In the following, we will only consider the **e**-to-**f** direction. The transliteration module which is used to calculate the conditional transliteration probability is described in Algorithm 3.

We build a transliteration system by training Moses on the filtered transliteration corpus (using Algorithm 1) and apply it to the **e** side of the list of word pairs. For every source word, we generate the list of 10-best transliterations $nbestTI(e)$. Then, we extract every **f** that cooccurs with **e** in a parallel sentence and add it to $nbestTI(e)$ which gives us the list of candidate transliteration pairs $candidateTI(e)$. We use the sum of transliteration probabilities $\sum_{f' \in CandidateTI(e)} p_{moses}(f', e)$ as an approximation for the prior probability $p_{moses}(e) = \sum_{f'} p_{moses}(f', e)$ which is needed to convert the joint transliteration probability into a conditional probability. We use the constraint decoding option of Moses to compute the joint probability of **e** and **f**. It computes the probability by dividing the translation score of the best target sentence given a source sentence by the normalization factor.

Algorithm 3 Estimation of transliteration probabilities, **e**-to-**f** direction

```
unfiltered data ←list of word pairs
filtered data ←transliteration pairs extracted using Algorithm 1
Train a transliteration system on the filtered data
for all e do
    nbestTI(e) ← 10 best transliterations for e according to the transliteration system
    cooc(e) ← set of all f that cooccur with e in a parallel sentence
    candidateTI(e) ← cooc(e) ∪ nbestTI(e)
end for
for all f do
    p_moses(f, e) ← joint transliteration probability of e and f according to the transliterator
    p_ti(f|e) ← p_moses(f,e) / Σ_{f'∈CandidateTI(e)} p_moses(f',e)
end for
```

We combine the transliteration probabilities with the translation probabilities of the IBM models and the HMM model. The normal translation probability $p_{ta}(f|e)$ of the word alignment models is computed with relative frequency estimates.

We smooth the alignment frequencies by adding the transliteration probabilities weighted by the factor λ and get the following modified translation probabilities

$$\hat{p}(f|e) = \frac{f_{ta}(f, e) + \lambda p_{ti}(f|e)}{f_{ta}(e) + \lambda} \qquad (2)$$

where $f_{ta}(f, e) = p_{ta}(f|e)f(e)$. $p_{ta}(f|e)$ is obtained from the original t-table of the alignment model. $f(e)$ is the total corpus frequency of **e**. λ is the transliteration weight which is optimized for every language pair (see section 4.3.2). Apart from the definition of the weight λ, our smoothing method is equivalent to Witten-Bell smoothing.

We smooth after every iteration of the IBM models and the HMM model except the last iteration of each model. Algorithm 4 shows the smoothing for IBM Model4. IBM Model1 and the HMM model are smoothed in the same way. We also apply Algorithm 3 and Algorithm 4 in the alignment direction

Algorithm 4 Interpolation with the IBM Model4, **e**-to-**f** direction

1: {We want to run four iterations of Model4}
2: $f(e) \leftarrow$ total frequency of e in the corpus
3: Run MGIZA++ for one iteration of Model4
4: $I \leftarrow 1$
5: **while** $I < 4$ **do**
6: Look up $p_{ta}(f|e)$ in the t-table of Model4
7: $f_{ta}(f,e) \leftarrow p_{ta}(f|e)f(e)$ for all (f,e)
8: $\hat{p}(f|e) \leftarrow \frac{f_{ta}(f,e)+\lambda p_{ti}(f|e)}{f_{ta}(e)+\lambda}$ for all (f,e)
9: Resume MGIZA++ training for 1 iteration using the modified t-table probabilities $\hat{p}(f|e)$
10: $I \leftarrow I + 1$
11: **end while**

f to **e**. The final alignments are generated using the grow-diag-final-and heuristic (Koehn et al., 2003).

4.3.2 Evaluation

The English/Hindi corpus available from WA05 consists of training, development and test data. As development and test data for English/Arabic, we use manually created gold standard word alignments for 155 sentences extracted from the Hansards corpus released by LDC. We use 50 sentences for development and 105 sentences for test.

Baseline: We align the data sets using GIZA++ (Och and Ney, 2003) and refine the alignments using the grow-diag-final-and heuristic (Koehn et al., 2003). We obtain the baseline F-measure by comparing the alignments of the test corpus with the gold standard alignments.

Experiments We use GIZA++ with 5 iterations of Model1, 4 iterations of HMM and 4 iterations of Model4. We interpolate translation and transliteration probabilities at different iterations (and different combinations of iterations) of the three models and always observe an improvement in alignment quality. For the final experiments, we interpolate at every iteration of the IBM models and the HMM model except the last iteration of every model where we could not interpolate for technical reasons.[5] Algorithm 4 shows the interpolation of the transliteration probabilities with IBM Model4. We used the same procedure with IBM Model1 and the HMM model.

The parameter λ is optimized on development data for every language pair. The word alignment system is not very sensitive to λ. Any λ in the range between 50 and 100 works fine for all language pairs. The optimization helps to maximize the improvement in word alignment quality. For our experiments, we use $\lambda = 80$.

On test data, we achieve an improvement of approximately 10% and 13.5% in precision and 3.5% and 13.5% in recall on English/Hindi and English/Arabic word alignment, respectively. Table 4 shows the scores of the baseline and our word alignment model.

Lang	P_b	R_b	F_b	P_{ti}	R_{ti}	F_{ti}
EH	49.1	48.5	51.2	59.1	52.1	55.4
EA	50.8	49.9	50.4	64.4	63.6	64

Table 4: Word alignment results on the test data of English/Hindi (EH) and English/Arabic (EA) where P_b is the precision of baseline GIZA++ and P_{ti} is the precision of our word alignment system

We compared our word alignment results with the systems presented at WA05. Three systems, one limited and two un-limited, participated in the English/Hindi task. We outperform the limited system and one un-limited system.

5 Previous Research

Previous work on transliteration mining uses a manually labelled set of training data to extract transliteration pairs from a parallel corpus or comparable corpora. The training data may contain a few hundred randomly selected transliteration pairs from a transliteration dictionary (Yoon et al., 2007; Sproat et al., 2006; Lee and Chang, 2003) or just a few carefully selected transliteration pairs (Sherif and Kondrak, 2007; Klementiev and Roth, 2006). Our work is more challenging as we extract transliteration pairs without using transliteration dictionaries or gold standard transliteration pairs.

Klementiev and Roth (2006) initialize their transliteration model with a list of 20 transliteration

[5] We had problems in resuming MGIZA++ training when training was supposed to continue from a different model, such as if we stopped after the 5th iteration of Model1 and then tried to resume MGIZA++ from the first iteration of the HMM model. In this case, we ran the 5th iteration of Model1, then the first iteration of the HMM and only then stopped for interpolation; so we did not interpolate in just those iterations of training where we were transitioning from one model to the next.

pairs. Their model makes use of temporal scoring to rank the candidate transliterations. A lot of work has been done on discovering and learning transliterations from comparable corpora by using temporal and phonetic information (Tao et al., 2006; Klementiev and Roth, 2006; Sproat et al., 2006). We do not have access to this information.

Sherif and Kondrak (2007) train a probabilistic transducer on 14 manually constructed transliteration pairs of English/Arabic. They iteratively extract transliteration pairs from the test data and add them to the training data. Our method is different from the method of Sherif and Kondrak (2007) as our method is fully unsupervised, and because in each iteration, they add the most probable transliteration pairs to the training data, while we filter out the least probable transliteration pairs from the training data.

The transliteration mining systems of the four NEWS10 participants are either based on discriminative or on generative methods. All systems use manually labelled (seed) data for the initial training. The system based on the edit distance method submitted by Jiampojamarn et al. (2010) performs best for the English/Russian task. Jiampojamarn et al. (2010) submitted another system based on a standard n-gram kernel which ranked first for the English/Hindi and English/Tamil tasks.[6] For the English/Arabic task, the transliteration mining system of Noeman and Madkour (2010) was best. They normalize the English and Arabic characters in the training data which increases the recall.[7]

Our transliteration extraction method differs in that we extract transliteration pairs from a parallel corpus without supervision. The results of the NEWS10 experiments (Kumaran et al., 2010) show that no single system performs well on all language pairs. Our unsupervised method seems robust as its performance is similar to or better than many of the semi-supervised systems on three language pairs.

We are only aware of one previous work which uses transliteration information for word alignment. Hermjakob (2009) proposed a linguistically focused word alignment system which uses many features including hand-crafted transliteration rules for Arabic/English alignment. His evaluation did not explicitly examine the effect of transliteration (alone) on word alignment. We show that the integration of a transliteration system based on unsupervised transliteration mining increases the word alignment quality for the two language pairs we tested.

[6] They use the seed data as positive examples. In order to obtain also negative examples, they generate all possible word pairs from the source and target words in the seed data and extract the ones which are not transliterations but have a common substring of some minimal length.

[7] They use the phrase table of Moses to build a mapping table between source and target characters. The mapping table is then used to construct a finite state transducer.

6 Conclusion

We proposed a method to automatically extract transliteration pairs from parallel corpora without supervision or linguistic knowledge. We evaluated it against the semi-supervised systems of NEWS10 and achieved high F-measure and performed better than most of the semi-supervised systems. We also evaluated our method on parallel corpora and achieved high F-measure. We integrated the transliteration extraction module into the GIZA++ word aligner and showed gains in alignment quality. We will release our transliteration mining system and word alignment system in the near future.

Abstract

Efficient decoding for syntactic parsing has become a necessary research area as statistical grammars grow in accuracy and size and as more NLP applications leverage syntactic analyses. We review prior methods for pruning and then present a new framework that unifies their strengths into a single approach. Using a log linear model, we learn the optimal beam-search pruning parameters for each CYK chart cell, effectively predicting the most promising areas of the model space to explore. We demonstrate that our method is faster than coarse-to-fine pruning, exemplified in both the Charniak and Berkeley parsers, by empirically comparing our parser to the Berkeley parser using the same grammar and under identical operating conditions.

1 Introduction

Statistical constituent parsers have gradually increased in accuracy over the past ten years. This accuracy increase has opened the door to automatically derived syntactic information within a number of NLP tasks. Prior work incorporating parse structure into machine translation (Chiang, 2010) and Semantic Role Labeling (Tsai et al., 2005; Punyakanok et al., 2008) indicate that such hierarchical structure can have great benefit over shallow labeling techniques like chunking and part-of-speech tagging.

Although syntax is becoming increasingly important for large-scale NLP applications, constituent parsing is slow — too slow to scale to the size of many potential consumer applications. The exhaustive CYK algorithm has computational complexity $O(n^3|G|)$ where n is the length of the sentence and $|G|$ is the number of grammar productions, a non-negligible constant. Increases in accuracy have primarily been accomplished through an increase in the size of the grammar, allowing individual grammar rules to be more sensitive to their surrounding context, at a considerable cost in efficiency. Grammar transformation techniques such as linguistically inspired non-terminal annotations (Johnson, 1998; Klein and Manning, 2003b) and latent variable grammars (Matsuzaki et al., 2005; Petrov et al., 2006) have increased the grammar size $|G|$ from a few thousand rules to several million in an explicitly enumerable grammar, or even more in an implicit grammar. Exhaustive search for the maximum likelihood parse tree with a state-of-the-art grammar can require over a minute of processing for a single sentence of 25 words, an unacceptable amount of time for real-time applications or when processing millions of sentences. Deterministic algorithms for dependency parsing exist that can extract syntactic dependency structure very quickly (Nivre, 2008), but this approach is often undesirable as constituent parsers are more accurate and more adaptable to new domains (Petrov et al., 2010).

The most accurate constituent parsers, e.g., Charniak (2000), Petrov and Klein (2007a), make use of approximate inference, limiting their search to a fraction of the total search space and achieving speeds of between one and four newspaper sentences per second. The paradigm for building state-of-the-art parsing models is to first design a model structure that can achieve high accuracy and then, after the model has been built, design effective approximate inference methods around that particular model; e.g., coarse-to-fine non-terminal hierarchies for a given model, or agenda-based methods

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 440–449,
Portland, Oregon, June 19-24, 2011.

that are empirically tuned to achieve acceptable efficiency/accuracy operating points. While both of the above mentioned papers use the CYK dynamic programming algorithm to search through possible solutions, their particular methods of approximate inference are quite distinct.

In this paper, we examine a general approach to approximate inference in constituent parsing that learns cell-specific thresholds for arbitrary grammars. For each cell in the CYK chart, we sort all potential constituents in a local agenda, ordered by an estimate of their posterior probability. Given features extracted from the chart cell context – e.g., span width; POS-tags and words surrounding the boundary of the cell – we train a log linear model to predict how many constituents should be popped from the local agenda and added to the chart. As a special case of this approach, we simply predict whether the number to add should be zero or greater than zero, in which case the method can be seen as a cell-by-cell generalization of Roark and Hollingshead's (2008; 2009) tagger-derived Chart Constraints. More generally, instead of a binary classification decision, we can also use this method to predict the desired cell population directly and get cell closure for free when the classifier predicts a beam-width of zero. In addition, we use a non-symmetric loss function during optimization to account for the imbalance between over-predicting or under-predicting the beam-width.

A key feature of our approach is that it does not rely upon reference syntactic annotations when learning to search. Rather, the beam-width prediction model is trained to learn the rank of constituents in the maximum likelihood trees.[1] We will illustrate this by presenting results using a latent-variable grammar, for which there is no "true" reference latent variable parse. We simply parse sections 2-21 of the WSJ treebank and train our search models from the output of these trees, with no prior knowledge of the non-terminal set or other grammar characteristics to guide the process. Hence, this approach is broadly applicable to a wide range of scenarios, including tuning the search to new domains where domain mismatch may yield very different efficiency/accuracy operating points.

[1]Note that we do not call this method "unsupervised" because all grammars used in this paper are induced from supervised data, although our framework can also accommodate unsupervised grammars. We emphasize that we are learning to search using only maximum likelihood trees, not that we are doing unsupervised parsing.

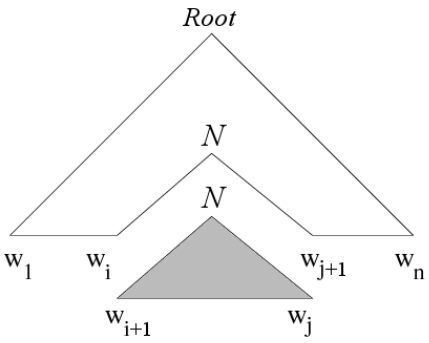

Figure 1: Inside (grey) and outside (white) representations of an example chart edge $N_{i,j}$.

In the next section, we present prior work on approximate inference in parsing, and discuss how our method to learn optimal beam-search parameters unite many of their strengths into a single framework. We then explore using our approach to open or close cells in the chart as an alternative to Roark and Hollingshead (2008; 2009). Finally, we present results which combine cell closure and adaptive beam-width prediction to achieve the most efficient parser.

2 Background

2.1 Preliminaries and notation

Let $S = w_1 \dots w_{|S|}$ represent an input string of $|S|$ words. Let $w_{i,j}$ denote the substring from word w_{i+1} to w_j; i.e., $S = w_{0,|S|}$. We use the term chart *edge* to refer to a non-terminal spanning a specific substring of the input sentence. Let $N_{i,j}$ denote the edge labeled with non-terminal N spanning $w_{i,j}$, for example $\text{NP}_{3,7}$. We define an edge's figure-of-merit (FOM) as an estimate of the product of its inside (β) and outside (α) scores, conceptually the relative merit the edge has to participate in the final parse tree (see Figure 1). More formally:

$$\begin{aligned} \alpha(N_{i,j}) &= P(w_{0,i}, N_{i,j}, w_{j,n}) \\ \beta(N_{i,j}) &= P(w_{i,j}|N) \\ \text{FOM}(N_{i,j}) &= \hat{\alpha}(N_{i,j})\hat{\beta}(N_{i,j}) \end{aligned}$$

With bottom-up parsing, the true inside probability is accumulated and $\beta(N_{i,j})$ does not need to be estimated, improving the FOMs ability to represent the true inside/outside distribution.

In this paper, we use a modified version of the Caraballo and Charniak **Boundary FOM** (1998) for local edge comparison, which computes $\hat{\alpha}(N_{i,j})$ using POS forward-backward scores and POS-to-nonterminal constituent boundary transition probabilities. Details can be found in (**?**).

We also note that in this paper we only use the FOM scoring function to rank constituents in a local agenda. Alternative approaches to ranking competitors are also possible, such as Learning as Search Optimization (Daumé and Marcu, 2005). The method we present in this paper to learn the optimal beam-search parameters is applicable to any ranking function, and we demonstrate this by computing results with both the Boundary FOM and only the inside probability in Section 6.

2.2 Agenda-based parsing

Agenda-based parsers maintain a global agenda of edges, ranked by FOM score. At each iteration, the highest-scoring edge is popped off of the agenda, added to the chart, and combined with other edges already in the chart. The agenda-based approach includes best-first parsing (Bobrow, 1990) and A* parsing (Klein and Manning, 2003a), which differ in whether an admissible FOM estimate $\hat{\alpha}(N_{i,j})$ is required. A* uses an admissible FOM, and thus guarantees finding the maximum likelihood parse, whereas an inadmissible heuristic (best-first) may require less exploration of the search space. Much work has been pursued in both admissible and inadmissible heuristics for agenda parsing (Caraballo and Charniak, 1998; Klein and Manning, 2003a; Pauls et al., 2010).

In this paper, we also make use of agendas, but at a local rather than a global level. We maintain an agenda for each cell, which has two significant benefits: 1) Competing edges can be compared directly, avoiding the difficulty inherent in agenda-based approaches of comparing edges of radically different span lengths and characteristics; and 2) Since the agendas are very small, the overhead of agenda maintenance — a large component of agenda-based parse time — is minimal.

2.3 Beam-search parsing

CYK parsing with a beam-search is a local pruning strategy, comparing edges within the same chart cell. The beam-width can be defined in terms of a threshold in the number of edges allowed, or in terms of a threshold on the difference in probability relative to the highest scoring edge (Collins, 1999; Zhang et al., 2010). For the current paper, we use both kinds of thresholds, avoiding pathological cases that each individual criteria is prone to encounter. Further, unlike most beam-search approaches we will make use of a FOM estimate of the posterior probability of an edge, defined above, as our ranking function. Finally, we will learn log linear models to assign cell-specific thresholds, rather than relying on a single search parameter.

2.4 Coarse-to-Fine Parsing

Coarse-to-fine parsing, also known as multiple pass parsing (Goodman, 1997; Charniak, 2000; Charniak and Johnson, 2005), first parses the input sentence with a simplified (coarse) version of the target (fine) grammar in which multiple non-terminals are merged into a single state. Since the coarse grammar is quite small, parsing is much faster than with the fine grammar, and can quickly yield an estimate of the outside probability $\alpha(\cdot)$ for use in subsequent agenda or beam-search parsing with the fine grammar. This approach can also be used iteratively with grammars of increasing complexity (Petrov and Klein, 2007a).

Building a coarse grammar from a fine grammar is a non-trivial problem, and most often approached with detailed knowledge of the fine grammar being used. For example, Goodman (1997) suggests using a coarse grammar consisting of regular non-terminals, such as NP and VP, and then non-terminals augmented with head-word information for the more accurate second-pass grammar. Such an approach is followed by Charniak (2000) as well. Petrov and Klein (2007a) derive coarse grammars in a more statistically principled way, although the technique is closely tied to their latent variable grammar representation.

To the extent that our cell-specific threshold classifier predicts that a chart cell should contain zero edges or more than zero edges, it is making coarse

predictions about the unlabeled constituent structure of the target parse tree. This aspect of our work is can be viewed as a coarse-to-fine process, though without considering specific grammatical categories or rule productions.

2.5 Chart Constraints

Roark and Hollingshead (2008; 2009) introduced a pruning technique that ignores entire chart cells based on lexical and POS features of the input sentence. They train two finite-state binary taggers: one that allows multi-word constituents to start at a word, and one that allows constituents to end at a word. Given these tags, it is straightforward to completely skip many chart cells during processing.

In this paper, instead of tagging word positions to infer valid constituent spans, we classify chart cells directly. We further generalize this cell classification to predict the beam-width of the chart cell, where a beam-width of zero indicates that the cell is completely closed. We discuss this in detail in the next section.

3 Open/Closed Cell Classification

3.1 Constituent Closure

We first look at the binary classification of chart cells as either open or closed to full constituents, and predict this value from the input sentence alone. This is the same problem that Roark and Hollingshead (2008; 2009) solve with Chart Constraints; however, where they classify lexical items as either beginning or ending a constituent, we classify individual chart cells as open or closed, an approach we call *Constituent Closure*. Although the number of classifications scales quadratically with our approach, the total parse time is still dominated by the $O(n^3|G|)$ parsing complexity and we find that the added level of specificity reduces the search space significantly.

To learn to classify a chart cell spanning words $w_{i+1} \dots w_j$ of a sentence S as open or closed to full constituents, we first map cells in the training corpus to tuples:

$$\Phi(S, i, j) = (\boldsymbol{x}, y) \tag{1}$$

where $\boldsymbol{x}$ is a feature-vector representation of the chart cell and y is the target class 1 if the cell contains an edge from the maximum likelihood parse tree, 0 otherwise. The feature vector $\boldsymbol{x}$ is encoded with the chart cell's absolute and relative span width, as well as unigram and bigram lexical and part-of-speech tag items from $w_{i-1} \dots w_{j+2}$.

Given feature/target tuples $(\boldsymbol{x}, y)$ for every chart cell in every sentence of a training corpus τ, we train a weight vector θ using the averaged perceptron algorithm (Collins, 2002) to learn an open/closed binary decision boundary:

$$\hat{\theta} = \underset{\theta}{\operatorname{argmin}} \sum_{(\boldsymbol{x},y)\in\Phi(\tau)} L_\lambda(H(\theta \cdot \boldsymbol{x}), y) \tag{2}$$

where $H(\cdot)$ is the unit step function: 1 if the inner product $\theta \cdot \boldsymbol{x} > 0$, and 0 otherwise; and $L_\lambda(\cdot, \cdot)$ is an asymmetric loss function, defined below.

When predicting cell closure, all misclassifications are not equal. If we leave open a cell which contains no edges in the maximum likelihood (ML) parse, we incur the cost of additional processing, but are still able to recover the ML tree. However, if we close a chart cell which contains an ML edge, search errors occur. To deal with this imbalance, we introduce an asymmetric loss function $L_\lambda(\cdot, \cdot)$ to penalize false-negatives more severely during training.

$$L_\lambda(h, y) = \begin{cases} 0 & \text{if } h = y \\ 1 & \text{if } h > y \\ \lambda & \text{if } h < y \end{cases} \tag{3}$$

We found the value $\lambda = 10^2$ to give the best performance on our development set, and we use this value in all of our experiments.

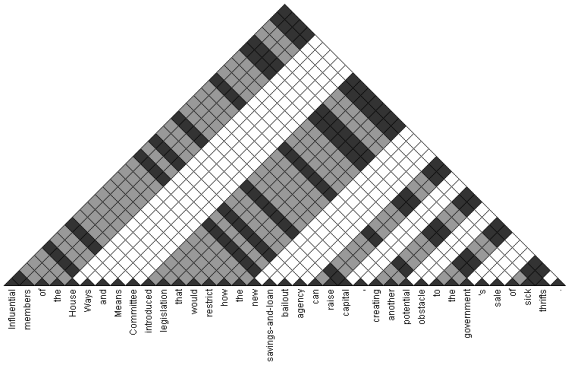
Figures 2a and 2b compare the pruned charts of Chart Constraints and Constituent Closure for a single sentence in the development set. Note that both of these methods are predicting where a complete constituent may be located in the chart, not partial constituents headed by factored nonterminals within a binarized grammar. Depending on the grammar factorization (right or left) we can infer chart cells that are restricted to only edges with a factored left-hand-side non-terminal. In Figure 2 these chart cells are colored gray. Note that Constituent Closure reduces the number of completely open cells considerably vs. Chart Constraints, and the number of cells open to factored categories somewhat.

3.2 Complete Closure

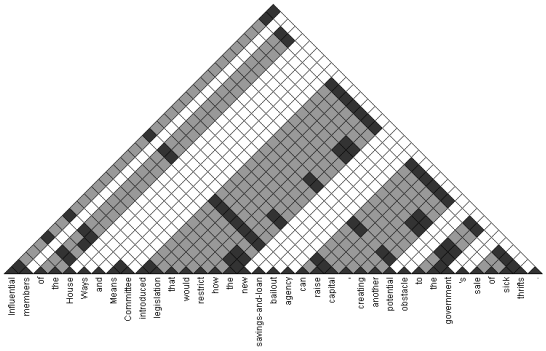
Alternatively, we can predict whether a chart cell contains any edge, either a partial or a full constituent, an approach we call *Complete Closure*. This is a more difficult classification problem as partial constituents occur in a variety of contexts. Nevertheless, learning this directly allows us to remove a large number of internal chart cells from consideration, since no additional cells need to be left open to partial constituents. The learning algorithm is identical to Equation 2, but training examples are now assigned a positive label if the chart cell contains any edge from the binarized maximum likelihood tree. Figure 2c gives a visual representation of Complete Closure for the same sentence; the number of completely open cells increases somewhat, but the total number of open cells (including those open to factored categories) is greatly reduced.

We compare the effectiveness of Constituent Closure, Complete Closure, and Chart Constraints, by decreasing the percentage of chart cells closed until accuracy over all sentences in our development set start to decline. For Constituent and Complete Closure, we also vary the loss function, adjusting the relative penalty between a false-negative (closing off a chart cell that contains a maximum likelihood edge) and a false-positive. Results show that using Chart Constrains as a baseline, we prune (skip) 33% of the total chart cells. Constituent Closure improves on this baseline only slightly (36%), but we see our biggest gains with Complete Closure, which prunes 56% of all chart cells in the development set.

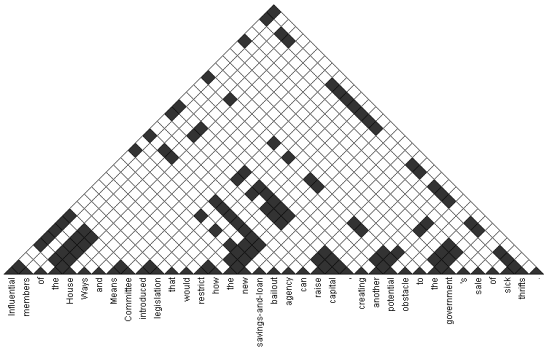
All of these open/closed cell classification methods can improve the efficiency of the exhaustive CYK algorithm, or any of the approximate inference methods mentioned in Section 2. We empirically evaluate them when applied to CYK parsing and beam-search parsing in Section 6.



(a) Chart Constraints (Roark and Hollingshead, 2009)



(b) Constituent Closure (this paper)



(c) Complete Closure (this paper)

Figure 2: Comparison of Chart Constraints (Roark and Hollingshead, 2009) to Constituent and Complete Closure for a single example sentence. Black cells are open to all edges while grey cells only allow factored edges (incomplete constituents).

4 Beam-Width Prediction

The cell-closing approaches discussed in Section 3 make binary decisions to either allow or completely block all edges in each cell. This all-on/all-off tactic ignores the characteristics of the local cell population, which, given a large statistical grammar, may contain hundred of edges, even if very improbable. Retaining all of these partial derivations forces the search in larger spans to continue down improbable paths, adversely affecting efficiency. We can further improve parsing speed in these open cells by leveraging local pruning methods, such as beam-search.

When parsing with a beam-search, finding the optimal beam-width threshold(s) to balance speed and accuracy is a necessary step. As mentioned in Sec-

tion 2.3, two variations of the beam-width are often considered: a fixed number of allowed edges, or a relative probability difference from the highest scoring local edge. For the remainder of this paper we fix the relative probability threshold for all experiments and focus on adapting the number of allowed edges per cell. We will refer to this number-of-allowed-edges value as the beam-width, notated by b, and leave adaptation of the relative probability difference to future work.

The standard way to tune the beam-width is a simple sweep over possible values until accuracy on a heldout data set starts to decline. The optimal point will necessarily be very conservative, allowing outliers (sentences or sub-phrases with above average ambiguity) to stay within the beam and produce valid parse trees. The majority of chart cells will require much fewer than b entries to find the maximum likelihood (ML) edge, yet, constrained by a constant beam-width, the cell will continue to be filled with unfruitful edges, exponentially increasing downstream computation.

For example, when parsing with the Berkeley latent-variable grammar and Boundary FOM, we find we can reduce the global beam-width b to 15 edges in each cell before accuracy starts to decline. However we find that 73% of the ML edges are ranked *first* in their cell and 96% are ranked in the top three. Thus, in 24 of every 25 cells, 80% of the edges are unnecessary (12 of the top 15). Clearly, it would be advantageous to adapt the beam-width such that it is restrictive when we are confident in the FOM ranking and more forgiving in ambiguous contexts.

To address this problem, we learn the optimal beam-width for each chart cell directly. We define $R_{i,j}$ as the rank of the ML edge in the chart cell spanning $w_{i+1} \dots w_j$. If no ML edge exists in the cell, then $R_{i,j} = 0$. Given a global maximum beam-width b, we train b different binary classifiers, each using separate mapping functions Φ_k, where the target value y produced by Φ_k is 1 if $R_{i,j} > k$ and 0 otherwise.

The same asymmetry noted in Section 3 applies in this task as well. When in doubt, we prefer to over-predict the beam-width and risk an increase in processing time opposed to under-predicting at the expense of accuracy. Thus we use the same loss function L_λ, this time training several classifiers:

$$\hat{\theta}_k = \operatorname*{argmin}_{\theta} \sum_{(\boldsymbol{x},y)\in\Phi_k(\tau)} L_\lambda(H(\theta \cdot \boldsymbol{x}), y) \qquad (4)$$

Note that in Equation 4 when $k = 0$, we recover the open/closed cell classification of Equation 2, since a beam width of 0 indicates that the chart cell is completely closed.

During decoding, we assign the beam-width for chart cell spanning $w_{i+1} \dots w_j$ given models $\theta_0, \theta_1, ...\theta_{b-1}$ by finding the lowest value k such that the binary classifier θ_k classifies $R_{i,j} \leq k$. If no such k exists, $\hat{R}_{i,j}$ is set to the maximum beam-width value b:

$$\hat{R}_{i,j} = \operatorname*{argmin}_{k} \theta_k \cdot x_i \leq 0 \qquad (5)$$

In Equation 5 we assume there are b unique classifiers, one for each possible beam-width value between 0 and $b-1$, but this level of granularity is not required. Choosing the number of classification bins to minimize total parsing time is dependent on the FOM function and how it ranks ML edges. With the Boundary FOM we use in this paper, 97.8% of ML edges have a local rank less than five and we find that the added cost of computing b decision boundaries for each cell is not worth the added specificity. We searched over possible classification bins and found that training four classifiers with beam-width decision boundaries at 0, 1, 2, and 4 is faster than 15 individual classifiers and more memory efficient, since each model θ_k has over 800,000 parameters. All beam-width prediction results reported in this paper use these settings.

Figure 3 is a visual representation of beam-width prediction on a single sentence of the development set using the Berkeley latent-variable grammar and Boundary FOM. In this figure, the gray scale represents the relative size of the beam-width, black being the maximum beam-width value, b, and the lightest gray being a beam-width of size one. We can see from this figure that very few chart cells are classified as needing the full 15 edges, apart from span-1 cells which we do not classify.

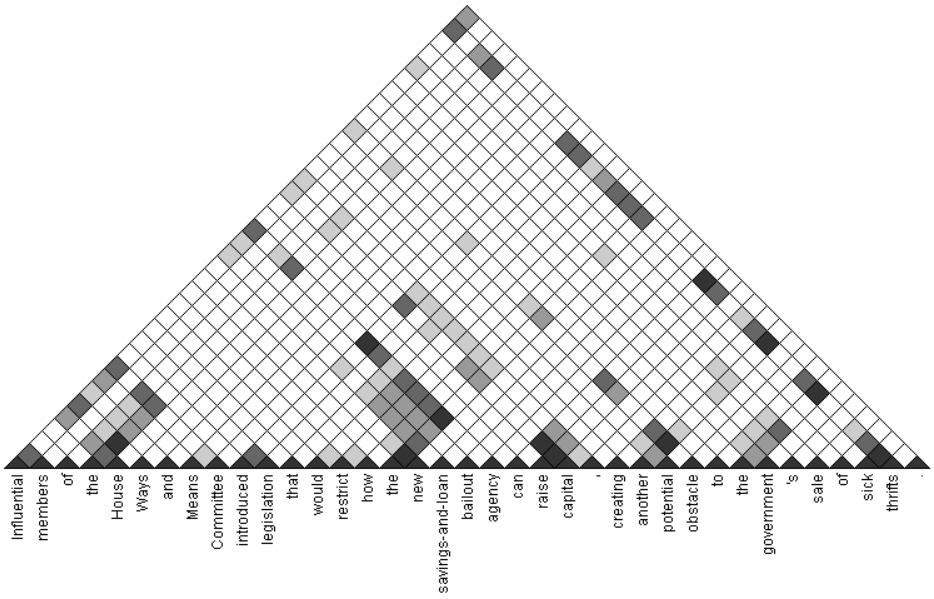


Figure 3: Visualization of Beam-Width Prediction for a single example sentence. The grey scale represents the size of the predicted beam-width: white is 0 (cell is skipped) and black is the maximum value b (b=15 in this example).

5 Experimental Setup

We run all experiments on the WSJ treebank (Marcus et al., 1999) using the standard splits: section 2-21 for training, section 22 for development, and section 23 for testing. We preprocess the treebank by removing empty nodes, temporal labels, and spurious unary productions ($X \rightarrow X$), as is standard in published works on syntactic parsing.

The pruning methods we present in this paper can be used to parse with any grammar. To achieve state-of-the-art accuracy levels, we parse with the Berkeley SM6 latent-variable grammar (Petrov and Klein, 2007b) where the original treebank non-terminals are automatically split into subclasses to optimize parsing accuracy. This is an explicit grammar consisting of 4.3 million productions, 2.4 million of which are lexical productions. Exhaustive CYK parsing with the grammar takes more than a minute per sentence.

Accuracy is computed from the 1-best Viterbi (max) tree extracted from the chart. Alternative decoding methods, such as marginalizing over the latent variables in the grammar or MaxRule decoding (Petrov and Klein, 2007a) are certainly possible in our framework, but it is unknown how effective these methods will be given the heavily pruned nature of the chart. We leave investigation of this to future work. We compute the precision and recall of constituents from the 1-best Viterbi trees using the standard EVALB script (**?**), which ignores punctuation and the root symbol. Accuracy results are reported as F-measure (F_1), the harmonic mean between precision and recall.

We ran all timing tests on an Intel 3.00GHz processor with 6MB of cache and 16GB of memory. Our parser is written in Java and publicly available at http://nlp.csee.ogi.edu.

6 Results

We empirically demonstrate the advantages of our pruning methods by comparing the total parse time of each system, including FOM initialization, chart cell classification, and beam-width prediction. The parse times reported for Chart Constraints do not include tagging times as we were provided with this pre-tagged data, but tagging all of Section 22 takes less than three seconds and we choose to ignore this contribution for simplicity.

Figure 4 contains a timing comparison of the three components of our final parser: Boundary FOM initialization (which includes the forward-backward algorithm over ambiguous part-of-speech tags), beam-

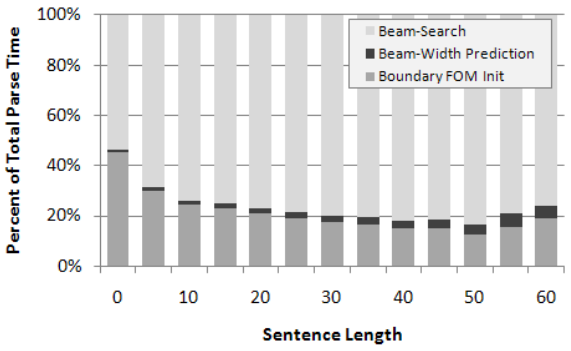

Figure 4: Timing breakdown by sentence length for major components of our parser.

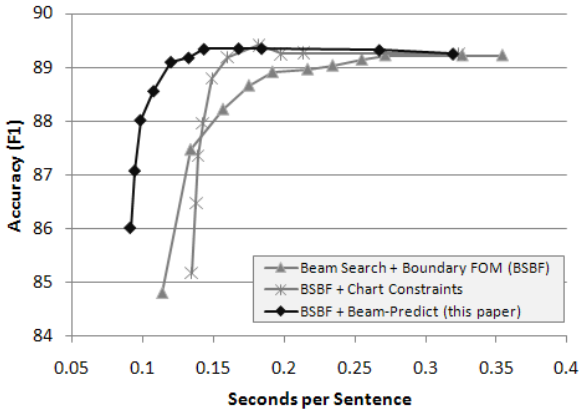

Figure 5: Time vs. accuracy curves comparing beam-width prediction (Beam-Predict) and Chart Constraints.

width prediction, and the final beam-search, including 1-best extraction. We bin these relative times with respect to sentence length to see how each component scales with the number of input words. As expected, the $O(n^3|G|)$ beam-search begins to dominate as the sentence length grows, but Boundary FOM initialization is not cheap, and absorbs, on average, 20% of the total parse time. Beam-width prediction, on the other hand, is almost negligible in terms of processing time even though it scales quadratically with the length of the sentence.

We compare the accuracy degradation of beam-width prediction and Chart Constraints in Figure 5 as we incrementally tighten their respective pruning parameters. We also include the baseline beam-search parser with Boundary FOM in this figure to demonstrate the accuracy/speed trade-off of adjusting a global beam-width alone. In this figure we see that the knee of the beam-width prediction curve (Beam-Predict) extends substantially further to the left before accuracy declines, indicating that our pruning method is intelligently removing a significant portion of the search space that remains unpruned with Chart Constraints.

In Table 1 we present the accuracy and parse time for three baseline parsers on the development set: exhaustive CYK parsing, beam-search parsing using only the inside score $\beta(\cdot)$, and beam-search parsing using the Boundary FOM. We then apply our two cell-closing methods, Constituent Closure and Complete Closure, to all three baselines. As expected, the relative speedup of these methods across the various baselines is similar since the open/closed cell classification does not change across parsers. We also see that Complete Closure is between 22% and 31% faster than Constituent Closure, indicating that the greater number of cells closed translates directly into a reduction in parse time. We can further apply beam-width prediction to the two beam-search baseline parsers in Table 1. Dynamically adjusting the beam-width for the remaining open cells decreases parse time by an additional 25% when using the Inside FOM, and 28% with the boundary FOM.

We apply our best model to the test set and report results in Table 2. Beam-width prediction, again, outperforms the baseline of a constant beam-width by 65% and the open/closed classification of Chart Constraints by 49%. We also compare beam-width prediction to the Berkeley Coarse-to-Fine parser. Both our parser and the Berkeley parser are written in Java, both are run with Viterbi decoding, and both parse with the same grammar, so a direct comparison of speed and accuracy is fair.[2]

7 Conclusion and Future Work

We have introduced three new pruning methods, the best of which unites figure-of-merit estimation from agenda-based parsing, local pruning from beam-search parsing, and unlabeled constituent structure

[2]We run the Berkeley parser with the default search parameterization to achieve the fastest possible parsing time. We note that 3 of 2416 sentences fail to parse under these settings. Using the '-accurate' option provides a valid parse for all sentences, but increases parsing time of section 23 to 0.293 seconds per sentence with no increase in F-score. We assume a back-off strategy for failed parses could be implemented to parse all sentences with a parsing time close to the default parameterization.

Parser	Sec/Sent	F_1
CYK	70.383	89.4
CYK + Constituent Closure	47.870	89.3
CYK + Complete Closure	32.619	89.3
Beam + Inside FOM (BI)	3.977	89.2
BI + Constituent Closure	2.033	89.2
BI + Complete Closure	1.575	89.3
BI + Beam-Predict	1.180	89.3
Beam + Boundary FOM (BB)	0.326	89.2
BB + Constituent Closure	0.279	89.2
BB + Complete Closure	0.199	89.3
BB + Beam-Predict	0.143	89.3

Parser	Sec/Sent	F_1
CYK	64.610	88.7
Berkeley CTF MaxRule	0.213	90.2
Berkeley CTF Viterbi	0.208	88.8
Beam + Boundary FOM (BB)	0.334	88.6
BB + Chart Constraints	0.244	88.7
BB + Beam-Predict (this paper)	0.125	88.7

Table 2: Section 23 test set results for multiple parsers using the Berkeley latent-variable grammar.

prediction from coarse-to-fine parsing and Chart Constraints. Furthermore, our pruning method is trained using only maximum likelihood trees, allowing it to be tuned to specific domains without labeled data. Using this framework, we have shown that we can decrease parsing time by 65% over a standard beam-search without any loss in accuracy, and parse significantly faster than both the Berkeley parser and Chart Constraints.

We plan to explore a number of remaining questions in future work. First, we will try combining our approach with constituent-level Coarse-to-Fine pruning. The two methods prune the search space in very different ways and may prove to be complementary. On the other hand, our parser currently spends 20% of the total parse time initializing the FOM, and adding additional preprocessing costs, such as parsing with a coarse grammar, may not outweigh the benefits gained in the final search.

Second, as with Chart Constraints we do not prune lexical or unary edges in the span-1 chart cells (i.e., chart cells that span a single word). We expect pruning entries in these cells would notably reduce parse time since they cause exponentially many chart edges to be built in larger spans. Initial work constraining span-1 chart cells has promising results (Bodenstab et al., 2011) and we hope to investigate its interaction with beam-width prediction even further.

Finally, the size and structure of the grammar is the single largest contributor to parse efficiency. In contrast to the current paradigm, we plan to investigate new algorithms that jointly optimize accuracy and efficiency during grammar induction, leading to more efficient decoding.

Acknowledgments

We would like to thank Kristy Hollingshead for her valuable discussions, as well as the anonymous reviewers who gave very helpful feedback. Abstract

We study the problem of finding the best *head-driven* parsing strategy for Linear Context-Free Rewriting System productions. A head-driven strategy must begin with a specified righthand-side nonterminal (the head) and add the remaining nonterminals one at a time in any order. We show that it is NP-hard to find the best head-driven strategy in terms of either the time or space complexity of parsing.

1 Introduction

Linear Context-Free Rewriting Systems (LCFRSs) (Vijay-Shankar et al., 1987) constitute a very general grammatical formalism which subsumes context-free grammars (CFGs) and tree adjoining grammars (TAGs), as well as the synchronous context-free grammars (SCFGs) and synchronous tree adjoining grammars (STAGs) used as models in machine translation.[1] LCFRSs retain the fundamental property of CFGs that grammar nonterminals rewrite independently, but allow nonterminals to generate discontinuous phrases, that is, to generate more than one span in the string being produced. This important feature has been recently exploited by Maier and Søgaard (2008) and Kallmeyer and Maier (2010) for modeling phrase structure treebanks with discontinuous constituents, and by Kuhlmann and Satta (2009) for modeling non-projective dependency treebanks.

The rules of a LCFRS can be analyzed in terms of the properties of *rank* and *fan-out*. Rank is the number of nonterminals on the right-hand side (rhs) of a rule, while fan-out is the number of spans of the string generated by the nonterminal in the left-hand side (lhs) of the rule. CFGs are equivalent to LCFRSs with fan-out one, while TAGs are one type of LCFRSs with fan-out two. Rambow and Satta (1999) show that rank and fan-out induce an infinite, two-dimensional hierarchy in terms of generative power; while CFGs can always be reduced to rank two (Chomsky Normal Form), this is not the case for LCFRSs with any fan-out greater than one.

General algorithms for parsing LCFRSs build a dynamic programming chart of recognized nonterminals bottom-up, in a manner analogous to the CKY algorithm for CFGs (Hopcroft and Ullman, 1979), but with time and space complexity that are dependent on the rank and fan-out of the grammar rules. Whenever it is possible, binarization of LCFRS rules, or reduction of rank to two, is therefore important for parsing, as it reduces the time complexity needed for dynamic programming. This has lead to a number of binarization algorithms for LCFRSs, as well as *factorization* algorithms that factor rules into new rules with smaller rank, without necessarily reducing rank all the way to two. Kuhlmann and Satta (2009) present an algorithm for binarizing certain LCFRS rules without increasing their fan-out, and Sagot and Satta (2010) show how to reduce rank to the lowest value possible for LCFRS rules of fan-out two, again without increasing fan-out. Gómez-Rodríguez et al. (2010) show how to factorize *well-nested* LCFRS rules of arbitrary fan-out for efficient parsing.

In general there may be a trade-off required between rank and fan-out, and a few recent papers have investigated this trade-off taking gen-

[1] To be more precise, SCFGs and STAGs generate languages composed by pair of strings, while LCFRSs generate string languages. We can abstract away from this difference by assuming concatenation of components in a string pair.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 450–459,
Portland, Oregon, June 19-24, 2011.

eral LCFRS rules as input. Gómez-Rodríguez et al. (2009) present an algorithm for binarization of LCFRSs while keeping fan-out as small as possible. The algorithm is exponential in the resulting fan-out, and Gómez-Rodríguez et al. (2009) mention as an important open question whether polynomial-time algorithms to minimize fan-out are possible. Gildea (2010) presents a related method for binarizing rules while keeping the time complexity of parsing as small as possible. Binarization turns out to be possible with no penalty in time complexity, but, again, the factorization algorithm is exponential in the resulting time complexity. Gildea (2011) shows that a polynomial time algorithm for factorizing LCFRSs in order to minimize time complexity would imply an improved approximation algorithm for the well-studied graph-theoretic property known as treewidth. However, whether the problem of factorizing LCFRSs in order to minimize time complexity is NP-hard is still an open question in the above works.

Similar questions have arisen in the context of machine translation, as the SCFGs used to model translation are also instances of LCFRSs, as already mentioned. For SCFG, Satta and Peserico (2005) showed that the exponent in the time complexity of parsing algorithms must grow at least as fast as the square root of the rule rank, and Gildea and Štefankovič (2007) tightened this bound to be linear in the rank. However, neither paper provides an algorithm for finding the best parsing strategy, and Huang et al. (2009) mention that whether finding the optimal parsing strategy for an SCFG rule is NP-hard is an important problem for future work.

In this paper, we investigate the problem of rule binarization for LCFRSs in the context of *head-driven* parsing strategies. Head-driven strategies begin with one rhs symbol, and add one nonterminal at a time. This rules out any factorization in which two subsets of nonterminals of size greater than one are combined in a single step. Head-driven strategies allow for the techniques of lexicalization and Markovization that are widely used in (projective) statistical parsing (Collins, 1997). The statistical LCFRS parser of Kallmeyer and Maier (2010) binarizes rules head-outward, and therefore adopts what we refer to as a head-driven strategy. However, the binarization used by Kallmeyer and Maier (2010) simply proceeds left to right through the rule, without considering the impact of the parsing strategy on either time or space complexity. We examine the question of whether we can efficiently find the strategy that minimizes either the time complexity or the space complexity of parsing. While a naive algorithm can evaluate all $r!$ head-driven strategies in time $O(n \cdot r!)$, where r is the rule's rank and n is the total length of the rule's description, we wish to determine whether a polynomial-time algorithm is possible.

Since parsing problems can be cast in terms of logic programming (Shieber et al., 1995), we note that our problem can be thought of as a type of query optimization for logic programming. Query optimization for logic programming is NP-complete since query optimization for even simple conjunctive database queries is NP-complete (Chandra and Merlin, 1977). However, the fact that variables in queries arising from LCFRS rules correspond to the endpoints of spans in the string to be parsed means that these queries have certain structural properties (Gildea, 2011). We wish to determine whether the structure of LCFRS rules makes efficient factorization algorithms possible.

In the following, we show both the the time- and space-complexity problems to be NP-hard for head-driven strategies. We provide what is to our knowledge the first NP-hardness result for a grammar factorization problem, which we hope will aid in understanding parsing algorithms in general.

2 LCFRSs and parsing complexity

In this section we briefly introduce LCFRSs and define the problem of optimizing head-driven parsing complexity for these formalisms. For a positive integer n, we write $[n]$ to denote the set $\{1, \ldots, n\}$.

As already mentioned in the introduction, LCFRSs generate tuples of strings over some finite alphabet. This is done by associating each production p of a grammar with a function g that takes as input the tuples generated by the nonterminals in p's rhs, and rearranges their string components into a new tuple, possibly adding some alphabet symbols.

Let V be some finite alphabet. We write V^* for the set of all (finite) strings over V. For natural numbers $r \geq 0$ and $f, f_1, \ldots, f_r \geq 1$, consider a func-

tion $g : (V^*)^{f_1} \times \cdots \times (V^*)^{f_r} \rightarrow (V^*)^f$ defined by an equation of the form

$$g(\langle x_{1,1}, \ldots, x_{1,f_1}\rangle, \ldots, \langle x_{r,1}, \ldots, x_{r,f_r}\rangle) = \vec{\alpha}\ .$$

Here the $x_{i,j}$'s denote variables over strings in V^*, and $\vec{\alpha} = \langle \alpha_1, \ldots, \alpha_f\rangle$ is an f-tuple of strings over g's argument variables and symbols in V. We say that g is **linear, non-erasing** if $\vec{\alpha}$ contains *exactly one* occurrence of each argument variable. We call r and f the **rank** and the **fan-out** of g, respectively, and write $r(g)$ and $f(g)$ to denote these quantities.

Example 1 $g_1(\langle x_{1,1}, x_{1,2}\rangle) = \langle x_{1,1}x_{1,2}\rangle$ takes as input a tuple with two strings and returns a tuple with a single string, obtained by concatenating the components in the input tuple. $g_2(\langle x_{1,1}, x_{1,2}\rangle) = \langle ax_{1,1}b, cx_{1,2}d\rangle$ takes as input a tuple with two strings and wraps around these strings with symbols $a, b, c, d \in V$. Both functions are linear, non-erasing, and we have $r(g_1) = r(g_2) = 1$, $f(g_1) = 1$ and $f(g_2) = 2$. □

A **linear context-free rewriting system** is a tuple $G = (V_N, V_T, P, S)$, where V_N and V_T are finite, disjoint alphabets of nonterminal and terminal symbols, respectively. Each $A \in V_N$ is associated with a value $f(A)$, called its **fan-out**. The nonterminal S is the start symbol, with $f(S) = 1$. Finally, P is a set of productions of the form

$$p:\ \ A\ \ \rightarrow\ \ g(A_1, A_2, \ldots, A_{r(g)})\ , \qquad (1)$$

where $A, A_1, \ldots, A_{r(g)} \in V_N$, and $g : (V_T^*)^{f(A_1)} \times \cdots \times (V_T^*)^{f(A_{r(g)})} \rightarrow (V_T^*)^{f(A)}$ is a linear, non-erasing function.

Production (1) can be used to transform the $r(g)$ string tuples generated by the nonterminals $A_1, \ldots, A_{r(g)}$ into a tuple of $f(A)$ strings generated by A. The values $r(g)$ and $f(g)$ are called the **rank** and **fan-out** of p, respectively, written $r(p)$ and $f(p)$. Given that $f(S) = 1$, S generates a set of strings, defining the language $L(G)$.

Example 2 Let g_1 and g_2 be as in Example 1, and let $g_3() = \langle \varepsilon, \varepsilon\rangle$. Consider the LCFRS G defined by the productions $p_1 : S \rightarrow g_1(A)$, $p_2 : A \rightarrow g_2(A)$ and $p_3 : A \rightarrow g_3()$. We have $f(S) = 1$, $f(A) = f(G) = 2$, $r(p_3) = 0$ and $r(p_1) = r(p_2) = r(G) = 1$. We have $L(G) = \{a^n b^n c^n d^n \mid n \geq 1\}$. For instance, the string $a^3b^3c^3d^3$ is generated by means of the following bottom-up process. First, the tuple $\langle \varepsilon, \varepsilon\rangle$ is generated by A through p_3. We then iterate three times the application of p_2 to $\langle \varepsilon, \varepsilon\rangle$, resulting in the tuple $\langle a^3b^3, c^3d^3\rangle$. Finally, the tuple (string) $\langle a^3b^3c^3d^3\rangle$ is generated by S through application of p_1. □

fan-out	*strategy*
4	$((A_1 \oplus A_4) \oplus A_3)^* \oplus A_2$
3	$(A_1 \oplus A_4)^* \oplus (A_2 \oplus A_3)$
3	$((A_1 \oplus A_2)^* \oplus A_4) \oplus A_3$
2	$((A_2^* \oplus A_3) \oplus A_4) \oplus A_1$

Figure 1: Some parsing strategies for production p in Example 3, and the associated maximum value for fan-out. Symbol $\oplus$ denotes the merging operation, and superscript $*$ marks the first step in the strategy in which the highest fan-out is realized.

Existing parsing algorithms for LCFRSs exploit dynamic programming. These algorithms compute partial parses of the input string w, represented by means of specialized data structures called items. Each **item** indexes the boundaries of the segments of w that are spanned by the partial parse. In the special case of parsing based on CFGs, an item consists of two indices, while for TAGs four indices are required.

In the general case of LCFRSs, parsing of a production p as in (1) can be carried out in $r(g) - 1$ steps, collecting already available parses for nonterminals $A_1, \ldots, A_{r(g)}$ one at a time, and 'merging' these into intermediate partial parses. We refer to the order in which nonterminals are merged as a parsing strategy, or, equivalently, a factorization of the original grammar rule. Any parsing strategy results in a complete parse of p, spanning $f(p) = f(A)$ segments of w and represented by some item with $2f(A)$ indices. However, intermediate items obtained in the process might span more than $f(A)$ segments. We illustrate this through an example.

Example 3 Consider a linear non-erasing function $g(\langle x_{1,1}, x_{1,2}\rangle, \langle x_{2,1}, x_{2,2}\rangle, \langle x_{3,1}, x_{3,2}\rangle, \langle x_{4,1}, x_{4,2}\rangle) = \langle x_{1,1}x_{2,1}x_{3,1}x_{4,1},\ x_{3,2}x_{2,2}x_{4,2}x_{1,2}\rangle$, and a production $p : A \rightarrow g(A_1, A_2, A_3, A_4)$, where all the nonterminals involved have fan-out 2. We could parse p starting from A_1, and then merging with A_4,

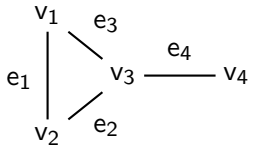

Figure 2: Example input graph for our construction of an LCFRS production.

A_3, and A_2. In this case, after we have collected the first three nonterminals, we have obtained a partial parse having fan-out 4, that is, an item spanning 4 segments of the input string. Alternatively, we could first merge A_1 and A_4, then merge A_2 and A_3, and finally merge the two obtained partial parses. This strategy is slightly better, resulting in a maximum fan-out of 3. Other possible strategies can be explored, displayed in Figure 1. It turns out that the best parsing strategy leads to fan-out 2. □

The maximum fan-out f realized by a parsing strategy determines the space complexity of the parsing algorithm. For an input string w, items will require (in the worst-case) $2f$ indices, each taking $\mathcal{O}(|w|)$ possible values. This results in space complexity of $\mathcal{O}(|w|^{2f})$. In the special cases of parsing based on CFGs and TAGs, this provides the well-known space complexity of $\mathcal{O}(|w|^2)$ and $\mathcal{O}(|w|^4)$, respectively.

It can also be shown that, if a partial parse having fan-out f is obtained by means of the combination of two partial parses with fan-out f_1 and f_2, respectively, the resulting time complexity will be $\mathcal{O}(|w|^{f+f_1+f_2})$ (Seki et al., 1991; Gildea, 2010). As an example, in the case of parsing based on CFGs, nonterminals as well as partial parses all have fan-out one, resulting in the standard time complexity of $\mathcal{O}(|w|^3)$ of dynamic programming methods. When parsing with TAGs, we have to manipulate objects with fan-out two (in the worst case), resulting in time complexity of $\mathcal{O}(|w|^6)$.

We investigate here the case of general LCFRS productions, whose internal structure is considerably more complex than the context-free or the tree adjoining case. Optimizing the parsing complexity for a production means finding a parsing strategy that results in minimum space or time complexity.

We now turn the above optimization problems into decision problems. In the MIN SPACE STRATEGY problem one takes as input an LCFRS production p and an integer k, and must decide whether there exists a parsing strategy for p with maximum fan-out not larger than k. In the MIN TIME STRATEGY problem one is given p and k as above and must decide whether there exists a parsing strategy for p such that, in any of its steps merging two partial parses with fan-out f_1 and f_2 and resulting in a partial parse with fan-out f, the relation $f + f_1 + f_2 \leq k$ holds.

In this paper we investigate the above problems in the context of a specific family of linguistically motivated parsing strategies for LCFRSs, called head-driven. In a **head-driven** strategy, one always starts parsing a production p from a fixed nonterminal in its rhs, called the **head** of p, and merges the remaining nonterminals one at a time with the partial parse containing the head. Thus, under these strategies, the construction of partial parses that do not include the head is forbidden, and each parsing step involves at most one partial parse. In Figure 1, all of the displayed strategies but the one in the second line are head-driven (for different choices of the head).

3 NP-completeness results

For an LCFRS production p, let H be its head nonterminal, and let $A_1, \ldots, A_n$ be all the non-head nonterminals in p's rhs, with $n + 1 = r(p)$. A head-driven parsing strategy can be represented as a permutation π over the set $[n]$, prescribing that the non-head nonterminals in p's rhs should be merged with H in the order $A_{\pi(1)}, A_{\pi(2)}, \ldots, A_{\pi(n)}$. Note that there are $n!$ possible head-driven parsing strategies.

To show that MIN SPACE STRATEGY is NP-hard under head-driven parsing strategies, we reduce from the MIN CUT LINEAR ARRANGEMENT problem, which is a decision problem over (undirected) graphs. Given a graph $M = (V, E)$ with set of vertices V and set of edges E, a **linear arrangement** of M is a bijective function h from V to $[n]$, where $|V| = n$. The **cutwidth** of M at gap $i \in [n-1]$ and with respect to a linear arrangement h is the number of edges crossing the gap between the i-th vertex and its successor:

$$cw(M, h, i) = |\{(u, v) \in E \mid h(u) \leq i < h(v)\}| \,.$$

$$p: \quad A \rightarrow g(H, A_1, A_2, A_3, A_4)$$

$$g(\langle x_{H,e_1}, x_{H,e_2}, x_{H,e_3}, x_{H,e_4}\rangle, \langle x_{A_1,e_1,l}, x_{A_1,e_1,r}, x_{A_1,e_3,l}, x_{A_1,e_3,r}\rangle, \langle x_{A_2,e_1,l}, x_{A_2,e_1,r}, x_{A_2,e_2,l}, x_{A_2,e_2,r}\rangle,$$
$$\langle x_{A_3,e_2,l}, x_{A_3,e_2,r}, x_{A_3,e_3,l}, x_{A_3,e_3,r}, x_{A_3,e_4,l}, x_{A_3,e_4,r}\rangle, \langle x_{A_4,e_4,l}, x_{A_4,e_4,r}\rangle) =$$
$$\langle \quad x_{A_1,e_1,l}x_{A_2,e_1,l}x_{H,e_1}x_{A_1,e_1,r}x_{A_2,e_1,r}, \quad x_{A_2,e_2,l}x_{A_3,e_2,l}x_{H,e_2}x_{A_2,e_2,r}x_{A_3,e_2,r},$$
$$x_{A_1,e_3,l}x_{A_3,e_3,l}x_{H,e_3}x_{A_1,e_3,r}x_{A_3,e_3,r}, \quad x_{A_3,e_4,l}x_{A_4,e_4,l}x_{H,e_4}x_{A_3,e_4,r}x_{A_4,e_4,r} \quad \rangle$$

Figure 3: The construction used to prove Theorem 1 builds the LCFRS production p shown, when given as input the graph of Figure 2.

The cutwidth of M is then defined as

$$cw(M) = \min_{h} \max_{i \in [n-1]} cw(M, h, i) \ .$$

In the MIN CUT LINEAR ARRANGEMENT problem, one is given as input a graph M and an integer k, and must decide whether $cw(M) \leq k$. This problem has been shown to be NP-complete (Gavril, 1977).

Theorem 1 *The* MIN SPACE STRATEGY *problem restricted to head-driven parsing strategies is NP-complete.*

PROOF We start with the NP-hardness part. Let $M = (V, E)$ and k be an input instance for MIN CUT LINEAR ARRANGEMENT, and let $V = \{v_1, \ldots, v_n\}$ and $E = \{e_1, \ldots, e_q\}$. We assume there are no self loops in M, since these loops do not affect the value of the cutwidth and can therefore be removed. We construct an LCFRS production p and an integer k' as follows.

Production p has a head nonterminal H and a non-head nonterminal A_i for each vertex $v_i \in V$. We let H generate tuples with a string component for each edge $e_i \in E$. Thus, we have $f(H) = q$. Accordingly, we use variables x_{H,e_i}, for each $e_i \in E$, to denote the string components in tuples generated by H.

For each $v_i \in V$, let $E(v_i) \subseteq E$ be the set of edges impinging on v_i; thus $|E(v_i)|$ is the degree of v_i. We let A_i generate a tuple with two string components for each $e_j \in E(v_i)$. Thus, we have $f(A_i) = 2 \cdot |E(v_i)|$. Accordingly, we use variables $x_{A_i,e_j,l}$ and $x_{A_i,e_j,r}$, for each $e_j \in E(v_i)$, to denote the string components in tuples generated by A_i (here subscripts l and r indicate left and right positions, respectively; see below).

We set $r(p) = n + 1$ and $f(p) = q$, and define p by $A \rightarrow g(H, A_1, A_2, \ldots, A_n)$, with $g(t_H, t_{A_1}, \ldots, t_{A_n}) = \langle \alpha_1, \ldots, \alpha_q \rangle$. Here t_H is the tuple of variables for H and each t_{A_i}, $i \in [n]$, is the tuple of variables for A_i. Each string α_i, $i \in [q]$, is specified as follows. Let v_s and v_t be the endpoints of e_i, with $v_s, v_t \in V$ and $s < t$. We define

$$\alpha_i \quad = \quad x_{A_s,e_i,l}x_{A_t,e_i,l}x_{H,e_i}x_{A_s,e_i,r}x_{A_t,e_i,r} \ .$$

Observe that whenever edge e_i impinges on vertex v_j, then the left and right strings generated by A_j and associated with e_i wrap around the string generated by H and associated with the same edge. Finally, we set $k' = q + k$.

Example 4 Given the input graph of Figure 2, our reduction constructs the LCFRS production shown in Figure 3. Figure 4 gives a visualization of how the spans in this production fit together. For each edge in the graph of Figure 2, we have a group of five spans in the production: one for the head nonterminal, and two spans for each of the two nonterminals corresponding to the edge's endpoints. □

Assume now some head-driven parsing strategy π for p. For each $i \in [n]$, we define D_i^π to be the partial parse obtained after step i in π, consisting of the merge of nonterminals $H, A_{\pi(1)}, \ldots, A_{\pi(i)}$. Consider some edge $e_j = (v_s, v_t)$. We observe that for any D_i^π that includes or excludes both nonterminals A_s and A_t, the α_j component in the definition of p is associated with a single string, and therefore contributes with a single unit to the fan-out of the partial parse. On the other hand, if D_i^π includes only one nonterminal between A_s and A_t, the α_j component is associated with two strings and contributes with two units to the fan-out of the partial parse.

We can associate with π a linear arrangement h_π of M by letting $h_\pi(v_{\pi(i)}) = i$, for each $v_i \in V$. From the above observation on the fan-out of D_i^π,

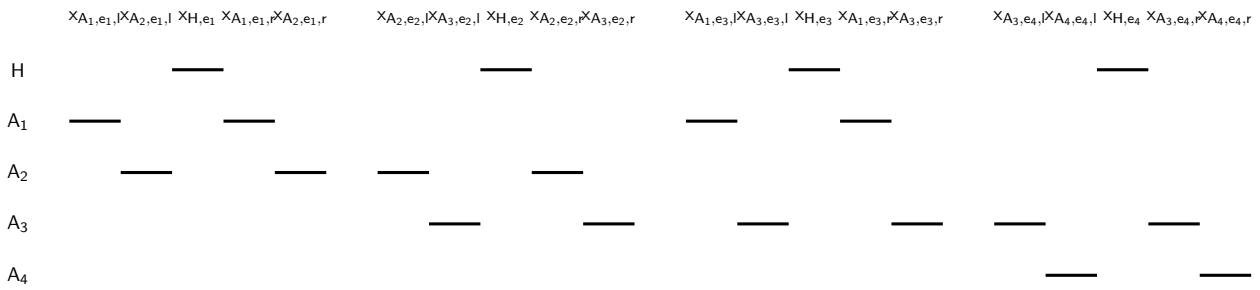

Figure 4: A visualization of how the spans for each nonterminal fit together in the left-to-right order defined by the production of Figure 3.

we have the following relation, for every $i \in [n-1]$:

$$f(D_i^\pi) \;\; = \;\; q + cw(M, h_\pi, i) \; .$$

We can then conclude that M, k is a positive instance of MIN CUT LINEAR ARRANGEMENT if and only if p, k' is a positive instance of MIN SPACE STRATEGY. This proves that MIN SPACE STRATEGY is NP-hard.

To show that MIN SPACE STRATEGY is in NP, consider a nondeterministic algorithm that, given an LCFRS production p and an integer k, guesses a parsing strategy π for p, and tests whether $f(D_i^\pi) \leq k$ for each $i \in [n]$. The algorithm accepts or rejects accordingly. Such an algorithm can clearly be implemented to run in polynomial time. ■

We now turn to the MIN TIME STRATEGY problem, restricted to head-driven parsing strategies. Recall that we are now concerned with the quantity $f_1 + f_2 + f$, where f_1 is the fan-out of some partial parse D, f_2 is the fan-out of a nonterminal A, and f is the fan out of the partial parse resulting from the merge of the two previous analyses.

We need to introduce the MODIFIED CUTWIDTH problem, which is a variant of the MIN CUT LINEAR ARRANGEMENT problem. Let $M = (V, E)$ be some graph with $|V| = n$, and let h be a linear arrangement for M. The **modified cutwidth** of M at position $i \in [n]$ and with respect to h is the number of edges crossing over the i-th vertex:

$$mcw(M, h, i) = |\{(u, v) \in E \,|\, h(u) < i < h(v)\}| \; .$$

The modified cutwidth of M is defined as

$$mcw(M) = \min_h \max_{i \in [n]} \; mcw(M, h, i) \; .$$

In the MODIFIED CUTWIDTH problem one is given as input a graph M and an integer k, and must decide whether $mcw(M) \leq k$. The MODIFIED CUTWIDTH problem has been shown to be NP-complete by Lengauer (1981). We strengthen this result below; recall that a cubic graph is a graph without self loops where each vertex has degree three.

Lemma 1 *The* MODIFIED CUTWIDTH *problem restricted to cubic graphs is NP-complete.*

PROOF The MODIFIED CUTWIDTH problem has been shown to be NP-complete when restricted to graphs of maximum degree three by Makedon et al. (1985), reducing from a graph problem known as bisection width (see also Monien and Sudborough (1988)). Specifically, the authors construct a graph G' of maximum degree three and an integer k' from an input graph $G = (V, E)$ with an even number n of vertices and an integer k, such that $mcw(G') \leq k'$ if and only if the **bisection width** $bw(G)$ of G is not greater than k, where

$$bw(G) = \min_{A,B \subseteq V} |\{(u, v) \in E \,|\, u \in A \wedge v \in B\}|$$

with $A \cap B = \emptyset$, $A \cup B = V$, and $|A| = |B|$.

The graph G' has vertices of degree two and three only, and it is based on a grid-like gadget $R(r, c)$; see Figure 5. For each vertex of G, G' includes a component $R(2n^4, 8n^4+8)$. Moreover, G' has a component called an H-shaped graph, containing left and right columns $R(3n^4, 12n^4 + 12)$ connected by a middle bar $R(2n^4, 12n^4 + 9)$; see Figure 6. From each of the n vertex components there is a sheaf of $2n^2$ edges connecting distinct degree 2 vertices in the component to $2n^2$ distinct degree 2 vertices in

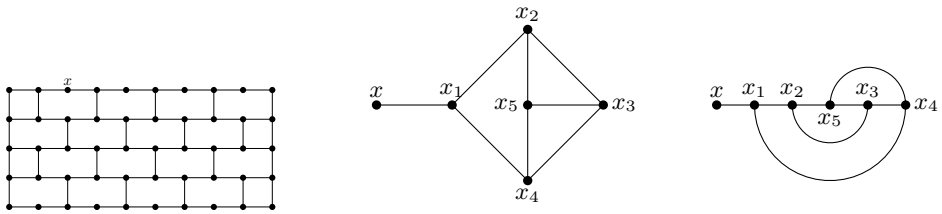

Figure 5: The $R(5, 10)$ component (left), the modification of its degree 2 vertex x (middle), and the corresponding arrangement (right).

the middle bar of the H-shaped graph. Finally, for each edge (v_i, v_j) of G there is an edge in G' connecting a degree 2 vertex in the component corresponding to the vertex v_i with a degree 2 vertex in the component corresponding to the vertex v_j. The integer k' is set to $3n^4 + n^3 + k - 1$.

Makedon et al. (1985) show that the modified cutwidth of $R(r, c)$ is $r - 1$ whenever $r \geq 3$ and $c \geq 4r + 8$. They also show that an optimal linear arrangement for G' has the form depicted in Figure 6, where half of the vertex components are to the left of the H-shaped graph and all the other vertex components are to the right. In this arrangement, the modified cutwidth is attested by the number of edges crossing over the vertices in the left and right columns of the H-shaped graph, which is equal to

$$3n^4 - 1 + \frac{n}{2}2n^2 + \gamma = 3n^4 + n^3 + \gamma - 1 \quad (2)$$

where γ denotes the number of edges connecting vertices to the left with vertices to the right of the H-shaped graph. Thus, $bw(G) \leq k$ if and only if $mcw(G') \leq k'$.

All we need to show now is how to modify the components of G' in order to make it cubic.

Modifying the vertex components All vertices x of degree 2 of the components corresponding to a vertex in G can be transformed into a vertex of degree 3 by adding five vertices $x_1, \ldots, x_5$ connected as shown in the middle bar of Figure 5. Observe that these five vertices can be positioned in the arrangement immediately after x in the order x_1, x_2, x_5, x_3, x_4 (see the right part of the figure). The resulting maximum modified cutwidth can increase by 2 in correspondence of vertex x_5. Since the vertices of these components, in the optimal arrangement, have modified cutwidth smaller than $2n^4 + n^3 + n^2$, an increase by 2 is still smaller than the maximum modified cutwidth of the entire graph, which is $3n^4 + \mathcal{O}(n^3)$.

Modifying the middle bar of the H-shaped graph The vertices of degree 2 of this part of the graph can be modified as in the previous paragraph. Indeed, in the optimal arrangement, these vertices have modified cutwidth smaller than $2n^4 + 2n^3 + n^2$, and an increase by 2 is still smaller than the maximum cutwidth of the entire graph.

Modifying the left/right columns of the H-shaped graph We replace the two copies of component $R(3n^4, 12n^4 + 12)$ with two copies of the new component $D(3n^4, 24n^4 + 16)$ shown in Figure 7, which is a cubic graph. In order to prove that relation (2) still holds, it suffices to show that the modified cutwidth of the component $D(r, c)$ is still $r - 1$ whenever $r \geq 3$ and $c = 8r + 16$.

We first observe that the linear arrangement obtained by visiting the vertices of $D(r, c)$ from top to bottom and from left to right has modified cutwidth $r - 1$. Let us now prove that, for any partition of the vertices into two subsets V_1 and V_2 with $|V_1|, |V_2| \geq 4r^2$, there exist at least r disjoint paths between vertices of V_1 and vertices of V_2. To this aim, we distinguish the following three cases.

- Any row has (at least) one vertex in V_1 and one vertex in V_2: in this case, it is easy to see there exist at least r disjoint paths between vertices of V_1 and vertices of V_2.

- There exist at least $3r$ 'mixed' columns, that is, columns with (at least) one vertex in V_1 and one vertex in V_2. Again, it is easy to see that there exist at least r disjoint paths between vertices

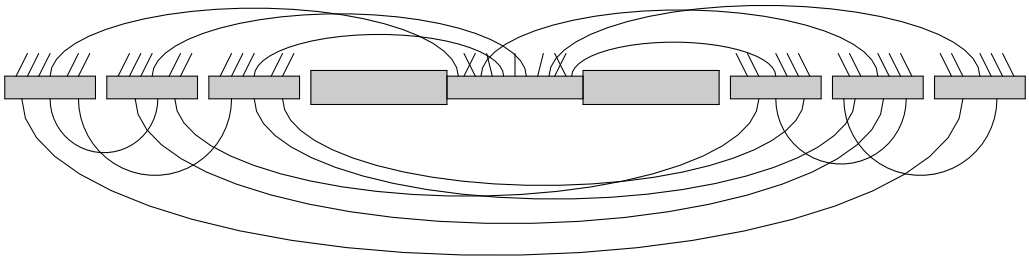

Figure 6: The optimal arrangement of G'.

of V_1 and vertices of V_2 (at least one path every three columns).

- The previous two cases do not apply. Hence, there exists a row entirely formed by vertices of V_1 (or, equivalently, of V_2). The worst case is when this row is the smallest one, that is, the one with $\frac{(c-3-1)}{2} + 1 = 4r + 7$ vertices. Since at most $3r - 1$ columns are mixed, we have that at most $(3r - 1)(r - 2) = 3r^2 - 7r + 2$ vertices of V_2 are on these mixed columns. Since $|V_2| \geq 4r^2$, this implies that at least r columns are fully contained in V_2. On the other hand, at least $4r+7-(3r-1) = r+8$ columns are fully contained in V_1. If the V_1-columns interleave with the V_2-columns, then there exist at least $2(r-1)$ disjoint paths between vertices of V_1 and vertices of V_2. Otherwise, all the V_1-columns precede or follow all the V_2-columns (this corresponds to the optimal arrangement): in this case, there are r disjoint paths between vertices of V_1 and vertices of V_2.

Observe now that any linear arrangement partitions the set of vertices in $D(r, c)$ into the sets V_1, consisting of the first $4r^2$ vertices in the arrangement, and V_2, consisting of all the remaining vertices. Since there are r disjoint paths connecting V_1 and V_2, there must be at least $r-1$ edges passing over every vertex in the arrangement which is assigned to a position between the $(4r^2 + 1)$-th and the position $4r^2 + 1$ from the right end of the arrangement: thus, the modified cutwidth of any linear arrangement of the vertices of $D(r, c)$ is at least $r - 1$.

We can then conclude that the original proof of Makedon et al. (1985) still applies, according to relation (2). ■

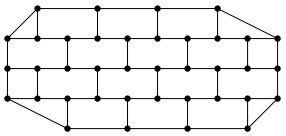

Figure 7: The $D(5, 10)$ component.

We can now reduce from the MODIFIED CUTWIDTH problem for cubic graphs to the MIN TIME STRATEGY problem restricted to head-driven parsing strategies.

Theorem 2 *The* MIN TIME STRATEGY *problem restricted to head-driven parsing strategies is NP-complete.*

PROOF We consider hardness first. Let M and k be an input instance of the MODIFIED CUTWIDTH problem restricted to cubic graphs, where $M = (V, E)$ and $V = \{v_1, \ldots, v_n\}$. We construct an LCFRS production p exactly as in the proof of Theorem 1, with rhs nonterminals $H, A_1, \ldots, A_n$. We also set $k' = 2 \cdot k + 2 \cdot |E| + 9$.

Assume now some head-driven parsing strategy π for p. After parsing step $i \in [n]$, we have a partial parse D_i^π consisting of the merge of nonterminals $H, A_{\pi(1)}, \ldots, A_{\pi(i)}$. We write $tc(p, \pi, i)$ to denote the exponent of the time complexity due to step i. As already mentioned, this quantity is defined as the sum of the fan-out of the two antecedents involved in the parsing step and the fan-out of its result:

$$tc(p, \pi, i) \quad = \quad f(D_{i-1}^\pi) + f(A_{\pi(i)}) + f(D_i^\pi) \; .$$

Again, we associate with π a linear arrangement h_π of M by letting $h_\pi(v_{\pi(i)}) = i$, for each $v_i \in V$. As in the proof of Theorem 1, the fan-out of D_i^π is then related to the cutwidth of the linear arrange-

ment h_π of M at position i by

$$f(D_i^\pi) \;=\; |E| + cw(M, h_\pi, i) \; .$$

From the proof of Theorem 1, the fan-out of nonterminal $A_{\pi(i)}$ is twice the degree of vertex $v_{\pi(i)}$, denoted by $|E(v_{\pi(i)})|$. We can then rewrite the above equation in terms of our graph M:

$$\begin{aligned} tc(p, \pi, i) = 2 \cdot |E| + cw(M, h_\pi, i-1) + \\ + 2 \cdot |E(v_{\pi(i)})| + cw(M, h_\pi, i) \; . \end{aligned}$$

The following general relation between cutwidth and modified cutwidth is rather intuitive:

$$\begin{aligned} mcw(M, h_\pi, i) = \frac{1}{2} \cdot [cw(M, h_\pi, i-1) + \\ - |E(v_{\pi(i)})| + cw(M, h_\pi, i)] \; . \end{aligned}$$

Combining the two equations above we obtain:

$$\begin{aligned} tc(p, \pi, i) \;=\; 2 \cdot |E| + 3 \cdot |E(v_{\pi(i)})| + \\ + 2 \cdot mcw(M, h_\pi, i) \; . \end{aligned}$$

Because we are restricting M to the class of cubic graphs, we can write:

$$tc(p, \pi, i) \;=\; 2 \cdot |E| + 9 + 2 \cdot mcw(M, h_\pi, i) \; .$$

We can thus conclude that there exists a head-driven parsing strategy for p with time complexity not greater than $2 \cdot |E| + 9 + 2 \cdot k = k'$ if and only if $mcw(M) \leq k$.

The membership of MODIFIED CUTWIDTH in NP follows from an argument similar to the one in the proof of Theorem 1. ∎

We have established the NP-completeness of both the MIN SPACE STRATEGY and the MIN TIME STRATEGY decision problems. It is now easy to see that the problem of finding a space- or time-optimal parsing strategy for a LCFRS production is NP-hard as well, and thus cannot be solved in polynomial (deterministic) time unless P = NP.

4 Concluding remarks

Head-driven strategies are important in parsing based on LCFRSs, both in order to allow statistical modeling of head-modifier dependencies and in order to generalize the Markovization of CFG parsers to parsers with discontinuous spans. However, there are $n!$ possible head-driven strategies for an LCFRS production with a head and n modifiers. Choosing among these possible strategies affects both the time and the space complexity of parsing. In this paper we have shown that optimizing the choice according to either metric is NP-hard. To our knowledge, our results are the first NP-hardness results for a grammar factorization problem.

SCFGs and STAGs are specific instances of LCFRSs. Grammar factorization for synchronous models is an important component of current machine translation systems (Zhang et al., 2006), and algorithms for factorization have been studied by Gildea et al. (2006) for SCFGs and by Nesson et al. (2008) for STAGs. These algorithms do not result in what we refer as head-driven strategies, although, as machine translation systems improve, lexicalized rules may become important in this setting as well. However, the results we have presented in this paper do not carry over to the above mentioned synchronous models, since the fan-out of these models is bounded by two, while in our reductions in Section 3 we freely use unbounded values for this parameter. Thus the computational complexity of optimizing the choice of the parsing strategy for SCFGs is still an open problem.

Finally, our results for LCFRSs only apply when we restrict ourselves to head-driven strategies. This is in contrast to the findings of Gildea (2011), which show that, for unrestricted parsing strategies, a polynomial time algorithm for minimizing parsing complexity would imply an improved approximation algorithm for finding the treewidth of general graphs. Our result is stronger, in that it shows strict NP-hardness, but also weaker, in that it applies only to head-driven strategies. Whether NP-hardness can be shown for unrestricted parsing strategies is an important question for future work.

Abstract

We present a method for the computation of prefix probabilities for synchronous context-free grammars. Our framework is fairly general and relies on the combination of a simple, novel grammar transformation and standard techniques to bring grammars into normal forms.

1 Introduction

Within the area of statistical machine translation, there has been a growing interest in so-called syntax-based translation models, that is, models that define mappings between languages through hierarchical sentence structures. Several such statistical models that have been investigated in the literature are based on synchronous rewriting or tree transduction. Probabilistic synchronous context-free grammars (PSCFGs) are one among the most popular examples of such models. PSCFGs subsume several syntax-based statistical translation models, as for instance the stochastic inversion transduction grammars of Wu (1997), the statistical model used by the Hiero system of Chiang (2007), and systems which extract rules from parsed text, as in Galley et al. (2004).

Despite the widespread usage of models related to PSCFGs, our theoretical understanding of this class is quite limited. In contrast to the closely related class of probabilistic context-free grammars, a syntax model for which several interesting mathematical and statistical properties have been investigated, as for instance by Chi (1999), many theoretical problems are still unsolved for the class of PSCFGs.

This paper considers a parsing problem that is well understood for probabilistic context-free grammars but that has never been investigated in the context of PSCFGs, viz. the computation of prefix probabilities. In the case of a probabilistic context-free grammar, this problem is defined as follows. We are asked to compute the probability that a sentence generated by our model starts with a prefix string v given as input. This quantity is defined as the (possibly infinite) sum of the probabilities of all strings of the form vw, for any string w over the alphabet of the model. This problem has been studied by Jelinek and Lafferty (1991) and by Stolcke (1995). Prefix probabilities can be used to compute probability distributions for the next word or part-of-speech. This has applications in incremental processing of text or speech from left to right; see again (Jelinek and Lafferty, 1991). Prefix probabilities can also be exploited in speech understanding systems to score partial hypotheses in beam search (Corazza et al., 1991).

This paper investigates the problem of computing prefix probabilities for PSCFGs. In this context, a pair of strings v_1 and v_2 is given as input, and we are asked to compute the probability that any string in the source language starting with prefix v_1 is translated into any string in the target language starting with prefix v_2. This probability is more precisely defined as the sum of the probabilities of translation pairs of the form $[v_1w_1, v_2w_2]$, for any strings w_1 and w_2.

A special case of prefix probability for PSCFGs is the right prefix probability. This is defined as the probability that some (complete) input string w in the source language is translated into a string in the target language starting with an input prefix v.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 460–469,
Portland, Oregon, June 19-24, 2011.

Prefix probabilities and right prefix probabilities for PSCFGs can be exploited to compute probability distributions for the next word or part-of-speech in left-to-right incremental translation, essentially in the same way as described by Jelinek and Lafferty (1991) for probabilistic context-free grammars, as discussed later in this paper.

Our solution to the problem of computing prefix probabilities is formulated in quite different terms from the solutions by Jelinek and Lafferty (1991) and by Stolcke (1995) for probabilistic context-free grammars. In this paper we reduce the computation of prefix probabilities for PSCFGs to the computation of inside probabilities under the same model. Computation of inside probabilities for PSCFGs is a well-known problem that can be solved using off-the-shelf algorithms that extend basic parsing algorithms. Our reduction is a novel grammar transformation, and the proof of correctness proceeds by fairly conventional techniques from formal language theory, relying on the correctness of standard methods for the computation of inside probabilities for PSCFG. This contrasts with the techniques proposed by Jelinek and Lafferty (1991) and by Stolcke (1995), which are extensions of parsing algorithms for probabilistic context-free grammars, and require considerably more involved proofs of correctness.

Our method for computing the prefix probabilities for PSCFGs runs in exponential time, since that is the running time of existing methods for computing the inside probabilities for PSCFGs. It is unlikely this can be improved, because the recognition problem for PSCFG is NP-complete, as established by Satta and Peserico (2005), and there is a straightforward reduction from the recognition problem for PSCFGs to the problem of computing the prefix probabilities for PSCFGs.

2 Definitions

In this section we introduce basic definitions related to synchronous context-free grammars and their probabilistic extension; our notation follows Satta and Peserico (2005).

Let N and Σ be sets of nonterminal and terminal symbols, respectively. In what follows we need to represent bijections between the occurrences of nonterminals in two strings over $N \cup \Sigma$. This is realized by annotating nonterminals with **indices** from an infinite set. We define $\mathcal{I}(N) = \{A^{\boxed{t}} \mid A \in N,\ t \in \mathbb{N}\}$ and $V_I = \mathcal{I}(N) \cup \Sigma$. For a string $\gamma \in V_I^*$, we write $\mathsf{index}(\gamma)$ to denote the set of all indices that appear in symbols in γ.

Two strings $\gamma_1, \gamma_2 \in V_I^*$ are **synchronous** if each index from $\mathbb{N}$ occurs at most once in γ_1 and at most once in γ_2, and $\mathsf{index}(\gamma_1) = \mathsf{index}(\gamma_2)$. Therefore γ_1, γ_2 have the general form:

$$\gamma_1 = u_{10} A_{11}^{\boxed{t_1}} u_{11} A_{12}^{\boxed{t_2}} u_{12} \cdots u_{1r-1} A_{1r}^{\boxed{t_r}} u_{1r}$$
$$\gamma_2 = u_{20} A_{21}^{\boxed{t_{\pi(1)}}} u_{21} A_{22}^{\boxed{t_{\pi(2)}}} u_{22} \cdots u_{2r-1} A_{2r}^{\boxed{t_{\pi(r)}}} u_{2r}$$

where $r \geq 0$, $u_{1i}, u_{2i} \in \Sigma^*$, $A_{1i}^{\boxed{t_i}}, A_{2i}^{\boxed{t_{\pi(i)}}} \in \mathcal{I}(N)$, $t_i \neq t_j$ for $i \neq j$, and π is a permutation of the set $\{1, \ldots, r\}$.

A **synchronous context-free grammar** (SCFG) is a tuple $G = (N, \Sigma, P, S)$, where N and Σ are finite, disjoint sets of nonterminal and terminal symbols, respectively, $S \in N$ is the start symbol and P is a finite set of **synchronous rules**. Each synchronous rule has the form $s : [A_1 \rightarrow \alpha_1,\ \ A_2 \rightarrow \alpha_2]$, where $A_1, A_2 \in N$ and where $\alpha_1, \alpha_2 \in V_I^*$ are synchronous strings. The symbol s is the label of the rule, and each rule is uniquely identified by its label. For technical reasons, we allow the existence of multiple rules that are identical apart from their labels. We refer to $A_1 \rightarrow \alpha_1$ and $A_2 \rightarrow \alpha_2$, respectively, as the left and right **components** of rule s.

Example 1 The following synchronous rules implicitly define a SCFG:

$$\begin{aligned}
s_1 &: \ [S \rightarrow A^{\boxed{1}}\ B^{\boxed{2}},\ S \rightarrow B^{\boxed{2}}\ A^{\boxed{1}}] \\
s_2 &: \ [A \rightarrow aA^{\boxed{1}}b,\ A \rightarrow bA^{\boxed{1}}a] \\
s_3 &: \ [A \rightarrow ab,\ A \rightarrow ba] \\
s_4 &: \ [B \rightarrow cB^{\boxed{1}}d,\ B \rightarrow dB^{\boxed{1}}c] \\
s_5 &: \ [B \rightarrow cd,\ B \rightarrow dc]
\end{aligned}$$

□

In each step of the derivation process of a SCFG G, two nonterminals with the same index in a pair of synchronous strings are rewritten by a synchronous rule. This is done in such a way that the result is once more a pair of synchronous strings. An auxiliary notion is that of **reindexing**, which is an injective function f from $\mathbb{N}$ to $\mathbb{N}$. We extend f to V_I by letting $f(A^{\boxed{t}}) = A^{\boxed{f(t)}}$ for $A^{\boxed{t}} \in \mathcal{I}(N)$ and $f(a) = a$ for $a \in \Sigma$. We also extend f to strings in V_I^* by

letting $f(\varepsilon) = \varepsilon$ and $f(X\gamma) = f(X)f(\gamma)$, for each $X \in V_I$ and $\gamma \in V_I^*$.

Let γ_1, γ_2 be synchronous strings in V_I^*. The **derive** relation $[\gamma_1,\ \gamma_2] \Rightarrow_G [\delta_1,\ \delta_2]$ holds whenever there exist an index t in $\mathsf{index}(\gamma_1) = \mathsf{index}(\gamma_2)$, a synchronous rule $s : [A_1 \rightarrow \alpha_1,\ A_2 \rightarrow \alpha_2]$ in P and some reindexing f such that:

(i) $\mathsf{index}(f(\alpha_1)) \cap (\mathsf{index}(\gamma_1) \setminus \{t\}) = \emptyset$;

(ii) $\gamma_1 = \gamma_1' A_1^{\boxed{t}} \gamma_1''$, $\gamma_2 = \gamma_2' A_2^{\boxed{t}} \gamma_2''$; and

(iii) $\delta_1 = \gamma_1' f(\alpha_1) \gamma_1''$, $\delta_2 = \gamma_2' f(\alpha_2) \gamma_2''$.

We also write $[\gamma_1,\ \gamma_2] \Rightarrow_G^s [\delta_1,\ \delta_2]$ to explicitly indicate that the derive relation holds through rule s.

Note that δ_1, δ_2 above are guaranteed to be synchronous strings, because α_1 and α_2 are synchronous strings and because of (i) above. Note also that, for a given pair $[\gamma_1,\ \gamma_2]$ of synchronous strings, an index t and a rule s, there may be infinitely many choices of reindexing f such that the above constraints are satisfied. In this paper we will not further specify the choice of f.

We say the pair $[A_1, A_2]$ of nonterminals is **linked** (in G) if there is a rule of the form $s : [A_1 \rightarrow \alpha_1,\ A_2 \rightarrow \alpha_2]$. The set of linked nonterminal pairs is denoted by $N^{[2]}$.

A derivation is a sequence $\sigma = s_1 s_2 \cdots s_d$ of synchronous rules $s_i \in P$ with $d \geq 0$ ($\sigma = \varepsilon$ for $d = 0$) such that $[\gamma_{1i-1},\ \gamma_{2i-1}] \Rightarrow_G^{s_i} [\gamma_{1i},\ \gamma_{2i}]$ for every i with $1 \leq i \leq d$ and synchronous strings $[\gamma_{1i},\ \gamma_{2i}]$ with $0 \leq i \leq d$. Throughout this paper, we always implicitly assume some canonical form for derivations in G, by demanding for instance that each step rewrites a pair of nonterminal occurrences of which the first is leftmost in the left component. When we want to focus on the specific synchronous strings being derived, we also write derivations in the form $[\gamma_{10},\ \gamma_{20}] \Rightarrow_G^{\sigma} [\gamma_{1d},\ \gamma_{2d}]$, and we write $[\gamma_{10},\ \gamma_{20}] \Rightarrow_G^* [\gamma_{1d},\ \gamma_{2d}]$ when σ is not further specified. The **translation** generated by a SCFG G is defined as:

$$T(G) = \{[w_1,\ w_2] \mid [S^{\boxed{1}},\ S^{\boxed{1}}] \Rightarrow_G^* [w_1,\ w_2],\ w_1, w_2 \in \Sigma^*\}$$

For $w_1, w_2 \in \Sigma^*$, we write $D(G, [w_1, w_2])$ to denote the set of all (canonical) derivations σ such that $[S^{\boxed{1}},\ S^{\boxed{1}}] \Rightarrow_G^{\sigma} [w_1,\ w_2]$.

Analogously to standard terminology for context-free grammars, we call a SCFG **reduced** if every rule occurs in at least one derivation $\sigma \in D(G, [w_1, w_2])$, for some $w_1, w_2 \in \Sigma^*$. We assume without loss of generality that the start symbol S does not occur in the right-hand side of either component of any rule.

Example 2 Consider the SCFG G from example 1. The following is a canonical derivation in G, since it is always the leftmost nonterminal occurrence in the left component that is involved in a derivation step:

$$\begin{aligned}
[S^{\boxed{1}},\ S^{\boxed{1}}] &\Rightarrow_G [A^{\boxed{1}}B^{\boxed{2}}, B^{\boxed{2}}A^{\boxed{1}}] \\
&\Rightarrow_G [aA^{\boxed{3}}bB^{\boxed{2}}, B^{\boxed{2}}bA^{\boxed{3}}a] \\
&\Rightarrow_G [aaA^{\boxed{4}}bbB^{\boxed{2}}, B^{\boxed{2}}bbA^{\boxed{4}}aa] \\
&\Rightarrow_G [aaabbbB^{\boxed{2}}, B^{\boxed{2}}bbbaaa] \\
&\Rightarrow_G [aaabbbcB^{\boxed{5}}d, dB^{\boxed{5}}cbbbaaa] \\
&\Rightarrow_G [aaabbbccdd, ddccbbbaaa]
\end{aligned}$$

It is not difficult to see that the generated translation is $T(G) = \{[a^p b^p c^q d^q,\ d^q c^q b^p a^p] \mid p, q \geq 1\}$. □

The size of a synchronous rule $s : [A_1 \rightarrow \alpha_1,\ A_2 \rightarrow \alpha_2]$, is defined as $|s| = |A_1 \alpha_1 A_2 \alpha_2|$. The size of G is defined as $|G| = \sum_{s \in P} |s|$.

A **probabilistic** SCFG (PSCFG) is a pair $\mathcal{G} = (G, p_G)$ where $G = (N, \Sigma, P, S)$ is a SCFG and p_G is a function from P to real numbers in $[0, 1]$. We say that $\mathcal{G}$ is **proper** if for each pair $[A_1, A_2] \in N^{[2]}$ we have:

$$\sum_{s:[A_1 \rightarrow \alpha_1,\ A_2 \rightarrow \alpha_2]} p_G(s) = 1$$

Intuitively, properness ensures that where a pair of nonterminals in two synchronous strings can be rewritten, there is a probability distribution over the applicable rules.

For a (canonical) derivation $\sigma = s_1 s_2 \cdots s_d$, we define $p_G(\sigma) = \prod_{i=1}^{d} p_G(s_i)$. For $w_1, w_2 \in \Sigma^*$, we also define:

$$p_G([w_1, w_2]) = \sum_{\sigma \in D(G, [w_1, w_2])} p_G(\sigma) \qquad (1)$$

We say a PSCFG is **consistent** if p_G defines a probability distribution over the translation, or formally:

$$\sum_{w_1, w_2} p_G([w_1, w_2]) = 1$$

If the grammar is reduced, proper and consistent, then also:

$$\sum_{\substack{w_1,w_2\in\Sigma^*,\ \sigma\in P^* \\ \text{s.t. } [A_1^{\boxed{1}},\ A_2^{\boxed{1}}]\Rightarrow_G^{\sigma}[w_1,\ w_2]}} p_G(\sigma) \quad = \quad 1$$

for every pair $[A_1, A_2] \in N^{[2]}$. The proof is identical to that of the corresponding fact for probabilistic context-free grammars.

3 Effective PSCFG parsing

If $w = a_1 \cdots a_n$ then the expression $w[i, j]$, with $0 \leq i \leq j \leq n$, denotes the substring $a_{i+1} \cdots a_j$ (if $i = j$ then $w[i, j] = \varepsilon$). In this section, we assume the input is the pair $[w_1, w_2]$ of terminal strings. The task of a **recognizer** for SCFG G is to decide whether $[w_1, w_2] \in T(G)$.

We present a general algorithm for solving the above problem in terms of the specification of a deduction system, following Shieber et al. (1995). The items that are constructed by the system have the form $[m_1, A_1, m_1';\ m_2, A_2, m_2']$, where $[A_1, A_2] \in N^{[2]}$ and where m_1, m_1', m_2, m_2' are non-negative integers such that $0 \leq m_1 \leq m_1' \leq |w_1|$ and $0 \leq m_2 \leq m_2' \leq |w_2|$. Such an item can be derived by the deduction system if and only if:

$$[A_1^{\boxed{1}},\ A_2^{\boxed{1}}] \quad \Rightarrow_G^* \quad [w_1[m_1, m_1'],\ w_2[m_2, m_2']]$$

The deduction system has one inference rule, shown in figure 1. One of its side conditions has a synchronous rule in P of the form:

$$\begin{aligned} s : [A_1 \rightarrow u_{10} A_{11}^{\boxed{t_1}} u_{11} \cdots u_{1r-1} A_{1r}^{\boxed{t_r}} u_{1r}, \\ A_2 \rightarrow u_{20} A_{21}^{\boxed{t_{\pi(1)}}} u_{21} \cdots u_{2r-1} A_{2r}^{\boxed{t_{\pi(r)}}} u_{2r}] \end{aligned} \quad (2)$$

Observe that, in the right-hand side of the two rule components above, nonterminals A_{1i} and $A_{2\pi^{-1}(i)}$, $1 \leq i \leq r$, have both the same index. More precisely, A_{1i} has index t_i and $A_{2\pi^{-1}(i)}$ has index $t_{i'}$ with $i' = \pi(\pi^{-1}(i)) = i$. Thus the nonterminals in each antecedent item in figure 1 form a linked pair.

We now turn to a computational analysis of the above algorithm. In the inference rule in figure 1 there are $2(r + 1)$ variables that can be bound to positions in w_1, and as many that can be bound to positions in w_2. However, the side conditions imply $m_{ij}' = m_{ij} + |u_{ij}|$, for $i \in \{1, 2\}$ and $0 \leq j \leq r$, and therefore the number of free variables is only $r + 1$ for each component. By standard complexity analysis of deduction systems, for example following McAllester (2002), the time complexity of a straightforward implementation of the recognition algorithm is $\mathcal{O}(|P| \cdot |w_1|^{r_{\max}+1} \cdot |w_2|^{r_{\max}+1})$, where $r_{\max}$ is the maximum number of right-hand side nonterminals in either component of a synchronous rule. The algorithm therefore runs in exponential time, when the grammar G is considered as part of the input. Such computational behavior seems unavoidable, since the recognition problem for SCFG is NP-complete, as reported by Satta and Peserico (2005). See also Gildea and Stefankovic (2007) and Hopkins and Langmead (2010) for further analysis of the upper bound above.

The recognition algorithm above can easily be turned into a parsing algorithm by letting an implementation keep track of which items were derived from which other items, as instantiations of the consequent and the antecedents, respectively, of the inference rule in figure 1.

A probabilistic parsing algorithm that computes $p_G([w_1, w_2])$, defined in (1), can also be obtained from the recognition algorithm above, by associating each item with a probability. To explain the basic idea, let us first assume that each item can be inferred in finitely many ways by the inference rule in figure 1. Each instantiation of the inference rule should be associated with a term that is computed by multiplying the probability of the involved rule s and the product of all probabilities previously associated with the instantiations of the antecedents. The probability associated with an item is then computed as the sum of each term resulting from some instantiation of an inference rule deriving that item. This is a generalization to PSCFG of the inside algorithm defined for probabilistic context-free grammars (Manning and Schütze, 1999), and we can show that the probability associated with item $[0, S, |w_1|\,;\ \ 0, S, |w_2|]$ provides the desired value $p_G([w_1, w_2])$. We refer to the procedure sketched above as the **inside** algorithm for PSCFGs.

However, this simple procedure fails if there are cyclic dependencies, whereby the derivation of an item involves a proper subderivation of the same item. Cyclic dependencies can be excluded if it can

$$\frac{\begin{array}{c}[m'_{10}, A_{11}, m_{11};\ m'_{2\pi^{-1}(1)-1}, A_{2\pi^{-1}(1)}, m_{2\pi^{-1}(1)}] \\ \vdots \\ [m'_{1r-1}, A_{1r}, m_{1r};\ m'_{2\pi^{-1}(r)-1}, A_{2\pi^{-1}(r)}, m_{2\pi^{-1}(r)}]\end{array}}{[m_{10}, A_1, m'_{1r};\ m_{20}, A_2, m'_{2r}]} \quad \begin{cases} s{:}[A_1 \rightarrow u_{10} A_{11}^{\boxed{t_1}} u_{11} \cdots u_{1r-1} A_{1r}^{\boxed{t_r}} u_{1r}, \\ \quad A_2 \rightarrow u_{20} A_{21}^{\boxed{t_{\pi(1)}}} u_{21} \cdots u_{2r-1} A_{2r}^{\boxed{t_{\pi(r)}}} u_{2r}] \in P, \\ w_1[m_{10}, m'_{10}] = u_{10}, \quad w_2[m_{20}, m'_{20}] = u_{20}, \\ \quad \vdots \qquad\qquad\qquad \vdots \\ w_1[m_{1r}, m'_{1r}] = u_{1r}, \quad w_2[m_{2r}, m'_{2r}] = u_{2r} \end{cases}$$

Figure 1: SCFG recognition, by a deduction system consisting of a single inference rule.

be guaranteed that, in figure 1, $m'_{1r} - m_{10}$ is greater than $m_{1j} - m'_{1j-1}$ for each j ($1 \leq j \leq r$), or $m'_{2r} - m_{20}$ is greater than $m_{2j} - m'_{2j-1}$ for each j ($1 \leq j \leq r$).

Consider again a synchronous rule s of the form in (2). We say s is an **epsilon** rule if $r = 0$ and $u_{10} = u_{20} = \epsilon$. We say s is a **unit** rule if $r = 1$ and $u_{10} = u_{11} = u_{20} = u_{21} = \epsilon$. Similarly to context-free grammars, absence of epsilon rules and unit rules guarantees that there are no cyclic dependencies between items and in this case the inside algorithm correctly computes $p_G([w_1, w_2])$.

Epsilon rules can be eliminated from PSCFGs by a grammar transformation that is very similar to the transformation eliminating epsilon rules from a probabilistic context-free grammar (Abney et al., 1999). This is sketched in what follows. We first compute the set of all **nullable** linked pairs of nonterminals of the underlying SCFG, that is, the set of all $[A_1, A_2] \in N^{[2]}$ such that $[A_1^{\boxed{1}},\ A_2^{\boxed{1}}] \Rightarrow_G^* [\varepsilon,\ \varepsilon]$. This can be done in linear time $\mathcal{O}(|G|)$ using essentially the same algorithm that identifies nullable nonterminals in a context-free grammar, as presented for instance by Sippu and Soisalon-Soininen (1988).

Next, we identify all occurrences of nullable pairs $[A_1, A_2]$ in the right-hand side components of a rule s, such that A_1 and A_2 have the same index. For every possible choice of a subset $\mathcal{U}$ of these occurrences, we add to our grammar a new rule $s_{\mathcal{U}}$ constructed by omitting all of the nullable occurrences in $\mathcal{U}$. The probability of $s_{\mathcal{U}}$ is computed as the probability of s multiplied by terms of the form:

$$\sum_{\sigma \text{ s.t. } [A_1^{\boxed{1}}, A_2^{\boxed{1}}] \Rightarrow_G^{\sigma} [\varepsilon,\ \varepsilon]} p_G(\sigma) \tag{3}$$

for every pair $[A_1, A_2]$ in $\mathcal{U}$. After adding these extra rules, which in effect circumvents the use of epsilon-generating subderivations, we can safely remove all epsilon rules, with the only exception of a possible rule of the form $[S \rightarrow \epsilon, S \rightarrow \epsilon]$. The translation and the associated probability distribution in the resulting grammar will be the same as those in the source grammar.

One problem with the above construction is that we have to create new synchronous rules $s_{\mathcal{U}}$ for each possible choice of subset $\mathcal{U}$. In the worst case, this may result in an exponential blow-up of the source grammar. In the case of context-free grammars, this is usually circumvented by casting the rules in binary form prior to epsilon rule elimination. However, this is not possible in our case, since SCFGs do not allow normal forms with a constant bound on the length of the right-hand side of each component. This follows from a result due to Aho and Ullman (1969) for a formalism called syntax directed translation schemata, which is a syntactic variant of SCFGs.

An additional complication with our construction is that finding any of the values in (3) may involve solving a system of non-linear equations, similarly to the case of probabilistic context-free grammars; see again Abney et al. (1999), and Stolcke (1995). Approximate solution of such systems might take exponential time, as pointed out by Kiefer et al. (2007).

Notwithstanding the worst cases mentioned above, there is a special case that can be easily dealt with. Assume that, for each nullable pair $[A_1, A_2]$ in G we have that $[A_1^{\boxed{1}},\ A_2^{\boxed{1}}] \Rightarrow_G^* [w_1,\ w_2]$ does not hold for any w_1 and w_2 with $w_1 \neq \varepsilon$ or $w_2 \neq \varepsilon$. Then each of the values in (3) is guaranteed to be 1, and furthermore we can remove the instances of the nullable pairs in the source rule s all at the same time. This means that the overall construction of

elimination of nullable rules from G can be implemented in linear time $|G|$. It is this special case that we will encounter in section 4.

After elimination of epsilon rules, one can eliminate unit rules. We define $C^{\text{unit}}([A_1, A_2], [B_1, B_2])$ as the sum of the probabilities of all derivations deriving $[B_1, B_2]$ from $[A_1, A_2]$ with arbitrary indices, or more precisely:

$$\sum_{\substack{\sigma \in P^* \text{ s.t. } \exists t \in \mathbb{N}, \\ [A_1^{\boxed{1}}, A_2^{\boxed{1}}] \Rightarrow_G^{\sigma} [B_1^{\boxed{t}}, B_2^{\boxed{t}}]}} p_G(\sigma)$$

Note that $[A_1, A_2]$ may be equal to $[B_1, B_2]$ and σ may be ε, in which case $C^{\text{unit}}([A_1, A_2], [B_1, B_2])$ is at least 1, but it may be larger if there are unit rules. Therefore $C^{\text{unit}}([A_1, A_2], [B_1, B_2])$ should *not* be seen as a probability.

Consider a pair $[A_1, A_2] \in N^{[2]}$ and let all unit rules with left-hand sides A_1 and A_2 be:

$$\begin{aligned} s_1 &: [A_1, A_2] \rightarrow [A_{11}^{\boxed{t_1}}, A_{21}^{\boxed{t_1}}] \\ &\vdots \\ s_m &: [A_1, A_2] \rightarrow [A_{1m}^{\boxed{t_m}}, A_{2m}^{\boxed{t_m}}] \end{aligned}$$

The values of $C^{\text{unit}}(\cdot, \cdot)$ are related by the following:

$$\begin{aligned} &C^{\text{unit}}([A_1, A_2], [B_1, B_2]) = \\ &\quad \delta([A_1, A_2] = [B_1, B_2]) + \\ &\quad \sum_i p_G(s_i) \cdot C^{\text{unit}}([A_{1i}, A_{2i}], [B_1, B_2]) \end{aligned}$$

where $\delta([A_1, A_2] = [B_1, B_2])$ is defined to be 1 if $[A_1, A_2] = [B_1, B_2]$ and 0 otherwise. This forms a system of linear equations in the unknown variables $C^{\text{unit}}(\cdot, \cdot)$. Such a system can be solved in polynomial time in the number of variables, for example using Gaussian elimination.

The elimination of unit rules starts with adding a rule $s' : [A_1 \rightarrow \alpha_1, A_2 \rightarrow \alpha_2]$ for each non-unit rule $s : [B_1 \rightarrow \alpha_1, B_2 \rightarrow \alpha_2]$ and pair $[A_1, A_2]$ such that $C^{\text{unit}}([A_1, A_2], [B_1, B_2]) > 0$. We assign to the new rule s' the probability $p_G(s) \cdot C^{\text{unit}}([A_1, A_2], [B_1, B_2])$. The unit rules can now be removed from the grammar. Again, in the resulting grammar the translation and the associated probability distribution will be the same as those in the source grammar. The new grammar has size $\mathcal{O}(|G|^2)$, where G is the input grammar. The time complexity is dominated by the computation of the solution of the linear system of equations. This computation takes cubic time in the number of variables. The number of variables in this case is $\mathcal{O}(|G|^2)$, which makes the running time $\mathcal{O}(|G|^6)$.

4 Prefix probabilities

The **joint prefix probability** $p_G^{\text{prefix}}([v_1, v_2])$ of a pair $[v_1, v_2]$ of terminal strings is the sum of the probabilities of all pairs of strings that have v_1 and v_2, respectively, as their prefixes. Formally:

$$p_G^{\text{prefix}}([v_1, v_2]) = \sum_{w_1, w_2 \in \Sigma^*} p_G([v_1 w_1, v_2 w_2])$$

At first sight, it is not clear this quantity can be effectively computed, as it involves a sum over infinitely many choices of w_1 and w_2. However, analogously to the case of context-free prefix probabilities (Jelinek and Lafferty, 1991), we can isolate two parts in the computation. One part involves infinite sums, which are independent of the input strings v_1 and v_2, and can be precomputed by solving a system of linear equations. The second part does rely on v_1 and v_2, and involves the actual evaluation of $p_G^{\text{prefix}}([v_1, v_2])$. This second part can be realized effectively, on the basis of the precomputed values from the first part.

In order to keep the presentation simple, and to allow for simple proofs of correctness, we solve the problem in a modular fashion. First, we present a transformation from a PSCFG $\mathcal{G} = (G, p_G)$, with $G = (N, \Sigma, P, S)$, to a PSCFG $\mathcal{G}_{\text{prefix}} = (G_{\text{prefix}}, p_{G_{\text{prefix}}})$, with $G_{\text{prefix}} = (N_{\text{prefix}}, \Sigma, P_{\text{prefix}}, S^{\downarrow})$. The latter grammar derives all possible pairs $[v_1, v_2]$ such that $[v_1 w_1, v_2 w_2]$ can be derived from G, for some w_1 and w_2. Moreover, $p_{G_{\text{prefix}}}([v_1, v_2]) = p_G^{\text{prefix}}([v_1, v_2])$, as will be verified later.

Computing $p_{G_{\text{prefix}}}([v_1, v_2])$ directly using a generic probabilistic parsing algorithm for PSCFGs is difficult, due to the presence of epsilon rules and unit rules. The next step will be to transform $\mathcal{G}_{\text{prefix}}$ into a third grammar $\mathcal{G}'_{\text{prefix}}$ by eliminating epsilon rules and unit rules from the underlying SCFG, and preserving the probability distribution over pairs of strings. Using $\mathcal{G}'_{\text{prefix}}$ one can then effectively

apply generic probabilistic parsing algorithms for PSCFGs, such as the inside algorithm discussed in section 3, in order to compute the desired prefix probabilities for the source PSCFG $\mathcal{G}$.

For each nonterminal A in the source SCFG G, the grammar G_{prefix} contains three nonterminals, namely A itself, $A^{\downarrow}$ and A^{ε}. The meaning of A remains unchanged, whereas $A^{\downarrow}$ is intended to generate a string that is a suffix of a known prefix v_1 or v_2. Nonterminals A^{ε} generate only the empty string, and are used to simulate the generation by G of infixes of the unknown suffix w_1 or w_2. The two left-hand sides of a synchronous rule in G_{prefix} can contain different combinations of nonterminals of the forms A, $A^{\downarrow}$, or A^{ε}. The start symbol of G_{prefix} is $S^{\downarrow}$. The structure of the rules from the source grammar is largely retained, except that some terminal symbols are omitted in order to obtain the intended interpretation of $A^{\downarrow}$ and A^{ε}.

In more detail, let us consider a synchronous rule $s : [A_1 \rightarrow \alpha_1, \quad A_2 \rightarrow \alpha_2]$ from the source grammar, where for $i \in \{1, 2\}$ we have:

$$\alpha_i = u_{i0} A_{i1}^{\boxed{t_{i1}}} u_{i1} \cdots u_{ir-1} A_{ir}^{\boxed{t_{ir}}} u_{ir}$$

The transformed grammar then contains a large number of rules, each of which is of the form $s' : [B_1 \rightarrow \beta_1, \quad B_2 \rightarrow \beta_2]$, where $B_i \rightarrow \beta_i$ is of one of three forms, namely $A_i \rightarrow \alpha_i$, $A_i^{\downarrow} \rightarrow \alpha_i^{\downarrow}$ or $A_i^{\varepsilon} \rightarrow \alpha_i^{\varepsilon}$, where $\alpha_i^{\downarrow}$ and α_i^{ε} are explained below. The choices for $i = 1$ and for $i = 2$ are independent, so that we can have $3 * 3 = 9$ kinds of synchronous rules, to be further subdivided in what follows. A unique label s' is produced for each new rule, and the probability of each new rule equals that of s.

The right-hand side α_i^{ε} is constructed by omitting all terminals and propagating downwards the ε superscript, resulting in:

$$\alpha_i^{\varepsilon} = A_{i1}^{\varepsilon\boxed{t_{i1}}} \cdots A_{ir}^{\varepsilon\boxed{t_{ir}}}$$

It is more difficult to define $\alpha_i^{\downarrow}$. In fact, there can be a number of choices for $\alpha_i^{\downarrow}$ and, for each choice, the transformed grammar contains an instance of the synchronous rule $s' : [B_1 \rightarrow \beta_1, \quad B_2 \rightarrow \beta_2]$ as defined above. The reason why different choices need to be considered is because the boundary between the known prefix v_i and the unknown suffix w_i can occur at different positions, either within a terminal string u_{ij} or else further down in a subderivation involving A_{ij}. In the first case, we have for some j $(0 \leq j \leq r)$:

$$\begin{aligned}\alpha_i^{\downarrow} = {} & u_{i0} A_{i1}^{\boxed{t_{i1}}} u_{i1} A_{i2}^{\boxed{t_{i2}}} \cdots \\ & u_{ij-1} A_{ij}^{\boxed{t_{ij}}} u'_{ij} A_{ij+1}^{\varepsilon\boxed{t_{ij+1}}} A_{ij+2}^{\varepsilon\boxed{t_{ij+2}}} \cdots A_{ir}^{\varepsilon\boxed{t_{ir}}}\end{aligned}$$

where u'_{ij} is a choice of a prefix of u_{ij}. In words, the known prefix ends after u'_{ij} and, thereafter, no more terminals are generated. We demand that u'_{ij} must not be the empty string, unless $A_i = S$ and $j = 0$. The reason for this restriction is that we want to avoid an overlap with the second case. In this second case, we have for some j $(1 \leq j \leq r)$:

$$\begin{aligned}\alpha_i^{\downarrow} = {} & u_{i0} A_{i1}^{\boxed{t_{i1}}} u_{i1} A_{i2}^{\boxed{t_{i2}}} \cdots \\ & u_{ij-1} A_{ij}^{\downarrow\boxed{t_{ij}}} A_{ij+1}^{\varepsilon\boxed{t_{ij+1}}} A_{ij+2}^{\varepsilon\boxed{t_{ij+2}}} \cdots A_{ir}^{\varepsilon\boxed{t_{ir}}}\end{aligned}$$

Here the known prefix of the input ends within a subderivation involving A_{ij}, and further to the right no more terminals are generated.

Example 3 Consider the synchronous rule $s : [A \rightarrow aB^{\boxed{1}}bc\,C^{\boxed{2}}d, D \rightarrow efE^{\boxed{2}}F^{\boxed{1}}]$. The first component of a synchronous rule derived from this can be one of the following eight:

$$\begin{aligned}A^{\varepsilon} &\rightarrow B^{\varepsilon\boxed{1}} C^{\varepsilon\boxed{2}} \\ A^{\downarrow} &\rightarrow aB^{\varepsilon\boxed{1}} C^{\varepsilon\boxed{2}} \\ A^{\downarrow} &\rightarrow aB^{\downarrow\boxed{1}} C^{\varepsilon\boxed{2}} \\ A^{\downarrow} &\rightarrow aB^{\boxed{1}}b\,C^{\varepsilon\boxed{2}} \\ A^{\downarrow} &\rightarrow aB^{\boxed{1}}bc\,C^{\varepsilon\boxed{2}} \\ A^{\downarrow} &\rightarrow aB^{\boxed{1}}bc\,C^{\downarrow\boxed{2}} \\ A^{\downarrow} &\rightarrow aB^{\boxed{1}}bc\,C^{\boxed{2}}d \\ A &\rightarrow aB^{\boxed{1}}bc\,C^{\boxed{2}}d\end{aligned}$$

The second component can be one of the following six:

$$\begin{aligned}D^{\varepsilon} &\rightarrow E^{\varepsilon\boxed{2}} F^{\varepsilon\boxed{1}} \\ D^{\downarrow} &\rightarrow eE^{\varepsilon\boxed{2}} F^{\varepsilon\boxed{1}} \\ D^{\downarrow} &\rightarrow efE^{\varepsilon\boxed{2}} F^{\varepsilon\boxed{1}} \\ D^{\downarrow} &\rightarrow efE^{\downarrow\boxed{2}} F^{\varepsilon\boxed{1}} \\ D^{\downarrow} &\rightarrow efE^{\boxed{2}} F^{\downarrow\boxed{1}} \\ D &\rightarrow efE^{\boxed{2}} F^{\boxed{1}}\end{aligned}$$

In total, the transformed grammar will contain $8 * 6 = 48$ synchronous rules derived from s. □

For each synchronous rule s, the above grammar transformation produces $\mathcal{O}(|s|)$ left rule components and as many right rule components. This means the number of new synchronous rules is $\mathcal{O}(|s|^2)$, and the size of each such rule is $\mathcal{O}(|s|)$. If we sum $\mathcal{O}(|s|^3)$ for every rule s we obtain a time and space complexity of $\mathcal{O}(|G|^3)$.

We now investigate formal properties of our grammar transformation, in order to relate it to prefix probabilities. We define the relation $\vdash$ between P and P_{prefix} such that $s \vdash s'$ if and only if s' was obtained from s by the transformation described above. This is extended in a natural way to derivations, such that $s_1 \cdots s_d \vdash s'_1 \cdots s'_{d'}$ if and only if $d = d'$ and $s_i \vdash s'_i$ for each i ($1 \leq i \leq d$).

The formal relation between G and G_{prefix} is revealed by the following two lemmas.

Lemma 1 *For each v_1, v_2, w_1, $w_2 \in \Sigma^*$ and $\sigma \in P^*$ such that $[S, S] \Rightarrow_G^{\sigma} [v_1 w_1, v_2 w_2]$, there is a unique $\sigma' \in P^*_{\text{prefix}}$ such that $[S^{\downarrow}, S^{\downarrow}] \Rightarrow_{G_{\text{prefix}}}^{\sigma'} [v_1, v_2]$ and $\sigma \vdash \sigma'$.* □

Lemma 2 *For each v_1, $v_2 \in \Sigma^*$ and derivation $\sigma' \in P^*_{\text{prefix}}$ such that $[S^{\downarrow}, S^{\downarrow}] \Rightarrow_{G_{\text{prefix}}}^{\sigma'} [v_1, v_2]$, there is a unique $\sigma \in P^*$ and unique $w_1, w_2 \in \Sigma^*$ such that $[S, S] \Rightarrow_G^{\sigma} [v_1 w_1, v_2 w_2]$ and $\sigma \vdash \sigma'$.* □

The only non-trivial issue in the proof of Lemma 1 is the uniqueness of σ'. This follows from the observation that the length of v_1 in $v_1 w_1$ uniquely determines how occurrences of left components of rules in P found in σ are mapped to occurrences of left components of rules in P_{prefix} found in σ'. The same applies to the length of v_2 in $v_2 w_2$ and the right components.

Lemma 2 is easy to prove as the structure of the transformation ensures that the terminals that are in rules from P but not in the corresponding rules from P_{prefix} occur at the end of a string v_1 (and v_2) to form the longer string $v_1 w_1$ (and $v_2 w_2$, respectively).

The transformation also ensures that $s \vdash s'$ implies $p_G(s) = p_{G_{\text{prefix}}}(s')$. Therefore $\sigma \vdash \sigma'$ implies $p_G(\sigma) = p_{G_{\text{prefix}}}(\sigma')$. By this and Lemmas 1 and 2 we may conclude:

Theorem 1 $p_{G_{\text{prefix}}}([v_1, v_2]) = p_G^{\text{prefix}}([v_1, v_2])$. □

Because of the introduction of rules with left-hand sides of the form A^{ε} in both the left and right components of synchronous rules, it is not straightforward to do effective probabilistic parsing with the grammar $\mathcal{G}_{\text{prefix}}$. We can however apply the transformations from section 3 to eliminate epsilon rules and thereafter eliminate unit rules, in a way that leaves the derived string pairs and their probabilities unchanged.

The simplest case is when the source grammar $\mathcal{G}$ is reduced, proper and consistent, and has no epsilon rules. The only nullable pairs of nonterminals in $\mathcal{G}_{\text{prefix}}$ will then be of the form $[A_1^{\varepsilon}, A_2^{\varepsilon}]$. Consider such a pair $[A_1^{\varepsilon}, A_2^{\varepsilon}]$. Because of reduction, properness and consistency of $\mathcal{G}$ we have:

$$\sum_{\substack{w_1, w_2 \in \Sigma^*,\ \sigma \in P^* \text{ s.t.} \\ [A_1^{\boxed{1}},\ A_2^{\boxed{1}}] \Rightarrow_G^{\sigma} [w_1,\ w_2]}} p_G(\sigma) \quad = \quad 1$$

Because of the structure of the grammar transformation by which $\mathcal{G}_{\text{prefix}}$ was obtained from $\mathcal{G}$, we also have:

$$\sum_{\substack{\sigma \in P^* \text{ s.t.} \\ [A_1^{\varepsilon \boxed{1}},\ A_2^{\varepsilon \boxed{1}}] \Rightarrow_{G_{\text{prefix}}}^{\sigma} [\varepsilon,\ \varepsilon]}} p_{G_{\text{prefix}}}(\sigma) = 1$$

Therefore pairs of occurrences of A_1^{ε} and A_2^{ε} with the same index in synchronous rules of G_{prefix} can be systematically removed without affecting the probability of the resulting rule, as outlined in section 3. Thereafter, unit rules can be removed to allow parsing by the inside algorithm for PSCFGs.

Following the computational analyses for all of the constructions presented in section 3, and for the grammar transformation discussed in this section, we can conclude that the running time of the proposed algorithm for the computation of prefix probabilities is dominated by the running time of the inside algorithm, which in the worst case is exponential in $|G|$. This result is not unexpected, as already pointed out in the introduction, since the recognition problem for PSCFGs is NP-complete, as established by Satta and Peserico (2005), and there is a straightforward reduction from the recognition problem for PSCFGs to the problem of computing the prefix probabilities for PSCFGs.

One should add that, in real world machine translation applications, it has been observed that recognition (and computation of inside probabilities) for SCFGs can typically be carried out in low-degree polynomial time, and the worst cases mentioned above are not observed with real data. Further discussion on this issue is due to Zhang et al. (2006).

5 Discussion

We have shown that the computation of joint prefix probabilities for PSCFGs can be reduced to the computation of inside probabilities for the same model. Our reduction relies on a novel grammar transformation, followed by elimination of epsilon rules and unit rules.

Next to the joint prefix probability, we can also consider the **right prefix probability**, which is defined by:

$$p_G^{\mathrm{r-prefix}}([v_1, v_2]) \quad = \quad \sum_w p_G([v_1, v_2 w])$$

In words, the entire left string is given, along with a prefix of the right string, and the task is to sum the probabilities of all string pairs for different suffixes following the given right prefix. This can be computed as a special case of the joint prefix probability. Concretely, one can extend the input and the grammar by introducing an end-of-sentence marker \$. Let G' be the underlying SCFG grammar after the extension. Then:

$$p_G^{\mathrm{r-prefix}}([v_1, v_2]) = p_{G'}^{\mathrm{prefix}}([v_1 \$, v_2])$$

Prefix probabilities and right prefix probabilities for PSCFGs can be exploited to compute probability distributions for the next word or part-of-speech in left-to-right incremental translation of speech, or alternatively as a predictive tool in applications of interactive machine translation, of the kind described by Foster et al. (2002). We provide some technical details here, generalizing to PSCFGs the approach by Jelinek and Lafferty (1991).

Let $\mathcal{G} = (G, p_G)$ be a PSCFG, with Σ the alphabet of terminal symbols. We are interested in the probability that the next terminal in the target translation is $a \in \Sigma$, after having processed a prefix v_1 of the source sentence and having produced a prefix v_2 of the target translation. This can be computed as:

$$p_G^{\mathrm{r-word}}(a \mid [v_1, v_2]) \quad = \quad \frac{p_G^{\mathrm{prefix}}([v_1, v_2 a])}{p_G^{\mathrm{prefix}}([v_1, v_2])}$$

Two considerations are relevant when applying the above formula in practice. First, the computation of $p_G^{\mathrm{prefix}}([v_1, v_2 a])$ need not be computed from scratch if $p_G^{\mathrm{prefix}}([v_1, v_2])$ has been computed already. Because of the tabular nature of the inside algorithm, one can extend the table for $p_G^{\mathrm{prefix}}([v_1, v_2])$ by adding new entries to obtain the table for $p_G^{\mathrm{prefix}}([v_1, v_2 a])$. The same holds for the computation of $p_G^{\mathrm{prefix}}([v_1 b, v_2])$.

Secondly, the computation of $p_G^{\mathrm{prefix}}([v_1, v_2 a])$ for all possible $a \in \Sigma$ may be impractical. However, one may also compute the probability that the next part-of-speech in the target translation is A. This can be realised by adding a rule $s' : [B \to b, A \to c_A]$ for each rule $s : [B \to b, A \to a]$ from the source grammar, where A is a nonterminal representing a part-of-speech and c_A is a (pre-)terminal specific to A. The probability of s' is the same as that of s. If G' is the underlying SCFG after adding such rules, then the required value is $p_{G'}^{\mathrm{prefix}}([v_1, v_2\, c_A])$.

One variant of the definitions presented in this paper is the notion of *infix* probability, which is useful in island-driven speech translation. Here we are interested in the probability that any string in the source language with infix v_1 is translated into any string in the target language with infix v_2. However, just as infix probabilities are difficult to compute for probabilistic context-free grammars (Corazza et al., 1991; Nederhof and Satta, 2008) so (joint) infix probabilities are difficult to compute for PSCFGs. The problem lies in the possibility that a given infix may occur more than once in a string in the language. The computation of infix probabilities can be reduced to that of solving non-linear systems of equations, which can be approximated using for instance Newton's algorithm. However, such a system of equations is built from the input strings, which entails that the computational effort of solving the system primarily affects parse time rather than parser-generation time.

Abstract

Via an oracle experiment, we show that the upper bound on accuracy of a CCG parser is significantly lowered when its search space is pruned using a supertagger, though the supertagger also prunes many bad parses. Inspired by this analysis, we design a single model with both supertagging and parsing features, rather than separating them into distinct models chained together in a pipeline. To overcome the resulting increase in complexity, we experiment with both belief propagation and dual decomposition approaches to inference, the first empirical comparison of these algorithms that we are aware of on a structured natural language processing problem. On CCGbank we achieve a labelled dependency F-measure of 88.8% on gold POS tags, and 86.7% on automatic part-of-speeoch tags, the best reported results for this task.

1 Introduction

Accurate and efficient parsing of Combinatorial Categorial Grammar (CCG; Steedman, 2000) is a long-standing problem in computational linguistics, due to the complexities associated its mild context sensitivity. Even for practical CCG that are strongly context-free (Fowler and Penn, 2010), parsing is much harder than with Penn Treebank-style context-free grammars, with vast numbers of nonterminal categories leading to increased grammar constants. Where a typical Penn Treebank grammar may have fewer than 100 nonterminals (Hockenmaier and Steedman, 2002), we found that a CCG grammar derived from CCGbank contained over 1500. The same grammar assigns an average of 22 lexical categories per word (Clark and Curran, 2004a), resulting in an enormous space of possible derivations.

The most successful approach to CCG parsing is based on a pipeline strategy (§2). First, we tag (or multitag) each word of the sentence with a lexical category using a *supertagger*, a sequence model over these categories (Bangalore and Joshi, 1999; Clark, 2002). Second, we parse the sentence under the requirement that the lexical categories are fixed to those preferred by the supertagger. Variations on this approach drive the widely-used, broad coverage C&C parser (Clark and Curran, 2004a; Clark and Curran, 2007; Kummerfeld et al., 2010). However, it fails when the supertagger makes errors. We show experimentally that this pipeline significantly lowers the upper bound on parsing accuracy (§3).

The same experiment shows that the supertagger prunes many bad parses. So, while we want to avoid the error propagation inherent to a pipeline, ideally we still want to benefit from the key insight of supertagging: that a sequence model over lexical categories can be quite accurate. Our solution is to combine the features of both the supertagger and the parser into a single, less aggressively pruned model. The challenge with this model is its prohibitive complexity, which we address with *approximate* methods: dual decomposition and belief propagation (§4). We present the first side-by-side comparison of these algorithms on an NLP task of this complexity, measuring accuracy, convergence behavior, and runtime. In both cases our model significantly outperforms the pipeline approach, leading to the best published results in CCG parsing (§5).

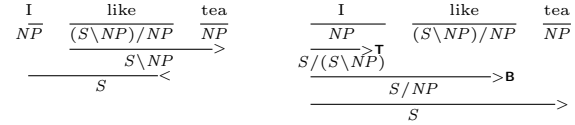
Portland, Oregon, June 19-24, 2011.

2 CCG and Supertagging

CCG is a lexicalized grammar formalism encoding for each word lexical categories that are either basic (eg. NN, JJ) or complex. Complex lexical categories specify the number and directionality of arguments. For example, one lexical category for the verb *like* is $(S\backslash NP)/NP$, specifying the first argument as an NP to the right and the second as an NP to the left; there are over 100 lexical categories for *like* in our lexicon. In parsing, adjacent spans are combined using a small number of binary combinatory rules like forward application or composition (Steedman, 2000; Fowler and Penn, 2010). In the first derivation below, $(S\backslash NP)/NP$ and NP combine to form the spanning category $S\backslash NP$, which only requires an NP to its left to form a complete sentence-spanning S. The second derivation uses type-raising to change the category type of *I*.



As can be inferred from even this small example, a key difficulty in parsing CCG is that the number of categories quickly becomes extremely large, and there are typically many ways to analyze every span of a sentence.

Supertagging (Bangalore and Joshi, 1999; Clark, 2002) treats the assignment of lexical categories (or *supertags*) as a sequence tagging problem. Because they do this with high accuracy, they are often exploited to prune the parser's search space: the parser only considers lexical categories with high posterior probability (or other figure of merit) under the supertagging model (Clark and Curran, 2004a). The posterior probabilities are then discarded; it is the extensive pruning of lexical categories that leads to substantially faster parsing times.

Pruning the categories in advance this way has a specific failure mode: sometimes it is not possible to produce a sentence-spanning derivation from the tag sequences preferred by the supertagger, since it does not enforce grammaticality. A workaround for this problem is the *adaptive supertagging* (AST) approach of Clark and Curran (2004a). It is based on a step function over supertagger beam widths, relaxing the pruning threshold for lexical categories only if the parser fails to find an analysis. The process either succeeds and returns a parse after some iteration or gives up after a predefined number of iterations. As Clark and Curran (2004a) show, most sentences can be parsed with a very small number of supertags per word. However, the technique is inherently approximate: it will return a lower probability parse under the parsing model if a higher probability parse can only be constructed from a supertag sequence returned by a subsequent iteration. In this way it prioritizes speed over exactness, although the tradeoff can be modified by adjusting the beam step function. Regardless, the effect of the approximation is unbounded.

We will also explore *reverse adaptive supertagging*, a much less aggressive pruning method that seeks only to make sentences parseable when they otherwise would not be due to an impractically large search space. Reverse AST starts with a wide beam, narrowing it at each iteration only if a maximum chart size is exceeded. In this way it prioritizes exactness over speed.

3 Oracle Parsing

What is the effect of these approximations? To answer this question we computed oracle best and worst values for labelled dependency F-score using the algorithm of Huang (2008) on the hybrid model of Clark and Curran (2007), the best model of their C&C parser. We computed the oracle on our development data, Section 00 of CCGbank (Hockenmaier and Steedman, 2007), using both AST and Reverse AST beams settings shown in Table 1.

The results (Table 2) show that the oracle best accuracy for reverse AST is more than 3% higher than the aggressive AST pruning.[1] In fact, it is almost as high as the upper bound oracle accuracy of 97.73% obtained using *perfect* supertags—in other words, the search space for reverse AST is theoretically near-optimal.[2] We also observe that the oracle

[1]The numbers reported here and in later sections differ slightly from those in a previously circulated draft of this paper, for two reasons: we evaluate only on sentences for which a parse was returned instead of all parses, to enable direct comparison with Clark and Curran (2007); and we use their hybrid model instead of their normal-form model, except where noted. Despite these changes our main findings remained unchanged.

[2]This idealized oracle reproduces a result from Clark and Cur-

Condition	Parameter	Iteration 1	2	3	4	5
AST	β (beam width)	0.075	0.03	0.01	0.005	0.001
	k (dictionary cutoff)	20	20	20	20	150
Reverse	β	0.001	0.005	0.01	0.03	0.075
	k	150	20	20	20	20

Table 1: Beam step function used for standard (AST) and less aggressive (Reverse) AST throughout our experiments. Parameter β is a beam threshold while k bounds the use of a part-of-speech tag dictionary, which is used for words seen less than k times.

	Viterbi F-score			Oracle Max F-score			Oracle Min F-score			
	LF	LP	LR	LF	LP	LR	LF	LP	LR	cat/word
AST	**87.38**	**87.83**	86.93	94.35	95.24	93.49	54.31	54.81	53.83	1.3-3.6
Reverse	87.36	87.55	**87.17**	**97.65**	**98.21**	**97.09**	18.09	17.75	18.43	3.6-1.3

Table 2: Comparison of adaptive supertagging (AST) and a less restrictive setting (Reverse) with Viterbi and oracle F-scores on CCGbank Section 00. The table shows the labelled F-score (LF), precision (LP) and recall (LR) and the the number of lexical categories per word used (from first to last parsing attempt).

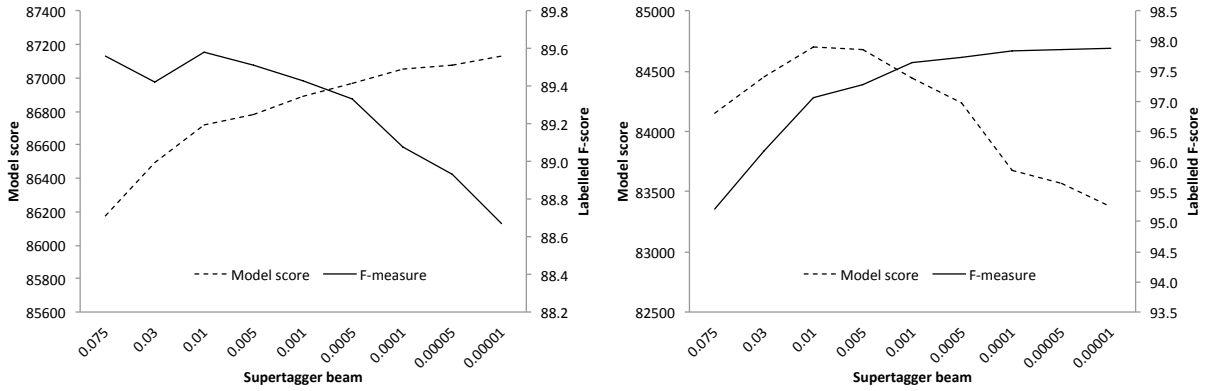


Figure 1: Comparison between model score and Viterbi F-score (left); and between model score and oracle F-score (right) for different supertagger beams on a subset of CCGbank Section 00.

worst accuracy is much lower in the reverse setting. It is clear that the supertagger pipeline has two effects: while it beneficially prunes many bad parses, it harmfully prunes some very good parses. We can also see from the scores of the Viterbi parses that while the reverse condition has access to much better parses, the model doesn't actually find them. This mirrors the result of Clark and Curran (2007) that they use to justify AST.

Digging deeper, we compared parser model score against Viterbi F-score and oracle F-score at a variety of fixed beam settings (Figure 1), considering only the subset of our development set which could be parsed with *all* beam settings. The inverse relationship between model score and F-score shows that the supertagger restricts the parser to mostly good parses (under F-measure) that the model would otherwise disprefer. Exactly this effect is exploited in the pipeline model. However, when the supertagger makes a mistake, the parser cannot recover.

4 Integrated Supertagging and Parsing

The supertagger obviously has good but not perfect predictive features. An obvious way to exploit this without being bound by its decisions is to incorporate these features directly into the parsing model.

ran (2004b). The reason that using the gold-standard supertags doesn't result in 100% oracle parsing accuracy is that some of the development set parses cannot be constructed by the learned grammar.

In our case both the parser and the supertagger are feature-based models, so from the perspective of a single parse tree, the change is simple: the tree is simply scored by the weights corresponding to all of its active features. However, since the features of the supertagger are all Markov features on adjacent supertags, the change has serious implications for search. If we think of the supertagger as defining a weighted regular language consisting of all supertag sequences, and the parser as defining a weighted mildly context-sensitive language consisting of only a *subset* of these sequences, then the search problem is equivalent to finding the optimal derivation in the weighted intersection of a regular and mildly context-sensitive language. Even allowing for the observation of Fowler and Penn (2010) that our practical CCG is context-free, this problem still reduces to the construction of Bar-Hillel et al. (1964), making search very expensive. Therefore we need approximations.

Fortunately, recent literature has introduced two relevant approximations to the NLP community: loopy belief propagation (Pearl, 1988), applied to dependency parsing by Smith and Eisner (2008); and dual decomposition (Dantzig and Wolfe, 1960; Komodakis et al., 2007; Sontag et al., 2010, *inter alia*), applied to dependency parsing by Koo et al. (2010) and lexicalized CFG parsing by Rush et al. (2010). We apply both techniques to our integrated supertagging and parsing model.

4.1 Loopy Belief Propagation

Belief propagation (BP) is an algorithm for computing marginals (i.e. expectations) on structured models. These marginals can be used for decoding (parsing) in a minimum-risk framework (Smith and Eisner, 2008); or for training using a variety of algorithms (Sutton and McCallum, 2010). We experiment with both uses in §5. Many researchers in NLP are familiar with two special cases of belief propagation: the forward-backward and inside-outside algorithms, used for computing expectations in sequence models and context-free grammars, respectively.[3] Our use of belief propagation builds directly on these two familiar algorithms.

[3]Forward-backward and inside-outside are formally shown to be special cases of belief propagation by Smyth et al. (1997) and Sato (2007), respectively.

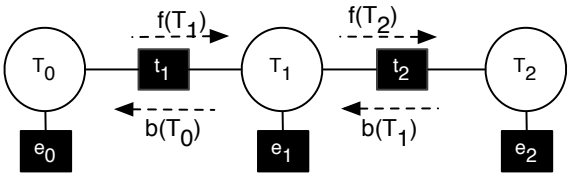

Figure 2: Supertagging factor graph with messages. Circles are variables and filled squares are factors.

BP is usually understood as an algorithm on bipartite *factor graphs*, which structure a global function into local functions over subsets of variables (Kschischang et al., 1998). Variables maintain a *belief* (expectation) over a distribution of values and BP passes *messages* about these beliefs between variables and factors. The idea is to iteratively update each variable's beliefs based on the beliefs of neighboring variables (through a shared factor), using the sum-product rule.

This results in the following equation for a message $m_{x\to f}(x)$ from a variable x to a factor f

$$m_{x\to f}(x) = \prod_{h\in n(x)\setminus f} m_{h\to x}(x) \qquad (1)$$

where $n(x)$ is the set of all neighbours of x. The message $m_{f\to x}$ from a factor to a variable is

$$m_{f\to x}(x) = \sum_{\sim\{x\}} f(X) \prod_{y\in n(f)\setminus x} m_{y\to f}(y) \qquad (2)$$

where $\sim\{x\}$ represents all variables other than x, $X = n(f)$ and $f(X)$ is the set of arguments of the factor function f.

Making this concrete, our supertagger defines a distribution over tags $T_0...T_I$, based on emission factors $e_0...e_I$ and transition factors $t_1...t_I$ (Figure 2). The message f_i a variable T_i receives from its neighbor to the left corresponds to the forward probability, while messages from the right correspond to backward probability b_i.

$$f_i(T_i) = \sum_{T_{i-1}} f_{i-1}(T_{i-1}) e_{i-1}(T_{i-1}) t_i(T_{i-1}, T_i) \quad (3)$$

$$b_i(T_i) = \sum_{T_{i+1}} b_{i+1}(T_{i+1}) e_{i+1}(T_{i+1}) t_{i+1}(T_i, T_{i+1}) \quad (4)$$

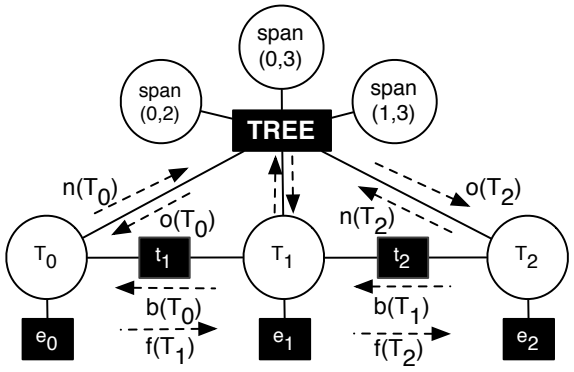

Figure 3: Factor graph for the combined parsing and supertagging model.

The current belief $B_x(x)$ for variable x can be computed by taking the normalized product of all its incoming messages.

$$B_x(x) = \frac{1}{Z} \prod_{h \in n(x)} m_{h \to x}(x) \tag{5}$$

In the supertagger model, this is just:

$$p(T_i) = \frac{1}{Z} f_i(T_i) b_i(T_i) e_i(T_i) \tag{6}$$

Our parsing model is *also* a distribution over variables T_i, along with an additional quadratic number of $span(i, j)$ variables. Though difficult to represent pictorially, a distribution over parses is captured by an extension to graphical models called case-factor diagrams (McAllester et al., 2008). We add this complex distribution to our model as a single factor (Figure 3). This is a natural extension to the use of complex factors described by Smith and Eisner (2008) and Dreyer and Eisner (2009).

When a factor graph is a tree as in Figure 2, BP converges in a single iteration to the exact marginals. However, when the model contains cycles, as in Figure 3, we can iterate message passing. Under certain assumptions this *loopy* BP it will converge to approximate marginals that are bounded under an interpretation from statistical physics (Yedidia et al., 2001; Sutton and McCallum, 2010).

The TREE factor exchanges *inside* n_i and *outside* o_i messages with the tag and span variables, taking into account beliefs from the sequence model. We will omit the unchanged outside recursion for brevity, but inside messages $n(C_{i,j})$ for category $C_{i,j}$ in $span(i, j)$ are computed using rule probabilities r as follows:

$$n(C_{i,j}) = \begin{cases} f_i(C_{i,j}) b_i(C_{i,j}) e_i(C_{i,j}) & \text{if j=i+1} \\ \sum_{k,X,Y} n(X_{i,k}) n(Y_{k,j}) r(C_{i,j}, X_{i,k}, Y_{k,j}) \end{cases} \tag{7}$$

Note that the only difference from the classic inside algorithm is that the recursive base case of a category spanning a single word has been replaced by a message from the supertag that contains both forward and backward factors, along with a unary emission factor, which doubles as a unary rule factor and thus contains the only shared features of the original models. This difference is also mirrored in the forward and backward messages, which are identical to Equations 3 and 4, except that they also incorporate outside messages from the tree factor.

Once all forward-backward and inside-outside probabilities have been calculated the belief of supertag T_i can be computed as the product of all incoming messages. The only difference from Equation 6 is the addition of the outside message.

$$p(T_i) = \frac{1}{Z} f_i(T_i) b_i(T_i) e_i(T_i) o_i(T_i) \tag{8}$$

The algorithm repeatedly runs forward-backward and inside-outside, passing their messages back and forth, until these quantities converge.

4.2 Dual Decomposition

Dual decomposition (Rush et al., 2010; Koo et al., 2010) is a decoding (i.e. search) algorithm for problems that can be decomposed into exactly solvable subproblems: in our case, supertagging and parsing. Formally, given Y as the set of valid parses, Z as the set of valid supertag sequences, and T as the set of supertags, we want to solve the following optimization for parser $f(y)$ and supertagger $g(z)$.

$$\arg\max_{y \in Y, z \in Z} f(y) + g(z) \tag{9}$$

$$\text{such that } y(i,t) = z(i,t) \text{ for all } (i,t) \in I \tag{10}$$

Here $y(i, t)$ is a binary function indicating whether word i is assigned supertag t by the parser, for the

set $I = \{(i,t) : i \in 1 \ldots n, t \in T\}$ denoting the set of permitted supertags for each word; similarly $z(i,t)$ for the supertagger. To enforce the constraint that the parser and supertagger agree on a tag sequence we introduce Lagrangian multipliers $u = \{u(i,t) : (i,t) \in I\}$ and construct a dual objective over variables $u(i,t)$.

$$L(u) = \max_{y \in Y}(f(y) - \sum_{i,t} u(i,t)y(i,t)) \quad (11)$$
$$+ \max_{z \in Z}(f(z) + \sum_{i,t} u(i,t)z(i,t))$$

This objective is an upper bound that we want to make as tight as possible by solving for $\min_u L(u)$. We optimize the values of the $u(i,t)$ variables using the same algorithm as Rush et al. (2010) for their tagging and parsing problem (essentially a perceptron update).[4] An advantages of DD is that, on convergence, it recovers *exact* solutions to the combined problem. However, if it does not converge or we stop early, an approximation must be returned: following Rush et al. (2010) we used the highest scoring output of the parsing submodel over all iterations.

5 Experiments

Parser. We use the C&C parser (Clark and Curran, 2007) and its supertagger (Clark, 2002). Our baseline is the hybrid model of Clark and Curran (2007); our integrated model simply adds the supertagger features to this model. The parser relies solely on the supertagger for pruning, using CKY for search over the pruned space. Training requires repeated calculation of feature expectations over packed charts of derivations. For training, we limited the number of items in this chart to 0.3 million, and for testing, 1 million. We also used a more permissive training supertagger beam (Table 3) than in previous work (Clark and Curran, 2007). Models were trained with the parser's L-BFGS trainer.

Evaluation. We evaluated on CCGbank (Hockenmaier and Steedman, 2007), a right-most normal-form CCG version of the Penn Treebank. We use sections 02-21 (39603 sentences) for training, section 00 (1913 sentences) for development and section 23 (2407 sentences) for testing. We supply gold-standard part-of-speech tags to the parsers. Evaluation is based on labelled and unlabelled predicate argument structure recovery and supertag accuracy. We only evaluate on sentences for which an analysis was returned; the coverage for *all* parsers is 99.22% on section 00, and 99.63% on section 23.

Model combination. We combine the parser and the supertagger over the search space defined by the set of supertags within the supertagger beam (see Table 1); this avoids having to perform inference over the prohibitively large set of parses spanned by all supertags. Hence at each beam setting, the model operates over the same search space as the baseline; the difference is that we search with our integrated model.

5.1 Parsing Accuracy

We first experiment with the separately trained supertagger and parser, which are then combined using belief propagation (BP) and dual decomposition (DD). We run the algorithms for many iterations, and irrespective of convergence, for BP we compute the minimum risk parse from the current marginals, and for DD we choose the highest-scoring parse seen over all iterations. We measured the evolving accuracy of the models on the development set (Figure 4). In line with our oracle experiment, these results demonstrate that we can coax more accurate parses from the larger search space provided by the reverse setting; the influence of the supertagger features allow us to exploit this advantage.

One behavior we observe in the graph is that the DD results tend to incrementally improve in accuracy while the BP results quickly stabilize, mirroring the result of Smith and Eisner (2008). This occurs because DD continues to find higher scoring parses at each iteration, and hence the results change. However for BP, even if the marginals have not converged, the minimum risk solution turns out to be fairly stable across successive iterations.

We next compare the algorithms against the baseline on our test set (Table 4). We find that the early stability of BP's performance generalises to the test set as does DD's improvement over several iterations. More importantly, we find that the applying

[4] The u terms can be interpreted as the *messages* from factors to variables (Sontag et al., 2010) and the resulting message passing algorithms are similar to the *max-product algorithm*, a sister algorithm to BP.

Table 4: Results for individually-trained submodels combined using dual decomposition (DD) or belief propagation (BP) for k iterations, evaluated by labelled and unlabelled F-score (LF/UF) and supertag accuracy (ST). We compare against the previous best result of Clark and Curran (2007); our baseline is their model with wider training beams (cf. Table 3).

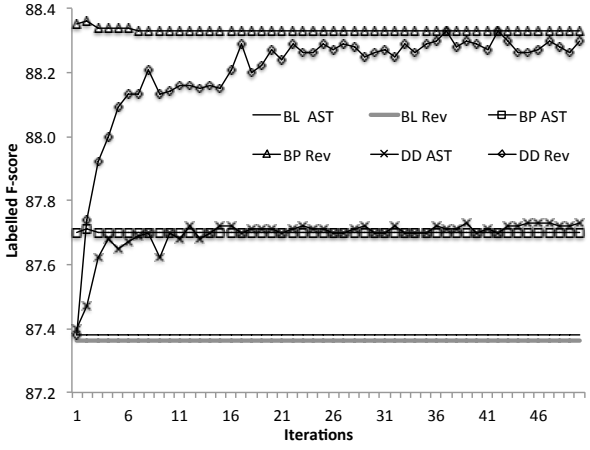

Figure 4: Labelled F-score of baseline (BL), belief propagation (BP), and dual decomposition (DD) on section 00.

our combined model using either algorithm *consistently* outperforms the baseline after only a few iterations. Overall, we improve the labelled F-measure by almost 1.1% and unlabelled F-measure by 0.6% over the baseline. To the best of our knowledge, the results obtained with BP and DD are the best reported results on this task using gold POS tags.

Next, we evaluate performance when using *automatic* part-of-speech tags as input to our parser and supertagger (Table 5). This enables us to compare against the results of Fowler and Penn (2010), who trained the Petrov parser (Petrov et al., 2006) on CCGbank. We outperform them on all criteria. Hence our combined model represents the best CCG parsing results under any setting.

Finally, we revisit the oracle experiment of §3 using our combined models (Figure 5). Both show an improved relationship between model score and F-measure.

5.2 Algorithmic Convergence

Figure 4 shows that parse accuracy converges after a few iterations. Do the *algorithms* converge? BP converges when the marginals do not change between iterations, and DD converges when both submodels agree on all supertags. We measured the convergence of each algorithm under these criteria over 1000 iterations (Figure 6). DD converges much faster, while BP in the reverse condition converges quite slowly. This is interesting when contrasted with its behavior on parse accuracy—its rate of convergence after one iteration is 1.5%, but its accuracy is already the highest at this point. Over the entire 1000 iterations, most sentences converge: all but 3 for BP (both in AST and reverse) and all but

41 (2.6%) for DD in reverse (6 in AST).

5.3 Parsing Speed

Because the C&C parser with AST is very fast, we wondered about the effect on speed for our model. We measured the runtime of the algorithms under the condition that we stopped at a particular iteration (Table 6). Although our models improve substantially over C&C, there is a significant cost in speed for the best result.

5.4 Training the Integrated Model

In the experiments reported so far, the parsing and supertagging models were trained separately, and only combined at test time. Although the outcome of these experiments was successful, we wondered if we could obtain further improvements by training the model parameters together.

Since the gradients produced by (loopy) BP are approximate, for these experiments we used a stochastic gradient descent (SGD) trainer (Bottou, 2003). We found that the SGD parameters described by Finkel et al. (2008) worked equally well for our models, and, on the baseline, produced similar results to L-BFGS. Curiously, however, we found that the combined model does not perform as well when

	AST		Reverse	
	sent/sec	LF	sent/sec	LF

Table 7: Results of training with SGD on approximate gradients from LPB on section 00. We test LBP in both inference and training (train) as well as in inference only (inf); a maximum number of 10 iterations is used.

the parameters are trained together (Table 7). A possible reason for this is that we used a stricter supertagger beam setting during training (Clark and Curran, 2007) to make training on a single machine practical. This leads to lower performance, particularly in the Reverse condition. Training a model using DD would require a different optimization algorithm based on Viterbi results (e.g. the perceptron) which we will pursue in future work.

6 Conclusion and Future Work

Our approach of combining models to avoid the pipeline problem (Felzenszwalb and McAllester, 2007) is very much in line with much recent work in NLP. Such diverse topics as machine translation (Dyer et al., 2008; Dyer and Resnik, 2010; Mi et al., 2008), part-of-speech tagging (Jiang et al., 2008), named entity recognition (Finkel and Manning, 2009) semantic role labelling (Sutton and McCallum, 2005; Finkel et al., 2006), and others have also been improved by combined models. Our empirical comparison of BP and DD also complements the theoretically-oriented comparison of marginal- and margin-based variational approximations for parsing described by Martins et al. (2010).

We have shown that the aggressive pruning used in adaptive supertagging significantly harms the oracle performance of the parser, though it mostly prunes bad parses. Based on these findings, we combined parser and supertagger features into a single model. Using belief propagation and dual decomposition, we obtained more principled—and more accurate—approximations than a pipeline. Models combined using belief propagation achieve very good performance immediately, despite an initial convergence rate just over 1%, while dual decomposition produces comparable results after several iterations, and algorithmically converges more quickly. Our best result of 88.8% represents the state-of-the art in CCG parsing accuracy.

In future work we plan to integrate the POS tagger, which is crucial to parsing accuracy (Clark and Curran, 2004b). We also plan to revisit the idea of combined training. Though we have focused on CCG in this work we expect these methods to be equally useful for other linguistically motivated but computationally complex formalisms such as lexicalized tree adjoining grammar.

Jointly Learning to Extract and Compress

Taylor Berg-Kirkpatrick **Dan Gillick** **Dan Klein**

Abstract

We learn a joint model of sentence extraction and compression for multi-document summarization. Our model scores candidate summaries according to a combined linear model whose features factor over (1) the n-gram types in the summary and (2) the compressions used. We train the model using a margin-based objective whose loss captures end summary quality. Because of the exponentially large set of candidate summaries, we use a cutting-plane algorithm to incrementally detect and add active constraints efficiently. Inference in our model can be cast as an ILP and thereby solved in reasonable time; we also present a fast approximation scheme which achieves similar performance. Our jointly extracted and compressed summaries outperform both unlearned baselines and our learned extraction-only system on both ROUGE and Pyramid, without a drop in judged linguistic quality. We achieve the highest published ROUGE results to date on the TAC 2008 data set.

1 Introduction

Applications of machine learning to automatic summarization have met with limited success, and, as a result, many top-performing systems remain largely ad-hoc. One reason learning may have provided limited gains is that typical models do not learn to optimize end summary quality directly, but rather learn intermediate quantities in isolation. For example, many models learn to score each input sentence independently (Teufel and Moens, 1997; Shen et al., 2007; Schilder and Kondadadi, 2008), and then assemble extractive summaries from the top-ranked sentences in a way not incorporated into the learning process. This extraction is often done in the presence of a heuristic that limits redundancy. As another example, Yih et al. (2007) learn predictors of individual words' appearance in the references, but in isolation from the sentence selection procedure. Exceptions are Li et al. (2009) who take a max-margin approach to learning sentence values jointly, but still have ad hoc constraints to handle redundancy. One main contribution of the current paper is the direct optimization of summary quality in a single model; we find that our learned systems substantially outperform unlearned counterparts on both automatic and manual metrics.

While pure extraction is certainly simple and does guarantee some minimal readability, Lin (2003) showed that sentence compression (Knight and Marcu, 2001; McDonald, 2006; Clarke and Lapata, 2008) has the potential to improve the resulting summaries. However, attempts to incorporate compression into a summarization system have largely failed to realize large gains. For example, Zajic et al (2006) use a pipeline approach, pre-processing to yield additional candidates for extraction by applying heuristic sentence compressions, but their system does not outperform state-of-the-art purely extractive systems. Similarly, Gillick and Favre (2009), though not learning weights, do a limited form of compression jointly with extraction. They report a marginal increase in the automatic word-overlap metric ROUGE (Lin, 2004), but a decline in manual Pyramid (Nenkova and Passonneau, 2004).

A second contribution of the current work is to show a system for jointly learning to jointly compress and extract that exhibits gains in both ROUGE and content metrics over purely extractive systems. Both Martins and Smith (2009) and Woodsend and Lapata (2010) build models that jointly extract and compress, but learn scores for sentences (or phrases) using independent classifiers. Daumé III (2006)

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 481–490,
Portland, Oregon, June 19-24, 2011.

learns parameters for compression and extraction jointly using an approximate training procedure, but his results are not competitive with state-of-the-art extractive systems, and he does not report improvements on manual content or quality metrics.

In our approach, we define a linear model that scores candidate summaries according to features that factor over the n-gram types that appear in the summary and the structural compressions used to create the sentences in the summary. We train these parameters jointly using a margin-based objective whose loss captures end summary quality through the ROUGE metric. Because of the exponentially large set of candidate summaries, we use a cutting plane algorithm to incrementally detect and add active constraints efficiently. To make joint learning possible we introduce a new, manually-annotated data set of extracted, compressed sentences. Inference in our model can be cast as an integer linear program (ILP) and solved in reasonable time using a generic ILP solver; we also introduce a fast approximation scheme which achieves similar performance. Our jointly extracted and compressed summaries outperform both unlearned baselines and our learned extraction-only system on both ROUGE and Pyramid, without a drop in judged linguistic quality. We achieve the highest published comparable results (ROUGE) to date on our test set.

2 Joint Model

We focus on the task of multi-document summarization. The input is a collection of documents, each consisting of multiple sentences. The output is a summary of length no greater than L_{max}. Let x be the input document set, and let $\mathbf{y}$ be a representation of a summary as a vector. For an extractive summary, $\mathbf{y}$ is as a vector of indicators $\mathbf{y} = (y_s : s \in x)$, one indicator y_s for each sentence s in x. A sentence s is present in the summary if and only if its indicator $y_s = 1$ (see Figure 1a). Let $Y(x)$ be the set of valid summaries of document set x with length no greater than L_{max}.

While past extractive methods have assigned value to individual sentences and then explicitly represented the notion of redundancy (Carbonell and Goldstein, 1998), recent methods show greater success by using a simpler notion of coverage: bigrams

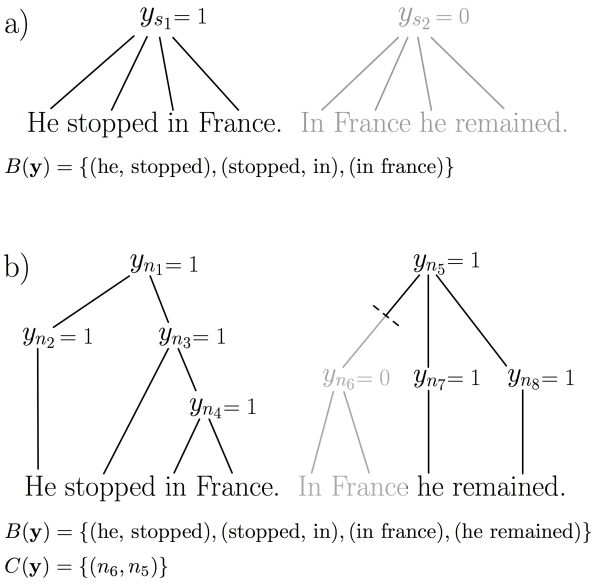

Figure 1: Diagram of (a) extractive and (b) joint extractive and compressive summarization models. Variables y_s indicate the presence of sentences in the summary. Variables y_n indicate the presence of parse tree nodes. Note that there is intentionally a bigram missing from (a).

contribute content, and redundancy is implicitly encoded in the fact that redundant sentences cover fewer bigrams (Nenkova and Vanderwende, 2005; Gillick and Favre, 2009). This later approach is associated with the following objective function:

$$\max_{\mathbf{y} \in Y(x)} \sum_{b \in B(\mathbf{y})} v_b \quad (1)$$

Here, v_b is the value of bigram b, and $B(\mathbf{y})$ is the set of bigrams present in the summary encoded by $\mathbf{y}$. Gillick and Favre (2009) produced a state-of-the-art system[1] by directly optimizing this objective. They let the value v_b of each bigram be given by the number of input documents the bigram appears in. Our implementation of their system will serve as a baseline, referred to as EXTRACTIVE BASELINE.
