A *template* defines a specific type of event (e.g., a bombing) with a set of *semantic roles* (or slots) for the typical entities involved in such an event (e.g., perpetrator, target, instrument). In contrast to work in relation discovery that focuses on learning atomic facts (Banko et al., 2007a; Carlson et al., 2010), templates can extract a richer representation of a particular domain. However, unlike relation discovery, most template-based IE approaches assume foreknowledge of the domain's templates. Very little work addresses how to learn the template structure itself. Our goal in this paper is to perform the standard template filling task, but to first automatically induce the templates from an unlabeled corpus.

There are many ways to represent events, ranging from role-based representations such as frames (Baker et al., 1998) to sequential events in scripts (Schank and Abelson, 1977) and narrative schemas (Chambers and Jurafsky, 2009; Kasch and Oates, 2010). Our approach learns narrative-like knowledge in the form of IE templates; we learn sets of related events and semantic roles, as shown in this sample output from our system:

Bombing Template

{detonate, blow up, plant, explode, defuse, destroy}

Perpetrator:	Person who detonates, plants, blows up
Instrument:	Object that is planted, detonated, defused
Target:	Object that is destroyed, is blown up

A semantic role, such as *target*, is a cluster of syntactic functions of the template's event words (e.g., the objects of *detonate* and *explode*). Our goal is to characterize a domain by learning this template structure completely automatically. We learn templates by first clustering event words based on their proximity in a training corpus. We then use a novel approach to role induction that clusters the syntactic functions of these events based on selectional preferences and coreferring arguments. The induced roles are template-specific (e.g., perpetrator), not universal (e.g., agent or patient) or verb-specific.

After learning a domain's template schemas, we perform the standard IE task of role filling from individual documents, for example:

Perpetrator:	guerrillas
Instrument:	dynamite
Target:	embassy

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 976–986,
Portland, Oregon, June 19-24, 2011.

This extraction stage identifies entities using the learned syntactic functions of our roles. We evaluate on the MUC-4 terrorism corpus with results approaching those of supervised systems.

The core of this paper focuses on how to characterize a domain-specific corpus by learning rich template structure. We describe how to first expand the small corpus' size, how to cluster its events, and finally how to induce semantic roles. Section 5 then describes the extraction algorithm, followed by evaluations against previous work in section 6 and 7.

2 Previous Work

Many template extraction algorithms require full knowledge of the templates and labeled corpora, such as in rule-based systems (Chinchor et al., 1993; Rau et al., 1992) and modern supervised classifiers (Freitag, 1998; Chieu et al., 2003; Bunescu and Mooney, 2004; Patwardhan and Riloff, 2009). Classifiers rely on the labeled examples' surrounding context for features such as nearby tokens, document position, syntax, named entities, semantic classes, and discourse relations (Maslennikov and Chua, 2007). Ji and Grishman (2008) also supplemented labeled with unlabeled data.

Weakly supervised approaches remove some of the need for fully labeled data. Most still require the templates and their slots. One common approach is to begin with unlabeled, but clustered event-specific documents, and extract common word patterns as extractors (Riloff and Schmelzenbach, 1998; Sudo et al., 2003; Riloff et al., 2005; Patwardhan and Riloff, 2007). Filatova et al. (2006) integrate named entities into pattern learning (*PERSON won*) to approximate unknown semantic roles. Bootstrapping with seed examples of known slot fillers has been shown to be effective (Surdeanu et al., 2006; Yangarber et al., 2000). In contrast, this paper removes these data assumptions, learning instead from a corpus of unknown events and unclustered documents, without seed examples.

Shinyama and Sekine (2006) describe an approach to *template learning* without labeled data. They present *unrestricted relation discovery* as a means of discovering relations in unlabeled documents, and extract their fillers. Central to the algorithm is collecting multiple documents describing the same exact event (e.g. Hurricane Ivan), and observing repeated word patterns across documents connecting the same proper nouns. Learned patterns represent binary relations, and they show how to construct tables of extracted entities for these relations. Our approach draws on this idea of using unlabeled documents to discover relations in text, and of defining semantic roles by sets of entities. However, the limitations to their approach are that (1) redundant documents about specific events are required, (2) relations are binary, and (3) only slots with named entities are learned. We will extend their work by showing how to learn without these assumptions, obviating the need for redundant documents, and learning templates with any type and any number of slots.

Large-scale learning of scripts and narrative schemas also captures template-like knowledge from unlabeled text (Chambers and Jurafsky, 2008; Kasch and Oates, 2010). Scripts are sets of related event words and semantic roles learned by linking syntactic functions with coreferring arguments. While they learn interesting event structure, the structures are limited to frequent topics in a large corpus. We borrow ideas from this work as well, but our goal is to instead characterize a specific domain with limited data. Further, we are the first to apply this knowledge to the IE task of filling in template mentions in documents.

In summary, our work extends previous work on unsupervised IE in a number of ways. We are the first to learn MUC-4 templates, and we are the first to extract entities without knowing how many templates exist, without examples of slot fillers, and without event-clustered documents.

3 The Domain and its Templates

Our goal is to learn the general event structure of a domain, and then extract the instances of each learned event. In order to measure performance in both tasks (learning structure and extracting instances), we use the terrorism corpus of MUC-4 (Sundheim, 1991) as our target domain. This corpus was chosen because it is annotated with templates that describe all of the entities involved in each event. An example snippet from a *bombing* document is given here:

*The terrorists **used** explosives against the town hall. El Comercio reported that alleged Shining Path members also **attacked** public facilities in huarpacha, Ambo, tomayquichua, and kichki. Municipal official Sergio Horna was seriously **wounded** in an explosion in Ambo.*

The entities from this document fill the following slots in a MUC-4 bombing template.

Perp: Shining Path members **Victim**: Sergio Horna
Target: public facilities **Instrument**: explosives

We focus on these four string-based slots[1] from the MUC-4 corpus, as is standard in this task. The corpus consists of 1300 documents, 733 of which are labeled with at least one template. There are six types of templates, but only four are modestly frequent: *bombing* (208 docs), *kidnap* (83 docs), *attack* (479 docs), and *arson* (40 docs). 567 documents do not have any templates. Our learning algorithm does not know which documents contain (or do not contain) which templates. After learning event words that represent templates, we induce their slots, not knowing a priori how many there are, and then fill them in by extracting entities as in the standard task. In our example above, the three bold verbs (use, attack, wound) indicate the Bombing template, and their syntactic arguments fill its slots.

4 Learning Templates from Raw Text

Our goal is to learn templates that characterize a domain as described in unclustered, unlabeled documents. This presents a two-fold problem to the learner: it does not know how many events exist, and it does not know which documents describe which event (some may describe multiple events). We approach this problem with a three step process: (1) cluster the domain's event patterns to approximate the template topics, (2) build a new corpus *specific to each cluster* by retrieving documents from a larger unrelated corpus, (3) induce each template's slots using its new (larger) corpus of documents.

4.1 Clustering Events to Learn Templates

We cluster *event patterns* to create templates. An *event pattern* is either (1) a verb, (2) a noun in WordNet under the Event synset, or (3) a verb and the head word of its syntactic object. Examples of each include (1) 'explode', (2) 'explosion', and (3) 'explode:bomb'. We also tag the corpus with an NER system and allow patterns to include named entity types, e.g., 'kidnap:PERSON'. These patterns are crucially needed later to learn a template's slots. However, we first need an algorithm to cluster these patterns to learn the domain's core events. We consider two unsupervised algorithms: Latent Dirichlet Allocation (LDA) (Blei et al., 2003), and agglomerative clustering based on word distance.

4.1.1 LDA for Unknown Data

LDA is a probabilistic model that treats documents as mixtures of topics. It learns topics as discrete distributions (multinomials) over the event patterns, and thus meets our needs as it clusters patterns based on co-occurrence in documents. The algorithm requires the number of topics to be known ahead of time, but in practice this number is set relatively high and the resulting topics are still useful. Our best performing LDA model used 200 topics. We had mixed success with LDA though, and ultimately found our next approach performed slightly better on the document classification evaluation.

4.1.2 Clustering on Event Distance

Agglomerative clustering does not require foreknowledge of the templates, but its success relies on how event pattern similarity is determined.

Ideally, we want to learn that *detonate* and *destroy* belong in the same cluster representing a bombing. Vector-based approaches are often adopted to represent words as feature vectors and compute their distance with cosine similarity. Unfortunately, these approaches typically learn clusters of *synonymous* words that can miss detonate and destroy. Our goal is to instead capture world knowledge of co-occuring events. We thus adopt an assumption that *closeness* in the world is reflected by *closeness* in a text's discourse. We hypothesize that two patterns are related if they occur near each other in a document more often than chance.

Let $g(w_i, w_j)$ be the distance between two events (1 if in the same sentence, 2 in neighboring, etc). Let $C_{dist}(w_i, w_j)$ be the distance-weighted frequency of

[1]There are two Perpetrator slots in MUC-4: Organization and Individual. We consider their union as a single slot.

kidnap: kidnap, kidnap:PER, abduct, release, kidnapping, ransom, robbery, registration
bombing: explode, blow up, locate, place:bomb, detonate, damage, explosion, cause, damage, ...
attack: kill, shoot down, down, kill:civilian, kill:PER, kill:soldier, kill:member, killing, shoot:PER, wave, ...
arson: burn, search, burning, clip, collaborate, ...

Figure 1: The 4 clusters mapped to MUC-4 templates.

two events occurring together:

$$C_{dist}(w_i, w_j) = \sum_{d \in D} \sum_{w_i, w_j \in d} 1 - log_4(g(w_i, w_j)) \quad (1)$$

where d is a document in the set of all documents D. The base 4 logarithm discounts neighboring sentences by 0.5 and within the same sentence scores 1. Using this definition of distance, pointwise mutual information measures our similarity of two events:

$$pmi(w_i, w_j) = P_{dist}(w_i, w_j)/(P(w_i)P(w_j)) \quad (2)$$

$$P(w_i) = \frac{C(w_i)}{\sum_j C(w_j)} \quad (3)$$

$$P_{dist}(w_i, w_j) = \frac{C_{dist}(w_i, w_j)}{\sum_k \sum_l C_{dist}(w_k, w_l)} \quad (4)$$

We run agglomerative clustering with pmi over all event patterns. Merging decisions use the average link score between all new links across two clusters. As with all clustering algorithms, a stopping criterion is needed. We continue merging clusters until any single cluster grows beyond m patterns. We briefly inspected the clustering process and chose $m = 40$ to prevent learned scenarios from intuitively growing too large and ambiguous. Post-evaluation analysis shows that this value has wide flexibility. For example, the Kidnap and Arson clusters are unchanged in $30 < m < 80$, and Bombing unchanged in $30 < m < 50$. Figure 1 shows 3 clusters (of 77 learned) that characterize the main template types.

4.2 Information Retrieval for Templates

Learning a domain often suffers from a lack of training data. The previous section clustered events from the MUC-4 corpus, but its 1300 documents do not provide enough examples of verbs and argument counts to further learn the semantic roles in each cluster. Our solution is to assemble a larger *IR-corpus* of documents for each cluster. For example, MUC-4 labels 83 documents with Kidnap, but our learned cluster (*kidnap*, *abduct*, *release*, ...) retrieved 3954 documents from a general corpus.

We use the Associated Press and New York Times sections of the Gigaword Corpus (Graff, 2002) as our general corpus. These sections include approximately 3.5 million news articles spanning 12 years.

Our retrieval algorithm retrieves documents that score highly with a cluster's tokens. The document score is defined by two common metrics: word match, and word coverage. A document's match score is defined as the average number of times the words in cluster c appear in document d:

$$avgm(d, c) = \frac{\sum_{w \in c} \sum_{t \in d} 1\{w = t\}}{|c|} \quad (5)$$

We define *word coverage* as the number of seen cluster words. Coverage penalizes documents that score highly by repeating a single cluster word a lot. We only score a document if its coverage, $cvg(d, c)$, is at least 3 words (or less for tiny clusters):

$$ir(d, c) = \begin{cases} avgm(d, c) & \text{if } cvg(d, c) > min(3, |c|/4) \\ 0 & \text{otherwise} \end{cases}$$

A document d is retrieved for a cluster c if $ir(d, c) > 0.4$. Finally, we emphasize precision by pruning away 50% of a cluster's retrieved documents that are farthest in distance from the mean document of the retrieved set. Distance is the cosine similarity between bag-of-words vector representations. The confidence value of 0.4 was chosen from a manual inspection among a single cluster's retrieved documents. Pruning 50% was arbitrarily chosen to improve precision, and we did not experiment with other quantities. A search for optimum parameter values may lead to better results.

4.3 Inducing Semantic Roles (Slots)

Having successfully clustered event words and retrieved an *IR-corpus* for each cluster, we now address the problem of *inducing semantic roles*. Our learned roles will then extract entities in the next section and we will evaluate their per-role accuracy.

Most work on unsupervised role induction focuses on learning *verb-specific* roles, starting with seed examples (Swier and Stevenson, 2004; He and

Gildea, 2006) and/or knowing the number of roles (Grenager and Manning, 2006; Lang and Lapata, 2010). Our previous work (Chambers and Jurafsky, 2009) learned *situation-specific* roles over narrative schemas, similar to frame roles in FrameNet (Baker et al., 1998). Schemas link the syntactic relations of verbs by clustering them based on observing coreferring arguments in those positions. This paper extends this intuition by introducing a new vector-based approach to coreference similarity.

4.3.1 Syntactic Relations as Roles

We learn the roles of cluster C by clustering the syntactic relations R_C of its words. Consider the following example:

C = {*go off, explode, set off, damage, destroy*}
R_C = {*go_off:s, go_off:p_in, explode:s, set_off:s*}

where *verb:s* is the verb's subject, *:o* the object, and *p_in* a preposition. We ideally want to cluster R_C as:

bomb = {*go_off:s, explode:s, set_off:o, destroy:s*}
suspect = {*set_off:s*}
target = {*go_off:p_in, destroy:o*}

We want to cluster all subjects, objects, and prepositions. Passive voice is normalized to active[2].

We adopt two views of relation similarity: coreferring arguments and selectional preferences. Chambers and Jurafsky (2008) observed that coreferring arguments suggest a semantic relation between two predicates. In the sentence, *he ran and then he fell*, the subjects of run and fall corefer, and so they likely belong to the same scenario-specific semantic role. We applied this idea to a new vector similarity framework. We represent a relation as a vector of all relations with which their arguments coreferred. For instance, arguments of the relation *go_off:s* were seen coreferring with mentions in *plant:o*, *set_off:o* and *injure:s*. We represent *go_off:s* as a vector of these relation counts, calling this its *coref vector representation*.

Selectional preferences (SPs) are also useful in measuring similarity (Erk and Pado, 2008). A relation can be represented as a vector of its observed arguments during training. The SPs for *go_off:s* in our data include {*bomb, device, charge, explosion*}.

We measure similarity using cosine similarity between the vectors in both approaches. However, coreference and SPs measure different types of similarity. Coreference is a looser narrative similarity (bombings cause injuries), while SPs capture synonymy (plant and place have similar arguments). We observed that many narrative relations are not synonymous, and vice versa. We thus take the maximum of either cosine score as our final similarity metric between two relations. We then back off to the average of the two cosine scores if the max is not confident (less than 0.7); the average penalizes the pair. We chose the value of 0.7 from a grid search to optimize extraction results on the training set.

4.3.2 Clustering Syntactic Functions

We use agglomerative clustering with the above pairwise similarity metric. Cluster similarity is the average link score over all new links crossing two clusters. We include the following sparsity penalty $r(c_a, c_b)$ if there are too few links between clusters c_a and c_b.

$$score(c_a, c_b) = \sum_{w_i \in c_a} \sum_{w_j \in c_b} sim(w_i, w_j) * r(c_a, c_b) \quad (6)$$

$$r(c_a, c_b) = \frac{\sum_{w_i \in c_a} \sum_{w_j \in c_b} 1\{sim(w_i, w_j) > 0\}}{\sum_{w_i \in c_a} \sum_{w_j \in c_b} 1} \quad (7)$$

This penalizes clusters from merging when they share only a few high scoring edges. Clustering stops when the merged cluster scores drop below a threshold optimized to extraction performance on the training data.

We also begin with two assumptions about syntactic functions and semantic roles. The first assumes that the subject and object of a verb carry different semantic roles. For instance, the subject of *sell* fills a different role (Seller) than the object (Good). The second assumption is that each semantic role has a high-level entity type. For instance, the subject of *sell* is a Person or Organization, and the object is a Physical Object.

We implement the first assumption as a constraint in the clustering algorithm, preventing two clusters from merging if their union contains the same verb's subject and object.

We implement the second assumption by automatically labeling each syntactic function with a role type based on its observed arguments. The role types are broad general classes: *Person/Org*, *Physical Object*, or *Other*. A syntactic function is labeled as a

[2]We use the Stanford Parser at nlp.stanford.edu/software

Bombing Template (MUC-4)

Perpetrator *Person/Org* who detonates, blows up, plants, hurls, stages, is detained, is suspected, is blamed on, launches

Instrument A *physical object* that is exploded, explodes, is hurled, causes, goes off, is planted, damages, is set off, is defused

Target A *physical object* that is damaged, is destroyed, is exploded at, is damaged, is thrown at, is hit, is struck

Police *Person/Org* who raids, questions, discovers, investigates, defuses, arrests

N/A A *physical object* that is blown up, destroys

Attack/Shooting Template (MUC-4)

Perpetrator *Person/Org* who assassinates, patrols, ambushes, raids, shoots, is linked to

Victim *Person/Org* who is assassinated, is toppled, is gunned down, is executed, is evacuated

Target *Person/Org* who is hit, is struck, is downed, is set fire to, is blown up, surrounded

Instrument A *physical object* that is fired, injures, downs, is set off, is exploded

Kidnap Template (MUC-4)

Perpetrator *Person/Org* who releases, abducts, kidnaps, ambushes, holds, forces, captures, is imprisoned, frees

Target *Person/Org* who is kidnapped, is released, is freed, escapes, disappears, travels, is harmed, is threatened

Police *Person/Org* who rules out, negotiates, condemns, is pressured, finds, arrests, combs

Weapons Smuggling Template (NEW)

Perpetrator *Person/Org* who smuggles, is seized from, is captured, is detained

Police *Person/Org* who raids, seizes, captures, confiscates, detains, investigates

Instrument A *physical object* that is smuggled, is seized, is confiscated, is transported

Election Template (NEW)

Voter *Person/Org* who chooses, is intimidated, favors, is appealed to, turns out

Government *Person/Org* who authorizes, is chosen, blames, authorizes, denies

Candidate *Person/Org* who resigns, unites, advocates, manipulates, pledges, is blamed

Figure 2: Five learned example templates. All knowledge except the template/role names (e.g., 'Victim') is learned.

class if 20% of its arguments appear under the corresponding WordNet synset[3], or if the NER system labels them as such. Once labeled by type, we separately cluster the syntactic functions for each role type. For instance, Person functions are clustered separate from Physical Object functions. Figure 2 shows some of the resulting roles.

Finally, since agglomerative clustering makes hard decisions, related events to a template may have been excluded in the initial event clustering stage. To address this problem, we identify the 200 *nearby events* to each event cluster. These are simply the top scoring event patterns with the cluster's original events. We add their syntactic functions to their best matching roles. This expands the coverage of each learned role. Varying the 200 amount does not lead to wide variation in extraction performance. Once induced, the roles are evaluated by their entity extraction performance in Section 5.

4.4 Template Evaluation

We now compare our learned templates to those hand-created by human annotators for the MUC-4 terrorism corpus. The corpus contains 6 template types, but two of them occur in only 4 and 14 of the 1300 training documents. We thus only evaluate the 4 main templates (*bombing*, *kidnapping*, *attack*, and *arson*). The gold slots are shown in figure 3.

	Bombing	Kidnap	Attack	Arson
Perpetrator	x	x	x	x
Victim	x	x	x	x
Target	x		x	x
Instrument	x		x	

Figure 3: Slots in the hand-crafted MUC-4 templates.

We evaluate the four learned templates that score highest in the document classification evaluation (to be described in section 5.1), aligned with their MUC-4 types. Figure 2 shows three of our four templates, and two brand new ones that our algorithm learned. Of the four templates, we learned 12 of the 13 semantic roles as created for MUC. In addition, we learned a new role not in MUC for bombings, kidnappings, and arson: the *Police* or *Authorities* role. The annotators chose not to include this in their labeling, but this knowledge is clearly relevant when understanding such events, so we consider it correct. There is one additional Bombing and one Arson role that does not align with MUC-4, marked incorrect.

[3]Physical objects are defined as non-person physical objects

We thus report 92% slot recall, and precision as 14 of 16 (88%) learned slots.

We only measure agreement with the MUC template schemas, but our system learns other events as well. We show two such examples in figure 2: the Weapons Smuggling and Election Templates.

5 Information Extraction: Slot Filling

We now present how to apply our learned templates to information extraction. This section will describe how to extract slot fillers using our templates, but without knowing which templates are correct.

We could simply use a standard IE approach, for example, creating seed words for our new learned templates. But instead, we propose a new method that obviates the need for even a limited human labeling of seed sets. We consider each learned semantic role as a potential slot, and we extract slot fillers using the syntactic functions that were previously learned. Thus, the learned syntactic patterns (e.g., the subject of *release*) serve the dual purpose of both inducing the template slots, and extracting appropriate slot fillers from text.

5.1 Document Classification

A document is labeled for a template if two different conditions are met: (1) it contains at least one trigger phrase, and (2) its average per-token conditional probability meets a strict threshold.

Both conditions require a definition of the conditional probability of a template given a token. The conditional is defined as the token's importance relative to its uniqueness across all templates. This is not the usual conditional probability definition as IR-corpora are different sizes.

$$P(t|w) = \frac{P_{IR_t}(w)}{\sum_{s \in T} P_{IR_s}(w)} \quad (8)$$

where $P_{IR_t}(w)$ is the probability of pattern w in the IR-corpus of template t.

$$P_{IR_t}(w) = \frac{C_t(w)}{\sum_v C_t(v)} \quad (9)$$

where $C_t(w)$ is the number of times word w appears in the IR-corpus of template t. A template's trigger words are defined as words satisfying $P(t|w) > 0.2$.

	Kidnap	Bomb	Attack	Arson
Precision	.64	.83	.66	.30
Recall	.54	.63	.35	1.0
F1	**.58**	**.72**	**.46**	**.46**

Figure 4: Document classification results on test.

Trigger phrases are thus template-specific patterns that are highly indicative of that template.

After identifying triggers, we use the above definition to score a document with a template. A document is labeled with a template if it contains at least one trigger, and its average word probability is greater than a parameter optimized on the training set. A document can be (and often is) labeled with multiple templates.

Finally, we label the sentences that contain triggers and use them for extraction in section 5.2.

5.1.1 Experiment: Document Classification

The MUC-4 corpus links templates to documents, allowing us to evaluate our document labels. We treat each link as a gold label (kidnap, bomb, or attack) for that document, and documents can have multiple labels. Our learned clusters naturally do not have MUC labels, so we report results on the four clusters that score highest with each label.

Figure 4 shows the document classification scores. The bombing template performs best with an F1 score of .72. Arson occurs very few times, and Attack is lower because it is essentially an agglomeration of diverse events (discussed later).

5.2 Entity Extraction

Once documents are labeled with templates, we next extract entities into the template slots. Extraction occurs in the trigger sentences from the previous section. The extraction process is two-fold:

1. Extract all NPs that are arguments of patterns in the template's induced roles.

2. Extract NPs whose heads are observed frequently with one of the roles (e.g., 'bomb' is seen with Instrument relations in figure 2).

Take the following MUC-4 sentence as an example:

> *The two bombs were planted with the exclusive purpose of intimidating the owners of...*

The verb *plant* is in our learned bombing cluster, so step (1) will extract its passive subject *bombs* and map it to the correct instrument role (see figure 2). The human target, *owners*, is missed because *intimidate* was not learned. However, if *owner* is in the selectional preferences of the learned 'human target' role, step (2) correctly extracts it into that role.

These are two different, but complementary, views of semantic roles. The first is that a role is defined by the set of syntactic relations that describe it. Thus, we find all role relations and save their arguments (pattern extraction). The second view is that a role is defined by the arguments that fill it. Thus, we extract all arguments that filled a role in training, regardless of their current syntactic environment.

Finally, we filter extractions whose WordNet or named entity label does not match the learned slot's type (e.g., a Location does not match a Person).

6 Standard Evaluation

We trained on the 1300 documents in the MUC-4 corpus and tested on the 200 document TST3 and TST4 test set. We evaluate the four string-based slots: perpetrator, physical target, human target, and instrument. We merge MUC's two perpetrator slots (individuals and orgs) into one gold Perpetrator slot. As in Patwardhan and Riloff (2007; 2009), we ignore missed optional slots in computing recall. We induced clusters in training, performed IR, and induced the slots. We then extracted entities from the test documents as described in section 5.2.

The standard evaluation for this corpus is to report the F1 score for slot type accuracy, ignoring the template type. For instance, a perpetrator of a bombing and a perpetrator of an attack are treated the same. This allows supervised classifiers to train on all perpetrators at once, rather than template-specific learners. Although not ideal for our learning goals, we report it for comparison against previous work.

Several supervised approaches have presented results on MUC-4, but unfortunately we cannot compare against them. Maslennikov and Chua (2006; 2007) evaluated a random subset of test (they report .60 and .63 F1), and Xiao et al. (2004) did not evaluate all slot types (they report .57 F1).

Figure 5 thus shows our results with previous work that is comparable: the fully supervised and weakly supervised approaches of Patwardhan and Riloff (2009; 2007). We give two numbers for our system: mapping one learned template to Attack, and mapping five. Our learned templates for Attack have a different granularity than MUC-4. Rather than one broad Attack type, we learn several: Shooting, Murder, Coup, General Injury, and Pipeline Attack. We see these subtypes as strengths of our algorithm, but it misses the MUC-4 granularity of Attack. We thus show results when we apply the best five learned templates to Attack, rather than just one. The final F1 with these Attack subtypes is .40.

	P	R	F1
Patwardhan & Riloff-09 : Supervised	48	59	53
Patwardhan & Riloff-07 : Weak-Sup	42	48	44
Our Results (1 attack)	48	25	33
Our Results (5 attack)	**44**	**36**	**40**

Figure 5: MUC-4 extraction, ignoring template type.

F1 Score	Kidnap	Bomb	Arson	Attack
Results	.53	.43	.42	.16 / .25

Figure 6: Performance of individual templates. Attack compares our 1 vs 5 best templates.

Our precision is as good as (and our F1 score near) two algorithms that require knowledge of the templates and/or labeled data. Our algorithm instead learned this knowledge without such supervision.

7 Specific Evaluation

In order to more precisely evaluate each learned template, we also evaluated per-template performance. Instead of merging all slots across all template types, we score the slots within each template type. This is a stricter evaluation than Section 6; for example, bombing victims assigned to attacks were previously deemed correct[4].

Figure 6 gives our results. Three of the four templates score at or above .42 F1, showing that our lower score from the previous section is mainly due to the Attack template. Arson also unexpectedly

[4]We do not address the task of template instance identification (e.g., splitting two bombings into separate instances). This requires deeper discourse analysis not addressed by this paper.

	Precision	Recall	F1
Kidnap	.82	.47	.60 (+.07)
Bomb	.60	.36	.45 (+.02)
Arson	1.0	.29	.44 (+.02)
Attack	.36	.09	.15 (0.0)

Figure 7: Performance of each template type, but only evaluated on documents labeled with each type. All others are removed from test. The parentheses indicate F1 gain over evaluating on all test documents (figure 6).

scored well. It only occurs in 40 documents overall, suggesting our algorithm works with little evidence.

Per-template performace is good, and our .40 overall score from the previous section illustrates that we perform quite well in comparison to the .44-.53 range of weakly and fully supervised results.

These evaluations use the standard TST3 and TST4 test sets, including the documents that are not labeled with any templates. 74 of the 200 test documents are unlabeled. In order to determine where the system's false positives originate, we also measure performance only on the 126 test documents that have at least one template. Figure 7 presents the results on this subset. Kidnap improves most significantly in F1 score (7 F1 points absolute), but the others only change slightly. Most of the false positives in the system thus do not originate from the unlabeled documents (the 74 unlabeled), but rather from extracting incorrect entities from correctly identified documents (the 126 labeled).

8 Discussion

Template-based IE systems typically assume knowledge of the domain and its templates. We began by showing that domain knowledge isn't necessarily required; we learned the MUC-4 template structure with surprising accuracy, learning new semantic roles and several new template structures. We are the first to our knowledge to automatically induce MUC-4 templates. It is possible to take these learned slots and use a previous approach to IE (such as seed-based bootstrapping), but we presented an algorithm that instead uses our learned syntactic patterns. We achieved results with comparable precision, and an F1 score of .40 that approaches prior algorithms that rely on hand-crafted knowledge.

The extraction results are encouraging, but the template induction itself is a central contribution of this work. Knowledge induction plays an important role in moving to new domains and assisting users who may not know what a corpus contains. Recent work in Open IE learns atomic relations (Banko et al., 2007b), but little work focuses on structured scenarios. We learned more templates than just the main MUC-4 templates. A user who seeks to know what information is in a body of text would instantly recognize these as key templates, and could then extract the central entities.

We hope to address in the future how the algorithm's unsupervised nature hurts recall. Without labeled or seed examples, it does not learn as many patterns or robust classifiers as supervised approaches. We will investigate new text sources and algorithms to try and capture more knowledge. The final experiment in figure 7 shows that perhaps new work should first focus on pattern learning and entity extraction, rather than document identification.

Finally, while our pipelined approach (template induction with an IR stage followed by entity extraction) has the advantages of flexibility in development and efficiency, it does involve a number of parameters. We believe the IR parameters are quite robust, and did not heavily focus on improving this stage, but the two clustering steps during template induction require parameters to control stopping conditions and word filtering. While all learning algorithms require parameters, we think it is important for future work to focus on removing some of these to help the algorithm be even more robust to new domains and genres.

Abstract

Argumentation schemes are structures or templates for various kinds of arguments. Given the text of an argument with premises and conclusion identified, we classify it as an instance of one of five common schemes, using features specific to each scheme. We achieve accuracies of 63–91% in one-against-others classification and 80–94% in pairwise classification (baseline = 50% in both cases).

1 Introduction

We investigate a new task in the computational analysis of arguments: the classification of arguments by the *argumentation schemes* that they use. An argumentation scheme, informally, is a framework or structure for a (possibly defeasible) argument; we will give a more-formal definition and examples in Section 3. Our work is motivated by the need to determine the unstated (or implicitly stated) premises that arguments written in natural language normally draw on. Such premises are called *enthymemes*.

For instance, the argument in Example 1 consists of one explicit premise (the first sentence) and a conclusion (the second sentence):

Example 1 ***[Premise:]*** *The survival of the entire world is at stake.*
[Conclusion:] *The treaties and covenants aiming for a world free of nuclear arsenals and other conventional and biological weapons of mass destruction should be adhered to scrupulously by all nations.*

Another premise is left implicit — "*Adhering to those treaties and covenants is a means of realizing survival of the entire world*". This proposition is an enthymeme of this argument.

Our ultimate goal is to reconstruct the enthymemes in an argument, because determining these unstated assumptions is an integral part of understanding, supporting, or attacking an entire argument. Hence reconstructing enthymemes is an important problem in argument understanding. We believe that first identifying the particular argumentation scheme that an argument is using will help to bridge the gap between stated and unstated propositions in the argument, because each argumentation scheme is a relatively fixed "template" for arguing. That is, given an argument, we first classify its argumentation scheme; then we fit the stated propositions into the corresponding template; and from this we infer the enthymemes.

In this paper, we present an argument scheme classification system as a stage following argument detection and proposition classification. First in Section 2 and Section 3, we introduce the background to our work, including related work in this field, the two core concepts of argumentation schemes and scheme-sets, and the Araucaria dataset. In Section 4 and Section 5 we present our classification system, including the overall framework, data preprocessing, feature selection, and the experimental setups. In the remaining section, we present the essential approaches to solve the leftover problems of this paper which we will study in our future work, and discuss the experimental results, and potential directions for future work.

2 Related work

Argumentation has not received a great deal of attention in computational linguistics, although it has been a topic of interest for many years. Cohen (1987) presented a computational model of argumentative discourse. Dick (1987; 1991a; 1991b) developed a representation for retrieval of judicial decisions by the structure of their legal argument — a necessity for finding legal precedents independent of their domain. However, at that time no corpus of arguments was available, so Dick's system was purely theoretical. Recently, the Araucaria project at University of Dundee has developed a software tool for manual argument analysis, with a point-and-click interface for users to reconstruct and diagram an argument (Reed and Rowe, 2004; Rowe and Reed, 2008). The project also maintains an online repository, called AraucariaDB, of marked-up naturally occurring arguments collected by annotators worldwide, which can be used as an experimental corpus for automatic argumentation analysis (for details see Section 3.2).

Recent work on argument interpretation includes that of George, Zukerman, and Nieman (2007), who interpret constructed-example arguments (not naturally occurring text) as Bayesian networks. Other contemporary research has looked at the automatic detection of arguments in text and the classification of premises and conclusions. The work closest to ours is perhaps that of Mochales and Moens (2007; 2008; 2009a; 2009b). In their early work, they focused on automatic detection of arguments in legal texts. With each sentence represented as a vector of shallow features, they trained a multinomial naïve Bayes classifier and a maximum entropy model on the Araucaria corpus, and obtained a best average accuracy of 73.75%. In their follow-up work, they trained a support vector machine to further classify each argumentative clause into a premise or a conclusion, with an F_1 measure of 68.12% and 74.07% respectively. In addition, their context-free grammar for argumentation structure parsing obtained around 60% accuracy.

Our work is "downstream" from that of Mochales and Moens. Assuming the eventual success of their, or others', research program on detecting and classifying the components of an argument, we seek to determine how the pieces fit together as an instance of an argumentation scheme.

3 Argumentation schemes, scheme-sets, and annotation

3.1 Definition and examples

Argumentation schemes are structures or templates for forms of arguments. The arguments need not be deductive or inductive; on the contrary, most argumentation schemes are for *presumptive* or *defeasible* arguments (Walton and Reed, 2002). For example, *argument from cause to effect* is a commonly used scheme in everyday arguments. A list of such argumentation schemes is called a *scheme-set*.

It has been shown that argumentation schemes are useful in evaluating common arguments as fallacious or not (van Eemeren and Grootendorst, 1992). In order to judge the weakness of an argument, a set of critical questions are asked according to the particular scheme that the argument is using, and the argument is regarded as valid if it matches all the requirements imposed by the scheme.

Walton's set of 65 argumentation schemes (Walton et al., 2008) is one of the best-developed scheme-sets in argumentation theory. The five schemes defined in Table 1 are the most commonly used ones, and they are the focus of the scheme classification system that we will describe in this paper.

3.2 Araucaria dataset

One of the challenges for automatic argumentation analysis is that suitable annotated corpora are still very rare, in spite of work by many researchers. In the work described here, we use the Araucaria database[1], an online repository of arguments, as our experimental dataset. Araucaria includes approximately 660 manually annotated arguments from various sources, such as newspapers and court cases, and keeps growing. Although Araucaria has several limitations, such as rather small size and low agreement among annotators[2], it is nonetheless one of the best argumentative corpora available to date.

[1] http://araucaria.computing.dundee.ac.uk/doku.php#araucaria_argumentation_corpus

[2] The developers of Araucaria did not report on inter-annotator agreement, probably because some arguments are annotated by only one commentator.

Argument from example *Premise*: In this particular case, the individual *a* has property *F* and also property *G*. *Conclusion:* Therefore, generally, if *x* has property *F*, then it also has property *G*.
Argument from cause to effect *Major premise*: Generally, if *A* occurs, then *B* will (might) occur. *Minor premise*: In this case, *A* occurs (might occur). *Conclusion*: Therefore, in this case, *B* will (might) occur.
Practical reasoning *Major premise*: I have a goal *G*. *Minor premise*: Carrying out action *A* is a means to realize *G*. *Conclusion*: Therefore, I ought (practically speaking) to carry out this action *A*.
Argument from consequences *Premise*: If *A* is (is not) brought about, good (bad) consequences will (will not) plausibly occur. *Conclusion*: Therefore, *A* should (should not) be brought about.
Argument from verbal classification *Individual premise*: *a* has a particular property *F*. *Classification premise*: For all *x*, if *x* has property *F*, then *x* can be classified as having property *G*. *Conclusion*: Therefore, *a* has property *G*.

Table 1: The five most frequent schemes and their definitions in Walton's scheme-set.

Arguments in Araucaria are annotated in a XML-based format called "AML" (Argument Markup Language). A typical argument (see Example 2) consists of several AU nodes. Each AU node is a complete argument unit, composed of a conclusion proposition followed by optional premise proposition(s) in a linked or convergent structure. Each of these propositions can be further defined as a hierarchical collection of smaller AUs. INSCHEME is the particular scheme (e.g., *"Argument from Consequences"*) of which the current proposition is a member; enthymemes that have been made explicit are annotated as "missing = yes".

Example 2 ***Example of argument markup from Araucaria***

```
<TEXT>If we stop the free creation of art, we will stop
 the free viewing of art.</TEXT>
<AU>
  <PROP identifier="C" missing="yes">
    <PROPTEXT offset="-1">
      The prohibition of the free creation of art should
      not be brought about.</PROPTEXT>
    <INSCHEME scheme="Argument from Consequences"
     schid="0" />
  </PROP>
  <LA>
    <AU>
      <PROP identifier="A" missing="no">
        <PROPTEXT offset="0">
          If we stop the free creation of art, we will
          stop the free viewing of art.</PROPTEXT>
        <INSCHEME scheme="Argument from Consequences"
         schid="0" />
      </PROP>
    </AU>
    <AU>
      <PROP identifier="B" missing="yes">
        <PROPTEXT offset="-1">
          The prohibition of free viewing of art is not
          acceptable.</PROPTEXT>
        <INSCHEME scheme="Argument from Consequences"
        schid="0" />
      </PROP>
    </AU>
  </LA>
</AU>
```

There are three scheme-sets used in the annotations in Araucaria: Walton's scheme-set, Katzav and Reed's (2004) scheme-set, and Pollock's (1995) scheme-set. Each of these has a different set of schemes; and most arguments in Araucaria are marked up according to only one of them. Our experimental dataset is composed of only those arguments annotated in accordance with Walton's scheme-set, within which the five schemes shown in Table 1 constitute 61% of the total occurrences.

4 Methods

4.1 Overall framework

As we noted above, our ultimate goal is to reconstruct enthymemes, the unstated premises, in an argument by taking advantage of the stated propositions; and in order to achieve this goal we need to first determine the particular argumentation scheme that the argument is using. This problem is depicted in Figure 1. Our scheme classifier is the dashed round-cornered rectangle portion of this

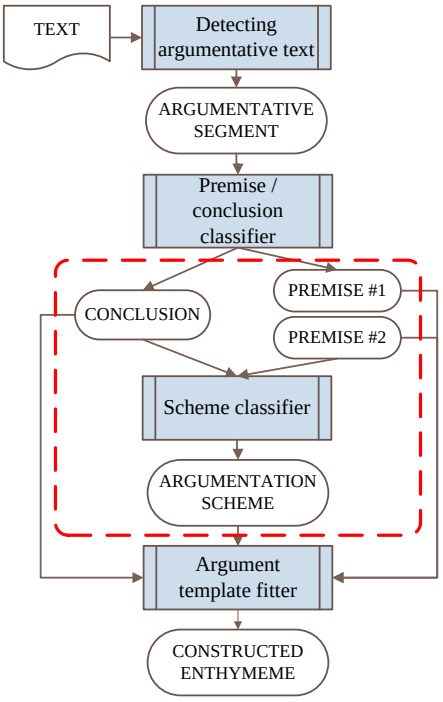

Figure 1: Overall framework of this research.

overall framework: its input is the extracted conclusion and premise(s) determined by an argument detector, followed by a premise / conclusion classifier, given an unknown text as the input to the entire system. And the portion below the dashed round-rectangle represents our long-term goal — to reconstruct the implicit premise(s) in an argument, given its argumentation scheme and its explicit conclusion and premise(s) as input. Since argument detection and classification are not the topic of this paper, we assume here that the input conclusion and premise(s) have already been retrieved, segmented, and classified, as for example by the methods of Mochales and Moens (see Section 2 above). And the scheme template fitter is the topic of our on-going work.

4.2 Data preprocessing

From all arguments in Araucaria, we first extract those annotated in accordance with Walton's scheme-set. Then we break each complex AU node into several simple AUs where no conclusion or premise proposition nodes have embedded AU nodes. From these generated simple arguments, we extract those whose scheme falls into one of the five most frequent schemes as described in Table 1. Furthermore, we remove all enthymemes that have been inserted by the annotator and ignore any argument with a missing conclusion, since the input to our proposed classifier, as depicted in Figure 1, cannot have any access to unstated argumentative propositions.

The resulting preprocessed dataset is composed of 393 arguments, of which 149, 106, 53, 44, and 41 respectively belong to the five schemes in the order shown in Table 1.

4.3 Feature selection

The features used in our work fall into two categories: general features and scheme-specific features.

4.3.1 General features

General features are applicable to arguments belonging to any of the five schemes (shown in Table 2).

For the features **conLoc**, **premLoc**, **gap**, and **lenRat**, we have two versions, differing in terms of their basic measurement unit: *sentence*-based and *token*-based. The final feature, **type**, indicates whether the premises contribute to the conclusion in a linked or convergent order. A *linked argument* (LA) is one that has two or more inter-dependent premise propositions, all of which are necessary to make the conclusion valid, whereas in a *convergent argument* (CA) exactly one premise proposition is sufficient to do so. Since it is observed that there exists a strong correlation between **type** and the particular scheme employed while arguing, we believe **type** can be a good indicator of argumentation scheme. However, although this feature is available to us because it is included in the Araucaria annotations, its value cannot be obtained from raw text as easily as other features mentioned above; but it is possible that we will in the future be able to determine it automatically by taking advantage of some scheme-independent cues such as the discourse relation between the conclusion and the premises.

4.3.2 Scheme-specific features

Scheme-specific features are different for each scheme, since each scheme has its own cue phrases or patterns. The features for each scheme are shown in Table 3 (for complete lists of features see Feng (2010)). In our experiments in Section 5 below, all these features are computed for all arguments; but

conLoc: the location (in token or sentence) of the conclusion in the text.

premLoc: the location (in token or sentence) of the first premise proposition.

conFirst: whether the conclusion appears before the first premise proposition.

gap: the interval (in token or sentence) between the conclusion and the first premise proposition.

lenRat: the ratio of the length (in token or sentence) of the premise(s) to that of the conclusion.

numPrem: the number of explicit premise propositions (PROP nodes) in the argument.

type: type of argumentation structure, i.e., linked or convergent.

Table 2: List of general features.

the features for any particular scheme are used only when it is the subject of a particular task. For example, when we classify *argument from example* in a one-against-others setup, we use the scheme-specific features of that scheme for all arguments; when we classify *argument from example* against *argument from cause to effect*, we use the scheme-specific features of those two schemes.

For the first three schemes (*argument from example*, *argument from cause to effect*, and *practical reasoning*), the scheme-specific features are selected cue phrases or patterns that are believed to be indicative of each scheme. Since these cue phrases and patterns have differing qualities in terms of their precision and recall, we do not treat them all equally. For each cue phrase or pattern, we compute "confidence", the degree of belief that the argument of interest belongs to a particular scheme, using the distribution characteristics of the cue phrase or pattern in the corpus, as described below.

For each argument $\mathcal{A}$, a vector $\mathbf{CV} = \{c_1, c_2, c_3\}$ is added to its feature set, where each c_i indicates the "confidence" of the existence of the specific features associated with each of the first three schemes, $scheme_i$. This is defined in Equation 1:

$$c_i = \frac{1}{N} \sum_{k=1}^{m_i} (P(scheme_i|cp_k) \cdot d_{ik}) \qquad (1)$$

Argument from example
8 keywords and phrases including *for example*, *such as*, *for instance*, etc.; 3 punctuation cues: ":", ";", and "—".

Argument from cause to effect
22 keywords and simple cue phrases including *result*, *related to*, *lead to*, etc.; 10 causal and non-causal relation patterns extracted from WordNet (Girju, 2003).

Practical reasoning
28 keywords and phrases including *want*, *aim*, *objective*, etc.; 4 modal verbs: *should*, *could*, *must*, and *need*; 4 patterns including imperatives and infinitives indicating the goal of the speaker.

Argument from consequences
The counts of positive and negative propositions in the conclusion and premises, calculated from the *General Inquirer*[2].

Argument from verbal classification
The maximal similarity between the *central word* pairs extracted from the conclusion and the premise; the counts of *copula*, *expletive*, and *negative modifier* dependency relations returned by the *Stanford parser*[3] in the conclusion and the premise.

[2] http://www.wjh.harvard.edu/~inquirer/
[3] http://nlp.stanford.edu/software/lex-parser.shtml

Table 3: List of scheme-specific features.

Here m_i is the number of scheme-specific cue phrases designed for $scheme_i$; $P(scheme_i|cp_k)$ is the prior probability that the argument $\mathcal{A}$ actually belongs to $scheme_i$, given that some particular cue phrase cp_k is found in $\mathcal{A}$; d_{ik} is a value indicating whether cp_k is found in $\mathcal{A}$; and the normalization factor N is the number of scheme-specific cue phrase patterns designed for $scheme_i$ with at least one support (at least one of the arguments belonging to $scheme_i$ contains that cue phrase). There are two ways to calculate d_{ik}, *Boolean* and *count*: in *Boolean* mode, d_{ik} is treated as 1 if $\mathcal{A}$ matches cp_k; in *count* mode, d_{ik} equals to the number of times $\mathcal{A}$ matches cp_k; and in both modes, d_{ik} is treated as 0 if cp_k is not found in $\mathcal{A}$.

For *argument from consequences*, since the arguer has an obvious preference for some particular consequence, sentiment orientation can be a good indicator for this scheme, which is quantified by the counts of positive and negative propositions in the conclusion and premise.

For *argument from verbal classification*, there exists a hypernymy-like relation between some pair of propositions (entities, concepts, or actions) located in the conclusion and the premise respectively. The existence of such a relation is quantified by the maximal Jiang-Conrath Similarity (Jiang and Conrath, 1997) between the "central word" pairs extracted from the conclusion and the premise. We parse each sentence of the argument with the Stanford dependency parser, and a word or phrase is considered to be a central word if it is the dependent or governor of several particular dependency relations, which basically represents the attribute or the action of an entity in a sentence, or the entity itself. For example, if a word or phrase is the dependent of the dependency relation *agent*, it is therefore considered as a "central word". In addition, an arguer tends to use several particular syntactic structures (*copula*, *expletive*, and *negative modifier*) when using this scheme, which can be quantified by the counts of those special relations in the conclusion and the premise(s).

5 Experiments

5.1 Training

We experiment with two kinds of classification: *one-against-others* and *pairwise*. We build a pruned C4.5 decision tree (Quinlan, 1993) for each different classification setup, implemented by Weka Toolkit 3.6[5] (Hall et al., 2009).

One-against-others classification A one-against-others classifier is constructed for each of the five most frequent schemes, using the general features and the scheme-specific features for the scheme of interest. For each classifier, there are two possible outcomes: *target_scheme* and other; 50% of the training dataset is arguments associated with *target_scheme*, while the rest is arguments of all the other schemes, which are treated as other. One-against-other classification thus tests the effectiveness of each scheme's specific features.

Pairwise classification A pairwise classifier is constructed for each of the ten possible pairings of the five schemes, using the general features and the scheme-specific features of the two schemes in the pair. For each of the ten classifiers, the training dataset is divided equally into arguments belonging to $scheme_1$ and arguments belonging to $scheme_2$, where $scheme_1$ and $scheme_2$ are two different schemes among the five. Only features associated with $scheme_1$ and $scheme_2$ are used.

5.2 Evaluation

We experiment with different combinations of general features and scheme-specific features (discussed in Section 4.3). To evaluate each experiment, we use the average accuracy over 10 pools of randomly sampled data (each with baseline at 50%[6]) with 10-fold cross-validation.

6 Results

We first present the best average accuracy (BAA) of each classification setup. Then we demonstrate the impact of the feature **type** (convergent or linked argument) on BAAs for different classification setups, since we believe **type** is strongly correlated with the particular argumentation scheme and its value is the only one directly retrieved from the annotations of the training corpus. For more details, see Feng (2010).

6.1 BAAs of each classification setup

target_scheme	*BAA*	d_{ik}	*base*	*type*
example	90.6	count	token	yes
cause	70.4	Boolean / count	token	no
reasoning	90.8	count	sentence	yes
consequences	62.9	–	sentence	yes
classification	63.2	–	token	yes

Table 4: Best average accuracies (BAAs) (%) of one-against-others classification.

[5] http://cs.waikato.ac.nz/ml/weka

[6] We also experiment with using general features only, but the results are consistently below or around the sampling baseline of 50%; therefore, we do not use them as a baseline here.

	example	*cause*	*reasoning*	*consequences*
cause	80.6			
reasoning	93.1	94.2		
consequences	86.9	86.7	97.9	
classification	86.0	85.6	98.3	64.2

Table 5: Best average accuracies (BAAs) (%) of pairwise classification.

Table 4 presents the best average accuracies of one-against-others classification for each of the five schemes. The subsequent three columns list the particular strategies of features incorporation under which those BAAs are achieved (the complete set of possible choices is given in Section 4.3.):

- $\mathbf{d_{ik}}$: *Boolean* or *count* — the strategy of combining scheme-specific cue phrases or patterns using either *Boolean* or *count* for d_{ik}.
- **base**: *sentence* or *token* — the basic unit of applying location- or length-related general features.
- **type**: *yes* or *no* — whether **type** (convergent or linked argument) is incorporated into the feature set.

As Table 4 shows, one-against-others classification achieves high accuracy for *argument from example* and *practical reasoning*: 90.6% and 90.8%. The BAA of *argument from cause to effect* is only just over 70%. However, with the last two schemes (*argument from consequences* and *argument from verbal classification*), accuracy is only in the low 60s; there is little improvement of our system over the majority baseline of 50%. This is probably due at least partly to the fact that these schemes do not have such obvious cue phrases or patterns as the other three schemes which therefore may require more world knowledge encoded, and also because the available training data for each is relatively small (44 and 41 instances, respectively). The BAA for each scheme is achieved with inconsistent choices of base and d_{ik}, but the accuracies that resulted from different choices vary only by very little.

Table 5 shows that our system is able to correctly differentiate between most of the different scheme pairs, with accuracies as high as 98%. It has poor performance (64.0%) only for the pair *argument from consequences* and *argument from verbal classification*; perhaps not coincidentally, these are the two schemes for which performance was poorest in the one-against-others task.

6.2 Impact of type on classification accuracy

As we can see from Table 6, for one-against-others classifications, incorporating **type** into the feature vectors improves classification accuracy in most cases: the only exception is that the best average accuracy of one-against-others classification between *argument from cause to effect* and *others* is obtained without involving **type** into the feature vector — but the difference is negligible, i.e., 0.5 percentage points with respect to the average difference. **Type** also has a relatively small impact on *argument from verbal classification* (2.6 points), compared to its impact on *argument from example* (22.3 points), *practical reasoning* (8.1 points), and *argument from consequences* (7.5 points), in terms of the maximal differences.

Similarly, for pairwise classifications, as shown in Table 7, **type** has significant impact on BAAs, especially on the pairs of *practical reasoning* versus *argument from cause to effect* (17.4 points), *practical reasoning* versus *argument from example* (22.6 points), and *argument from verbal classification* versus *argument from example* (20.2 points), in terms of the maximal differences; but it has a relatively small impact on *argument from consequences* versus *argument from cause to effect* (0.8 point), and *argument from verbal classification* versus *argument from consequences* (1.1 points), in terms of average differences.

7 Future Work

In future work, we will look at automatically classifying **type** (i.e., whether an argument is linked or convergent), as **type** is the only feature directly retrieved from annotations in the training corpus that has a strong impact on improving classification accuracies.

Automatically classifying **type** will not be easy, because sometimes it is subjective to say whether a premise is sufficient by itself to support the conclusion or not, especially when the argument is about

target_scheme	***BAA-t***	***BAA-no t***	***max diff***	***min diff***	***avg diff***

personal opinions or judgments. So for this task, we will initially focus on arguments that are (or at least seem to be) empirical or objective rather than value-based. It will also be non-trivial to determine whether an argument is convergent or linked — whether the premises are independent of one another or not. Cue words and discourse relations between the premises and the conclusion will be one helpful factor; for example, *besides* generally flags an independent premise. And one premise may be regarded as linked to another if either would become an enthymeme if deleted; but determining this in the general case, without circularity, will be difficult.

We will also work on the argument template fitter, which is the final component in our overall framework. The task of the argument template fitter is to map each explicitly stated conclusion and premise into the corresponding position in its scheme template and to extract the information necessary for enthymeme reconstruction. Here we propose a syntax-based approach for this stage, which is similar to tasks in information retrieval. This can be best explained by the argument in Example 1, which uses the particular argumentation scheme *practical reasoning*.

We want to fit the *Premise* and the *Conclusion* of this argument into the *Major premise* and the *Conclusion* slots of the definition of *practical reasoning* (see Table 1), and construct the following conceptual mapping relations:

1. *Survival of the entire world* ⟶ a goal *G*
2. *Adhering to the treaties and covenants aiming for a world free of nuclear arsenals and other conventional and biological weapons of mass destruction* ⟶ action *A*

Thereby we will be able to reconstruct the missing *Minor premise* — the enthymeme in this argument:

> Carrying out *adhering to the treaties and covenants aiming for a world free of nuclear arsenals and other conventional and biological*

weapons of mass destruction is a means of realizing *survival of the entire world*.

8 Conclusion

The argumentation scheme classification system that we have presented in this paper introduces a new task in research on argumentation. To the best of our knowledge, this is the first attempt to classify argumentation schemes.

In our experiments, we have focused on the five most frequently used schemes in Walton's scheme-set, and conducted two kinds of classification: in one-against-others classification, we achieved over 90% best average accuracies for two schemes, with other three schemes in the 60s to 70s; and in pairwise classification, we obtained 80% to 90% best average accuracies for most scheme pairs. The poor performance of our classification system on other experimental setups is partly due to the lack of training examples or to insufficient world knowledge.

Completion of our scheme classification system will be a step towards our ultimate goal of reconstructing the enthymemes in an argument by the procedure depicted in Figure 1. Because of the significance of enthymemes in reasoning and arguing, this is crucial to the goal of understanding arguments. But given the still-premature state of research of argumentation in computational linguistics, there are many practical issues to deal with first, such as the construction of richer training corpora and improvement of the performance of each step in the procedure.

Abstract

We present a novel model to represent and assess the discourse coherence of text. Our model assumes that coherent text implicitly favors certain types of discourse relation transitions. We implement this model and apply it towards the text ordering ranking task, which aims to discern an original text from a permuted ordering of its sentences. The experimental results demonstrate that our model is able to significantly outperform the state-of-the-art coherence model by Barzilay and Lapata (2005), reducing the error rate of the previous approach by an average of 29% over three data sets against human upper bounds. We further show that our model is synergistic with the previous approach, demonstrating an error reduction of 73% when the features from both models are combined for the task.

1 Introduction

The coherence of a text is usually reflected by its discourse structure and relations. In Rhetorical Structure Theory (RST), Mann and Thompson (1988) observed that certain RST relations tend to favor one of two possible canonical orderings. Some relations (*e.g.*, Concessive and Conditional) favor arranging their satellite span before the nucleus span. In contrast, other relations (*e.g.*, Elaboration and Evidence) usually order their nucleus before the satellite. If a text that uses non-canonical relation orderings is rewritten to use canonical orderings, it often improves text quality and coherence.

This notion of preferential ordering of discourse relations is observed in natural language in general, and generalizes to other discourse frameworks aside from RST. The following example shows a Contrast relation between the two sentences.

(1) [Everyone agrees that most of the nation's old bridges need to be repaired or replaced. $]_{S_1}$ [But there's disagreement over how to do it. $]_{S_2}$

Here the second sentence provides contrasting information to the first. If this order is violated without rewording (*i.e.*, if the two sentences are swapped), it produces an incoherent text (Marcu, 1996).

In addition to the intra-relation ordering, such preferences also extend to inter-relation ordering:

(2) [The Constitution does not expressly give the president such power. $]_{S_1}$ [However, the president does have a duty not to violate the Constitution. $]_{S_2}$ [The question is whether his only means of defense is the veto. $]_{S_3}$

The second sentence above provides a contrast to the previous sentence and an explanation for the next one. This pattern of Contrast-followed-by-Cause is rather common in text (Pitler et al., 2008). Ordering the three sentences differently results in incoherent, cryptic text.

Thus coherent text exhibits measurable preferences for specific intra- and inter-discourse relation ordering. Our key idea is to use the converse of this phenomenon to assess the coherence of a text. In this paper, we detail our model to capture the coherence of a text based on the statistical distribution of the discourse structure and relations. Our method specifically focuses on the discourse relation transitions between adjacent sentences, modeling them in a discourse role matrix.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 997–1006,
Portland, Oregon, June 19-24, 2011.

Our study makes additional contributions. We implement and validate our model on three data sets, which show robust improvements over the current state-of-the-art for coherence assessment. We also provide the first assessment of the upper-bound of human performance on the standard task of distinguishing coherent from incoherent orderings. To the best our knowledge, this is also the first study in which we show output from an automatic discourse parser helps in coherence modeling.

2 Related Work

The study of coherence in discourse has led to many linguistic theories, of which we only discuss algorithms that have been reduced to practice.

Barzilay and Lapata (2005; 2008) proposed an entity-based model to represent and assess *local* textual coherence. The model is motivated by Centering Theory (Grosz et al., 1995), which states that subsequent sentences in a locally coherent text are likely to continue to focus on the same entities as in previous sentences. Barzilay and Lapata operationalized Centering Theory by creating an entity grid model to capture discourse entity transitions at the sentence-to-sentence level, and demonstrated their model's ability to discern coherent texts from incoherent ones. Barzilay and Lee (2004) proposed a domain-dependent HMM model to capture topic shift in a text, where topics are represented by hidden states and sentences are observations. The *global* coherence of a text can then be summarized by the overall probability of topic shift from the first sentence to the last. Following these two directions, Soricut and Marcu (2006) and Elsner et al. (2007) combined the entity-based and HMM-based models and demonstrated that these two models are complementary to each other in coherence assessment.

Our approach differs from these models in that it introduces and operationalizes another indicator of discourse coherence, by modeling a text's discourse relation transitions. Karamanis (2007) has tried to integrate local discourse relations into the Centering-based coherence metrics for the task of information ordering, but was not able to obtain improvement over the baseline method, which is partly due to the much smaller data set and the way the discourse relation information is utilized in heuristic constraints and rules.

To implement our proposal, we need to identify the text's discourse relations. This task, *discourse parsing*, has been a recent focus of study in the natural language processing (NLP) community, largely enabled by the availability of large-scale discourse annotated corpora (Wellner and Pustejovsky, 2007; Elwell and Baldridge, 2008; Lin et al., 2009; Pitler et al., 2009; Pitler and Nenkova, 2009; Lin et al., 2010; Wang et al., 2010). The Penn Discourse Treebank (PDTB) (Prasad et al., 2008) is such a corpus which provides a discourse-level annotation on top of the Penn Treebank, following a predicate-argument approach (Webber, 2004). Crucially, the PDTB provides annotations not only on explicit (*i.e.*, signaled by discourse connectives such as *because*) discourse relations, but also implicit (*i.e.*, inferred by readers) ones.

3 Using Discourse Relations

To utilize discourse relations of a text, we first apply automatic discourse parsing on the input text. While any discourse framework, such as the Rhetorical Structure Theory (RST), could be applied in our work to encode discourse information, we have chosen to work with the Discourse Lexicalized Tree Adjoining Grammar (D-LTAG) by Webber (2004) as embodied in the PDTB, as a PDTB-styled discourse parser[1] developed by Lin et al. (2010) has recently become freely available.

This parser tags each explicit/implicit relation with two levels of relation types. In this work, we utilize the four PDTB Level-1 types: Temporal (Temp), Contingency (Cont), Comparison (Comp), and Expansion (Exp). This parser automatically identifies the discourse relations, labels the argument spans, and classifies the relation types, including identifying common entity and no relation (EntRel and NoRel) as types.

A simple approach to directly model the connections among discourse relations is to use the sequence of discourse relation transitions. Text (2) in Section 1 can be represented by $S_1 \stackrel{Comp}{\longrightarrow} S_2 \stackrel{Cont}{\longrightarrow} S_3$, for instance, when we use Level-1 types. In such a basic approach, we can compile a distribu-

[1] http://wing.comp.nus.edu.sg/~linzihen/parser/

tion of the n-gram discourse relation transition sequences in gold standard coherent text, and a similar one for incoherent text. For example, the above text would generate the transition bigram Comp→Cont. We can build a classifier to distinguish one from the other through learned examples or using a suitable distribution distance measure (*e.g.*, KL Divergence).

In our pilot work where we implemented such a basic model with n-gram features for relation transitions, the performance was very poor. Our analysis revealed a serious shortcoming: as the discourse relation transitions in short texts are few in number, we have very little data to base the coherence judgment on. However, when faced with even short text excerpts, humans can distinguish coherent texts from incoherent ones, as exemplified in our example texts. The basic approach also does not model the intra-relation preference. In Text (1), a Comparison (Comp) relation would be recorded between the two sentences, irregardless of whether S_1 or S_2 comes first. However, it is clear that the ordering of ($S_1 \prec S_2$) is more coherent.

4 A Refined Approach

The central problem with the basic approach is in its sparse modeling of discourse relations. In developing an improved model, we need to better exploit the discourse parser's output to provide more circumstantial evidence to support the system's coherence decision.

In this section, we introduce the concept of a discourse role matrix which aims to capture an expanded set of discourse relation transition patterns. We describe how to represent the coherence of a text with its discourse relations and how to transform such information into a matrix representation. We then illustrate how we use the matrix to formulate a preference ranking problem.

4.1 Discourse Role Matrix

Figure 1 shows a text and its gold standard PDTB discourse relations. When a term appears in a discourse relation, the discourse role of this term is defined as the discourse relation type plus the argument span in which the term is located (*i.e.*, the argument tag). For instance, consider the term "cananea" in the first relation. Since the relation type is a

[Japan normally depends heavily on the Highland Valley and **Cananea** mines as well as the Bougainville mine in Papua New Guinea. $]_{S_1}$ [Recently, Japan has been buying copper elsewhere. $]_{S_2}$ [[But as Highland Valley and **Cananea** begin operating, $]_{C_{3.1}}$ [they are expected to resume their roles as Japan's suppliers. $]_{C_{3.2}}$ $]_{S_3}$ [[According to Fred Demler, metals economist for Drexel Burnham Lambert, New York, $]_{C_{4.1}}$ ["Highland Valley has already started operating $]_{C_{4.2}}$ [and **Cananea** is expected to do so soon." $]_{C_{4.3}}$ $]_{S_4}$

5 discourse relations are present in the above text:

1. Implicit Comparison between S_1 as Arg1, and S_2 as Arg2
2. Explicit Comparison using "but" between S_2 as Arg1, and S_3 as Arg2
3. Explicit Temporal using "as" within S_3 (Clause $C_{3.1}$ as Arg1, and $C_{3.2}$ as Arg2)
4. Implicit Expansion between S_3 as Arg1, and S_4 as Arg2
5. Explicit Expansion using "and" within S_4 (Clause $C_{4.2}$ as Arg1, and $C_{4.3}$ as Arg2)

Figure 1: An excerpt with four contiguous sentences from wsj_0437, showing five gold standard discourse relations. "Cananea" is highlighted for illustration.

S#	Terms				
	copper	cananea	operat	depend	…
S_1	nil	Comp.Arg1	nil	Comp.Arg1	
S_2	Comp.Arg2 Comp.Arg1	nil	nil	nil	
S_3	nil	Comp.Arg2 Temp.Arg1 Exp.Arg1	Comp.Arg2 Temp.Arg1 Exp.Arg1	nil	
S_4	nil	Exp.Arg2	Exp.Arg1 Exp.Arg2	nil	

Table 1: Discourse role matrix fragment for Figure 1. Rows correspond to sentences, columns to stemmed terms, and cells contain extracted discourse roles.

Comparison and "cananea" is found in the Arg1 span, the discourse role of "cananea" is defined as Comp.Arg1. When terms appear in different relations and/or argument spans, they obtain different discourse roles in the text. For instance, "cananea" plays a different discourse role of Temp.Arg1 in the third relation in Figure 1. In the fourth relation, since "cananea" appears in both argument spans, it has two additional discourse roles, Exp.Arg1 and

Exp.Arg2. The discourse role matrix thus represents the different discourse roles of the terms across the continuous text units. We use sentences as the text units, and define terms to be the stemmed forms of the open class words: nouns, verbs, adjectives, and adverbs. We formulate the discourse role matrix such that it encodes the discourse roles of the terms across adjacent sentences.

Table 1 shows a fragment of the matrix representation of the text in Figure 1. Columns correspond to the extracted terms; rows, the contiguous sentences. A cell C_{T_i,S_j} then contains the set of the discourse roles of the term T_i that appears in sentence S_j. For example, the term "cananea" from S_1 takes part in the first relation, so the cell $C_{cananea,S_1}$ contains the role Comp.Arg1. A cell may be empty (*nil*, as in $C_{cananea,S_2}$) or contain multiple discourse roles (as in $C_{cananea,S_3}$, as "cananea" in S_3 participates in the second, third, and fourth relations). Given these discourse relations, building the matrix is straightforward: we note down the relations that a term T_i from a sentence S_j participates in, and record its discourse roles in the respective cell.

We hypothesize that the sequence of discourse role transitions in a coherent text provides clues that distinguish it from an incoherent text. The discourse role matrix thus provides the foundation for computing such role transitions, on a per term basis. In fact, each column of the matrix corresponds to a lexical chain (Morris and Hirst, 1991) for a particular term across the whole text. The key differences from the traditional lexical chains are that our chain nodes' entities are simplified (they share the same stemmed form, instead being connected by WordNet relations), but are further enriched by being typed with discourse relations.

We compile the set of sub-sequences of discourse role transitions for every term in the matrix. These transitions tell us how the discourse role of a term varies through the progression of the text. For instance, "cananea" functions as Comp.Arg1 in S_1 and Comp.Arg2 in S_3, and plays the role of Exp.Arg1 and Exp.Arg2 in S_3 and S_4, respectively. As we have six relation types (Temp(oral), Cont(ingency), Comp(arison), Exp(ansion), EntRel and NoRel) and two argument tags (Arg1 and Arg2) for each type, we have a total of $6 \times 2 = 12$ possible discourse roles, plus a *nil* value. We define a *discourse role transition* as the sub-sequence of discourse roles for a term in multiple consecutive sentences. For example, the discourse role transition of "cananea" from S_1 to S_2 is Comp.Arg1→nil. As a cell may contain multiple discourse roles, a transition may produce multiple sub-sequences. For example, the length 2 sub-sequences for "cananea" from S_3 to S_4, are Comp.Arg2→Exp.Arg2, Temp.Arg1→Exp.Arg2, and Exp.Arg1→Exp.Arg2.

Each sub-sequence has a probability that can be computed from the matrix. To illustrate the calculation, suppose the matrix fragment in Table 1 is the entire discourse role matrix. Then since there are in total 25 length 2 sub-sequences and the sub-sequence Comp.Arg2→Exp.Arg2 has a count of two, its probability is $2/25 = 0.08$. A key property of our approach is that, while discourse transitions are captured locally on a per-term basis, the probabilities of the discourse transitions are aggregated globally, across all terms. We believe that the overall distribution of discourse role transitions for a coherent text is distinguishable from that for an incoherent text. Our model captures the distributional differences of such sub-sequences in coherent and incoherent text in training to determine an unseen text's coherence. To evaluate the coherence of a text, we extract sub-sequences with various lengths from the discourse role matrix as features[2] and compute the sub-sequence probabilities as the feature values.

To further refine the computation of the sub-sequence distribution, we follow (Barzilay and Lapata, 2005) and divide the matrix into a salient matrix and a non-salient matrix. Terms (columns) with a frequency greater than a threshold form the salient matrix, while the rest form the non-salient matrix. The sub-sequence distributions are then calculated separately for these two matrices.

4.2 Preference Ranking

While some texts can be said to be simply coherent or incoherent, often it is a matter of degree. A text can be less coherent when compared to one text, but more coherent when compared to another. As such, since the notion of coherence is relative, we feel that coherence assessment is better represented as

[2]Sub-sequences consisting of only *nil* values are not used as features.

a ranking problem rather than a classification problem. Given a pair of texts, the system ranks them based on how coherent they are. Applications of such a system include differentiating a text from its permutation (*i.e.*, the sentence ordering of the text is shuffled) and identifying a more well-written essay from a pair. Such a system can easily generalize from pairwise ranking into listwise, suitable for the ordinal ranking of a set of texts. Coherence scoring equations can also be deduced (Lapata and Barzilay, 2005) from such a model, yielding coherence scores.

To induce a model for preference ranking, we use the SVM^{light} package[3] by (Joachims, 1999) with the preference ranking configuration for training and testing. All parameters are set to their default values.

5 Experiments

We evaluate our coherence model on the task of *text ordering ranking*, a standard coherence evaluation task used in both (Barzilay and Lapata, 2005) and (Elsner et al., 2007). In this task, the system is asked to decide which of two texts is more coherent. The pair of texts consists of a source text and one of its permutations (*i.e.*, the text's sentence order is randomized). Assuming that the original text is always more discourse-coherent than its permutation, an ideal system will prefer the original to the permuted text. A system's accuracy is thus the number of times the system correctly chooses the original divided by the total number of test pairs.

In order to acquire a large data set for training and testing, we follow the approach in (Barzilay and Lapata, 2005) to create a collection of synthetic data from *Wall Street Journal* (WSJ) articles in the Penn Treebank. All of the WSJ articles are randomly split into a training and a testing set; 40 articles are held out from the training set for development. For each article, its sentences are permuted up to 20 times to create a set of permutations[4]. Each permutation is paired with its source text to form a pair.

We also evaluate on two other data collections (cf. Table 2), provided by (Barzilay and Lapata, 2005), for a direct comparison with their entity-based model. These two data sets consist of Associated Press articles about earthquakes from the North American News Corpus, and narratives from the National Transportation Safety Board. These collections are much smaller than the WSJ data, as each training/testing set contains only up to 100 source articles. Similar to the WSJ data, we construct pairs by permuting each source article up to 20 times.

		WSJ	Earthquakes	Accidents
Train	# Articles	1040	97	100
	# Pairs	19120	1862	1996
	Avg. # Sents	22.0	10.4	11.5
Test	# Articles	1079	99	100
	# Pairs	19896	1956	1986

Table 2: Details of the WSJ, Earthquakes, and Accidents data sets, showing the number of training/testing articles, number of pairs of articles, and average length of an article (in sentences).

Our model has two parameters: (1) the term frequency (TF) that is used as a threshold to identify salient terms, and (2) the lengths of the subsequences that are extracted as features. These parameters are tuned on the development set, and the best ones that produce the optimal accuracy are TF $>= 2$ and lengths of the sub-sequences $<= 3$.

We must also be careful in using the automatic discourse parser. We note that the discourse parser of Lin et al. (2010) comes trained on the PDTB, which provides annotations on top of the whole WSJ data. As we also use the WSJ data for evaluation, we must avoid parsing an article that has already been used in training the parser to prevent training on the test data. We re-train the parser with 24 WSJ sections and use the trained parser to parse the sentences in our WSJ collection from the remaining section. We repeat this re-training/parsing process for all 25 sections. Because the Earthquakes and Accidents data do not overlap with the WSJ training data, we use the parser as distributed to parse these two data sets. Since the discourse parser utilizes paragraph boundaries but a permuted text does not have such boundaries, we ignore paragraph boundaries and treat the source text as if it has only one paragraph. This is to make sure that we do not give the system extra information because of this difference between the source and permuted text.

[3] `http://svmlight.joachims.org/`

[4] Short articles may produce less than 20 permutations.

5.1 Human Evaluation

While the text ordering ranking task has been used in previous studies, two key questions about this task have remained unaddressed in the previous work: (1) to what extent is the assumption that the source text is more coherent than its permutation correct? and (2) how well do humans perform on this task? The answer to the first is needed to validate the correctness of this synthetic task, while the second aims to obtain the upper bound for evaluation. We conduct a human evaluation to answer these questions.

We randomly select 50 source text/permutation pairs from each of the WSJ, Earthquakes, and Accidents training sets. We observe that some of the source texts have formulaic structures in their initial sentences that give away the correct ordering. Sources from the Earthquakes data always begin with a headline sentence and a location-newswire sentence, and many sources from the Accidents data start with two sentences of "This is preliminary ... errors. Any errors ... completed." We remove these sentences from the source and permuted texts, to avoid the subjects judging based on these clues instead of textual coherence. For each set of 50 pairs, we assigned two human subjects (who are not authors of this paper) to perform the ranking. The subjects are told to identify the source text from the pair. When both subjects rank a source text higher than its permutation, we interpret it as the subjects agreeing that the source text is more coherent than the permutation. Table 3 shows the inter-subject agreements.

WSJ	Earthquakes	Accidents	Overall
90.0	90.0	94.0	91.3

Table 3: Inter-subject agreements on the three data sets.

While our study is limited and only indicative, we conclude from these results that the task is tractable. Also, since our subjects' judgments correlate highly with the gold standard, the assumption that the original text is always more coherent than the permuted text is supported. Importantly though, human performance is not perfect, suggesting fair upper bound limits on system performance. We note that the Accidents data set is relatively easier to rank, as it has a higher upper bound than the other two.

5.2 Baseline

Barzilay and Lapata (2005) showed that their entity-based model is able to distinguish a source text from its permutation accurately. Thus, it can serve as a good comparison point for our discourse relation-based model. We compare against their Syntax+Salience setting. Since they did not automatically determine the coreferential information of a permuted text but obtained that from its corresponding source text, we do not perform automatic coreference resolution in our reimplementation of their system. For fair comparison, we follow their experiment settings as closely as possible. We re-use their Earthquakes and Accidents dataset as is, using their exact permutations and pre-processing. For the WSJ data, we need to perform our own pre-processing, thus we employed the Stanford parser[5] to perform sentence segmentation and constituent parsing, followed by entity extraction.

5.3 Results

We perform a series of experiments to answer the following four questions:

1. Does our model outperform the baseline?
2. How do the different features derived from using relation types, argument tags, and salience information affect performance?
3. Can the combination of the baseline and our model outperform the single models?
4. How does system performance of these models compare with human performance on the task?

Baseline results are shown in the first row of Table 4. The results on the Earthquakes and Accidents data are quite similar to those published in (Barzilay and Lapata, 2005) (they reported 83.4% on Earthquakes and 89.7% on Accidents), validating the correctness of our reimplementation of their method.

Row 2 in Table 4 shows the overall performance of the proposed refined model, answering Question 1. The model setting of Type+Arg+Sal means that the model makes use of the discourse roles consisting of 1) relation types and 2) argument tags (*e.g.*,

[5] `http://nlp.stanford.edu/software/lex-parser.shtml`

	WSJ	Earthquakes	Accidents
Baseline	85.71	83.59	89.93
Type+Arg+Sal	**88.06****	**86.50****	**89.38**
Arg+Sal	88.28**	85.89*	87.06
Type+Sal	87.06**	82.98	86.05
Type+Arg	85.98	82.67	87.87
Baseline & Type+Arg+Sal	89.25**	89.72**	91.64**

Table 4: Test set ranking accuracy. The first row shows the baseline performance, the next four show our model with different settings, and the last row is a combined model. Double (**) and single (*) asterisks indicate that the respective model significantly outperforms the baseline at $p < 0.01$ and $p < 0.05$, respectively. We follow Barzilay and Lapata (2008) and use the Fisher Sign test.

the discourse role Comp.Arg2 consists of the type Comp(arison) and the tag Arg2), and 3) two distinct feature sets from salient and non-salient terms. Comparing these accuracies to the baseline, our model significantly outperforms the baseline with $p < 0.01$ in the WSJ and Earthquakes data sets with accuracy increments of 2.35% and 2.91%, respectively. In Accidents, our model's performance is slightly lower than the baseline, but the difference is not statistically significant.

To answer Question 2, we perform feature ablation testing. We eliminate each of the information sources from the full model. In **Row 3**, we first delete relation types from the discourse roles, which causes discourse roles to only contain the argument tags. A discourse role such as Comp.Arg2 becomes Arg2 after deleting the relation type. Comparing Row 3 to Row 2, we see performance reductions on the Earthquakes and Accidents data after eliminating type information. **Row 4** measures the effect of omitting argument tags (Type+Sal). In this setting, the discourse role Comp.Arg2 reduces to Comp. We see a large reduction in performance across all three data sets. This model is also most similar to the basic naïve model in Section 3. These results suggest that the argument tag information plays an important role in our discourse role transition model. **Row 5** omits the salience information (Type+Arg), which also markedly reduces performance. This result supports the use of salience, in line with the conclusion drawn in (Barzilay and Lapata, 2005).

To answer Question 3, we train and test a combined model using features from both the baseline and our model (shown as **Row 6** in Table 4). The entity-based model of Barzilay and Lapata (2005) connects the local entity transition with textual coherence, while our model looks at the patterns of discourse relation transitions. As these two models focus on different aspects of coherence, we expect that they are complementary to each other. The combined model in all three data sets gives the highest performance in comparison to all single models, and it significantly outperforms the baseline model with $p < 0.01$. This confirms that the combined model is linguistically richer than the single models as it integrates different information together, and the entity-based model and our model are synergistic.

To answer Question 4, when compared to the human upper bound (Table 3), the performance gaps for the baseline model are relatively large, while those for our full model are more acceptable in the WSJ and Earthquakes data. For the combined model, the error rates are significantly reduced in all three data sets. The average error rate reductions against 100% are 9.57% for the full model and 26.37% for the combined model. If we compute the average error rate reductions against the human upper bounds (rather than an oracular 100%), the average error rate reduction for the full model is 29% and that for the combined model is 73%. While these are only indicative results, they do highlight the significant gains that our model is making towards reaching human performance levels.

We further note that some of the permuted texts may read as coherently as the original text. This phenomenon has been observed in several natural language synthesis tasks such as generation and summarization, in which a single gold standard is inadequate to fully assess performance. As such, both automated systems and humans may actually perform better than our performance measures indicate. We leave it to future work to measure the impact of this phenomenon.

6 Analysis and Discussion

When we compare the accuracies of the full model in the three data sets (Row 2), the accuracy in the Accidents data is the highest (89.38%), followed by

that in the WSJ (88.06%), with Earthquakes at the lowest (86.50%). To explain the variation, we examine the ratio between the number of the relations in the article and the article length (*i.e.*, number of sentences). This ratio is 1.22 for the Accidents source articles, 1.2 for the WSJ, and 1.08 for Earthquakes. The relation/length ratio gives us an idea of how often a sentence participates in discourse relations. A high ratio means that the article is densely interconnected by discourse relations, and may make distinguishing this article from its permutation easier compared to that for a loosely connected article.

We expect that when a text contains more discourse relation types (*i.e.*, Temporal, Contingency, Comparison, Expansion) and less EntRel and NoRel types, it is easier to compute how coherent this text is. This is because compared to EntRel and NoRel, these four discourse relations can combine to produce meaningful transitions, such as the example Text (2). To examine how this affects performance, we calculate the average ratio between the number of the four discourse relations in the permuted text and the length for the permuted text. The ratio is 0.58 for those that are correctly ranked by our system, and 0.48 for those that are incorrectly ranked, which supports our hypothesis.

We also examined the learning curves for our Type+Arg+Sal model, the baseline model, and the combined model on the data sets, as shown in Figure 2(a)–2(c). In the WSJ data, the accuracies for all three models increase rapidly as more pairs are added to the training set. After 2,000 pairs, the increase slows until 8,000 pairs, after which the curve is nearly flat. From the curves, our model consistently performs better than the baseline with a significant gap, and the combined model also consistently and significantly outperforms the other two. Only about half of the total training data is needed to reach optimal performance for all three models. The learning curves in the Earthquakes data show that the performance for all models is always increasing as more training pairs are utilized. The Type+Arg+Sal and combined models start with lower accuracies than the baseline, but catch up with it at 1,000 and 400 pairs, respectively, and consistently outperform the baseline beyond this point. On the other hand, the learning curves for the Type+Arg+Sal and baseline models in Accidents do not show any one curve consistently better than the other: our model outperforms in the middle segment but underperforms in the first and last segments. The curve for the combined model shows a consistently significant gap between it and the other two curves after the point at 400 pairs.

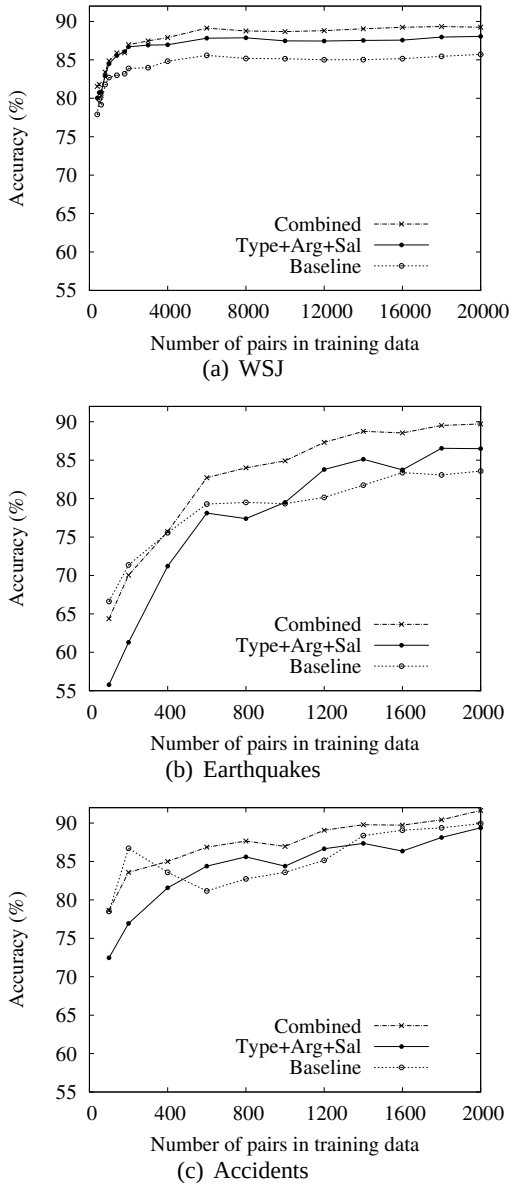

Figure 2: Learning curves for the Type+Arg+Sal, the baseline, and the combined models on the three data sets.

With the performance of the model as it is, how can future work improve upon it? We point out one weakness that we plan to explore. We use the full Type+Arg+Sal model trained on the WSJ training

data to test Text (2) from the introduction. As (2) has 3 sentences, permuting it gives rise to 5 permutations. The model is able to correctly rank four of these 5 pairs. The only permutation it fails on is ($S_3 \prec S_1 \prec S_2$), when the last sentence is moved to the beginning. A very good clue of coherence in Text (2) is the explicit Comp relation between S_1 and S_2. Since this clue is retained in ($S_3 \prec S_1 \prec S_2$), it is difficult for the system to distinguish this ordering from the source. In contrast, as this clue is not present in the other four permutations, it is easier to distinguish them as incoherent. By modeling longer range discourse relation transitions, we may be able to discern these two cases.

While performance on identifying explicit discourse relations in the PDTB is as high as 93% (Pitler et al., 2008), identifying implicit ones has been shown to be a difficult task with accuracy of 40% at Level-2 types (Lin et al., 2009). As the overall performance of the PDTB parser is still less accurate than we hope it to be, we expect that our proposed model will give better performance than it does now, when the current PDTB parser performance is improved.

7 Conclusion

We have proposed a new model for discourse coherence that leverages the observation that coherent texts preferentially follow certain discourse structures. We posit that these structures can be captured in and represented by the patterns of discourse relation transitions. We first demonstrate that simply using the sequence of discourse relation transition leads to sparse features and is insufficient to distinguish coherent from incoherent text. To address this, our method transforms the discourse relation transitions into a discourse role matrix. The matrix schematically represents term occurrences in text units and associates each occurrence with its discourse roles in the text units. In our approach, n-gram sub-sequences of transitions per term in the discourse role matrix then constitute the more fine-grained evidence used in our model to distinguish coherence from incoherence.

When applied to distinguish a source text from a sentence-reordered permutation, our model significantly outperforms the previous state-of-the-art, the entity-based local coherence model. While the entity-based model captures repetitive mentions of entities, our discourse relation-based model gleans its evidence from the argumentative and discourse structure of the text. Our model is complementary to the entity-based model, as it tackles the same problem from a different perspective. Experiments validate our claim, with a combined model outperforming both single models.

The idea of modeling coherence with discourse relations and formulating it in a discourse role matrix can also be applied to other NLP tasks. We plan to apply our methodology to other tasks, such as summarization, text generation and essay scoring, which also need to produce and assess discourse coherence.

Underspecifying and Predicting Voice for Surface Realisation Ranking

Sina Zarrieß, Aoife Cahill and Jonas Kuhn
Institut für maschinelle Sprachverarbeitung
Universität Stuttgart, Germany
{sina.zarriess,aoife.cahill,jonas.kuhn}@ims.uni-stuttgart.de

Abstract

This paper addresses a data-driven surface realisation model based on a large-scale reversible grammar of German. We investigate the relationship between the surface realisation performance and the character of the input to generation, i.e. its degree of underspecification. We extend a syntactic surface realisation system, which can be trained to choose among word order variants, such that the candidate set includes active and passive variants. This allows us to study the interaction of voice and word order alternations in realistic German corpus data. We show that with an appropriately underspecified input, a linguistically informed realisation model trained to regenerate strings from the underlying semantic representation achieves 91.5% accuracy (over a baseline of 82.5%) in the prediction of the original voice.

1 Introduction

This paper[1] presents work on modelling the usage of voice and word order alternations in a free word order language. Given a set of meaning-equivalent candidate sentences, such as in the simplified English Example (1), our model makes predictions about which candidate sentence is most appropriate or natural given the context.

(1) Context: *The Parliament started the debate about the state budget in April.*

a. It wasn't until June that the Parliament approved it.
b. It wasn't until June that it was approved by the Parliament.
c. It wasn't until June that it was approved.

We address the problem of predicting the usage of linguistic alternations in the framework of a *surface realisation ranking* system. Such ranking systems are practically relevant for the real-world application of grammar-based generators that usually generate several grammatical surface sentences from a given abstract input, e.g. (Velldal and Oepen, 2006). Moreover, this framework allows for detailed experimental studies of the interaction of specific linguistic features. Thus it has been demonstrated that for free word order languages like German, word order prediction quality can be improved with carefully designed, linguistically informed models capturing information-structural strategies (Filippova and Strube, 2007; Cahill and Riester, 2009).

This paper is situated in the same framework, using rich linguistic representations over corpus data for machine learning of realisation ranking. However, we go beyond the task of finding the correct ordering for an almost fixed set of word forms. Quite obviously, word order is only one of the means at a speaker's disposal for expressing some content in a contextually appropriate form; we add systematic alternations like the voice alternation (active vs. passive) to the picture. As an alternative way of promoting or demoting the prominence of a syntactic argument, its interaction with word ordering strategies in real corpus data is of high theoretical interest (Aissen, 1999; Aissen, 2003; Bresnan et al., 2001).

Our main goals are (i) to establish a corpus-based surface realisation framework for empirically investigating interactions of voice and word order in German, (ii) to design an input representation for generation capturing voice alternations in a variety of contexts, (iii) to better understand the relationship between the performance of a generation ranking model and the type of realisation candidates available in its input. In working towards these goals, this paper addresses the question of evaluation. We conduct a pilot human evaluation on the voice al-

Portland, Oregon, June 19-24, 2011.

ternation data and relate our findings to our results established in the automatic ranking experiments.

Addressing interactions among a range of grammatical and discourse phenomena on realistic corpus data turns out to be a major methodological challenge for data-driven surface realisation. The set of candidate realisations available for ranking will influence the findings, and here, existing surface realisers vary considerably. Belz et al. (2010) point out the differences across approaches in the type of syntactic and semantic information present and absent in the input representation; and it is the type of underspecification that determines the number (and character) of available candidate realisations and, hence, the complexity of the realisation task.

We study the effect of varying degrees of underspecification explicitly, extending a syntactic generation system by a semantic component capturing voice alternations. In regeneration studies involving underspecified underlying representations, corpus-oriented work reveals an additional methodological challenge. When using standard semantic representations, as common in broad-coverage work in semantic parsing (i.e., from the point of view of analysis), alternative variants for sentence realisation will often receive slightly different representations: In the context of (1), the continuation (1-c) is presumably more natural than (1-b), but with a standard sentence-bounded semantic analysis, only (1-a) and (1-b) would receive equivalent representations.

Rather than waiting for the availability of robust and reliable techniques for detecting the reference of implicit arguments in analysis (or for contextually aware reasoning components), we adopt a relatively simple heuristic approach (see Section 3.1) that approximates the desired equivalences by augmented representations for examples like (1-c). This way we can overcome an extremely skewed distribution in the naturally occurring meaning-equivalent active vs. passive sentences, a factor which we believe justifies taking the risk of occasional overgeneration.

The paper is structured as follows: Section 2 situates our methodology with respect to other work on surface realisation and briefly summarises the relevant theoretical linguistic background. In Section 3, we present our generation architecture and the design of the input representation. Section 4 describes the setup for the experiments in Section 5. In Section 6, we present the results from the human evaluation.

2 Related Work

2.1 Generation Background

The first widely known data-driven approach to surface realisation, or tactical generation, (Langkilde and Knight, 1998) used language-model n-gram statistics on a word lattice of candidate realisations to guide a ranker. Subsequent work explored ways of exploiting linguistically annotated data for trainable generation models (Ratnaparkhi, 2000; Marciniak and Strube, 2005; Belz, 2005, a.o.). Work on data-driven approaches has led to insights into the importance of linguistic features for sentence linearisation decisions (Ringger et al., 2004; Filippova and Strube, 2009). The availability of discriminative learning techniques for the ranking of candidate analyses output by broad-coverage grammars with rich linguistic representations, originally in parsing (Riezler et al., 2000; Riezler et al., 2002), has also led to a revival of interest in linguistically sophisticated reversible grammars as the basis for surface realisation (Velldal and Oepen, 2006; Cahill et al., 2007). The grammar generates candidate analyses for an underlying representation and the ranker's task is to predict the contextually appropriate realisation.

The work that is most closely related to ours is Velldal (2008). He uses an MRS representation derived by an HPSG grammar that can be underspecified for information status. In his case, the underspecification is encoded in the grammar and not directly controlled. In multilingually oriented linearisation work, Bohnet et al. (2010) generate from semantic corpus annotations included in the CoNLL'09 shared task data. However, they note that these annotations are not suitable for full generation since they are often incomplete. Thus, it is not clear to which degree these annotations are actually underspecified for certain paraphrases.

2.2 Linguistic Background

In competition-based linguistic theories (Optimality Theory and related frameworks), the use of argument alternations is construed as an effect of markedness hierarchies (Aissen, 1999; Aissen, 2003). Argument functions (subject, object, ...) on

the one hand and the various properties that argument phrases can bear (person, animacy, definiteness) on the other are organised in markedness hierarchies. Wherever possible, there is a tendency to *align* the hierarchies, i.e., use prominent functions to realise prominently marked argument phrases. For instance, Bresnan et al. (2001) find that there is a statistical tendency in English to passivise a verb if the patient is higher on the person scale than the agent, but an active is grammatically possible.

Bresnan et al. (2007) correlate the use of the English dative alternation to a number of features such as givenness, pronominalisation, definiteness, constituent length, animacy of the involved verb arguments. These features are assumed to reflect the discourse acessibility of the arguments.

Interestingly, the properties that have been used to model argument alternations in strict word order languages like English have been identified as factors that influence word order in free word order languages like German, see Filippova and Strube (2007) for a number of pointers. Cahill and Riester (2009) implement a model for German word order variation that approximates the information status of constituents through morphological features like definiteness, pronominalisation etc. We are not aware of any corpus-based generation studies investigating how these properties relate to argument alternations in free word order languages.

3 Generation Architecture

Our data-driven methodology for investigating factors relevant to surface realisation uses a regeneration set-up[2] with two main components: a) a grammar-based component used to parse a corpus sentence and map it to all its meaning-equivalent surface realisations, b) a statistical ranking component used to select the correct, i.e. contextually most appropriate surface realisation. Two variants of this set-up that we use are sketched in Figure 1.

We generally use a hand-crafted, broad-coverage LFG for German (Rohrer and Forst, 2006) to parse a corpus sentence into a f(unctional) structure[3] and generate all surface realisations from a given

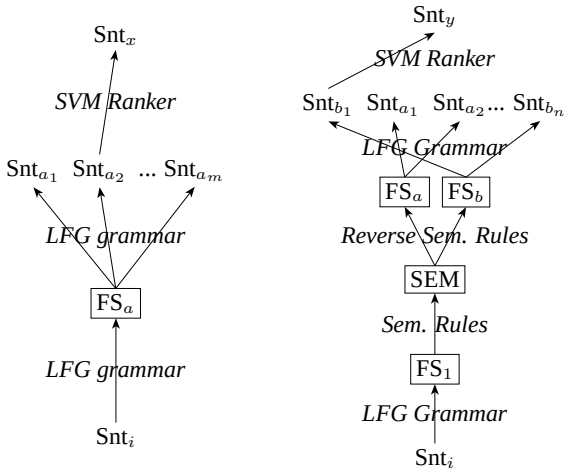

Figure 1: Generation pipelines

f-structure, following the generation approach of Cahill et al. (2007). F-structures are attribute-value matrices representing grammatical functions and morphosyntactic features; their theoretical motivation lies in the abstraction over details of surface realisation. The grammar is implemented in the XLE framework (Crouch et al., 2006), which allows for reversible use of the same declarative grammar in the parsing and generation direction.

To obtain a more abstract underlying representation (in the pipeline on the right-hand side of Figure 1), the present work uses an additional semantic construction component (Crouch and King, 2006; Zarrieß, 2009) to map LFG f-structures to meaning representations. For the reverse direction, the meaning representations are mapped to f-structures which can then be mapped to surface strings by the XLE generator (Zarrieß and Kuhn, 2010).

For the final realisation ranking step in both pipelines, we used SVMrank, a Support Vector Machine-based learning tool (Joachims, 1996). The ranking step is thus technically independent from the LFG-based component. However, the grammar is used to produce the training data, pairs of corpus sentences and the possible alternations.

The two pipelines allow us to vary the degree to which the generation input is underspecified. An f-structure abstracts away from word order, i.e. the candidate set will contain just word order alternations. In the semantic input, syntactic function and voice are underspecified, so a larger set of surface realisation candidates is generated. Figure 2 illustrates the two representation levels for an active and

[2]Compare the bidirectional competition set-up in some Optimality-Theoretic work, e.g., (Kuhn, 2003).

[3]The choice among alternative f-structures is done with a discriminative model (Forst, 2007).

a passive sentence. The subject of the passive and the object of the active f-structure are mapped to the same role (patient) in the meaning representation.

3.1 Issues with "naive" underspecification

In order to create an underspecified voice representation that does indeed leave open the realisation options available to the speaker/writer, it is often not sufficient to remove just the syntactic function information. For instance, the subject of the active sentence (2) is an arbitrary reference pronoun *man "one"* which cannot be used as an oblique agent in a passive, sentence (2-b) is ungrammatical.

(2) a. Man hat den Kanzler gesehen.
One has the chancellor seen.
b. *Der Kanzler wurde von man gesehen.
The chancellor was by one seen.

So, when combined with the grammar, the meaning representation for (2) in Figure 2 contains implicit information about the voice of the original corpus sentence; the candidate set will not include any passive realisations. However, a passive realisation without the oblique agent in the *by*-phrase, as in Example (3), is a very natural variant.

(3) Der Kanzler wurde gesehen.
The chancellor was seen.

The reverse situation arises frequently too: passive sentences where the agent role is not overtly realised. Given the standard, "analysis-oriented" meaning representation for Sentence (4) in Figure 2, the realiser will not generate an active realisation since the agent role cannot be instantiated by any phrase in the grammar. However, depending on the exact context there are typically options for realising the subject phrase in an active with very little descriptive content.

Ideally, one would like to account for these phenomena in a meaning representation that underspecifies the lexicalisation of discourse referents, and also captures the reference of implicit arguments. Especially the latter task has hardly been addressed in NLP applications (but see Gerber and Chai (2010)). In order to work around that problem, we implemented some simple heuristics which underspecify the realisation of certain verb arguments. These rules define: 1. a set of pronouns (generic and neutral pronouns, universal quantifiers) that correspond to "trivial" agents in active and implicit agents in passive sentences; 2. a set of prepositional adjuncts in passive sentences that correspond to subjects in active sentence (e.g. causative and instrumental prepositions like *durch* "*by means of*"); 3. certain syntactic contexts where special underspecification devices are needed, e.g. coordinations or embeddings, see Zarrieß and Kuhn (2010) for examples. In the following, we will distinguish 1-role transitives where the agent is "trivial" or implicit from 2-role transitives with a non-implicit agent.

	Active	Passive
2-role trans.	71% (82%)	10% (2%)
1-role trans.	11% (0%)	8% (16%)

Table 1: Distribution of voices in SEM_h (SEM_n)

By means of the extended underspecification rules for voice, the sentences in (2) and (3) receive an identical meaning representation. As a result, our surface realiser can produce an active alternation for (3) and a passive alternation for (2). In the following, we will refer to the extended representations as SEM_h ("heuristic semantics"), and to the original representations as SEM_n ("naive semantics").

We are aware of the fact that these approximations introduce some noise into the data and do not always represent the underlying referents correctly. For instance, the implicit agent in a passive need not be "trivial" but can correspond to an actual discourse referent. However, we consider these heuristics as a first step towards capturing an important discourse function of the passive alternation, namely the deletion of the agent role. If we did not treat the passives with an implicit agent on a par with certain actives, we would have to ignore a major portion of the passives occurring in corpus data.

Table 1 summarises the distribution of the voices for the heuristic meaning representation SEM_h on the data-set we will introduce in Section 4, with the distribution for the naive representation SEM_n in parentheses.

4 Experimental Set-up

Data To obtain a sizable set of realistic corpus examples for our experiments on voice alternations, we created our own dataset of input sentences and representations, instead of building on treebank examples as Cahill et al. (2007) do. We extracted 19,905 sentences, all containing at least one transitive verb,

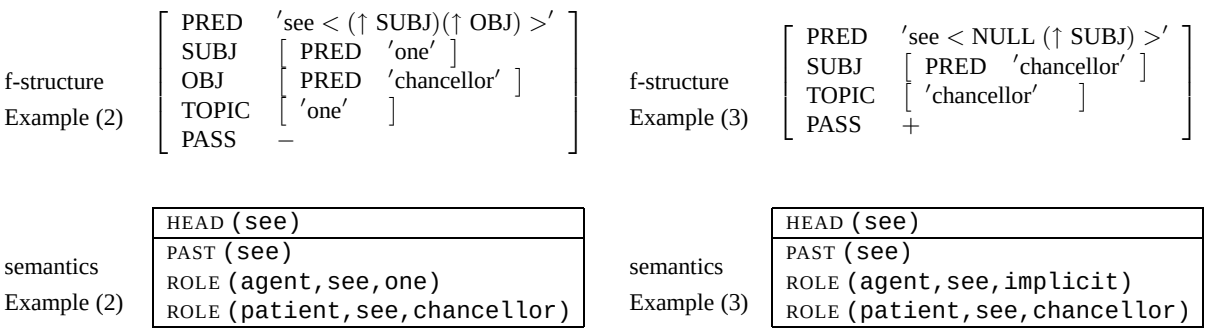

Figure 2: F-structure pair for passive-active alternation

from the HGC, a huge German corpus of newspaper text (204.5 million tokens). The sentences are automatically parsed with the German LFG grammar. The resulting f-structure parses are transferred to meaning representations and mapped back to f-structure charts. For our generation experiments, we only use those f-structure charts that the XLE generator can map back to a set of surface realisations. This results in a total of 1236 test sentences and 8044 sentences in our training set. The data loss is mostly due to the fact the XLE generator often fails on incomplete parses, and on very long sentences. Nevertheless, the average sentence length (17.28) and number of surface realisations (see Table 2) are higher than in Cahill et al. (2007).

Labelling For the training of our ranking model, we have to tell the learner how closely each surface realisation candidate resembles the original corpus sentence. We distinguish the rank categories: "1" identical to the corpus string, "2" identical to the corpus string ignoring punctuation, "3" small edit distance (< 4) to the corpus string ignoring punctuation, "4" different from the corpus sentence. In one of our experiments (Section 5.1), we used the rank category "5" to explicitly label the surface realisations derived from the alternation f-structure that does not correspond to the parse of the original corpus sentence. The intermediate rank categories "2" and "3" are useful since the grammar does not always regenerate the exact corpus string, see Cahill et al. (2007) for explanation.

Features The linguistic theories sketched in Section 2.2 correlate morphological, syntactic and semantic properties of constituents (or discourse referents) with their order and argument realisation. In our system, this correlation is modelled by a combination of linguistic properties that can be extracted from the f-structure or meaning representation and of the surface order that is read off the sentence string. Standard n-gram features are also used as features.[4] The feature model is built as follows: for every lemma in the f-structure, we extract a set of morphological properties (definiteness, person, pronominal status etc.), the voice of the verbal head, its syntactic and semantic role, and a set of informations status features following Cahill and Riester (2009). These properties are combined in two ways: a) Precedence features: relative order of properties in the surface string, e.g. "theme $<$ agent in passive", "1st person $<$ 3rd person"; b) "scale alignment" features (ScalAl.): combinations of voice and role properties with morphological properties, e.g. "subject is singular", "agent is 3rd person in active voice" (these are surface-independent, identical for each alternation candidate).

The model for which we present our results is based on sentence-internal features only; as Cahill and Riester (2009) showed, these feature carry a considerable amount of implicit information about the discourse context (e.g. in the shape of referring expressions). We also implemented a set of explicitly inter-sentential features, inspired by Centering Theory (Grosz et al., 1995). This model did not improve over the intra-sentential model.

Evaluation Measures In order to assess the general quality of our generation ranking models, we

[4]The language model is trained on the German data release for the 2009 ACL Workshop on Machine Translation shared task, 11,991,277 total sentences.

		FS	SEM$_n$	SEM$_h$
Avg. # strings		36.7	68.2	75.8
Random Match		16.98	10.72	7.28
LM	Match	15.45	15.04	11.89
	BLEU	0.68	0.68	0.65
	NIST	13.01	12.95	12.69
Ling. Model	Match	27.91	27.66	26.38
	BLEU	0.764	0.759	0.747
	NIST	13.18	13.14	13.01

Table 2: Evaluation of Experiment 1

use several standard measures: a) exact match: how often does the model select the original corpus sentence, b) BLEU: n-gram overlap between top-ranked and original sentence, c) NIST: modification of BLEU giving more weight to less frequent n-grams. Second, we are interested in the model's performance wrt. specific linguistic criteria. We report the following accuracies: d) Voice: how often does the model select a sentence realising the correct voice, e) Precedence: how often does the model generate the right order of the verb arguments (agent and patient), and f) Vorfeld: how often does the model correctly predict the verb arguments to appear in the sentence initial position before the finite verb, the so-called *Vorfeld*. See Sections 5.3 and 6 for a discussion of these measures.

5 Experiments

5.1 Exp. 1: Effect of Underspecified Input

We investigate the effect of the input's underspecification on a state-of-the-art surface realisation ranking model. This model implements the entire feature set described in Section 4 (it is further analysed in the subsequent experiments). We built 3 datasets from our alternation data: FS - candidates generated from the f-structure; SEM$_n$ - realisations from the naive meaning representations; SEM$_h$ - candidates from the heuristically underspecified meaning representation. Thus, we keep the set of original corpus sentences (=the target realisations) constant, but train and test the model on different candidate sets.

In Table 2, we compare the performance of the linguistically informed model described in Section 4 on the candidates sets against a random choice and a language model (LM) baseline. The differences in BLEU between the candidate sets and models are statistically significant.[5] In general, the linguistic model largely outperforms the LM and is less sensitive to the additional confusion introduced by the SEM$_h$ input. Its BLEU score and match accuracy decrease only slightly (though statistically significantly).

		FS	SEM$_n$	SEM$_h$	SEM$_n*$
All Trans.	Voice Acc.	100	98.06	91.05	97.59
	Voice Spec.	100	22.8	0	0
	Majority BL		82.4		98.1
2-role Trans.	Voice Acc.	100	97.7	91.8	97.59
	Voice Spec.	100	8.33	0	0
	Majority BL		88.5		98.1
1-role Trans.	Voice Acc.	100	100	90.0	-
	Voice Spec.	100	100	0	-
	Majority BL		53.9		-

Table 3: Accuracy of Voice Prediction by Ling. Model in Experiment 1

In Table 3, we report the performance of the linguistic model on the different candidate sets with respect to voice accuracy. Since the candidate sets differ in the proportion of items that underspecify the voice (see "Voice Spec." in Table 3), we also report the accuracy on the SEM$_n*$ test set, which is a subset of SEM$_n$ excluding the items where the voice is specified. Table 3 shows that the proportion of active realisations for the SEM$_n*$ input is very high, and the model does not outperform the majority baseline (which always selects active). In contrast, the SEM$_h$ model clearly outperforms the majority baseline.

Example (4) is a case from our development set where the SEM$_n$ model incorrectly predicts an active (4-a), and the SEM$_h$ correctly predicts a passive (4-b).

(4) a. 26 kostspielige Studien erwähnten die Finanzierung.
26 expensive studies mentioned the funding.

b. Die Finanzierung wurde von 26 kostspieligen Studien erwähnt.
The funding was by 26 expensive studies mentioned.

This prediction is according to the markedness hierarchy: the patient is singular and definite, the agent

[5] According to a bootstrap resampling test, $p < 0.05$

Prec.	16.3	0.70	88.43	64.1	59.1
ScalAl.	10.4	0.64	90.37	58.9	56.3
Union	26.4	0.75	91.50	80.2	70.9

Table 4: Evaluation of Experiment 2

is plural and indefinite. Counterexamples are possible, but there is a clear statistical preference – which the model was able to pick up.

On the one hand, the rankers can cope surprisingly well with the additional realisations obtained from the meaning representations. According to the global sentence overlap measures, their quality is not seriously impaired. On the other hand, the design of the representations has a substantial effect on the prediction of the alternations. The SEM$_n$ does not seem to learn certain preferences because of the extremely imbalanced distribution in the input data. This confirms the hypothesis sketched in Section 3.1, according to which the degree of the input's underspecification can crucially change the behaviour of the ranking model.

5.2 Exp. 2: Word Order and Voice

We examine the impact of certain feature types on the prediction of the variation types in our data. We are particularly interested in the interaction of voice and word order (precedence) since linguistic theories (see Section 2.2) predict similar information-structural factors guiding their use, but usually do not consider them in conjunction.

In Table 4, we report the performance of ranking models trained on the different feature subsets introduced in Section 4. The union of the features corresponds to the model trained on SEM$_h$ in Experiment 1. At a very broad level, the results suggest that the precedence and the scale alignment features interact both in the prediction of voice and word order.

The most pronounced effect on voice accuracy can be seen when comparing the precedence model to the union model. Adding the surface-independent scale alignment features to the precedence features leads to a big improvement in the prediction of word order. This is not a trivial observation since a) the surface-independent features do not discriminate between the word orders and b) the precedence features are built from the same properties (see Section 4). Thus, the SVM learner discovers dependencies between relative precedence preferences and abstract properties of a verb argument which cannot be encoded in the precedence alone.

It is worth noting that the precedence features improve the voice prediction. This indicates that wherever the application context allows it, voice should not be specified at a stage prior to word order. Example (5) is taken from our development set, illustrating a case where the union model predicted the correct voice and word order (5-a), and the scale alignment model top-ranked the incorrect voice and word order. The active verb arguments in (5-b) are both case-ambigous and placed in the non-canonical order (object $<$ subject), so the semantic relation can be easily misunderstood. The passive in (5-a) is unambiguous since the agent is realised in a PP (and placed in the Vorfeld).

(5) a. Von den deutschen Medien wurden die Ausländer
By the German media were the foreigners
nur erwähnt, wenn es Zoff gab.
only mentioned, when there trouble was.

b. Wenn es Zoff gab, erwähnten die Ausländer
When there trouble was, mentioned the foreigners
nur die deutschen Medien.
only the German media.

Moreover, our results confirm Filippova and Strube (2007) who find that it is harder to predict the correct Vorfeld occupant in a German sentence, than to predict the relative order of the constituents.

5.3 Exp. 3: Capturing Flexible Variation

The previous experiment has shown that there is a certain inter-dependence between word order and voice. This experiment addresses this interaction by varying the way the training data for the ranker is labelled. We contrast two ways of labelling the sentences (see Section 4): a) all sentences that are not (nearly) identical to the reference sentence have the rank category "4", irrespective of their voice (referred to as unlabelled model), b) the sentences that do not realise the correct voice are ranked lower than sentences with the correct voice ("4" vs. "5"), referred to as labelled model. Intuitively, the latter way of labelling tells the ranker that all sentences in the incorrect voice are worse than all sentences in the correct voice, independent of the word order. Given the first labelling strategy, the ranker can decide in an unsupervised way which combinations of word order and voice are to be preferred.

Model	Match	BLEU	NIST	Top 1 Voice	Top 1 Prec.	Top 1 Prec.+Voice	Top 2 Prec.+Voice	Top 3 Prec.+Voice
Labelled, no LM	21.52	0.73	12.93	91.9	76.25	71.01	78.35	82.31
Unlabelled, no LM	26.83	0.75	13.01	91.5	80.19	74.51	84.28	88.59
Unlabeled + LM	27.35	0.75	13.08	91.5	79.6	73.92	79.74	82.89

Table 5: Evaluation of Experiment 3

In Table 5, it can be seen that the unlabelled model improves over the labelled on all the sentence overlap measures. The improvements are statistically significant. Moreover, we compare the n-best accuracies achieved by the models for the joint prediction of voice and argument order. The unlabelled model is very flexible with respect to the word order-voice interaction: the accuracy dramatically improves when looking at the top 3 sentences. Table 5 also reports the performance of an unlabelled model that additionally integrates LM scores. Surprisingly, these scores have a very small positive effect on the sentence overlap features and no positive effect on the voice and precedence accuracy. The n-best evaluations even suggest that the LM scores negatively impact the ranker: the accuracy for the top 3 sentences increases much less as compared to the model that does not integrate LM scores.[6]

The n-best performance of a realisation ranker is practically relevant for re-ranking applications such as Velldal (2008). We think that it is also conceptually interesting. Previous evaluation studies suggest that the original corpus sentence is not always the only optimal realisation of a given linguistic input (Cahill and Forst, 2010; Belz and Kow, 2010). Humans seem to have varying preferences for word order contrasts in certain contexts. The n-best evaluation could reflect the behaviour of a ranking model with respect to the range of variations encountered in real discourse. The pilot human evaluation in the next Section deals with this question.

6 Human Evaluation

Our experiment in Section 5.3 has shown that the accuracy of our linguistically informed ranking model dramatically increases when we consider the three best sentences rather than only the top-ranked sentence. This means that the model sometimes predicts almost equal naturalness for different voice realisations. Moreover, in the case of word order, we know from previous evaluation studies, that humans sometimes prefer different realisations than the original corpus sentences. This Section investigates agreement in human judgements of voice realisation.

Whereas previous studies in generation mainly used human evaluation to compare different systems, or to correlate human and automatic evaluations, our primary interest is the agreement or correlation between human rankings. In particular, we explore the hypothesis that this agreement is higher in certain contexts than in others. In order to select these contexts, we use the predictions made by our ranking model.

The questionnaire for our experiment comprised 24 items falling into 3 classes: a) items where the 3 best sentences predicted by the model have the same voice as the original sentence ("Correct"), b) items where the 3 top-ranked sentences realise different voices ("Mixed"), c) items where the model predicted the incorrect voice in all 3 top sentences ("False"). Each item is composed of the original sentence, the 3 top-ranked sentences (if not identical to the corpus sentence) and 2 further sentences such that each item contains different voices. For each item, we presented the previous context sentence.

The experiment was completed by 8 participants, all native speakers of German, 5 had a linguistic background. The participants were asked to rank each sentence on a scale from 1-6 according to its naturalness and plausibility in the given context. The participants were explicitly allowed to use the same rank for sentences they find equally natural. The participants made heavy use of this option: out of the 192 annotated items, only 8 are ranked such that no two sentences have the same rank.

We compare the human judgements by correlat-

[6](Nakanishi et al., 2005) also note a negative effect of including LM scores in their model, pointing out that the LM was not trained on enough data. The corpus used for training our LM might also have been too small or distinct in genre.

ing them with Spearman's ρ. This measure is considered appropriate for graded annotation tasks in general (Erk and McCarthy, 2009), and has also been used for analysing human realisation rankings (Velldal, 2008; Cahill and Forst, 2010). We normalise the ranks according to the procedure in Velldal (2008). In Table 6, we report the correlations obtained from averaging over all pairwise correlations between the participants and the correlations restricted to the item and sentence classes. We used bootstrap re-sampling on the pairwise correlations to test that the correlations on the different item classes significantly differ from each other.

The correlations in Table 6 suggest that the agreement between annotators is highest on the false items, and lowest on the mixed items. Humans tended to give the best rank to the original sentence more often on the false items (91%) than on the others. Moreover, the agreement is generally higher on the sentences realising the correct voice.

These results seem to confirm our hypothesis that the general level of agreement between humans differs depending on the context. However, one has to be careful in relating the effects in our data solely to voice preferences. Since the sentences were chosen automatically, some examples contain very unnatural word orders that probably guided the annotators' decisions more than the voice. This is illustrated by Example (6) showing two passive sentences from our questionnaire which differ only in the position of the adverb *besser "better"*. Sentence (6-a) is completely implausible for a native speaker of German, whereas Sentence (6-b) sounds very natural.

(6) a. Durch das neue Gesetz sollen **besser**
By the new law should better
Eigenheimbesitzer geschützt werden.
house owners protected be.

b. Durch das neue Gesetz sollen Eigenheimbesitzer
By the new law should house owners
besser geschützt werden.
better protected be.

This observation brings us back to our initial point that the surface realisation task is especially challenging due to the interaction of a range of semantic and discourse phenomena. Obviously, this interaction makes it difficult to single out preferences for a specific alternation type. Future work will have to establish how this problem should be dealt with in the design of human evaluation experiments.

	Items			
	All	Correct	Mixed	False
"All" sent.	0.58	0.6	0.54	0.62
"Correct" sent.	0.64	0.63	0.56	0.72
"False" sent.	0.47	0.57	0.48	0.44
Top-ranked corpus sent.	84%	78%	83%	91%

Table 6: Human Evaluation

7 Conclusion

We have presented a grammar-based generation architecture which implements the surface realisation of meaning representations abstracting from voice and word order. In order to be able to study voice alternations in a variety of contexts, we designed heuristic underspecification rules which establish, for instance, the alternation relation between an active with a generic agent and a passive that does not overtly realise the agent. This strategy leads to a better balanced distribution of the alternations in the training data, such that our linguistically informed generation ranking model achieves high BLEU scores and accurately predicts active and passive. In future work, we will extend our experiments to a wider range of alternations and try to capture inter-sentential context more explicitly. Moreover, it would be interesting to carry over our methodology to a purely statistical linearisation system where the relation between an input representation and a set of candidate realisations is not so clearly defined as in a grammar-based system.

Our study also addressed the interaction of different linguistic variation types, i.e. word order and voice, by looking at different types of linguistic features and exploring different ways of labelling the training data. However, our SVM-based learning framework is not well-suited to directly assess the correlation between a certain feature (or feature combination) and the occurrence of an alternation. Therefore, it would be interesting to relate our work to the techniques used in theoretical papers, e.g. (Bresnan et al., 2007), where these correlations are analysed more directly.

Abstract

We present a novel computational formulation of speaker *authority* in discourse. This notion, which focuses on how speakers position themselves relative to each other in discourse, is first developed into a reliable coding scheme (0.71 agreement between human annotators). We also provide a computational model for automatically annotating text using this coding scheme, using supervised learning enhanced by constraints implemented with Integer Linear Programming. We show that this constrained model's analyses of speaker authority correlates very strongly with expert human judgments (r^2 coefficient of 0.947).

1 Introduction

In this work, we seek to formalize the ways speakers position themselves in discourse. We do this in a way that maintains a notion of discourse structure, and which can be aggregated to evaluate a speaker's overall stance in a dialogue. We define the body of work in positioning to include any attempt to formalize the processes by which speakers attempt to influence or give evidence of their relations to each other. Constructs such as Initiative and Control (Whittaker and Stenton, 1988), which attempt to operationalize the authority over a discourse's structure, fall under the umbrella of positioning. As we construe positioning, it also includes work on detecting certainty and confusion in speech (Liscombe et al., 2005), which models a speaker's understanding of the information in their statements. Work in dialogue act tagging is also relevant, as it seeks to describe the actions and moves with which speakers display these types of positioning (Stolcke et al., 2000).

To complement these bodies of work, we choose to focus on the question of how speakers position themselves as *authoritative* in a discourse. This means that we must describe the way speakers introduce new topics or discussions into the discourse; the way they position themselves relative to that topic; and how these functions interact with each other. While all of the tasks mentioned above focus on specific problems in the larger rhetorical question of speaker positioning, none explicitly address this framing of authority. Each does have valuable ties to the work that we would like to do, and in section 2, we describe prior work in each of those areas, and elaborate on how each relates to our questions.

We measure this as an *authoritativeness ratio*. Of the contentful dialogue moves made by a speaker, in what fraction of those moves is the speaker positioned as the primary authority on that topic? To measure this quantitatively, we introduce the Negotiation framework, a construct from the field of systemic functional linguistics (SFL), which addresses specifically the concepts that we are interested in. We present a reproducible formulation of this sociolinguistics research in section 3, along with our preliminary findings on reliability between human coders, where we observe inter-rater agreement of 0.71. Applying this coding scheme to data, we see strong correlations with important motivational constructs such as Self-Efficacy (Bandura, 1997) as well as learning gains.

Next, we address automatic coding of the Negotiation framework, which we treat as a two-

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1018–1026,
Portland, Oregon, June 19-24, 2011.

dimensional classification task. One dimension is a set of codes describing the authoritative status of a contribution[1]. The other dimension is a segmentation task. We impose constraints on both of these models based on the structure observed in the work of SFL. These constraints are formulated as boolean statements describing what a correct label sequence looks like, and are imposed on our model using an Integer Linear Programming formulation (Roth and Yih, 2004). In section 5, this model is evaluated on a subset of the MapTask corpus (Anderson et al., 1991) and shows a high correlation with human judgements of authoritativeness (r^2 = 0.947). After a detailed error analysis, we will conclude the paper in section 6 with a discussion of our future work.

2 Background

The Negotiation framework, as formulated by the SFL community, places a special emphasis on how speakers function in a discourse as sources or recipients of information or action. We break down this concept into a set of codes, one code per contribution. Before we break down the coding scheme more concretely in section 3, it is important to understand why we have chosen to introduce a new framework, rather than reusing existing computational work.

Much work has examined the emergence of discourse structure from the choices speakers make at the linguistic and intentional level (Grosz and Sidner, 1986). For instance, when a speaker asks a question, it is expected to be followed with an answer. In discourse analysis, this notion is described through dialogue games (Carlson, 1983), while conversation analysis frames the structure in terms of adjacency pairs (Schegloff, 2007). These expectations can be viewed under the umbrella of conditional relevance (Levinson, 2000), and the exchanges can be labelled *discourse segments*.

In prior work, the way that people influence discourse structure is described through the two tightly-related concepts of *initiative* and *control*. A speaker who begins a discourse segment is said to have initiative, while control accounts for which speaker is being addressed in a dialogue (Whittaker and Stenton, 1988). As initiative passes back and forth between discourse participants, control over the conversation similarly transfers from one speaker to another (Walker and Whittaker, 1990). This relation is often considered synchronous, though evidence suggests that the reality is not straightforward (Jordan and Di Eugenio, 1997).

Research in initiative and control has been applied in the form of mixed-initiative dialogue systems (Smith, 1992). This is a large and active field, with applications in tutorial dialogues (Core, 2003), human-robot interactions (Peltason and Wrede, 2010), and more general approaches to effective turn-taking (Selfridge and Heeman, 2010). However, that body of work focuses on influencing discourse structure through positioning. The question that we are asking instead focuses on how speakers view their authority as a source of information about the topic of the discourse.

In particular, consider questioning in discourse. In mixed-initiative analysis of discourse, asking a question always gives you control of a discourse. There is an expectation that your question will be followed by an answer. A speaker might already know the answer to a question they asked - for instance, when a teacher is verifying a student's knowledge. However, in most cases asking a question represents a lack of authority, treating the other speakers as a source for that knowledge. While there have been preliminary attempts to separate out these specific types of positioning in initiative, such as Chu-Carroll and Brown (1998), it has not been studied extensively in a computational setting.

Another similar thread of research is to identify a speaker's *certainty*, that is, the confidence of a speaker and how that self-evaluation affects their language (Pon-Barry and Shieber, 2010). Substantial work has gone into automatically identifying levels of speaker certainty, for example in Liscombe et al. (2005) and Litman et al. (2009). The major difference between our work and this body of literature is that work on certainty has rarely focused on how state translates into interaction between speakers (with some exceptions, such as the application of certainty to tutoring dialogues (Forbes-Riley and Litman, 2009)). Instead, the focus is on the person's self-evaluation, independent of the influence on the speaker's positioning within a discourse.

Dialogue act tagging seeks to describe the moves people make to express themselves in a discourse.

[1] We treat each line in our corpus as a single contribution.

This task involves defining the role of each contribution based on its function (Stolcke et al., 2000). We know that there are interesting correlations between these acts and other factors, such as learning gains (Litman and Forbes-Riley, 2006) and the relevance of a contribution for summarization (Wrede and Shriberg, 2003). However, adapting dialogue act tags to the question of how speakers position themselves is not straightforward. In particular, the granularity of these tagsets, which is already a highly debated topic (Popescu-Belis, 2008), is not ideal for the task we have set for ourselves. Many dialogue acts can be used in authoritative or non-authoritative ways, based on context, and can position a speaker as either giver or receiver of information. Thus these more general tagsets are not specific enough to the role of authority in discourse.

Each of these fields of prior work is highly valuable. However, none were designed to specifically describe how people present themselves as a source or recipient of knowledge in a discourse. Thus, we have chosen to draw on a different field of sociolinguistics. Our formalization of that theory is described in the next section.

3 The Negotiation Framework

We now present the Negotiation framework[2], which we use to answer the questions left unanswered in the previous section. Within the field of SFL, this framework has been continually refined over the last three decades (Berry, 1981; Martin, 1992; Martin, 2003). It attempts to describe how speakers use their role as a source of knowledge or action to position themselves relative to others in a discourse.

Applications of the framework include distinguishing between focus on teacher knowledge and student reasoning (Veel, 1999) and distribution of authority in juvenile trials (Martin et al., 2008). The framework can also be applied to problems similar to those studied through the lens of initiative, such as the distinction between authority over discourse structure and authority over content (Martin, 2000).

A challenge of applying this work to language technologies is that it has historically been highly qualitative, with little emphasis placed on reproducibility. We have formulated a pared-down, reproducible version of the framework, presented in Section 3.1. Evidence of the usefulness of that formulation for identifying authority, and of correlations that we can study based on these codes, is presented briefly in Section 3.2.

3.1 Our Formulation of Negotiation

The codes that we can apply to a contribution using the Negotiation framework are comprised of four main codes, K1, K2, A1, and A2, and two additional codes, ch and o. This is a reduction over the many task-specific or highly contextual codes used in the original work. This was done to ensure that a machine learning classification task would not be overwhelmed with many infrequent classes.

The main codes are divided by two questions. First, is the contribution related to exchanging information, or to exchanging services and actions? If the former, then it is a K move (knowledge); if the latter, then an A move (action). Second, is the contribution acting as a primary actor, or secondary? In the case of knowledge, this often correlates to the difference between assertions (K1) and queries (K2). For instance, a statement of fact or opinion is a K1:

g	K1	well i've got a great viewpoint here just below the east lake

By contrast, asking for someone else's knowledge or opinion is a K2:

g	K2	what have you got underneath the east lake
f	K1	rocket launch

In the case of action, the codes usually correspond to narrating action (A1) and giving instructions (A2), as below:

g	A2	go almost to the edge of the lake
f	A1	yeah

A challenge move (ch) is one which directly contradicts the content or assertion of the previous line, or makes that previous contribution irrelevant. For instance, consider the exchange below, where an instruction is rejected because its presuppositions are broken by the challenging statement.

g	A2	then head diagonally down towards the bottom of the dead tree
f	ch	i have don't have a dead tree i have a dutch elm

[2] All examples are drawn from the MapTask corpus and involve an instruction giver (g) and follower (f). Within examples, discourse segment boundaries are shown by horizontal lines.

All moves that do not fit into one of these categories are classified as other (o). This includes back-channel moves, floor-grabbing moves, false starts, and any other non-contentful contributions.

This theory makes use of discourse segmentation. Research in the SFL community has focused on intra-segment structure, and empirical evidence from this research has shown that exchanges between speakers follow a very specific pattern:

o* X2? o* X1+ o*

That is to say, each segment contains a primary move (a K1 or an A1) and an optional preceding secondary move, with other non-contentful moves interspersed throughout. A single statement of fact would be a K1 move comprising an entire segment, while a single question/answer pair would be a K2 move followed by a K1. Longer exchanges of many lines obviously also occur.

We iteratively developed a coding manual which describes, in a reproducible way, how to apply the codes listed above. The six codes we use, along with their frequency in our corpus, are given in Table 1. In the next section, we evaluate the reliability and utility of hand-coded data, before moving on to automation in section 4.

3.2 Preliminary Evaluation

This coding scheme was evaluated for reliability on two corpora using Cohen's kappa (Cohen, 1960). Within the social sciences community, a kappa above 0.7 is considered acceptable. Two conversations were each coded by hand by two trained annotators. The first conversation was between three students in a collaborative learning task; inter-rater reliability kappa for Negotiation labels was 0.78. The second conversation was from the MapTask corpus, and kappa was 0.71. Further data was labelled by hand by one trained annotator.

In our work, we label conversations using the coding scheme above. To determine how well these codes correlate with other interesting factors, we choose to assign a quantitative measure of authoritativeness to each speaker. This measure can then be compared to other features of a speaker. To do this, we use the coded labels to assign an *Authoritativeness Ratio* to each speaker. First, we define a function $A(S, c, L)$ for a speaker, a contribution, and a set of labels $L \subseteq \{K1, K2, A1, A2, o, ch\}$ as:

Code	Meaning	Count	Percent
K1	Primary Knower	984	22.5
K2	Secondary Knower	613	14.0
A1	Primary Actor	471	10.8
A2	Secondary Actor	708	16.2
ch	Challenge	129	2.9
o	Other	1469	33.6
	Total	4374	100.0

Table 1: The six codes in our coding scheme, along with their frequency in our corpus of twenty conversations.

$$A(S, c, L) = \begin{cases} 1 & c \text{ spoken by } S \text{ with label } l \in L \\ 0 & \text{otherwise.} \end{cases}$$

We then define the Authoritativeness ratio $Auth(S)$ for a speaker S in a dialogue consisting of contributions $c_1 ... c_n$ as:

$$Auth(S) = \frac{\sum_{i=1}^{n} A(S, c_i, \{K1, A2\})}{\sum_{i=1}^{n} A(S, c_i, \{K1, K2, A1, A2\})}$$

The intuition behind this ratio is that we are only interested in the four main label types in our analysis - at least for an initial description of authority, we do not consider the non-contentful o moves. Within these four main labels, there are clearly two that appear "dominant" - statements of fact or opinion, and commands or instructions - and two that appear less dominant - questions or requests for information, and narration of an action. We sum these together to reach a single numeric value for each speaker's projection of authority in the dialogue.

The full details of our external validations of this approach are available in Howley et al. (2011). To summarize, we considered two data sets involving student collaborative learning. The first data set consisted of pairs of students interacting over two days, and was annotated for aggressive behavior, to assess warning factors in social interactions. Our analysis

showed that aggressive behavior correlated with authoritativeness ratio ($p < .05$), and that less aggressive students became less authoritative in the second day ($p < .05$, effect size $.15\sigma$). The second data set was analyzed for Self-Efficacy - the confidence of each student in their own ability (Bandura, 1997) - as well as actual learning gains based on pre- and post-test scores. We found that the Authoritativeness ratio was a significant predictor of learning gains ($r^2 = .41$, $p < .04$). Furthermore, in a multiple regression, we determined that the Authoritativeness ratio of both students in a group predict the average Self-Efficacy of the pair ($r^2 = .12$, $p < .01$).

4 Computational Model

We know that our coding scheme is useful for making predictions about speakers. We now judge whether it can be reproduced fully automatically. Our model must select, for each contribution c_i in a dialogue, the most likely classification label l_i from $\{K1, K2, A1, A2, o, ch\}$. We also build in parallel a segmentation model to select s_i from the set $\{new, same\}$. Our baseline approach to both problems is to use a bag-of-words model of the contribution, and use machine learning for classification.

Certain types of interactions, explored in section 4.1, are difficult or impossible to classify without context. We build a contextual feature space, described in section 4.2, to enhance our baseline bag-of-words model. We can also describe patterns that appear in discourse segments, as detailed in section 3.1. In our coding manual, these instructions are given as rules for how segments should be coded by humans. Our hypothesis is that by enforcing these rules in the output of our automatic classifier, performance will increase. In section 4.3 we formalize these constraints using Integer Linear Programming.

4.1 Challenging cases

We want to distinguish between phenomena such as in the following two examples.

f	K2	so I'm like on the bank on the bank of the east lake
g	K1	yeah

In this case, a one-token contribution is indisputably a K1 move, answering a yes/no question. However, in the dialogue below, it is equally inarguable that the same move is an A1:

g	A2	go almost to the edge of the lake
f	A1	yeah

Without this context, these moves would be indistinguishable to a model. With it, they are both easily classified correctly.

We also observed that markers for segmentation of a segment vary between contentful initiations and non-contentful ones. For instance, filler noises can often initiate segments:

g	o	hmm...
g	K2	do you have a farmer's gate?
f	K1	no

Situations such as this are common. This is also a challenge for segmentation, as demonstrated below:

g	K1	oh oh it's on the right-hand side of my great viewpoint
f	o	okay yeah
g	o	right eh
g	A2	go almost to the edge of the lake
f	A1	yeah

A long statement or instruction from one speaker is followed up with a terse response (in the same segment) from the listener. However, after that backchannel move, a short floor-grabbing move is often made to start the next segment. This is a distinction that a bag-of-words model would have difficulty with. This is markedly different from contentful segment initiations:

g	A2	come directly down below the stone circle and we come up
f	ch	I don't have a stone circle
g	o	you don't have a stone circle

All three of these lines look like statements, which often initiate new segments. However, only the first should be marked as starting a new segment. The other two are topically related, in the second line by contradicting the instruction, and in the third by repeating the previous person's statement.

4.2 Contextual Feature Space Additions

To incorporate the insights above into our model, we append features to our bag-of-words model. First, in our classification model we include both lexical bigrams and part-of-speech bigrams to encode further lexical knowledge and some notion of syntactic structure. To account for restatements and topic shifts, we add a feature based on cosine similarity (using term vectors weighted by TF-IDF calculated

over training data). We then add a feature for the predicted label of the previous contribution - after each contribution is classified, the next contribution adds a feature for the automatic label. This requires our model to function as an on-line classifier.

We build two segmentation models, one trained on contributions of less than four tokens, and another trained on contributions of four or more tokens, to distinguish between characteristics of contentful and non-contentful contributions. To the short-contribution model, we add two additional features. The first represents the ratio between the length of the current contribution and the length of the previous contribution. The second represents whether a change in speaker has occurred between the current and previous contribution.

4.3 Constraints using Integer Linear Programming

We formulate our constraints using Integer Linear Programming (ILP). This formulation has an advantage over other sequence labelling formulations, such as Viterbi decoding, in its ability to enforce structure through constraints. We then enhance this classifier by adding constraints, which allow expert knowledge of discourse structure to be enforced in classification. We can use these constraints to eliminate label options which would violate the rules for a segment outlined in our coding manual.

Each classification decision is made at the contribution level, jointly optimizing the Negotiation label and segmentation label for a single contribution, then treating those labels as given for the next contribution classification.

To define our objective function for optimization, for each possible label, we train a one vs. all SVM, and use the resulting regression for each label as a score, giving us six values $\vec{l_i}$ for our Negotiation label and two values $\vec{s_i}$ for our segmentation label. Then, subject to the constraints below, we optimize:

$$\arg\max_{l \in \vec{l_i}, s \in \vec{s_i}} l + s$$

Thus, at each contribution, if the highest-scoring Negotiation label breaks a constraint, the model can optimize whether to drop to the next-most-likely label, or start a new segment.

Recall from section 3.1 that our discourse segments follow strict rules related to ordering and repetition of contributions. Below, we list the constraints that we used in our model to enforce that pattern, along with a brief explanation of the intuition behind each.

$$\begin{aligned} &\forall c_i \in s, (l_i = K2) \Rightarrow \\ &\forall j < i, c_j \in t \Rightarrow (l_j \neq K1) \end{aligned} \tag{1}$$

$$\begin{aligned} &\forall c_i \in s, (l_i = A2) \Rightarrow \\ &\forall j < i, c_j \in t \Rightarrow (l_j \neq A1) \end{aligned} \tag{2}$$

The first constraints enforce the rule that a primary move cannot occur before a secondary move in the same segment. For instance, a question must initiate a new segment if it follows a statement.

$$\begin{aligned} &\forall c_i \in s, (l_i \in \{A1, A2\}) \Rightarrow \\ &\forall j < i, c_j \in s \Rightarrow (l_j \notin \{K1, K2\}) \end{aligned} \tag{3}$$

$$\begin{aligned} &\forall c_i \in s, (l_i \in \{K1, K2\}) \Rightarrow \\ &\forall j < i, c_j \in s \Rightarrow (l_j \notin \{A1, A2\}) \end{aligned} \tag{4}$$

These constraints specify that A moves and K moves cannot cooccur in a segment. An instruction for action and a question requesting information must be considered separate segments.

$$\begin{aligned} &\forall c_i \in s, (l_i = A1) \Rightarrow ((l_{i-1} = A1) \vee \\ &\forall j < i, c_j \in s \Rightarrow (l_j \neq A1)) \end{aligned} \tag{5}$$

$$\begin{aligned} &\forall c_i \in s, (l_i = K1) \Rightarrow ((l_{i-1} = K1) \vee \\ &\forall j < i, c_j \in s \Rightarrow (l_j \neq K1)) \end{aligned} \tag{6}$$

This pair states that two primary moves cannot occur in the same segment unless they are contiguous, in rapid succession.

$$\begin{aligned} &\forall c_i \in s, (l_i = A1) \Rightarrow \\ &\forall j < i, c_j \in s, (l_j = A2) \Rightarrow (S_i \neq S_j) \end{aligned} \tag{7}$$

$$\begin{aligned} &\forall c_i \in s, (l_i = K1) \Rightarrow \\ &\forall j < i, c_j \in s, (l_j = K2) \Rightarrow (S_i \neq S_j) \end{aligned} \tag{8}$$

The last set of constraints enforce the intuitive notion that a speaker cannot follow their own secondary move with a primary move in that segment (such as answering their own question).

Computationally, an advantage of these constraints is that they do not extend past the current segment in history. This means that they usually are only enforced over the past few moves, and do not enforce any global constraint over the structure of the whole dialogue. This allows the constraints to be flexible to various conversational styles, and tractable for fast computation independent of the length of the dialogue.

5 Evaluation

We test our models on a twenty conversation subset of the MapTask corpus detailed in Table 1. We compare the use of four models in our results.

- **Baseline:** This model uses a bag-of-words feature space as input to an SVM classifier. No segmentation model is used and no ILP constraints are enforced.
- **Baseline+ILP:** This model uses the baseline feature space as input to both classification and segmentation models. ILP constraints are enforced between these models.
- **Contextual:** This model uses our enhanced feature space from section 4.2, with no segmentation model and no ILP constraints enforced.
- **Contextual+ILP:** This model uses the enhanced feature spaces for both Negotiation labels and segment boundaries from section 4.2 to enforce ILP constraints.

For segmentation, we evaluate our models using exact-match accuracy. We use multiple evaluation metrics to judge classification. The first and most basic is accuracy - the percentage of accurately chosen Negotiation labels. Secondly, we use Cohen's Kappa (Cohen, 1960) to judge improvement in accuracy over chance. The final evaluation is the r^2 coefficient computed between predicted and actual Authoritativeness ratios per speaker. This represents how much variance in authoritativeness is accounted for in the predicted ratios. This final metric is the most important for measuring reproducibility of human analyses of speaker authority in conversation.

We use SIDE for feature extraction (Mayfield and Rosé, 2010), SVM-Light for machine learning (Joachims, 1999), and Learning-Based Java for ILP inference (Rizzolo and Roth, 2010). Performance is evaluated by 20-fold cross-validation, where each fold is trained on 19 conversations and tested on the remaining one. Statistical significance was calculated using a student's paired t-test. For accuracy and kappa, $n = 20$ (one data point per conversation) and for r^2, $n = 40$ (one data point per speaker).

Model	**Accuracy**	**Kappa**	r^2
Baseline	59.7%	0.465	0.354
Baseline+ILP	61.6%	0.488	0.663
Segmentation	*72.3%*		
Contextual	66.7%	0.565	0.908
Contextual+ILP	68.4%	0.584	0.947
Segmentation	*74.9%*		

Table 2: Performance evaluation for our models. Each line is significantly improved in both accuracy and r^2 error from the previous line ($p < .01$).

5.1 Results

All classification results are given in Table 2 and charts showing correlation between predicted and actual speaker Authoritativeness ratios are shown in Figure 1. We observe that the baseline bag-of-words model performs well above random chance (kappa of 0.465); however, its accuracy is still very low and its ability to predict Authoritativeness ratio of a speaker is not particularly high (r^2 of 0.354 with ratios from manually labelled data). We observe a significant improvement when ILP constraints are applied to this model.

The contextual model described in section 4.2 performs better than our baseline constrained model. However, the gains found in the contextual model are somewhat orthogonal to the gains from using ILP constraints, as applying those constraints to the contextual model results in further performance gains (and a high r^2 coefficient of 0.947).

Our segmentation model was evaluated based on exact matches in boundaries. Switching from baseline to contextual features, we observe an improvement in accuracy of 2.6%.

5.2 Error Analysis

An error analysis of model predictions explains the large effect on correlation despite relatively smaller

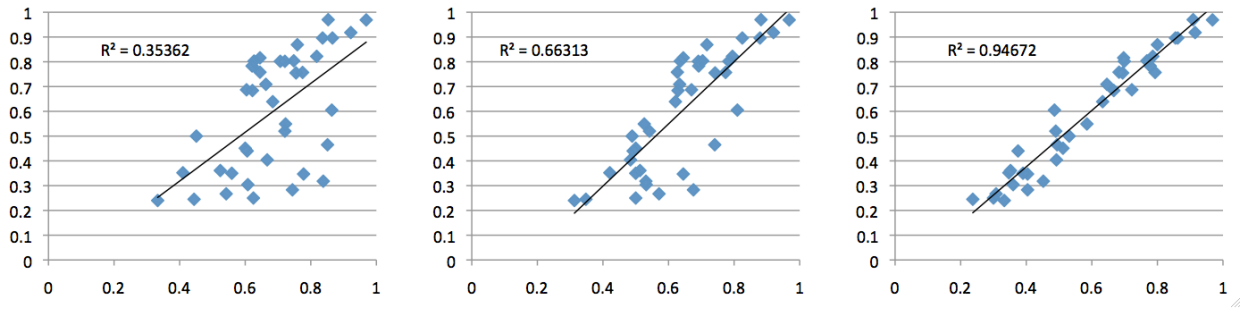

Figure 1: Plots of predicted (x axis) and actual (y axis) Authoritativeness ratios for speakers across 20 conversations, for the Baseline (left), Baseline+Constraints (center), and Contextual+Constraints (right) models.

changes in accuracy. Our Authoritativeness ratio does not take into account moves labelled o or ch. What we find is that the most advanced model still makes many mistakes at determining whether a move should be labelled as o or a core move. This error rate is, however, fairly consistent across the four core move codes. When a move is determined (correctly) to not be an o move, the system is highly accurate in distinguishing between the four core labels.

The one systematic confusion that continues to appear most frequently in our results is the inability to distinguish between a segment containing an $A2$ move followed by an $A1$ move, and a segment containing a $K1$ move followed by an o move. The surface structure of these types of exchanges is very similar. Consider the following two exchanges:

g	A2	if you come down almost to the bottom of the map that I've got
f	A1	uh-huh

f	K1	but the meadow's below my broken gate
g	o	right yes

These two exchanges on a surface level are highly similar. Out of context, making this distinction is very hard even for human coders, so it is not surprising then that this pattern is the most difficult one to recognize in this corpus. It contributes most of the remaining confusion between the four core codes.

6 Conclusions

In this work we have presented one formulation of authority in dialogue. This formulation allows us to describe positioning in discourse in a way that is complementary to prior work in mixed-initiative dialogue systems and analysis of speaker certainty. Our model includes a simple understanding of discourse structure while also encoding information about the types of moves used, and the certainty of a speaker as a source of information. This formulation is reproducible by human coders, with an inter-rater reliability of 0.71.

We have then presented a computational model for automatically applying these codes per contribution. In our best model, we see a good 68.4% accuracy on a six-way individual contribution labelling task. More importantly, this model replicates human analyses of authoritativeness very well, with an r^2 coefficient of 0.947.

There is room for improvement in our model in future work. Further use of contextual features will more thoroughly represent the information we want our model to take into account. Our segmentation accuracy is also fairly low, and further examination of segmentation accuracy using a more sophisticated evaluation metric, such as WindowDiff (Pevzner and Hearst, 2002), would be helpful.

In general, however, we now have an automated model that is reliable in reproducing human judgments of authoritativeness. We are now interested in how we can apply this to the larger questions of positioning we began this paper by asking, especially in describing speaker positioning at various instants throughout a single discourse. This will be the main thrust of our future work.

Reordering Metrics for MT

Abstract

One of the major challenges facing statistical machine translation is how to model differences in word order between languages. Although a great deal of research has focussed on this problem, progress is hampered by the lack of reliable metrics. Most current metrics are based on matching lexical items in the translation and the reference, and their ability to measure the quality of word order has not been demonstrated. This paper presents a novel metric, the LRscore, which explicitly measures the quality of word order by using permutation distance metrics. We show that the metric is more consistent with human judgements than other metrics, including the BLEU score. We also show that the LRscore can successfully be used as the objective function when training translation model parameters. Training with the LRscore leads to output which is preferred by humans. Moreover, the translations incur no penalty in terms of BLEU scores.

1 Introduction

Research in machine translation has focused broadly on two main goals, improving word choice and improving word order in translation output. Current machine translation metrics rely upon indirect methods for measuring the quality of the word order, and their ability to capture the quality of word order is poor (Birch et al., 2010).

There are currently two main approaches to evaluating reordering. The first is exemplified by the BLEU score (Papineni et al., 2002), which counts the number of matching n-grams between the reference and the hypothesis. Word order is captured by the proportion of longer n-grams which match. This method does not consider the position of matching words, and only captures ordering differences if there is an exact match between the words in the translation and the reference. Another approach is taken by two other commonly used metrics, METEOR (Banerjee and Lavie, 2005) and TER (Snover et al., 2006). They both search for an alignment between the translation and the reference, and from this they calculate a penalty based on the number of differences in order between the two sentences. When block moves are allowed the search space is very large, and matching stems and synonyms introduces errors. Importantly, none of these metrics capture the distance by which words are out of order. Also, they conflate reordering performance with the quality of the lexical items in the translation, making it difficult to tease apart the impact of changes. More sophisticated metrics, such as the RTE metric (Padó et al., 2009), use higher level syntactic or semantic analysis to determine the grammaticality of the output. These approaches require annotation and can be very slow to run. For most research, shallow metrics are more appropriate.

We introduce a novel shallow metric, the Lexical Reordering Score (LRscore), which explicitly measures the quality of word order in machine translations and interpolates it with a lexical metric. This results in a simple, decomposable metric which makes it easy for researchers to pinpoint the effect of their changes. In this paper we show that the LRscore is more consistent with human judgements

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1027–1035,
Portland, Oregon, June 19-24, 2011.

than other metrics for five out of eight different language pairs. We also apply the LRscore during Minimum Error Rate Training (MERT) to see whether information on reordering allows the translation model to produce better reorderings. We show that humans prefer the output of systems trained with the LRscore 52.5% as compared to 43.9% when training with the BLEU score. Furthermore, training with the LRscore does not result in lower BLEU scores.

The rest of the paper proceeds as follows. Section 2 describes the reordering and lexical metrics that are used and how they are combined. Section 3 presents the experiments on consistency with human judgements and describes how to train the language independent parameter of the LRscore. Section 4 reports the results of the experiments on MERT. Finally we discuss related work and conclude.

2 The LRscore

In this section we present the LRscore which measures reordering using permutation distance metrics. These reordering metrics have been demonstrated to correlate strongly with human judgements of word order quality (Birch et al., 2010). The LRscore combines the reordering metrics with lexical metrics to provide a complete metric for evaluating machine translations.

2.1 Reordering metrics

The relative ordering of words in the source and target sentences is encoded in alignments. We can interpret alignments as permutations which allows us to apply research into metrics for ordered encodings to measuring and evaluating reorderings. We use distance metrics over permutations to evaluate reordering performance. Figure 1 shows three permutations. Each position represents a source word and each value indicates the relative positions of the aligned target words. In Figure 1 (a) represents the identity permutation, which would result from a monotone alignment, (b) represents a small reordering consisting of two words whose orders are inverted, and (c) represents a large reordering where the two halves of the sentence are inverted in the target.

A translation can potentially have many valid word orderings. However, we can be reasonably certain that the ordering of the reference sentence must be acceptable. We therefore compare the ordering of a translation with that of the reference sentence. Where multiple references exist, we select the closest, i.e. the one that gives the best score. The underlying assumption is that most reasonable word orderings should be fairly similar to the reference, which is a necessary assumption for all automatic machine translation metrics.

(a) (1 2 3 4 5 6 7 8 9 10)
(b) (1 2 3 4 •6 •5 •7 8 9 10)
(c) (6 7 8 9 10 •1 2 3 4 5)

Figure 1. Three permutations: (a) monotone (b) with a small reordering and (b) with a large reordering. Bullet points highlight non-sequential neighbours.

Permutations encode one-one relations, whereas alignments contain null alignments and one-many, many-one and many-many relations. We make some simplifying assumptions to allow us to work with permutations. Source words aligned to null are assigned the target word position immediately after the target word position of the previous source word. Where multiple source words are aligned to the same target word or phrase, a many-to-one relation, the target ordering is assumed to be monotone. When one source word is aligned to multiple target words, a one-to-many relation, the source word is assumed to be aligned to the first target word. These simplifications are chosen so as to reduce the alignment to a bijective relationship without introducing any extraneous reorderings, i.e. they encode a basic monotone ordering assumption.

We choose permutation distance metrics which are sensitive to the number of words that are out of order, as humans are assumed to be sensitive to the number of words that are out of order in a sentence. The two permutations we refer to, π and σ, are the source-reference permutation and the source-translation permutation. The metrics are normalised so that 0 means that the permutations are completely inverted, and 1 means that they are identical. We report these scores as percentages.

2.1.1 Hamming Distance

The Hamming distance (Hamming, 1950) measures the number of disagreements between two permutations. It is defined as follows:

$$d_h(\pi, \sigma) = 1 - \frac{\sum_{i=1}^{n} x_i}{n}, x_i = \begin{cases} 0 \text{ if } \pi(i) = \sigma(i) \\ 1 \text{ otherwise} \end{cases}$$

Eg.	BLEU	METEOR	TER	d_h	d_k
(a)	100.0	100.0	100.0	100.0	100.0
(b)	61.8	86.9	90.0	80.0	85.1
(c)	81.3	92.6	90.0	0.0	25.5

Table 1. Metric scores for examples in Figure 1 which are calculated by comparing the permutations to the identity. All metrics are adjusted so that 100 is the best score and 0 the worst.

where n is the length of the permutation. The Hamming distance is the simplest permutation distance metric and is useful as a baseline. It has no concept of the relative ordering of words.

2.1.2 Kendall's Tau Distance

Kendall's tau distance is the minimum number of transpositions of two *adjacent* symbols necessary to transform one permutation into another (Kendall, 1938). It represents the percentage of pairs of elements which share the same order between two permutations. It is defined as follows:

$$
\begin{aligned}
d_k(\pi,\sigma) &= 1 - \sqrt{\frac{\sum_{i=1}^{n}\sum_{j=1}^{n} z_{ij}}{Z}} \\
\text{where } z_{ij} &= \begin{cases} 1 \text{ if } \pi(i) < \pi(j) \text{ and } \sigma(i) > \sigma(j) \\ 0 \text{ otherwise} \end{cases} \\
Z &= \frac{(n^2-n)}{2}
\end{aligned}
$$

Kendalls tau seems particularly appropriate for measuring word order differences as the relative ordering words is taken into account. However, most human and machine ordering differences are much closer to monotone than to inverted. The range of values of Kendall's tau is therefore too narrow and close to 1. For this reason we take the square root of the standard metric. This adjusted d_k is also more correlated with human judgements of reordering quality (Birch et al., 2010).

We use the example in Figure 1 to highlight the problem with current MT metrics, and to demonstrate how the permutation distance metrics are calculated. In Table 1 we present the metric results for the example permutations. The metrics are calculated by comparing the permutation string with the monotone permutation. (a) receives the best score for all metrics as it is compared to itself. BLEU and METEOR fail to recognise that (b) represents a small reordering and (c) a large reordering and they assign a lower score to (b). The reason for this is that they are sensitive to breaks in order, but not to the actual word order differences. BLEU matches more n-grams for (c) and consequently assigns it a higher score. METEOR counts the number of blocks that the translation is broken into, in order to align it with the source. (b) is aligned using four blocks, whereas (c) is aligned using only two blocks. TER counts the number of edits, allowing for block shifts, and applies one block shift for each example, resulting in an equal score for (b) and (c). Both the Hamming distance d_h and the Kendall's tau distance d_k correctly assign (c) a worse score than (b). Note that for (c), the Hamming distance was not able to reward the permutation for the correct relative ordering of words within the two large blocks and gave (c) a score of 0, whereas Kendall's tau takes relative ordering into account.

Wong and Kit (2009) also suggest a metric which combines a word choice and a word order component. They propose a type of F-measure which uses a matching function M to calculate precision and recall. M combines the number of matched words, weighted by their *tfidf* importance, with their position difference score, and finally subtracting a score for unmatched words. Including unmatched words in the M function undermines the interpretation of the supposed F-measure. The reordering component is the average difference of absolute and relative word positions which has no clear meaning. This score is not intuitive or easily decomposable and it is more similar to METEOR, with synonym and stem functionality mixed with a reordering penalty, than to our metric.

2.2 Combined Metric

The LRscore consists of a reordering distance metric which is linearly interpolated with a lexical score to form a complete machine translation evaluation metric. The metric is decomposable because the individual lexical and reordering components can be looked at individually. The following formula describes how to calculate the LRscore:

$$LRscore = \alpha R + (1-\alpha)L \qquad (1)$$

The metric contains only one parameter, α, which balances the contribution of the reordering metric, R, and the lexical metric, L. Here we use BLEU as

the lexical metric. R is the average permutation distance metric adjusted by the brevity penalty and it is calculated as follows:

$$R = \frac{\sum_{s \in S} d_s BP_s}{|S|} \quad (2)$$

Where S is a set of test sentences, d_s is the reordering distance for a sentence and BP is the brevity penalty.

The brevity penalty is calculated as:

$$BP = \begin{cases} 1 & \text{if } t > r \\ e^{1-r/t} & \text{if } t \leq r \end{cases} \quad (3)$$

where t is the length of the translation, and r is the closest reference length. If the reference sentence is slightly longer than the translation, then the brevity penalty will be a fraction somewhat smaller than 1. This has the effect of penalising translations that are shorter than the reference. The brevity penalty within the reordering component is necessary as the distance-based metric would provide the same score for a one word translation as it would for a longer monotone translation. R is combined with a system level lexical score.

In this paper we apply the BLEU score as the lexical metric, as it is well known and it measures lexical precision at different n-gram lengths. We experiment with the full BLEU score and the 1-gram BLEU score, BLEU1, which is purely a measure of the precision of the word choice. The 4-gram BLEU score includes some measure of the local reordering success in the precision of the longer n-grams. BLEU is an important baseline, and improving on it by including more reordering information is an interesting result. The lexical component of the system can be any meaningful metric for a particular target language. If a researcher was interested in morphologically rich languages, for example, METEOR could be used. We use the LRscore to return sentence level scores as well system level scores, and when doing so the smoothed BLEU (Lin and Och, 2004) is used.

3 Consistency with Human Judgements

Automatic metrics must be validated by comparing their scores with human judgements. We train the metric parameter to optimise consistency with human preference judgements across different language pairs and then we show that the LRscore is more consistent with humans than other commonly used metrics.

3.1 Experimental Design

Human judgement of rank has been chosen as the official determinant of translation quality for the 2009 Workshop on Machine Translation (Callison-Burch et al., 2009). We used human ranking data from this workshop to evaluate the LRscore. This consisted of German, French, Spanish and Czech translation systems that were run both into and out of English. In total there were 52,265 pairwise rank judgements collected.

Our reordering metric relies upon word alignments that are generated between the source and the reference sentences, and the source and the translated sentences. In an ideal scenario, the translation system outputs the alignments and the reference set can be selected to have gold standard human alignments. However, the data that we use to evaluate metrics does not have any gold standard alignments and we must train automatic alignment models to generate them. We used version two of the Berkeley alignment model (Liang et al., 2006), with the posterior threshold set at 0.5. Our Spanish-, French- and German-English alignment models are trained using Europarl version 5 (Koehn, 2005). The Czech-English alignment model is trained on sections 0-2 of the Czech-English Parallel Corpus, version 0.9 (Bojar and Zabokrtsky, 2009).

The metric scores are calculated for the test set from the 2009 workshop on machine translation. It consists of 2525 sentences in English, French, German, Spanish and Czech. These sentences have been translated by different machine translation systems and the output submitted to the workshop. The system output along with human evaluations can be downloaded from the web[1].

The BLEU score has five parameters, one for each n-gram, and one for the brevity penalty. These parameters are set to a default uniform value of one. METEOR has 3 parameters which have been trained for human judgements of rank (Lavie and Agarwal, 2008). METEOR version 0.7 was used. The other baseline metric used was TER version 0.7.25. We adapt TER by subtracting it from one, so that all

[1] http://www.statmt.org/wmt09/results.html

metric increases mean an improvement in the translation. The TER metric has five parameters which have not been trained.

Using rank judgements, we do not have absolute scores and so we cannot compare translations across different sentences and extract correlation statistics. We therefore use the method adopted in the 2009 workshop on machine translation (Callison-Burch et al., 2009). We ascertained how consistent the automatic metrics were with the human judgements by calculating consistency in the following manner. We take each pairwise comparison of translation output for single sentences by a particular judge, and we recorded whether or not the metrics were consistent with the human rank. I.e. we counted cases where both the metric and the human judge agreed that one system is better than another. We divided this by the total number of pairwise comparisons to get a percentage. We excluded pairs which the human annotators ranked as ties.

	de-en	es-en	fr-en	cz-en
d_k	73.9	80.5	80.4	81.1

Table 2. The average Kendall's tau reordering distance between the test and reference sentences. 100 means monotone thus de-en has the most reordering.

We present a novel method for setting the LRscore parameter. Using multiple language pairs, we train the parameter according to the amount of reordering seen in each test set. The advantage of this approach is that researchers do not need to train the parameter for new language pairs or test domains. They can simply calculate the amount of reordering in the test set and adjust the parameter accordingly. The amount of reordering is calculated as the Kendall's tau distance between the source and the reference sentences as compared to dummy monotone sentences. The amount of reordering for the test sentences is reported in Table 2. German-English shows more reordering than other language pairs as it has a lower d_k score of 73.9. The language independent parameter (θ) is adjusted by applying the reordering amount (d_k) as an exponent. θ is allowed to takes values of between 0 and 1. This works in a similar way to the brevity penalty. With more reordering, the d_k becomes smaller which leads to an increase in the final value of α. α represents the percentage contribution of the reordering component in the LRscore:

$$\alpha = \theta^{d_k} \tag{4}$$

The language independent parameter θ is trained once, over multiple language pairs. This procedure optimises the average of the consistency results across the different language pairs. We use greedy hillclimbing in order to find the optimal setting. As hillclimbing can end up in a local minima, we perform 20 random restarts, and retaining only the parameter value with the best consistency result.

3.2 Results

Table 3 reports the optimal consistency of the LRscore and baseline metrics with human judgements for each language pair. The LRscore variations are named as follows: LR refers to the LRscore, "H" refers to the Hamming distance and "K" to Kendall's tau distance. "B1" and "B4" refer to the smoothed BLEU score with the 1-gram and the complete scores. Table 3 shows that the LRscore is more consistent with human judgement for 5 out of the 8 language pairs. This is an important result which shows that combining lexical and reordering information makes for a stronger metric than the baseline metrics which do not have a strong reordering component.

METEOR is the most consistent for the Czech-English and English-Czech language pairs, which have the least amount of reordering. METEOR lags behind for the language pairs with the most reordering, the German-English and English-German pairs. Here LR-KB4 is the best metric, which shows that metrics which are sensitive to the distance words are out of order are more appropriate for situations with a reasonable amount of reordering.

4 Optimising Translation Models

Automatic metrics are useful for evaluation, but they are essential for training model parameters. In this section we apply the LRscore as the objective function in MERT training (Och, 2003). MERT minimises translation errors according to some automatic evaluation metric while searching for the best parameter settings over the N-best output. A MERT trained model is likely to exhibit the properties that

Metric	de-en	es-en	fr-en	cz-en	en-de	en-es	en-fr	en-cz	ave
METEOR	58.6	58.3	58.3	**59.4**	52.6	55.7	61.2	**55.6**	57.5
TER	53.2	50.1	52.6	47.5	48.6	49.6	58.3	45.8	50.7
BLEU1	56.1	57.0	56.7	52.5	52.1	54.2	62.3	53.3	55.6
BLEU	58.7	55.5	57.7	57.2	54.1	56.7	**63.7**	53.1	57.1
LR-HB1	59.7	**60.0**	58.6	53.2	54.6	55.6	63.7	54.5	57.5
LR-HB4	60.4	57.3	**58.7**	57.2	54.8	**57.3**	63.3	53.8	57.9
LR-KB1	60.4	59.7	58.0	54.0	54.1	54.7	63.4	54.9	57.5
LR-KB4	**61.0**	57.2	58.5	58.6	**54.8**	56.8	63.1	55.0	**58.7**

Table 3. The percentage consistency between human judgements of rank and metrics. The LRscore variations (LR-*) are optimised for average consistency across language pair (shown in right hand column). The bold numbers represent the best consistency score per language pair.

the metric rewards, but will be blind to aspects of translation quality that are not directly captured by the metric. We apply the LRscore in order to improve the reordering performance of a phrase-based translation model.

4.1 Experimental Design

We hypothesise that the LRscore is a good metric for training translation models. We test this by evaluating the output of the models, first with automatic metrics, and then by using human evaluation. We choose to run the experiment with Chinese-English as this language pair has a large amount of medium and long distance reorderings.

4.1.1 Training Setup

The experiments are carried out with Chinese-English data from GALE. We use the official test set of the 2006 NIST evaluation (1994 sentences). For the development test set, we used the evaluation set from the GALE 2008 evaluation (2010 sentences). Both development set and test set have four references. The phrase table was built from 1.727M parallel sentences from the GALE Y2 training data. The phrase-based translation model called MOSES was used, with all the default settings. We extracted phrases as in (Koehn et al., 2003) by running GIZA++ in both directions and merging alignments with the grow-diag-final heuristic. We used the Moses translation toolkit, including a lexicalised reordering model. The SRILM language modelling toolkit (Stolcke, 2002) was used with interpolated Kneser-Ney discounting. There are three separate 3-gram language models trained on the English side of parallel corpus, the AFP part of the Gigaword corpus, and the Xinhua part of the Gigaword corpus. A 4 or 5-gram language model would have led to higher scores for all objective functions, but would not have changed the findings in this paper. We used the MERT code available in the MOSES repository (Bertoldi et al., 2009).

LR-HB1	LR-HB4	LR-KB1	LR-KB4
26.40	07.19	43.33	26.23

Table 4. The parameter setting representing the % impact of the reordering component for the different versions of the LRscore metric.

The reordering metrics require alignments which were created using the Berkeley word alignment package version 1.1 (Liang et al., 2006), with the posterior probability to being 0.5.

We first extracted the LRscore Kendall's tau distance from the monotone for the Chinese-English test set and this value was 66.1%. This is far more reordering than the other language pairs shown in Table 2. We then calculated the optimal parameter setting, using the reordering amount as a power exponent. Table 4 shows the parameter settings we used in the following experiments. The optimal amount of reordering for LR-HB4 is low, but the results show it still makes an important contribution.

4.1.2 Human Evaluation Setup

Human judgements of translation quality are necessary to determine whether humans prefer sentences from models trained with the BLEU score or with the LRscore. There have been some recent studies which have used the online micro-market, Amazons Mechanical Turk, to collect human annotations (Snow et al., 2008; Callison-Burch, 2009). While some of the data generated is very noisy, invalid responses are largely due to a small number of workers (Kittur et al., 2008). We use Mechanical

Turk and we improve annotation quality by collecting multiple judgements, and eliminating workers who do not achieve a certain level of performance on gold standard questions.

We randomly selected a subset of sentences from the test set. We use 60 sentences each for comparing training with BLEU to training with LR-HB4 and with LR-KB4. These sentences were between 15 and 30 words long. Shorter sentences tend to have uninteresting differences, and longer sentences may have many conflicting differences.

Workers were presented with a reference sentence and two translations which were randomly ordered. They were told to compare the translations and select their preferred translation or "Don't Know". Workers were screened to guarantee reasonable judgement quality. 20 sentence pairs were randomly selected from the 120 test units and annotated as gold standard questions. Workers who got less than 60% of these gold questions correct were disqualified and their judgements discarded.

After disagreeing with a gold annotation, a worker is presented with the gold answer and an explanation. This guides the worker on how to perform the task and motivates them to be more accurate. We used the Crowdflower[2] interface to Mechanical Turk, which implements the gold functionality.

Even though experts can disagree on preference judgements, gold standard labels are necessary to weed out the poor standard workers. There were 21 trusted workers who achieved an average accuracy of 91% on the gold. There were 96 untrusted workers who averaged 29% accuracy on the gold. Their judgements were discarded. Three judgements were collected from the trusted workers for each of the 120 test sentences.

4.2 Results

4.2.1 Automatic Evaluation of MERT

In this experiment we demonstrate that the reordering metrics can be used as learning criterion in minimum error rate training to improve parameter estimation for machine translation.

Table 5 reports the average of three runs of MERT training with different objective functions. The lexical metric BLEU is used as an objective function in isolation, and also as part of the LRscore together with the Hamming distance and Kendall's tau distance. We test with these metrics, and we also report the TER and METEOR scores for comparison.

Metrics / Obj.Func.	BLEU	LR-HB4	LR-KB4	TER	MET.
BLEU	**31.1**	32.1	41.0	60.7	55.5
LRHB4	**31.1**	**32.2**	**41.3**	60.6	55.7
LRKB4	31.0	**32.2**	41.2	**61.0**	**55.8**

Table 5. Average results of three different MERT runs for different objective functions.

The first thing we note in Table 5 is that we would expect the highest scores when training with the same metric as that used for evaluation as MERT maximises the objective function on the development data set. Here, however, when testing with BLEU, we see that training with BLEU and with LR-HB4 leads to equally high BLEU scores. The reordering component is more discerning than the BLEU score. It reliably increases as the word order approaches that of the reference, whereas BLEU can reports the same score for a large number of different alternatives. This might make the reordering metric easier to optimise, leading to the joint best scores at test time. This is an important result, as it shows that by training with the LRscore objective function, BLEU scores do not decrease, which is desirable as BLEU scores are usually reported in the field.

The LRscore also results in better scores when evaluated with itself and the other two baseline metrics, TER and METEOR. Reordering and the lexical metrics are orthogonal information sources, and this shows that combining them results in better performing systems. BLEU has shown to be a strong baseline metric to use as an objective function (Cer et al., 2010), and so the LRscore performance in Table 5 is a good result.

Examining the weights that result from the different MERT runs, the only notable difference is that the weight of the distortion cost is considerably lower with the LRscore. This shows more trust in the quality of reorderings. Although it is interesting to look at the model weights, any final conclusion on the impact of the metrics on training must depend on human evaluation of translation quality.

Type	Sentence
Reference	silicon valley is still a rich area in the united states. the average salary in the area was us $62,400 a year, which was 64% higher than the american average.
LR-KB4	silicon valley is still an affluent area of the united states, the regional labor with an average annual salary of 6.24 million us dollars, higher than the average level of 60 per cent.
BLEU	silicon valley is still in the united states in the region in an affluent area of the workforce, the average annual salary of 6.24 million us dollars, higher than the average level of 60 per cent

Table 7. A reference sentence is compared with output from models trained with BLEU and with the LR-KB4 lrscore.

	Prefer LR	Prefer BLEU	Don't Know
LR-KB4	96	79	5
LR-HB4	93	79	8
Total	189 (52.5%)	158 (43.9%)	13

Table 6. The number of the times human judges preferred the output of systems trained either with the LRscore or with the BLEU score, or were unable to choose.

4.2.2 Human Evaluation

We collect human preference judgements for output from systems trained using the BLEU score and the LRscore in order to determine whether training with the LRscore leads to genuine improvements in translation quality. Table 6 shows the number of the times humans preferred the LRscore or the BLEU score output, or when they did not know. We can see that humans have a greater preference for the output for systems trained with the LRscore, which is preferred 52.5% of the time, compared to the BLEU score, which was only preferred 43.9% of the time.

The sign test can be used to determine whether this difference is significant. Our null hypothesis is that the probability of a human preferring the LRscore trained output is the same as that of preferring the BLEU trained output. The one-tailed alternative hypothesis is that humans prefer the LRscore output. If the null hypothesis is true, then there is only a probability of 0.048 that 189 out of 347 $(189 + 158)$ people will select the LRscore output. We therefore discard the null hypothesis and the human preference for the output of the LRscore trained system is significant to the 95% level.

In order to judge how reliable our judgements are we calculate the inter-annotator agreement. This is given by the Kappa coefficient (K), which balances agreement with expected agreement. The Kappa coefficient is 0.464 which is considered to be a moderate level of agreement.

In analysis of the results, we found that output from the system trained with the LRscore tend to produce sentences with better structure. In Table 7 we see a typical example. The word order of the sentence trained with BLEU is mangled, whereas the LR-KB4 model outputs a clear translation which more closely matches the reference. It also garners higher reordering and BLEU scores.

We expect that more substantial gains can be made in the future by using models which have more powerful reordering capabilities. A richer set of reordering features, and a model capable of longer distance reordering would better leverage metrics which reward good word orderings.

5 Conclusion

We introduced the LRscore which combines a lexical and a reordering metric. The main motivation for this metric is the fact that it measures the reordering quality of MT output by using permutation distance metrics. It is a simple, decomposable metric which interpolates the reordering component with a lexical component, the BLEU score. This paper demonstrates that the LRscore metric is more consistent with human preference judgements of machine translation quality than other machine translation metrics. We also show that when training a phrase-based translation model with the LRscore as the objective function, the model retains its performance as measured by the baseline metrics. Crucially, however, optimisation using the LRscore improves subjective evaluation. Ultimately, the availability of a metric which reliably measures reordering performance should accelerate progress towards developing more powerful reordering models.

Abstract

This paper proposes a novel reordering model for statistical machine translation (SMT) by means of modeling the translation orders of the source language collocations. The model is learned from a word-aligned bilingual corpus where the collocated words in source sentences are automatically detected. During decoding, the model is employed to softly constrain the translation orders of the source language collocations, so as to constrain the translation orders of those source phrases containing these collocated words. The experimental results show that the proposed method significantly improves the translation quality, achieving the absolute improvements of 1.1~1.4 BLEU score over the baseline methods.

1 Introduction

Reordering for SMT is first proposed in IBM models (Brown et al., 1993), usually called *IBM constraint* model, where the movement of words during translation is modeled. Soon after, Wu (1997) proposed an ITG (Inversion Transduction Grammar) model for SMT, called *ITG constraint* model, where the reordering of words or phrases is constrained to two kinds: straight and inverted. In order to further improve the reordering performance, many structure-based methods are proposed, including the reordering model in hierarchical phrase-based SMT systems (Chiang, 2005) and syntax-based SMT systems (Zhang et al., 2007; Marton and Resnik, 2008; Ge, 2010; Visweswariah et al., 2010). Although the sentence structure has been taken into consideration, these methods don't explicitly make use of the strong correlations between words, such as collocations, which can effectively indicate reordering in the target language.

In this paper, we propose a novel method to improve the reordering for SMT by estimating the reordering score of the source-language collocations (source collocations for short in this paper). Given a bilingual corpus, the collocations in the source sentence are first detected automatically using a monolingual word alignment (MWA) method without employing additional resources (Liu et al., 2009), and then the reordering model based on the detected collocations is learned from the word-aligned bilingual corpus. The source collocation based reordering model is integrated into SMT systems as an additional feature to softly constrain the translation orders of the source collocations in the sentence to be translated, so as to constrain the translation orders of those source phrases containing these collocated words.

This method has two advantages: (1) it can automatically detect and leverage collocated words in a sentence, including long-distance collocated words; (2) such a reordering model can be integrated into any SMT systems without resorting to any additional resources.

We implemented the proposed reordering model in a phrase-based SMT system, and the evaluation results show that our method significantly improves translation quality. As compared to the baseline systems, an absolute improvement of 1.1~1.4 BLEU score is achieved.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1036–1044,
Portland, Oregon, June 19-24, 2011.

The paper is organized as follows: In section 2, we describe the motivation to use source collocations for reordering, and briefly introduces the collocation extraction method. In section 3, we present our reordering model. And then we describe the experimental results in section 4 and 5. In section 6, we describe the related work. Lastly, we conclude in section 7.

2 Collocation

A collocation is generally composed of a group of words that occur together more often than by chance. Collocations effectively reveal the strong association among words in a sentence and are widely employed in a variety of NLP tasks (Mckeown and Radey, 2000).

Given two words in a collocation, they can be translated in the same order as in the source language, or in the inverted order. We name the first case as *straight*, and the second *inverted*. Based on the observation that some collocations tend to have fixed translation orders such as "金融 jin-rong 'financial' 危机 wei-ji 'crisis'" (financial crisis) whose English translation order is usually straight, and "法律 fa-lv 'law' 范围 fan-wei 'scope'" (scope of law) whose English translation order is generally inverted, some methods have been proposed to improve the reordering model for SMT based on the collocated words crossing the neighboring components (Xiong et al., 2006). We further notice that some words are translated in different orders when they are collocated with different words. For instance, when "潮流 chao-liu 'trend'" is collocated with "时代 shi-dai 'times'", they are often translated into the "trend of times"; when collocated with "历史 li-shi 'history'", the translation usually becomes the "historical trend". Thus, if we can automatically detect the collocations in the sentence to be translated and their orders in the target language, the reordering information of the collocations could be used to constrain the reordering of phrases during decoding. Therefore, in this paper, we propose to improve the reordering model for SMT by estimating the reordering score based on the translation orders of the source collocations.

In general, the collocations can be automatically identified based on syntactic information such as dependency trees (Lin, 1998). However these methods may suffer from parsing errors. Moreover, for many languages, no valid dependency parser exists. Liu et al. (2009) proposed to automatically detect the collocated words in a sentence with the MWA method. The advantage of this method lies in that it can identify the collocated words in a sentence without additional resources. In this paper, we employ MWA Model l~3 described in Liu et al. (2009) to detect collocations in sentences, which are shown in Eq. (1)~(3).

$$p_{\text{MWA Model 1}}(A \mid S) \propto \prod_{j=1}^{l} t(w_j \mid w_{c_j}) \tag{1}$$

$$p_{\text{MWA Model 2}}(A \mid S) \propto \prod_{j=1}^{l} t(w_j \mid w_{c_j}) \cdot d(j \mid c_j, l) \tag{2}$$

$$p_{\text{MWA Model 3}}(A \mid S) \propto \prod_{i=1}^{l} n(\phi_i \mid w_i) \cdot \prod_{j=1}^{l} t(w_j \mid w_{c_j}) \cdot d(j \mid c_j, l) \tag{3}$$

Where $S = w_1^l$ is a monolingual sentence; ϕ_i denotes the number of words collocating with w_i; $A = \{(i, c_i) \mid i \in [1,l] \,\&\, c_i \neq i\}$ denotes the potentially collocated words in S.

The MWA models measure the collocated words under different constraints. MWA Model 1 only models word collocation probabilities $t(w_j \mid w_{c_j})$. MWA Model 2 additionally employs position collocation probabilities $d(j \mid c_j, l)$. Besides the features in MWA Model 2, MWA Model 3 also considers fertility probabilities $n(\phi_i \mid w_i)$.

Given a sentence, the optimal collocated words can be obtained according to Eq. (4).

$$A^* = \arg\max_{A} p_{\text{MWA Model } i}(A \mid S) \tag{4}$$

Given a monolingual word aligned corpus, the collocation probabilities can be estimated as follows.

$$r(w_i, w_j) = \frac{p(w_i \mid w_j) + p(w_j \mid w_i)}{2} \tag{5}$$

Where, $p(w_i \mid w_j) = \dfrac{count(w_i, w_j)}{\sum_{w'} count(w', w_j)}$; (w_i, w_j) denotes the collocated words in the corpus and $count(w_i, w_j)$ denotes the co-occurrence frequency.

3 Reordering Model with Source Language Collocations

In this section, we first describe how to estimate the orientation probabilities for a given collocation, and then describe the estimation of the reordering score during translation. Finally, we describe the integration of the reordering model into the SMT system.

3.1 Reordering probability estimation

Given a source collocation (f_i, f_j) and its corresponding translations (e_{a_i}, e_{a_j}) in a bilingual sentence pair, the reordering orientation of the collocation can be defined as in Eq. (6).

$$o_{i,j,a_i,a_j} = \begin{cases} \text{straight if } i < j \,\&\, a_i < a_j \text{ or } i > j \,\&\, a_i > a_j \\ \text{inverted if } i > j \,\&\, a_i < a_j \text{ or } i < j \,\&\, a_i > a_j \end{cases} \quad (6)$$

In our method, only those collocated words in source language that are aligned to different target words, are taken into consideration, and those being aligned to the same target word are ignored.

Given a word-aligned bilingual corpus where the collocations in source sentences are detected, the probabilities of the translation orientation of collocations in the source language can be estimated, as follows:

$$p(o = \text{straight} \mid f_i, f_j) = \frac{count(o = \text{straight}, f_i, f_j)}{\sum_{o'} count(o', f_i, f_j)} \quad (7)$$

$$p(o = \text{inverted} \mid f_i, f_j) = \frac{count(o = \text{inverted}, f_i, f_j)}{\sum_{o'} count(o', f_i, f_j)} \quad (8)$$

Here, $count(o, f_i, f_j)$ is collected according to the algorithm in Figure 1.

3.2 Reordering model

Given a sentence $F = f_1^l$ to be translated, the collocations are first detected using the algorithm described in Eq. (4). Then the reordering score is estimated according to the reordering probability weighted by the collocation probability of the collocated words. Formally, for a generated translation candidate T, the reordering score is calculated as follows.

$$P_O(F,T) = \sum_{(i,c_i)} r(f_i, f_{c_i}) \log p(o_{i,c_i,a_i,a_{c_i}} \mid f_i, f_{c_i}) \quad (9)$$

Input: A word-aligned bilingual corpus where the source collocations are detected
Initialization: $count(o, f_i, f_j) = 0$
for each sentence pair <*F*, *E*> in the corpus **do**
  for each collocated word pair (f_i, f_{c_i}) in *F* **do**
    if $i < c_i \,\&\, a_i < a_{c_i}$ or $i > c_i \,\&\, a_i > a_{c_i}$ **then**
      $count(o = straight, f_i, f_{c_i})$++
    if $i < c_i \,\&\, a_i > a_{c_i}$ or $i > c_i \,\&\, a_i < a_{c_i}$ **then**
      $count(o = inverted, f_i, f_{c_i})$++
Output: $count(o, f_i, f_j)$

Figure 1. Algorithm of estimating reordering frequency

Here, $r(f_i, f_{c_i})$ denotes the collocation probability of f_i and f_{c_i} as shown in Eq. (5).

In addition to the detected collocated words in the sentence, we also consider other possible word pairs whose collocation probabilities are higher than a given threshold. Thus, the reordering score is further improved according to Eq. (10).

$$P_O(F,T) = \alpha \cdot \sum_{(i,c_i)} r(f_i, f_{c_i}) \log p(o_{i,c_i,a_i,a_{c_i}} \mid f_i, f_{c_i}) + \beta \cdot \sum_{\substack{(i,j) \notin \{(i,c_i)\} \\ \& \, r(f_i,f_j) > \theta}} r(f_i, f_j) \log p(o_{i,j,a_i,a_j} \mid f_i, f_j) \} \quad (10)$$

Where α and β are two interpolation weights. θ is the threshold of collocation probability. The weights and the threshold can be tuned using a development set.

3.3 Integrated into SMT system

The SMT systems generally employ the log-linear model to integrate various features (Chiang, 2005; Koehn et al., 2007). Given an input sentence *F*, the final translation *E** with the highest score is chosen from candidates, as in Eq. (11).

$$E^* = \arg\max_E \{ \sum_{m=1}^{M} \lambda_m h_m(E,F) \} \quad (11)$$

Where $h_m(E, F)$ (m=1,...,M) denotes features. λ_m is a feature weight.

Our reordering model can be integrated into the system as one feature as shown in (10).

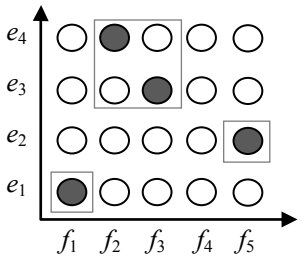

Figure 2. An example for reordering

4 Evaluation of Our Method

4.1 Implementation

We implemented our method in a phrase-based SMT system (Koehn et al., 2007). Based on the GIZA++ package (Och and Ney, 2003), we implemented a MWA tool for collocation detection. Thus, given a sentence to be translated, we first identify the collocations in the sentence, and then estimate the reordering score according to the translation hypothesis. For a translation option to be expanded, the reordering score inside this source phrase is calculated according to their translation orders of the collocations in the corresponding target phrase. The reordering score crossing the current translation option and the covered parts can be calculated according to the relative position of the collocated words. If the source phrase matched by the current translation option is behind the covered parts in the source sentence, then $\log p(o = \text{staight} \mid ...)$ is used, otherwise $\log p(o = \text{inverted} \mid ...)$. For example, in Figure 2, the current translation option is ($f_2\, f_3 \rightarrow e_3\, e_4$). The collocations related to this translation option are (f_1, f_3) , (f_2, f_3) , (f_3, f_5) . The reordering scores can be estimated as follows:

$$r(f_1, f_3) \log p(o = \text{straight} \mid f_1, f_3)$$
$$r(f_2, f_3) \log p(o = \text{inverted} \mid f_2, f_3)$$
$$r(f_3, f_5) \log p(o = \text{inverted} \mid f_3, f_5)$$

In order to improve the performance of the decoder, we design a heuristic function to estimate the future score, as shown in Figure 3. For any uncovered word and its collocates in the input sentence, if the collocate is uncovered, then the higher reordering probability is used. If the collocate has been covered, then the reordering orientation can be determined according to the relative positions of the words and the corresponding reordering probability is employed.

Input: Input sentence $F = f_1^L$
Initialization: *Score* = 0
for each uncovered word f_i **do**
  for each word f_j ($j = c_i$ or $r(f_{i,} f_j) > \theta$) **do**
    if f_j is covered **then**
      if $i > j$ **then**
        $Score \mathrel{+}= r(f_{i,} f_j) \log p(o = \text{straight} \mid f_i, f_j)$
      else
        $Score \mathrel{+}= r(f_{i,} f_j) \log p(o = \text{inverted} \mid f_i, f_j)$
    else
      $Score \mathrel{+}= \arg\max_o r(f_{i,} f_j) \log p(o \mid f_i, f_j)$
Output: *Score*

Figure 3. Heuristic function for estimating future score

4.2 Settings

We use the FBIS corpus (LDC2003E14) to train a Chinese-to-English phrase-based translation model. And the SRI language modeling toolkit (Stolcke, 2002) is used to train a 5-gram language model on the English sentences of FBIS corpus.

We used the NIST evaluation set of 2002 as the development set to tune the feature weights of the SMT system and the interpolation parameters, based on the minimum error rate training method (Och, 2003), and the NIST evaluation sets of 2004 and 2008 (MT04 and MT08) as the test sets.

We use BLEU (Papineni et al., 2002) as evaluation metrics. We also calculate the statistical significance differences between our methods and the baseline method by using the paired bootstrap resample method (Koehn, 2004).

4.3 Translation results

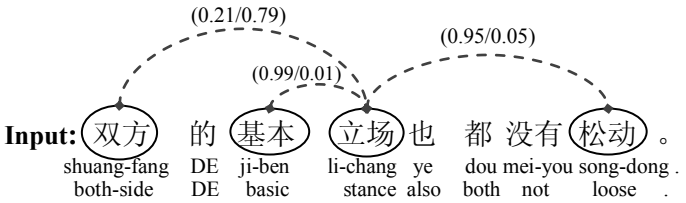
We compare the proposed method with various reordering methods in previous work.

Monotone model: no reordering model is used.

Distortion based reordering (DBR) model: a distortion based reordering method (Al-Onaizan & Papineni, 2006). In this method, the distortion cost is defined in terms of words, rather than phrases. This method considers *outbound*, *inbound*, and *pairwise* distortions that

Reorder models		MT04	MT08
Monotone model		26.99	18.30
DBR model		26.64	17.83
MSDR model (Baseline)		28.77	18.42
MSDR+	DBR model	28.91	18.58
	SCBR Model 1	29.21	19.28
	SCBR Model 2	29.44	19.36
	SCBR Model 3	29.50	19.44
	SCBR models (1+2)	29.65	19.57
	SCBR models (1+2+3)	29.75	19.61

Table 1. Translation results on various reordering models



T1: The two sides are also the basic stand of not relaxed.
T2: The basic stance of the two sides have not relaxed.
Reference: The basic stances of both sides did not move.

Figure 4. Translation example. (*/*) denotes ($p_{straight}$ / $p_{inverted}$)

are directly estimated by simple counting over alignments in the word-aligned bilingual corpus. This method is similar to our proposed method. But our method considers the translation order of the collocated words.

msd-bidirectional-fe reordering (MSDR or Baseline) model: it is one of the reordering models in Moses. It considers three different orientation types (*monotone*, *swap*, and *discontinuous*) on both source phrases and target phrases. And the translation orders of both the next phrase and the previous phrase in respect to the current phrase are modeled.

Source collocation based reordering (SCBR) model: our proposed method. We investigate three reordering models based on the corresponding MWA models and their combinations. In SCBR Model *i* (*i*=1~3), we use MWA Model *i* as described in section 2 to obtain the collocated words and estimate the reordering probabilities according to section 3.

The experiential results are shown in Table 1. The DBR model suffers from serious data sparseness. For example, the reordering cases in the trained pairwise distortion model only covered 32~38% of those in the test sets. So its performance is worse than that of the monotone model. The MSDR model achieves higher BLEU scores than the monotone model and the DBR model. Our models further improve the translation quality, achieving better performance than the combination of MSDR model and DBR model. The results in Table 1 show that "MSDR + SCBR Model 3" performs the best among the SCBR models. This is because, as compared to MWA Model 1 and 2, MWA Model 3 takes more information into consideration, including not only the co-occurrence information of lexical tokens and the position of words, but also the fertility of words in a sentence. And when the three SCBR models are combined, the performance of the SMT system is further improved. As compared to other reordering models, our models achieve an absolute improvement of 0.98~1.19 BLEU score on the test sets, which are statistically significant ($p < 0.05$).

Figure 4 shows an example: T1 is generated by the baseline system and T2 is generated by the system where the SCBR models (1+2+3)[1] are used.

[1] In the remainder of this paper, "SCBR models" means the combination of the SCBR models (1+2+3) unless it is explicitly explained.

Reordering models		MT04	MT08
MSDR model		28.77	18.42
MSDR+	DBR model	28.91	18.58
	CBR model	28.96	18.77
	WCBR model	29.15	19.10
	WCBR+SCBR models	29.87	19.83

Table 2. Translation results of co-occurrence based reordering models

	CBR model	SCBR Model3
Consecutive words	77.9%	73.5%
Interrupted words	74.1%	87.8%
Total	74.3%	84.9%

Table 3. Precisions of the reordering models on the development set

The input sentence contains three collocations. The collocation (基本, 立场) is included in the same phrase and translated together as a whole. Thus its translation is correct in both translations. For the other two long-distance collocations (双方, 立场) and (立场, 松动), their translation orders are not correctly handled by the reordering model in the baseline system. For the collocation (双方, 立场), since the SCBR models indicate $p(o$=straight|双方, 立场$) < p(o$=inverted|双方, 立场$)$, the system finally generates the translation T2 by constraining their translation order with the proposed model.

5 Collocations vs. Co-occurring Words

We compared our method with the method that models the reordering orientations based on co-occurring words in the source sentences, rather than the collocations.

5.1 Co-occurrence based reordering model

We use the similar algorithm described in section 3 to train the co-occurrence based reordering (CBR) model, except that the probability of the reordering orientation is estimated on the co-occurring words and the relative distance. Given an input sentence and a translation candidate, the reordering score is estimated as shown in Eq. (12).

$$P_O(F,T) = \sum_{(i,j)} \log p(o_{i,j,a_i,a_j} \mid f_i, f_j, \Delta_{i-j}) \quad (12)$$

Here, Δ_{i-j} is the relative distance of two words in the source sentence.

We also construct the weighted co-occurrence based reordering (WCBR) model. In this model, the probability of the reordering orientation is additionally weighted by the pointwise mutual information[2] score of the two words (Manning and Schütze, 1999), which is estimated as shown in Eq. (13).

$$P_O(F,T) = \sum_{(i,j)} s_{\mathrm{MI}}(f_i, f_j) \log p(o_{i,j,a_i,a_j} \mid f_i, f_j, \Delta_{i-j}) \quad (13)$$

5.2 Translation results

Table 2 shows the translation results. It can be seen that the performance of the SMT system is improved by integrating the CBR model. The performance of the CBR model is also better than that of the DBR model. It is because the former is trained based on all co-occurring aligned words, while the latter only considers the adjacent aligned words. When the WCBR model is used, the translation quality is further improved. However, its performance is still inferior to that of the SCBR models, indicating that our method (SCBR models) of modeling the translation orders of source collocations is more effective. Furthermore, we combine the weighted co-occurrence based model and our method, which outperform all the other models.

5.3 Result analysis

Precision of prediction

First of all, we investigate the performance of the reordering models by calculating precisions of the translation orders predicted by the reordering models. Based on the source sentences and reference translations of the development set, where the source words and target words are automatically aligned by the bilingual word alignment method, we construct the reference translation orders for two words. Against the references, we calculate three kinds of precisions as follows:

$$P_{\mathrm{CW}} = \frac{|\{|i-j|=1 \;\&\; o_{i,j} = o_{i,j,a_i,a_j}\}|}{|\{o_{i,j} \parallel i-j|=1\}|} \quad (14)$$

[2] For occurring words extraction, the window size is set to [-6, +6].

$$P_{\mathrm{IW}} = \frac{|\{|i-j|>1 \;\&\; o_{i,j} = o_{i,j,a_i,a_j}\}|}{|\{o_{i,j} \parallel i-j|>1\}|} \quad (15)$$

$$P_{\mathrm{total}} = \frac{|\{o_{i,j} = o_{i,j,a_i,a_j}\}|}{|\{o_{i,j}\}|} \quad (16)$$

Here, $o_{i,j}$ denotes the translation order of (f_i, f_j) predicted by the reordering models. If $p(o=\text{straight}\,|\,f_i,f_j) > p(o=\text{inverted}\,|f_i,f_j)$, then $o_{i,j}=\text{straight}$, else if $p(o=\text{straight}\,|\,f_i,f_j) < p(o=\text{inverted}\,|f_i,f_j)$, then $o_{i,j}=\text{inverted}$. o_{i,j,a_i,a_j} denotes the translation order derived from the word alignments. If $o_{i,j}=o_{i,j,a_i,a_j}$, then the predicted translation order is correct, otherwise wrong. P_{CW} and P_{IW} denote the precisions calculated on the consecutive words and the interrupted words in the source sentences, respectively. P_{total} denotes the precision on both cases. Here, the CBR model and SCBR Model 3 are compared. The results are shown in Table 3.

From the results in Table 3, it can be seen that the CBR model has a higher precision on the consecutive words than the SCBR model, but lower precisions on the interrupted words. It is mainly because the CBR model introduces more noise when the relative distance of words is set to a large number, while the MWA method can effectively detect the long-distance collocations in sentences (Liu et al., 2009). This explains why the combination of the two models can obtain the highest BLEU score as shown in Table 2. On the whole, the SCBR Model 3 achieves higher precision than the CBR model.

Effect of the reordering model

Then we evaluate the reordering results of the generated translations in the test sets. Using the above method, we construct the reference translation orders of collocations in the test sets. For a given word pair in a source sentence, if the translation order in the generated translation is the same as that in the reference translations, then it is correct, otherwise wrong.

We compare the translations of the baseline method, the co-occurrence based method, and our method (SCBR models). The precisions calculated on both kinds of words are shown in Table 4. From the results, it can be seen that our method achieves higher precisions than both the baseline and the method modeling the translation orders of the co-occurring words. It indicates that the proposed method effectively constrains the reordering of source words during decoding and improves the translation quality.

Test sets	Baseline (MSDR)	MSDR+ WCBR	MSDR+ SCBR
MT04	78.9%	80.8%	82.5%
MT08	80.7%	83.8%	85.0%

Table 4. Precisions (total) of the reordering models on the test sets

6 Related Work

Reordering was first proposed in the IBM models (Brown et al., 1993), later was named *IBM constraint* by Berger et al. (1996). This model treats the source word sequence as a coverage set that is processed sequentially and a source token is covered when it is translated into a new target token. In 1997, another model called *ITG constraint* was presented, in which the reordering order can be hierarchically modeled as *straight* or *inverted* for two nodes in a binary branching structure (Wu, 1997). Although the *ITG constraint* allows more flexible reordering during decoding, Zens and Ney (2003) showed that the *IBM constraint* results in higher BLEU scores. Our method models the reordering of collocated words in sentences instead of all words in IBM models or two neighboring blocks in ITG models.

For phrase-based SMT models, Koehn et al. (2003) linearly modeled the distance of phrase movements, which results in poor global reordering. More methods are proposed to explicitly model the movements of phrases (Tillmann, 2004; Koehn et al., 2005) or to directly predict the orientations of phrases (Tillmann and Zhang, 2005; Zens and Ney, 2006), conditioned on current source phrase or target phrase. Hierarchical phrase-based SMT methods employ SCFG bilingual translation model and allow flexible reordering (Chiang, 2005). However, these methods ignored the correlations among words in the source language or in the target language. In our method, we automatically detect the collocated words in sentences and

their translation orders in the target languages, which are used to constrain the ordering models with the estimated reordering (straight or inverted) score. Moreover, our method allows flexible reordering by considering both consecutive words and interrupted words.

In order to further improve translation results, many researchers employed syntax-based reordering methods (Zhang et al., 2007; Marton and Resnik, 2008; Ge, 2010; Visweswariah et al., 2010). However these methods are subject to parsing errors to a large extent. Our method directly obtains collocation information without resorting to any linguistic knowledge or tools, therefore is suitable for any language pairs.

In addition, a few models employed the collocation information to improve the performance of the ITG constraints (Xiong et al., 2006). Xiong et al. used the consecutive co-occurring words as collocation information to constrain the reordering, which did not lead to higher translation quality in their experiments. In our method, we first detect both consecutive and interrupted collocated words in the source sentence, and then estimated the reordering score of these collocated words, which are used to softly constrain the reordering of source phrases.

7 Conclusions

We presented a novel model to improve SMT by means of modeling the translation orders of source collocations. The model was learned from a word-aligned bilingual corpus where the potentially collocated words in source sentences were automatically detected by the MWA method. During decoding, the model is employed to softly constrain the translation orders of the source language collocations. Since we only model the reordering of collocated words, our methods can partially alleviate the data sparseness encountered by other methods directly modeling the reordering based on source phrases or target phrases. In addition, this kind of reordering information can be integrated into any SMT systems without resorting to any additional resources.

The experimental results show that the proposed method significantly improves the translation quality of a phrase based SMT system, achieving an absolute improvement of 1.1~1.4 BLEU score over the baseline methods.

A Joint Sequence Translation Model with Integrated Reordering

Nadir Durrani **Helmut Schmid** **Alexander Fraser**

Abstract

We present a novel machine translation model which models translation by a linear sequence of *operations*. In contrast to the "N-gram" model, this sequence includes not only translation but also reordering operations. Key ideas of our model are (i) a new reordering approach which better restricts the position to which a word or phrase can be moved, and is able to handle short and long distance reorderings in a unified way, and (ii) a joint sequence model for the translation and reordering probabilities which is more flexible than standard phrase-based MT. We observe statistically significant improvements in BLEU over Moses for German-to-English and Spanish-to-English tasks, and comparable results for a French-to-English task.

1 Introduction

We present a novel generative model that explains the translation process as a linear sequence of operations which generate a source and target sentence in parallel. Possible operations are (i) generation of a sequence of source and target words (ii) insertion of *gaps* as explicit target positions for reordering operations, and (iii) forward and backward jump operations which do the actual reordering. The probability of a sequence of operations is defined according to an N-gram model, i.e., the probability of an operation depends on the $n-1$ preceding operations. Since the translation (generation) and reordering operations are coupled in a single generative story, the reordering decisions may depend on preceding translation decisions and translation decisions may depend on preceding reordering decisions. This provides a natural reordering mechanism which is able to deal with local and long-distance reorderings in a consistent way. Our approach can be viewed as an extension of the N-gram SMT approach (Mariño et al., 2006) but our model does reordering as an integral part of a generative model.

The paper is organized as follows. Section 2 discusses the relation of our work to phrase-based and the N-gram SMT. Section 3 describes our generative story. Section 4 defines the probability model, which is first presented as a generative model, and then shifted to a discriminative framework. Section 5 provides details on the search strategy. Section 6 explains the training process. Section 7 describes the experimental setup and results. Section 8 gives a few examples illustrating different aspects of our model and Section 9 concludes the paper.

2 Motivation and Previous Work

2.1 Relation of our work to PBSMT

Phrase-based SMT provides a powerful translation mechanism which learns local reorderings, translation of short idioms, and the insertion and deletion of words sensitive to local context. However, PBSMT also has some drawbacks. (i) Dependencies across phrases are not directly represented in the translation model. (ii) Discontinuous phrases cannot be used. (iii) The presence of many different equivalent segmentations increases the search space.

Phrase-based SMT models dependencies between words and their translations inside of a phrase well. However, dependencies across phrase boundaries are largely ignored due to the strong phrasal inde-

German	English
hat er ein buch gelesen	he read a book
hat eine pizza gegessen	has eaten a pizza
er	he
hat	has
ein	a
eine	a
menge	lot of
butterkekse	butter cookies
gegessen	eaten
buch	book
zeitung	newspaper
dann	then

Table 1: Sample Phrase Table

pendence assumption. A phrase-based system using the phrase table[1] shown in Table 1, for example, correctly translates the German sentence "er hat eine pizza gegessen" to "he has eaten a pizza", but fails while translating "er hat eine menge butterkekse gegessen" (see Table 1 for a gloss) which is translated as "he has a lot of butter cookies eaten" unless the language model provides strong enough evidence for a different ordering. The generation of this sentence in our model starts with generating "er – he", "hat – has". Then a gap is inserted on the German side, followed by the generation of "gegessen – eaten". At this point, the (partial) German and English sentences look as follows:

er hat ☐ gegessen
he has eaten

We jump back to the gap on the German side and fill it by generating "eine – a" and "pizza – pizza", for the first example and generating "eine – a", "menge – lot of", "butterkekse – butter cookies" for the second example, thus handling both short and long distance reordering in a unified manner. Learning the pattern "hat ☐ gegessen – has eaten" helps us to generalize to the second example with unseen context. Notice how the reordering decision is triggered by the translation decision in our model. The probability of a gap insertion operation after the generation of the auxiliaries "hat – has" will be high because reordering is necessary in order to move the second part of the German verb complex ("gegessen") to its correct position at the end of the clause. This mechanism better restricts reordering

[1]The examples given in this section are not taken from the real data/system, but made-up for the sake of argument.

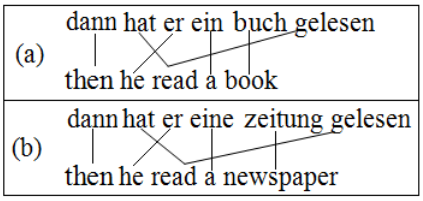

Figure 1: (a) Known Context (b) Unknown Context

than traditional PBSMT and is able to deal with local and long-distance reorderings in a consistent way.

Another weakness of the traditional phrase-based system is that it can only capitalize on continuous phrases. Given the phrase inventory in Table 1, phrasal MT is able to generate example in Figure 1(a). The information "hat...gelesen – read" is internal to the phrase pair "hat er ein buch gelesen – he read a book", and is therefore handled conveniently. On the other hand, the phrase table does not have the entry "hat er eine zeitung gelesen – he read a newspaper" (Figure 1(b)). Hence, there is no option but to translate "hat...gelesen" separately, translating "hat" to "has" which is a common translation for "hat" but wrong in the given context. Context-free hierarchical models (Chiang, 2007; Melamed, 2004) have rules like "hat er X gelesen – he read X" to handle such cases. Galley and Manning (2010) recently solved this problem for phrasal MT by extracting phrase pairs with source and target-side gaps. Our model can also use tuples with source-side discontinuities. The above sentence would be generated by the following sequence of operations: (i) generate "dann – then" (ii) insert a gap (iii) generate "er – he" (iv) backward jump to the gap (v) generate "hat...[gelesen] – read" (only "hat" and "read" are added to the sentences yet) (vi) jump forward to the right-most source word so far generated (vii) insert a gap (viii) continue the source cept ("gelesen" is inserted now) (ix) backward jump to the gap (x) generate "ein – a" (xi) generate "buch – book".

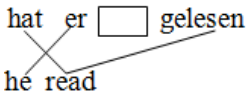

Figure 2: Pattern

From this operation sequence, the model learns a pattern (Figure 2) which allows it to generalize to the example in Figure 1(b). The open gap represented by ☐ serves a similar purpose as the non-terminal categories in a hierarchical phrase-based system such as Hiero. Thus it generalizes to translate "eine zeitung" in exactly the same way as "ein buch".

Another problem of phrasal MT is spurious phrasal segmentation. Given a sentence pair and a corresponding word alignment, phrasal MT can learn an arbitrary number of source segmentations. This is problematic during decoding because different compositions of the same minimal phrasal units are allowed to compete with each other.

2.2 Relation of our work to N-gram SMT

N-gram based SMT is an alternative to hierarchical and non-hierarchical phrase-based systems. The main difference between phrase-based and N-gram SMT is the extraction procedure of translation units and the statistical modeling of translation context (Crego et al., 2005a). The tuples used in N-gram systems are much smaller translation units than phrases and are extracted in such a way that a unique segmentation of each bilingual sentence pair is produced. This helps N-gram systems to avoid the spurious phrasal segmentation problem. Reordering works by linearization of the source side and tuple unfolding (Crego et al., 2005b). The decoder uses word lattices which are built with linguistically motivated re-write rules. This mechanism is further enhanced with an N-gram model of bilingual units built using POS tags (Crego and Yvon, 2010). A drawback of their reordering approach is that search is only performed on a small number of reorderings that are pre-calculated on the source side independently of the target side. Often, the evidence for the correct ordering is provided by the target-side language model (LM). In the N-gram approach, the LM only plays a role in selecting between the pre-calculated orderings.

Our model is based on the N-gram SMT model, but differs from previous N-gram systems in some important aspects. It uses operation n-grams rather than tuple n-grams. The reordering approach is entirely different and considers all possible orderings instead of a small set of pre-calculated orderings. The standard N-gram model heavily relies on POS tags for reordering and is unable to use lexical triggers whereas our model exclusively uses lexical triggers and no POS information. Linearization and unfolding of the source sentence according to the target sentence enables N-gram systems to handle source-side gaps. We deal with this phenomenon more directly by means of tuples with source-side discontinuities. The most notable feature of our work is that it has a complete generative story of translation which combines translation and reordering operations into a single operation sequence model.

Like the N-gram model[2], our model cannot deal with target-side discontinuities. These are eliminated from the training data by a post-editing process on the alignments (see Section 6). Galley and Manning (2010) found that target-side gaps were not useful in their system and not useful in the hierarchical phrase-based system Joshua (Li et al., 2009).

3 Generative Story

Our generative story is motivated by the complex reorderings in the German-to-English translation task. The German and English sentences are jointly generated through a sequence of operations. The English words are generated in linear order[3] while the German words are generated in parallel with their English translations. Occasionally the translator jumps back on the German side to insert some material at an earlier position. After this is done, it jumps forward again and continues the translation. The backward jumps always end at designated landing sites (gaps) which were explicitly inserted before. We use 4 translation and 3 reordering operations. Each is briefly discussed below.

Generate (X,Y): X and Y are German and English cepts[4] respectively, each with one or more words. Words in X (German) may be consecutive or discontinuous, but the words in Y (English) must be consecutive. This operation causes the words in Y and the first word in X to be added to the English and German strings respectively, that were generated so far. Subsequent words in X are added to a queue to be generated later. All the English words in Y are generated immediately because English is generated in linear order. The generation of the second (and subsequent) German word in a multi-word cept can be delayed by gaps, jumps and the Generate Source Only operation defined below.

Continue Source Cept: The German words added

[2]However, Crego and Yvon (2009), in their N-gram system, use split rules to handle target-side gaps and show a slight improvement on a Chinese-English translation task.

[3]Generating the English words in order is also what the decoder does when translating from German to English.

[4]A cept is a group of words in one language translated as a minimal unit in one specific context (Brown et al., 1993).

to the queue by the Generate (X,Y) operation are generated by the Continue Source Cept operation. Each Continue Source Cept operation removes one German word from the queue and copies it to the German string. If X contains more than one German word, say n many, then it requires n translation operations, an initial Generate $(X_1...X_n, Y)$ operation and $n-1$ Continue Source Cept operations. For example "hat...gelesen – read" is generated by the operation Generate (hat gelesen, read), which adds "hat" and "read" to the German and English strings and "gelesen" to a queue. A Continue Source Cept operation later removes "gelesen" from the queue and adds it to the German string.

Generate Source Only (X): The string X is added at the current position in the German string. This operation is used to generate a German word X with no corresponding English word. It is performed immediately after its preceding German word is covered. This is because there is no evidence on the English-side which indicates when to generate X. Generate Source Only (X) helps us learn a source word deletion model. It is used during decoding, where a German word (X) is either translated to some English word(s) by a Generate (X,Y) operation or deleted with a Generate Source Only (X) operation.

Generate Identical: The same word is added at the current position in both the German and English strings. The Generate Identical operation is used during decoding for the translation of unknown words. The probability of this operation is estimated from singleton German words that are translated to an identical string. For example, for a tuple "Portland – Portland", where German "Portland" was observed exactly once during training, we use a Generate Identical operation rather than Generate (Portland, Portland).

We now discuss the set of reordering operations used by the generative story. Reordering has to be performed whenever the German word to be generated next does not immediately follow the previously generated German word. During the generation process, the translator maintains an index which specifies the position after the previously covered German word (j), an index (Z) which specifies the index after the right-most German word covered so far, and an index of the next German word to be covered (j'). The set of reordering operations used in generation depends upon these indexes.

Operations	Generation	States
Generate (dann , then)	dann ↓ then	i=1 j=1 j'=2 k=0 Z=1
Insert Gap – Generate (er , he)	dann □ er ↓ then he	i=2 j=3 j'=1 k=0 Z=3 S=1
Jump Back(1) – Generate (hat gelesen, read)	dann hat ↓ er then he read	i=3 j=2 j'=5 k=1 Z=3
Jump Forward – Insert Gap – Continue Source Cept	dann hat er □ gelesen ↓ then he read	i=3 j=6 j'=3 k=0 Z=6 S=3
Jump Back(1) – Generate (ein , a)	dann hat er ein ↓ gelesen then he read a	i=4 j =4 j'=4 k=0 Z=6
Generate (buch , book)	dann hat er ein buch ↓ gelesen then he read a book	i=5 j=5 j'=6 k=0 Z=6

Table 2: Step-wise Generation of Example 1(a). The arrow indicates position j.

Insert Gap: This operation inserts a gap which acts as a place-holder for the skipped words. There can be more than one open gap at a time.

Jump Back (W): This operation lets the translator jump back to an open gap. It takes a parameter W specifying which gap to jump to. Jump Back (1) jumps to the closest gap to Z, Jump Back (2) jumps to the second closest gap to Z, etc. After the backward jump the target gap is closed.

Jump Forward: This operation makes the translator jump to Z. It is performed if some already generated German word is between the previously generated word and the word to be generated next. A Jump Back (W) operation is only allowed at position Z. Therefore, if $j \neq Z$, a Jump Forward operation has to be performed prior to a Jump Back operation.

Table 2 shows step by step the generation of a German/English sentence pair, the corresponding translation operations, and the respective values of the index variables. A formal algorithm for converting a word-aligned bilingual corpus into an operation sequence is presented in Algorithm 1.

4 Model

Our translation model $p(F, E)$ is based on operation N-gram model which integrates translation and reordering operations. Given a source string F, a sequence of tuples $T = (t_1, \ldots, t_n)$ as hypothesized by the decoder to generate a target string E, the translation model estimates the probability of a

Algorithm 1 Corpus Conversion Algorithm

i	Position of current English cept
j	Position of current German word
j'	Position of next German word
N	Total number of English cepts
f_j	German word at position j
E_i	English cept at position i
F_i	Sequence of German words linked to E_i
L_i	Number of German words linked with E_i
k	Number of already generated German words for E_i
a_{ik}	Position of k^{th} German translation of E_i
Z	Position after right-most generated German word
S	Position of the first word of a target gap

$i := 0; j := 0; k := 0$

while f_j is an unaligned word **do**
  Generate Source Only (f_j)
  $j := j + 1$
$Z := j$

while $i < N$ **do**
  $j' := a_{ik}$
  if $j < j'$ **then**
    if f_j was not generated yet **then**
      Insert Gap
    if $j = Z$ **then**
      $j := j'$
    else
      Jump Forward
  if $j' < j$ **then**
    if $j < Z$ and f_j was not generated yet **then**
      Insert Gap
    $W :=$ relative position of target gap
    Jump Back (W)
    $j := S$
  if $j < j'$ **then**
    Insert Gap
    $j := j'$
  if k = 0 **then**
    Generate (F_i, E_i) {or **Generate Identical**}
  else
    Continue Source Cept
  $j := j + 1; k := k + 1$
  while f_j is an unaligned word **do**
    Generate Source Only (f_j)
    $j := j + 1$
  if $Z < j$ **then**
    $Z := j$
  if $k = L_i$ **then**
    $i := i + 1; k := 0$

Remarks:
We use cept positions for English (not word positions) because English cepts are composed of consecutive words. German positions are word-based.
The relative position of the target gap is 1 if it is closest to Z, 2 if it is the second closest gap etc.
The operation **Generate Identical** is chosen if $F_i = E_i$ and the overall frequency of the German cept F_i is 1.

generated operation sequence $O = (o_1, \ldots, o_J)$ as:

$$p(F, E) \approx \prod_{j=1}^{J} p(o_j | o_{j-m+1} ... o_{j-1})$$

where m indicates the amount of context used. Our translation model is implemented as an N-gram model of operations using SRILM-Toolkit (Stolcke, 2002) with Kneser-Ney smoothing. We use a 9-gram model ($m = 8$).

Integrating the language model the search is defined as:

$$\hat{E} = \arg\max_{E} p_{LM}(E) p(F, E)$$

where $p_{LM}(E)$ is the monolingual language model and $p(F, E)$ is the translation model. But our translation model is a joint probability model, because of which E is generated twice in the numerator. We add a factor, prior probability $p_{pr}(E)$, in the denominator, to negate this effect. It is used to marginalize the joint-probability model $p(F, E)$. The search is then redefined as:

$$\hat{E} = \arg\max_{E} p_{LM}(E) \frac{p(F, E)}{p_{pr}(E)}$$

Both, the monolingual language and the prior probability model are implemented as standard word-based n-gram models:

$$p_x(E) \approx \prod_{j=1}^{J} p(w_j | w_{j-m+1}, \ldots, w_{j-1})$$

where $m = 4$ (5-gram model) for the standard monolingual model ($x = LM$) and $m = 8$ (same as the operation model[5]) for the prior probability model ($x = pr$).

In order to improve end-to-end accuracy, we introduce new features for our model and shift from the generative[6] model to the standard log-linear approach (Och and Ney, 2004) to tune[7] them. We search for a target string E which maximizes a linear combination of feature functions:

[5] In decoding, the amount of context used for the prior probability is synchronized with the position of back-off in the operation model.

[6] Our generative model is about 3 BLEU points worse than the best discriminative results.

[7] We tune the operation, monolingual and prior probability models as separate features. We expect the prior probability model to get a negative weight but we do not force MERT to assign a negative weight to this feature.

$$\hat{E} = \arg\max_{E} \left\{ \sum_{j=1}^{J} \lambda_j h_j(F, E) \right\}$$

where λ_j is the weight associated with the feature $h_j(F, E)$. Other than the 3 features discussed above (log probabilities of the operation model, monolingual language model and prior probability model), we train 8 additional features discussed below:

Length Bonus The length bonus feature counts the length of the target sentence in words.

Deletion Penalty Another feature for avoiding too short translations is the deletion penalty. Deleting a source word (Generate Source Only (X)) is a common operation in the generative story. Because there is no corresponding target-side word, the monolingual language model score tends to favor this operation. The deletion penalty counts the number of deleted source words.

Gap Bonus and Open Gap Penalty These features are introduced to guide the reordering decisions. We observe a large amount of reordering in the automatically word aligned training text. However, given only the source sentence (and little world knowledge), it is not realistic to try to model the reasons for all of this reordering. Therefore we can use a more robust model that reorders less than humans. The gap bonus feature sums to the total number of gaps inserted to produce a target sentence. The open gap penalty feature is a penalty (paid once for each translation operation performed) whose value is the number of open gaps. This penalty controls how quickly gaps are closed.

Distortion and Gap Distance Penalty We have two additional features to control the reordering decisions. One of them is similar[8] to the distance-based reordering model used by phrasal MT. The other feature is the gap distance penalty which calculates the distance between the first word of a source cept X and the start of the left-most gap. This cost is paid once for each Generate, Generate Identical and Generate Source Only. For a source cept coverd by indexes $X_1, \ldots, X_n$, we get the feature value $g_j = X_1 - S$, where S is the index of the left-most source word where a gap starts.

[8]Let $X_1, \ldots, X_n$ and $Y_1, \ldots, Y_m$ represent indexes of the source words covered by the tuples t_j and t_{j-1} respectively. The distance between t_j and t_{j-1} is given as $d_j = min(|X_k - Y_l| - 1) \; \forall \; X_k \in \{X_1, \ldots, X_n\}$ and $\forall \; Y_l \in \{Y_1, \ldots, Y_m\}$

Lexical Features We also use source-to-target $p(e|f)$ and target-to-source $p(f|e)$ lexical translation probabilities. Our lexical features are standard (Koehn et al., 2003). The estimation is motivated by IBM Model-1. Given a tuple t_i with source words $f = f_1, f_2, \ldots, f_n$, target words $e = e_1, e_2, \ldots, e_m$ and an alignment a between the source word positions $x = 1, \ldots, n$ and the target word positions $y = 1, \ldots, m$, the lexical feature $p_w(f|e)$ is computed as follows:

$$p_w(f|e, a) = \prod_{x=1}^{n} \frac{1}{|\{y : (x, y) \in a\}|} \sum_{\forall (x,y) \in a} w(f_x|e_y)$$

$p_w(e|f, a)$ is computed in the same way.

5 Decoding

Our decoder for the new model performs a stack-based search with a beam-search algorithm similar to that used in Pharoah (Koehn, 2004a). Given an input sentence F, it first extracts a set of matching source-side cepts along with their n-best translations to form a tuple inventory. During hypothesis expansion, the decoder picks a tuple from the inventory and generates the sequence of operations required for the translation with this tuple in light of the previous hypothesis.[9] The sequence of operations may include translation (generate, continue source cept etc.) and reordering (gap insertions, jumps) operations. The decoder also calculates the overall cost of the new hypothesis. Recombination is performed on hypotheses having the same coverage vector, monolingual language model context, and operation model context. We do histogram-based pruning, maintaining the 500 best hypotheses for each stack.[10]

[9]A hypothesis maintains the index of the last source word covered (j), the position of the right-most source word covered so far (Z), the number of open gaps, the number of gaps so far inserted, the previously generated operations, the generated target string, and the accumulated values of all the features discussed in Section 4.

[10]We need a higher beam size to produce translation units similar to the phrase-based systems. For example, the phrase-based system can learn the phrase pair "zum Beispiel – for example" and generate it in a single step placing it directly into the stack two words to the right. Our system generates this example with two separate tuple translations "zum – for" and "Beispiel – example" in two adjacent stacks. Because "zum – for" is not a frequent translation unit, it will be ranked quite low in the first stack until the tuple "Beispiel – example" appears in the second stack. Koehn and his colleagues have repeatedly shown that in-

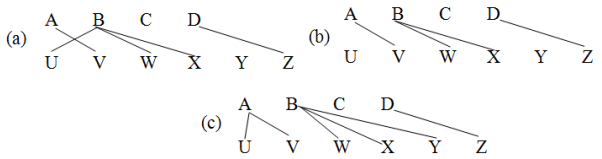

Figure 3: Post-editing of Alignments (a) Initial (b) No Target-Discontinuities (c) Final Alignments

6 Training

Training includes: (i) post-editing of the alignments, (ii) generation of the operation sequence (iii) estimation of the n-gram language models.

Our generative story does not handle target-side discontinuities and unaligned target words. Therefore we eliminate them from the training corpus in a 3-step process: If a source word is aligned with multiple target words which are not consecutive, first the link to the least frequent target word is identified, and the group of links containing this word is retained while the others are deleted. The intuition here is to keep the alignments containing content words (which are less frequent than functional words). The new alignment has no target-side discontinuities anymore, but might still contain unaligned target words. For each unaligned target word, we determine the (left or right) neighbour that it appears more frequently with and align it with the same source word as the neighbour. The result is an alignment without target-side discontinuities and unaligned target words. Figure 3 shows an illustrative example of the process. The tuples in Figure 3c are "A – U V", "B – W X Y", "C – NULL", "D – Z".

We apply Algorithm 1 to convert the preprocessed aligned corpus into a sequence of translation operations. The resulting operation corpus contains one sequence of operations per sentence pair.

In the final training step, the three language models are trained using the SRILM Toolkit. The operation model is estimated from the operation corpus. The prior probability model is estimated from the target side part of the bilingual corpus. The monolingual language model is estimated from the target side of the bilingual corpus and additional monolingual data.

creasing the Moses stack size from 200 to 1000 does not have a significant effect on translation into English, see (Koehn and Haddow, 2009) and other shared task papers.

7 Experimental Setup

7.1 Data

We evaluated the system on three data sets with German-to-English, Spanish-to-English and French-to-English news translations, respectively. We used data from the 4^{th} version of the *Europarl Corpus* and the *News Commentary* which was made available for the translation task of the *Fourth Workshop on Statistical Machine Translation*.[11] We use 200K bilingual sentences, composed by concatenating the entire news commentary ($\approx$ 74K sentences) and Europarl ($\approx$ 126K sentence), for the estimation of the translation model. Word alignments were generated with GIZA++ (Och and Ney, 2003), using the grow-diag-final-and heuristic (Koehn et al., 2005). In order to obtain the best alignment quality, the alignment task is performed on the entire parallel data and not just on the training data we use. All data is lowercased, and we use the Moses tokenizer and recapitalizer. Our monolingual language model is trained on 500K sentences. These comprise 300K sentences from the monolingual corpus (news commentary) and 200K sentences from the target-side part of the bilingual corpus. The latter part is also used to train the prior probability model. The dev and test sets are news-dev2009a and news-dev2009b which contain 1025 and 1026 parallel sentences. The feature weights are tuned with Z-MERT (Zaidan, 2009).

7.2 Results

Baseline: We compare our model to a recent version of Moses (Koehn et al., 2007) using Koehn's training scripts and evaluate with BLEU (Papineni et al., 2002). We provide Moses with the same initial alignments as we are using to train our system.[12] We use the default parameters for Moses, and a 5-gram English language model (the same as in our system).

We compare two variants of our system. The first system (Tw_{no-rl}) applies no hard reordering limit and uses the distortion and gap distance penalty features as soft constraints, allowing all possible reorderings. The second system (Tw_{rl-6}) uses no distortion and gap distance features, but applies a hard constraint which limits reordering to no more than 6

[11] http://www.statmt.org/wmt09/translation-task.html

[12] We tried applying our post-processing to the alignments provided to Moses and found that this made little difference.

Table 5: 10-best Translation Options With & Without Gaps and using our Heuristic

positions. Specifically, we do not extend hypotheses that are more than 6 words apart from the first word of the left-most gap during decoding. In this experiment, we disallowed tuples which were discontinuous on the source side. We compare our systems with two Moses systems as baseline, one using no reordering limit (Bl_{no-rl}) and one using the default distortion limit of 6 (Bl_{rl-6}).

Both of our systems (see Table 3) outperform Moses on the German-to-English and Spanish-to-English tasks and get comparable results for French-to-English. Our best system (Tw_{no-rl}), which uses no hard reordering limit, gives statistically significant ($p < 0.05$)[13] improvements over Moses (both baselines) for the German-to-English and Spanish-to-English translation task. The results for Moses drop by more than a BLEU point without the reordering limit (see Bl_{no-rl} in Table 3). All our results are statistically significant over the baseline Bl_{no-rl} for all the language pairs.

In another experiment, we tested our system also with tuples which were discontinuous on the source side. These gappy translation units neither improved the performance of the system with hard reordering limit ($Tw_{rl-6-asg}$) nor that of the system without reordering limit ($Tw_{no-rl-asg}$) as Table 4 shows. In an analysis of the output we found two reasons for this result: (i) Using tuples with source gaps increases the list of extracted n-best translation tuples exponentially which makes the search problem even more difficult. Table 5 shows the number of tuples (with and without gaps) extracted when decoding the test file with 10-best translations. (ii) The future cost[14] is poorly estimated in case of tuples with gappy source cepts, causing search errors.

In an experiment, we deleted gappy tuples with a score (future cost estimate) lower than the sum of the best scores of the parts. This heuristic removes many useless discontinuous tuples. We found that results improved ($Tw_{no-rl-hsg}$ and $Tw_{rl-6-hsg}$ in Table 4) compared to the version using all gaps ($Tw_{no-rl-asg}$, $Tw_{rl-6-asg}$), and are closer to the results without discontinuous tuples (Tw_{no-rl} and Tw_{rl-6} in Table 3).

8 Sample Output

In this section we compare the output of our systems and Moses. Example 1 in Figure 4 shows the powerful reordering mechanism of our model which moves the English verb phrase "do not want to negotiate" to its correct position between the subject "they" and the prepositional phrase "about concrete figures". Moses failed to produce the correct word order in this example. Notice that although our model is using smaller translation units "nicht – do not", "verhandlen – negotiate" and "wollen – want to", it is able to memorize the phrase translation "nicht verhandlen wollen – do not want to negotiate" as a sequence of translation and reordering operations. It learns the reordering of "verhandlen – negotiate" and "wollen – want to" and also captures dependencies across phrase boundaries.

Example 2 shows how our system without a reordering limit moves the English translation "vote" of the German clause-final verb "stimmen" across about 20 English tokens to its correct position behind the auxiliary "would".

Example 3 shows how the system with gappy tuples translates a German sentence with the particle verb "kehrten...zurück" using a single tuple (dashed lines). Handling phenomena like particle verbs

[13] We used Kevin Gimpel's implementation of pairwise bootstrap resampling (Koehn, 2004b), 1000 samples.

[14] The dynamic programming approach of calculating future cost for bigger spans gives erroneous results when gappy cepts can interleave. Details omitted due to space limitations.

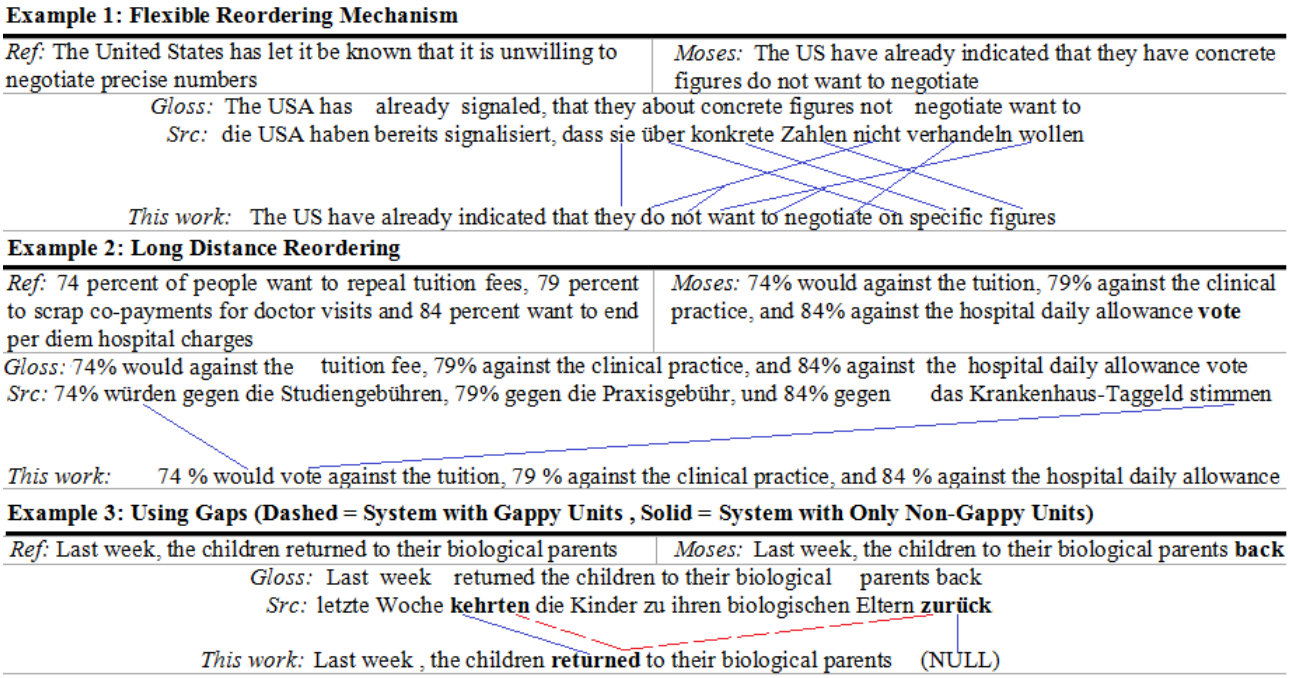

Figure 4: Sample Output Sentences

strongly motivates our treatment of source side gaps. The system without gappy units happens to produce the same translation by translating "kehrten" to "returned" and deleting the particle "zurück" (solid lines). This is surprising because the operation for translating "kehrten" to "returned" and for deleting the particle are too far apart to influence each other in an n-gram model. Moses run on the same example deletes the main verb ("kehrten"), an error that we frequently observed in the output of Moses.

Our last example (Figure 5) shows that our model learns idioms like "meiner Meinung nach – In my opinion ," and short phrases like "gibt es – there are" showing its ability to memorize these "phrasal" translations, just like Moses.

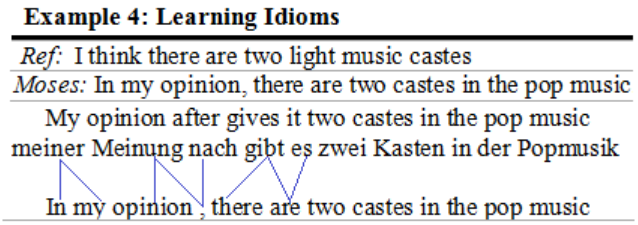

Figure 5: Learning Idioms

9 Conclusion

We have presented a new model for statistical MT which can be used as an alternative to phrase-based translation. Similar to N-gram based MT, it addresses three drawbacks of traditional phrasal MT by better handling dependencies across phrase boundaries, using source-side gaps, and solving the phrasal segmentation problem. In contrast to N-gram based MT, our model has a generative story which tightly couples translation and reordering. Furthermore it considers all possible reorderings unlike N-gram systems that perform search only on a limited number of pre-calculated orderings. Our model is able to correctly reorder words across large distances, and it memorizes frequent phrasal translations including their reordering as probable operations sequences. Our system outperformed Moses on standard Spanish-to-English and German-to-English tasks and achieved comparable results for French-to-English. A binary version of the corpus conversion algorithm and the decoder is available.[15]

Integrating surprisal and uncertain-input models in online sentence comprehension: formal techniques and empirical results

Abstract

A system making optimal use of available information in incremental language comprehension might be expected to use linguistic knowledge together with current input to revise beliefs about previous input. Under some circumstances, such an error-correction capability might induce comprehenders to adopt grammatical analyses that are inconsistent with the true input. Here we present a formal model of how such input-unfaithful garden paths may be adopted and the difficulty incurred by their subsequent disconfirmation, combining a rational noisy-channel model of syntactic comprehension under uncertain input with the surprisal theory of incremental processing difficulty. We also present a behavioral experiment confirming the key empirical predictions of the theory.

1 Introduction

In most formal theories of human sentence comprehension, input recognition and syntactic analysis are taken to be distinct processes, with the only feedback from syntax to recognition being prospective prediction of likely upcoming input (Jurafsky, 1996; Narayanan and Jurafsky, 1998, 2002; Hale, 2001, 2006; Levy, 2008a). Yet a system making optimal use of all available information might be expected to perform fully joint inference on sentence identity and structure given perceptual input, using linguistic knowledge both prospectively *and* retrospectively in drawing inferences as to how raw input should be segmented and recognized as a sequence of linguistic tokens, and about the degree to which each input token should be trusted during grammatical analysis. Formal models of such joint inference over uncertain input have been proposed (Levy, 2008b), and corroborative empirical evidence exists that strong coherence of current input with a perceptual neighbor of previous input may induce confusion in comprehenders as to the identity of that previous input (Connine et al., 1991; Levy et al., 2009).

In this paper we explore a more dramatic prediction of such an uncertain-input theory: that, when faced with sufficiently biasing input, comprehenders might under some circumstances adopt a grammatical analysis inconsistent with the true raw input comprising a sentence they are presented with, but consistent with a slightly perturbed version of the input that has higher prior probability. If this is the case, then subsequent input strongly disconfirming this "hallucinated" garden-path analysis might be expected to induce the same effects as seen in classic cases of garden-path disambiguation traditionally studied in the psycholinguistic literature. We explore this prediction by extending the rational uncertain-input model of Levy (2008b), integrating it with SURPRISAL THEORY (Hale, 2001; Levy, 2008a), which successfully accounts for and quantifies traditional garden-path disambiguation effects; and by testing predictions of the extended model in a self-paced reading study. Section 2 reviews surprisal theory and how it accounts for traditional garden-path effects. Section 3 provides background information on garden-path effects relevant to the current study, describes how we might hope to reveal comprehenders' use of grammatical knowledge to revise beliefs about the identity of previous linguistic sur-

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1055–1065,
Portland, Oregon, June 19-24, 2011.

face input and adopt grammatical analyses inconsistent with true input through a controlled experiment, and informally outlines how such belief revisions might arise as a side effect in a general theory of rational comprehension under uncertain input. Section 4 defines and estimates parameters for a model instantiating the general theory, and describes the predictions of the model for the experiment described in Section 3 (along with the inference procedures required to determine those predictions). Section 5 reports the results of the experiment. Section 6 concludes.

2 Garden-path disambiguation under surprisal

The SURPRISAL THEORY of incremental sentence-processing difficulty (Hale, 2001; Levy, 2008a) posits that the cognitive effort required to process a given word w_i of a sentence in its context is given by the simple information-theoretic measure of the log of the inverse of the word's conditional probability (also called its "surprisal" or "Shannon information content") in its intra-sentential context $w_{1,\ldots,i-1}$ and extra-sentential context *Ctxt*:

$$\text{Effort}(w_i) \propto \log \frac{1}{P(w_i|w_{1\ldots i-1}, \textit{Ctxt})}$$

(In the rest of this paper, we consider isolated-sentence comprehension and ignore *Ctxt*.) The theory derives empirical support not only from controlled experiments manipulating grammatical context but also from broad-coverage studies of reading times for naturalistic text (Demberg and Keller, 2008; Boston et al., 2008; Frank, 2009; Roark et al., 2009), including demonstration that the shape of the relationship between word probability and reading time is indeed log-linear (Smith and Levy, 2008).

Surprisal has had considerable success in accounting for one of the best-known phenomena in psycholinguistics, the GARDEN-PATH SENTENCE (Frazier, 1979), in which a local ambiguity biases the comprehender's incremental syntactic interpretation so strongly that upon encountering disambiguating input the correct interpretation can only be recovered with great effort, if at all. The most famous example is (1) below (Bever, 1970):

(1) The horse raced past the barn fell.

where the context before the final word is strongly biased toward an interpretation where *raced* is the main verb of the sentence (**MV**; Figure 1a), the intended interpretation, where *raced* begins a reduced relative clause (**RR**; Figure 1b) and *fell* is the main verb, is extremely difficult to recover. Letting T_j range over the possible incremental syntactic analyses of words $w_{1\ldots6}$ preceding *fell*, under surprisal the conditional probability of the disambiguating continuation *fell* can be approximated as

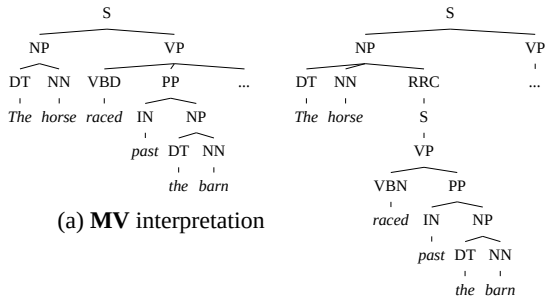
$$P(\textit{fell}|w_{1\ldots6}) = \sum_j P(\textit{fell}|T_j, w_{1\ldots6}) P(T_j|w_{1\ldots6}) \quad \text{(I)}$$

For all possible predisambiguation analyses T_j, either the analysis is disfavored by the context ($P(T_j|w_{1\ldots6})$ is low) or the analysis makes the disambiguating word unlikely ($P(\textit{fell}|T_j, w_{1\ldots6})$ is low). Since every summand in the marginalization of Equation (I) has a very small term in it, the total marginal probability is thus small and the surprisal is high. Hale (2001) demonstrated that surprisal thus predicts strong garden-pathing effects in the classic sentence *The horse raced past the barn fell* on basis of the overall rarity of reduced relative clauses alone. More generally, Jurafsky (1996) used a combination of syntactic probabilities (reduced RCs are rare) and argument-structure probabilities (*raced* is usually intransitive) to estimate the probability ratio of the two analyses of pre-disambiguation context in Figure 1 as roughly 82:1, putting a lower bound on the additional surprisal incurred at *fell* for the reduced-RC variant over the unreduced variant (*The horse that was raced past the barn fell*) of 6.4 bits.[1]

3 Garden-pathing and input uncertainty

We now move on to cases where garden-pathing can apparently be blocked by only small changes to the surface input, which we will take as a starting point for developing an integrated theory of uncertain-input inference and surprisal. The backdrop is what is known in the psycholinguistic literature as the **NP/Z** ambiguity, exemplified in (2) below:

[1] We say that this is a "lower bound" because incorporating even finer-grained information—such as the fact that *horse* is a canonical subject for intransitive *raced*—into the estimate would almost certainly push the probability ratio even farther in favor of the main-clause analysis.



(a) **MV** interpretation

(b) **RR** interpretation

Figure 1: Classic garden pathing

(2) While Mary was mending the socks fell off her lap.

In incremental comprehension, the phrase *the socks* is ambiguous between being the **NP** object of the preceding subordinate-clause verb *mending* versus being the subject of the main clause (in which case *mending* has a **Z**ero object); in sentences like (2) the initial bias is toward the **NP** interpretation. The main-clause verb *fell* disambiguates, ruling out the initially favored **NP** analysis. It has been known since Frazier and Rayner (1982) that this effect of garden-path disambiguation can be measured in reading times on the main-clause verb (see also Mitchell, 1987; Ferreira and Henderson, 1993; Adams et al., 1998; Sturt et al., 1999; Hill and Murray, 2000; Christianson et al., 2001; van Gompel and Pickering, 2001; Tabor and Hutchins, 2004; Staub, 2007). Small changes to the context can have huge effects on comprehenders' initial interpretations, however. It is unusual for sentence-initial subordinate clauses not to end with a comma or some other type of punctuation (searches in the parsed Brown corpus put the rate at about 18%); empirically it has consistently been found that a comma eliminates the garden-path effect in NP/Z sentences:

(3) While Mary was mending, the socks fell off her lap.

Understanding sentences like (3) is intuitively much easier, and reading times at the disambiguating verb are reliably lower when compared with (2). Fodor (2002) summarized the power of this effect succinctly:

> [w]ith a comma after *mending*, there would be no syntactic garden path left to be studied. (Fodor, 2002)

In a surprisal model with clean, veridical input, Fodor's conclusion is exactly what is predicted: separating a verb from its direct object with a comma effectively never happens in edited, published written English, so the conditional probability of the **NP** analysis should be close to zero.[2] When uncertainty about surface input is introduced, however—due to visual noise, imperfect memory representations, and/or beliefs about possible speaker error—analyses come into play in which some parts of the true string are treated as if they were absent. In particular, because the two sentences are perceptual neighbors, the pre-disambiguation garden-path analysis of (2) may be entertained in (3).

We can get a tighter handle on the effect of input uncertainty by extending Levy (2008b)'s analysis of the *expected* beliefs of a comprehender about the sequence of words constituting an input sentence to joint inference over both sentence identity and sentence structure. For a true sentence $\mathbf{w}^*$ which yields perceptual input I, joint inference on sentence identity $\mathbf{w}$ and structure T marginalizing over I yields:

$$P_C(T, \mathbf{w}|\mathbf{w}^*) = \int_I P_C(T, \mathbf{w}|I, \mathbf{w}^*) P_T(I|\mathbf{w}^*)\, dI$$

where $P_T(I|\mathbf{w}^*)$ is the true model of noise (perceptual inputs derived from the true sentence) and $P_C(\cdot)$ terms reflect the comprehender's linguistic knowledge and beliefs about the noise processes intervening between intended sentences and perceptual input. $\mathbf{w}^*$ and $\mathbf{w}$ must be conditionally independent given I since $\mathbf{w}^*$ is not observed by the comprehender, giving us (through Bayes' Rule):

$$P(T, \mathbf{w}|\mathbf{w}^*) = \int_I \frac{P_C(I|T, \mathbf{w}) P_C(T, \mathbf{w})}{P_C(I)} P_T(I|\mathbf{w}^*)\, dI$$

For present purposes we constrain the comprehender's model of noise so that T and I are conditionally independent given $\mathbf{w}$, an assumption that can be relaxed in future work.[3] This allows us the further

[2] A handful of `VP -> V , NP ...` rules can be found in the Penn Treebank, but they all involve appositives (*It [$_{VP}$ ran, this apocalyptic beast . . .]*), vocatives (*You should [$_{VP}$ understand, Jack, . . .]*), cognate objects (*She [$_{VP}$ smiled, a smile without humor]*), or indirect speech (*I [$_{VP}$ thought, you nasty brute. . .]*); none involve true direct objects of the type in (3).

[3] This assumption is effectively saying that noise processes are syntax-insensitive, which is clearly sensible for environmental noise but would need to be relaxed for some types of speaker error.

simplification to

$$P(T, \mathbf{w}|\mathbf{w}^*) = \overbrace{P_C(T, \mathbf{w})}^{\text{(i)}} \overbrace{\int_I \frac{P_C(I|\mathbf{w}) P_T(I|\mathbf{w}^*)}{P_C(I)} \, dI}^{\text{(ii)}} \quad \text{(II)}$$

That is, a comprehender's average inferences about sentence identity and structure involve a tradeoff between (i) the prior probability of a grammatical derivation given a speaker's linguistic knowledge and (ii) the fidelity of the derivation's yield to the true sentence, as measured by a combination of true noise processes and the comprehender's beliefs about those processes.

3.1 Inducing hallucinated garden paths through manipulating prior grammatical probabilities

Returning to our discussion of the NP/Z ambiguity, the relative ease of comprehending (3) entails an interpretation in the uncertain-input model that the cost of infidelity to surface input is sufficient to prevent comprehenders from deriving strong belief in a *hallucinated* garden-path analysis of (3) pre-disambiguation in which the comma is ignored. At the same time, the uncertain-input theory predicts that if we manipulate the balance of prior grammatical probabilities $P_C(T, \mathbf{w})$ strongly enough (term (i) in Equation (II)), it may shift the comprehender's beliefs toward a garden-path interpretation. This observation sets the stage for our experimental manipulation, illustrated below:

(4) As the soldiers marched, toward the tank lurched an injured enemy combatant.

Example (4) is qualitatively similar to (3), but with two crucial differences. First, there has been LOCATIVE INVERSION (Bolinger, 1971; Bresnan, 1994) in the main clause: a locative PP has been fronted before the verb, and the subject NP is realized postverbally. Locative inversion is a low-frequency construction, hence it is crucially disfavored by the comprehender's prior over possible grammatical structures. Second, the subordinate-clause verb is no longer transitive, as in (3); instead it is intransitive but could itself take the main-clause fronted PP as a dependent. Taken together, these properties should shift comprehenders' posterior inferences given prior grammatical knowledge and pre-disambiguation input more sharply than in (3) toward the input-unfaithful interpretation in which the immediately preverbal main-clause constituent (*toward the tank* in (4)) is interpreted as a dependent of the subordinate-clause verb, as if the comma were absent.

If comprehenders do indeed seriously entertain such interpretations, then we should be able to find the empirical hallmarks (e.g., elevated reading times) of garden-path disambiguation at the main-clause verb *lurched*, which is incompatible with the "hallucinated" garden-path interpretation. Empirically, however, it is important to disentangle these empirical hallmarks of garden-path disambiguation from more general disruption that may be induced by encountering locative inversion itself. We address this issue by introducing a control condition in which a postverbal PP is placed within the subordinate clause:

(5) As the soldiers marched *into the bunker*, toward the tank lurched an injured enemy combatant. **[+PP]**

Crucially, this PP fills a similar thematic role for the subordinate-clause verb *marched* as the main-clause fronted PP would, reducing the extent to which the comprehender's prior favors the input-unfaithful interpretation (that is, the prior ratio $\frac{P(\textit{marched into the bunker toward the tank}|\text{VP})}{P(\textit{marched into the bunker}|\text{VP})}$ for (5) is much lower than the corresponding prior ratio $\frac{P(\textit{marched toward the tank}|\text{VP})}{P(\textit{marched}|\text{VP})}$ for (4)), while leaving locative inversion present. Finally, to ensure that sentence length itself does not create a confound driving any observed processing-time difference, we cross presence/absence of the subordinate-clause PP with inversion in the main clause:

(6)

a. As the soldiers marched, the tank lurched toward an injured enemy combatant. **[Uninverted,−PP]**
b. As the soldiers marched into the bunker, the tank lurched toward an injured enemy combatant. **[Uninverted,+PP]**

4 Model instantiation and predictions

To determine the predictions of our uncertain-input/surprisal model for the above sentence types, we extracted a small grammar from the parsed

Table 1: A small PCFG (lexical rewrite rules omitted) covering the constructions used in (4)–(6), with probabilities estimated from the parsed Brown corpus.

Brown corpus (Kučera and Francis, 1967; Marcus et al., 1994), covering sentence-initial subordinate clause and locative-inversion constructions.[4,5] The non-terminal rewrite rules are shown in Table 1, along with their probabilities; of terminal rewrite rules for all words which either appear in the sentences to be parsed or appeared at least five times in the corpus, with probabilities estimated by relative frequency.

As we describe in the following two sections, uncertain input is represented as a weighted finite-state automaton (WFSA), allowing us to represent the incremental inferences of the comprehender through intersection of the input WFSA with the PCFG above (Bar-Hillel et al., 1964; Nederhof and Satta, 2003, 2008).

[4]Rule counts were obtained using `tgrep2/Tregex` patterns (Rohde, 2005; Levy and Andrew, 2006); the probabilities given are relative frequency estimates. The patterns used can be found at `http://idiom.ucsd.edu/~rlevy/papers/acl2011/tregex_patterns.txt`.

[5]Similar to the case noted in Footnote 2, a small number of `VP -> V , PP ...` rules can be found in the parsed Brown corpus. However, the PPs involved are overwhelmingly (i) set expressions, such as *for example*, *in essence*, and *of course*, or (ii) manner or temporal adjuncts. The handful of true locative PPs (5 in total) are all parentheticals intervening between the verb and a complement strongly selected by the verb (e.g., *[$_{VP}$ means, in my country, homosexual]*); none fulfill one of the verb's thematic requirements.

4.1 Uncertain-input representations

Levy (2008a) introduced the LEVENSHTEIN-DISTANCE KERNEL as a model of the average effect of noise in uncertain-input probabilistic sentence comprehension; this corresponds to term (ii) in our Equation (II). This kernel had a single noise parameter governing scaling of the cost of considering word *substitutions*, *insertions*, and *deletions* are considered, with the cost of a word substitution falling off exponentially with Levenshtein distance between the true word and the substituted word, and the cost of word insertion or deletion falling off exponentially with word length. The distribution over the infinite set of strings $\mathbf{w}$ can be encoded in a weighted finite-state automaton, facilitating efficient inference.

We use the Levenshtein-distance kernel here to capture the effects of perceptual noise, but make two modifications necessary for incremental inference and for the correct computation of surprisal values for new input: the distribution over already-seen input must be *proper*, and possible future inputs must be *costless*. The resulting weighted finite-state representation of noisy input for a true sentence prefix $\mathbf{w}^* = w_{1\ldots j}$ is a $j+1$-state automaton with arcs as follows:

- For each $i \in 1, \ldots, j$:
  - A *substitution* arc from $i-1$ to i with cost proportional to $\exp[-\text{LD}(w', w_i)\ \gamma]$ for each word w' in the lexicon, where $\gamma > 0$ is a noise parameter and $\text{LD}(w', w_i)$ is the Levenshtein distance between w' and w_i (when $w' = w_i$ there is no change to the word);
  - A *deletion* arc from $i-1$ to i labeled ϵ with cost proportional to $\exp[-\text{len}(w_i)/\gamma]$;
  - An *insertion* loop arc from $i-1$ to $i-1$ with cost proportional to $\exp[-\text{len}(w')/\gamma]$ for every word w' in the lexicon;
- A loop arc from j to j for each word w' in

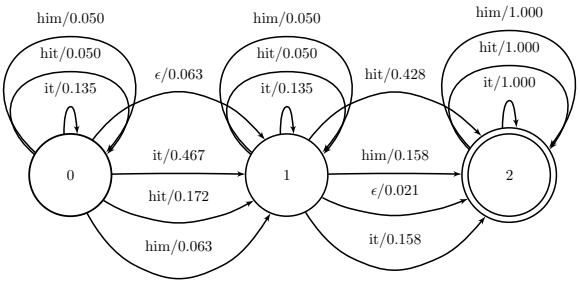

Figure 2: Noisy WFSA for partial input *it hit...* with lexicon {*it*,*hit*,*him*}, noise parameter γ=1

the lexicon, with zero cost (value 1 in the real semiring);

- State j is a zero-cost final state; no other states are final.

The addition of loop arcs at state n allows modeling of *incremental* comprehension through the automaton/grammar intersection (see also Hale, 2006); and the fact that these arcs are costless ensures that the partition function of the intersection reflects only the grammatical prior plus the costs of input already seen. In order to ensure that the distribution over already-seen input is proper, we normalize the costs on outgoing arcs from all states but j.[6] Figure 2 gives an example of a simple WFSA representation for a short partial input with a small lexicon.

4.2 Inference

Computing the surprisal incurred by the disambiguating element given an uncertain-input representation of the sentence involves a standard application of the definition of conditional probability (Hale, 2001):

$$\log \frac{1}{P(I_{1...i}|I_{1...i-1})} = \log \frac{P(I_{1...i-1})}{P(I_{1...i})} \qquad \text{(III)}$$

Since our uncertain inputs $I_{1...k}$ are encoded by a WFSA, the probability $P(I_{1...k})$ is equal to the partition function of the intersection of this WFSA with the PCFG given in Table 1.[7] PCFGs are a special class of weighted context-free grammars (WCFGs), which are closed under intersection with WFSAs; a constructive procedure exists for finding the intersection (Bar-Hillel et al., 1964; Nederhof and Satta, 2003). Hence we are left with finding the partition function of a WCFG, which cannot be computed exactly, but a number of approximation methods are known (Stolcke, 1995; Smith and Johnson, 2007; Nederhof and Satta, 2008). In practice, the computation required to compute the partition function under any of these methods increases with the size of the WCFG resulting from the intersection, which for a binarized PCFG with R rules and an n-state WFSA is Rn^2. To increase efficiency we implemented what is to our knowledge a novel method for finding the minimal grammar including all rules that will have non-zero probability in the intersection. We first parse the WFSA bottom-up with the item-based method of Goodman (1999) in the Boolean semiring, storing partial results in a chart. After completion of this bottom-up parse, every rule that will have non-zero probability in the intersection PCFG will be identifiable with a set of entries in the chart, but not all entries in this chart will have non-zero probability, since some are not connected to the root. Hence we perform a second, top-down Boolean-semiring parsing pass on the bottom-up chart, throwing out entries that cannot be derived from the root. We can then include in the intersection grammar only those rules from the classic construction that can be identified with a set of surviving entries in the final parse chart.[8] The partition functions for each category in this intersection grammar can then be computed; we used a fixed-point method preceded by a topological sort on the grammar's ruleset, as described by Nederhof and Satta (2008). To obtain the surprisal of the input deriving from a word w_i in its context, we can thus com-

[6] If a state's total unnormalized cost of insertion arcs is α and that of deletion and insertion arcs is β, its normalizing constant is $\frac{\beta}{1-\alpha}$. Note that we must have $\alpha < 1$, placing a constraint on the value that γ can take (above which the normalizing constant diverges).

[7] Using the WFSA representation of average noise effects here actually involves one simplifying assumption, that the average surprisal of I_i, or $E_{P_T}\left[\log \frac{1}{P_C(I_i|I_{1...i-1})}\right]$, is well approximated by the log of the ratio of the expected probabilities of the noisy inputs $I_{1...i-1}$ and $I_{1...i}$, since as discussed in Section 3 the quantities $P(I_{1...i-1})$ and $P(I_{1...i})$ are expectations under the true noise distribution. This simplifying assumption has the advantage of bypassing commitment to a specific representation of perceptual input and should be justifiable for reasonable noise functions, but the issue is worth further scrutiny.

[8] Note that a standard top-down algorithm such as Earley parsing cannot be used to avoid the need for both bottom-up and top-down passes, since the presence of loops in the WFSA breaks the ability to operate strictly left-to-right.

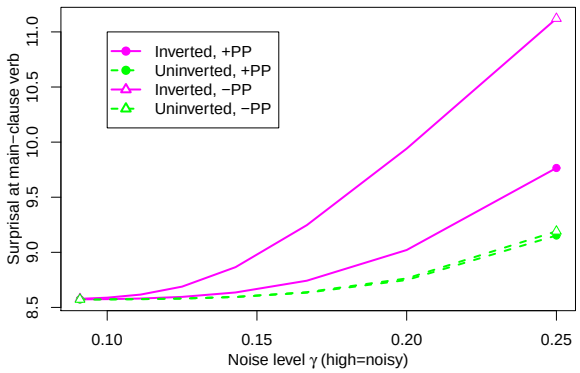

Figure 3: Model predictions for (4)–(6)

pute the partition functions for noisy inputs $I_{1...i-1}$ and $I_{1...i}$ corresponding to words $w_{1...i-1}$ and words $w_{1...i}$ respectively, and take the log of their ratio as in Equation (III).

4.3 Predictions

The noise level γ is a free parameter in this model, so we plot model predictions—the expected surprisal of input from the main-clause verb for each variant of the target sentence in (4)–(6)—over a wide range of its possible values (Figure 3). The far left of the graph asymptotes toward the predictions of *clean surprisal*, or noise-free input. With little to no input uncertainty, the presence of the comma rules out the garden-path analysis of the fronted PP *toward the tank*, and the surprisal at the main-clause verb is the same across condition (here reflecting only the uncertainty of verb identity for this small grammar). As input uncertainty increases, however, surprisal in the **[Inverted, −PP]** condition increases, reflecting the stronger belief given preceding context in an input-unfaithful interpretation.

5 Empirical results

To test these predictions we conducted a word-by-word self-paced reading study, in which participants read by pressing a button to reveal each successive word in a sentence; times between button presses are recorded and analyzed as an index of incremental processing difficulty (Mitchell, 1984). Forty monolingual native-English speaker participants read twenty-four sentence quadruplets ("items") on the pattern of (4)–(6), with a Latin-square design so that each participant saw an equal

	Inverted	Uninverted
-PP	0.76	0.93
+PP	0.85	0.92

Table 2: Question-answering accuracy

number of sentences in each condition and saw each item only once. Experimental items were pseudo-randomly interspersed with 62 filler sentences; no two experimental items were ever adjacent. Punctuation was presented with the word to its left, so that for (4) the four and fifth button presses would yield

```
-------------- marched, --------------
```

and

```
----------------------- toward --------
```

respectively (right-truncated here for reasons of space). Every sentence was followed by a yes/no comprehension question (e.g., *Did the tank lurch toward an injured enemy combatant?*); participants received feedback whenever they answered a question incorrectly.

Reading-time results are shown in Figure 4. As can be seen, the model's predictions are matched at the main-clause verb: reading times are highest in the **[Inverted, −PP]** condition, and there is an interaction between main-clause inversion and presence of a subordinate-clause PP such that presence of the latter reduces reading times more for inverted than for uninverted main clauses. This interaction is significant in both by-participants and by-items ANOVAs (both $p < 0.05$) and in a linear mixed-effects analysis with participants- and item-specific random interactions ($t > 2$; see Baayen et al., 2008). The same pattern persists and remains significant through to the end of the sentence, indicating considerable processing disruption, and is also observed in question-answering accuracies for experimental sentences, which are superadditively lowest in the **[Inverted, −PP]** condition (Table 2).

The inflated reading times for the **[Inverted, −PP]** condition beginning at the main-clause verb confirm the predictions of the uncertain-input/surprisal theory. Crucially, the input that would on our theory induce the comprehender to question the comma (the fronted main-clause PP)

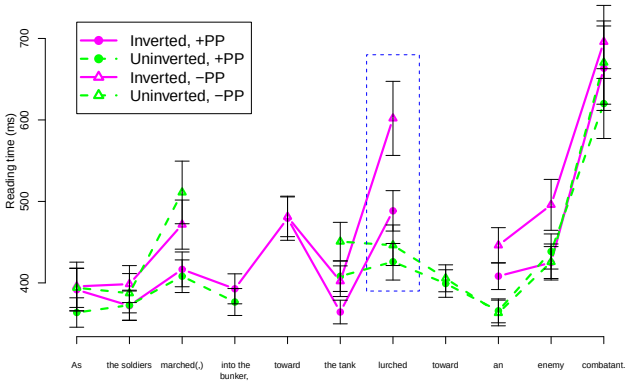

Figure 4: Average reading times for each part of the sentence, broken down by experimental condition

is not seen until after the comma is no longer visible (and presumably has been integrated into beliefs about syntactic analysis on veridical-input theories). This empirical result is hence difficult to accommodate in accounts which do not share our theory's crucial property that comprehenders can revise their belief in previous input on the basis of current input.

6 Conclusion

Language is redundant: the content of one part of a sentence carries predictive value both for what will precede and what will follow it. For this reason, and because the path from a speaker's intended utterance to a comprehender's perceived input is noisy and error-prone, a comprehension system making optimal use of available information would use current input not only for forward prediction but also to assess the veracity of previously encountered input. Here we have developed a theory of how such an adaptive error-correcting capacity is a consequence of noisy-channel inference, with a comprehender's beliefs regarding sentence form and structure at any moment in incremental comprehension reflecting a balance between fidelity to perceptual input and a preference for structures with higher prior probability. As a consequence of this theory, certain types of sentence contexts will cause the drive toward higher prior-probability analyses to overcome the drive to maintain fidelity to input, undermining the comprehender's belief in an earlier part of the input actually perceived in favor of an analysis unfaithful to part of the true input. If subsequent input strongly disconfirms this incorrect interpretation, we should see behavioral signatures of classic garden-path disambiguation. Within the theory, the size of this "hallucinated" garden-path effect is indexed by the surprisal value under uncertain input, marginalizing over the actual sentence observed. Based on a model implementing theory we designed a controlled psycholinguistic experiment making specific predictions regarding the role of fine-grained grammatical context in modulating comprehenders' strength of belief in a highly specific bit of linguistic input—a comma marking the end of a sentence-initial subordinate clause—and tested those predictions in a self-paced reading experiment. As predicted by the theory, reading times at the word disambiguating the "hallucinated" garden-path were inflated relative to control conditions. These results contribute to the theory of uncertain-input effects in online sentence processing by suggesting that comprehenders may be induced not only to entertain but to adopt relatively strong beliefs in grammatical analyses that require modification of the surface input itself. Our results also bring a new degree of nuance to surprisal theory, demonstrating that perceptual neighbors of true preceding input may need to be taken into account in order to estimate how surprising a comprehender will find subsequent input to be.

Beyond the domain of psycholinguistics, the methods employed here might also be usefully applied to practical problems such as parsing of degraded or fragmentary sentence input, allowing joint constraint derived from grammar and available input to fill in gaps (Lang, 1988). Of course, practical applications of this sort would raise challenges of their own, such as extending the grammar to broader coverage, which is delicate here since the surface input places a weaker check on overgeneration from the grammar than in traditional probabilistic parsing. Larger grammars also impose a technical burden since parsing uncertain input is in practice more computationally intensive than parsing clean input, raising the question of what approximate-inference algorithms might be well-suited to processing uncertain input with grammatical knowledge. Answers to this question might in turn be of interest for sentence processing, since the exhaustive-parsing idealization employed here is not psychologically plausible. It seems likely that human comprehension in-

volves approximate inference with severely limited memory that is nonetheless highly optimized to recover something close to the intended meaning of an utterance, even when the recovered meaning is not completely faithful to the input itself. Arriving at models that closely approximate this capacity would be of both theoretical and practical value.

Acknowledgments

Parts of this work have benefited from presentation at the 2009 Annual Meeting of the Linguistic Society of America and the 2009 CUNY Sentence Processing Conference. I am grateful to Natalie Katz and Henry Lu for assistance in preparing materials and collecting data for the self-paced reading experiment described here. Abstract

When designing grammars of natural language, typically, more than one formal analysis can account for a given phenomenon. Moreover, because analyses interact, the choices made by the engineer influence the possibilities available in further grammar development. The order in which phenomena are treated may therefore have a major impact on the resulting grammar. This paper proposes to tackle this problem by using metagrammar development as a methodology for grammar engineering. I argue that metagrammar engineering as an approach facilitates the systematic exploration of grammars through comparison of competing analyses. The idea is illustrated through a comparative study of auxiliary structures in HPSG-based grammars for German and Dutch. Auxiliaries form a central phenomenon of German and Dutch and are likely to influence many components of the grammar. This study shows that a special auxiliary+verb construction significantly improves efficiency compared to the standard argument-composition analysis for both parsing and generation.

1 Introduction

One of the challenges in designing grammars of natural language is that, typically, more than one formal analysis can account for a given phenomenon. The criteria for choosing between competing analyses are fairly clear (observational adequacy, analytical clarity, efficiency), but given that analyses of different phenomena interact, actually evaluating analyses on those criteria in a systematic manner is far from straightforward. The standard methodology involves either picking one analysis, and seeing how it goes, then backing out if it does not work out, or laboriously adapting a grammar to two versions supporting different analyses (Bender, 2010). The former approach is not in any way systematic, increasing the risk that the grammar is far from optimal in terms of efficiency. The latter approach potentially causes the grammar engineer an amount of work that will not scale for considering many different phenomena.

This paper proposes a more systematic and tractable alternative to grammar development: metagrammar engineering. I use "metagrammar" as a generic term to refer to a system that can generate implemented grammars. The key idea is that the grammar engineer adds alternative plausable analyses for linguistic phenomena to a metagrammar. This metagrammar can generate all possible combinations of these analyses automatically, creating different versions of a grammar that cover the same phenomena. The engineer can test directly how competing analyses for different phenomena interact, and determine which combinations are possible (after minor adaptations) and which analyses are incompatible.

The idea of metagrammar engineering is illustrated here through a case study of word order and auxiliaries in Germanic languages, which forms the second goal of this paper. Auxiliaries form a central phenomenon of German and Dutch and are likely to influence many components of the grammar. The results show that the analysis of auxiliary+verb structures presented in Bender (2010) significantly im-

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1066–1076,
Portland, Oregon, June 19-24, 2011.

proves efficiency of the grammar compared to the standard argument-composition analysis within the range of phenomena studied. Because future research is needed to determine whether the auxiliary+verb alternative can interact properly with additional phenomena and still lead to more efficient results than argument-composition, it is particularly useful to have a grammar generator that can automatically create grammars with either of the two analyses.

The remainder of this paper starts with the case study. Section 2 provides a description of the context of the study. The relevant linguistic properties and alternative analyses are described in Sections 3 and 4. After evaluating and discussing the case study's results, I return to the general approach of metagrammar engineering. Section 6 presents related work on metagrammars. It is followed by a conclusion and discussion on using metagrammars as a methodology for grammar engineering.

2 A metagrammar for Germanic Languages

2.1 The LinGO Grammar Matrix

The LinGO Grammar Matrix (Bender et al., 2002; Bender et al., 2010) provides the main context for the experiments described in this paper. To begin with, its further development plays a significant role for the motivation of the present study. More importantly, the Germanic metagrammar is implemented as a special branch of the LinGO Grammar Matrix and uses a significant amount of its code.

The Grammar Matrix customization system allows users to derive a starter grammar for a particular language from a common multi-lingual resource by specifying linguistic properties through a web-based questionnaire. The grammars are intended for parsing and generation with the LKB (Copestake, 2002) using Minimal Recursion Semantics (Copestake et al., 2005, MRS) as parsing output and generation input. After the starter grammar has been created, its development continues independently: engineers can thus make modifications to their grammar without affecting the multi-lingual resource.

Internally, the customization system works as follows: The web-based questionnaire registers linguistic properties in a file called "choices" (hence-forth choices file). The customization system takes this choices file as input to create grammar fragments, using so-called "libraries" that contain implementations of cross-linguistically variable phenomena. Depending on the definitions provided in the choices file, different analyses are retrieved from the customization system's libraries. The language specific implementations inherit from a core grammar which handles basic phrase types, semantic compositionality and general infrastructure, such as feature geometry (Bender et al., 2002).

The present study is part of a larger effort to improve the customization library for auxiliary structures in free word order and verb second languages. It examines whether Bender's observations concerning an improved analysis for auxiliaries in Wambaya (Bender, 2010) also hold for Germanic languages. A more elaborate study of German and Dutch (including both Flemish and (Northern) Dutch, which have slightly different word order constraints) is informative, because these languages are well-described and known to have distinctly challenging word order behavior.

2.2 Germanic branch

In order to create grammars for Germanic languages, a specialized branch of the Grammar Matrix customization system was developed. This Germanic grammars generator uses the Grammar Matrix's facilities to generate types in type description language (tdl). At present, the generator uses the Grammar Matrix analyses for agreement and case marking as well as basics from its morphotactics, coordination and lexicon implementations.

In the first stage, the word order library and auxiliary implementation were extended to cover two alternative analyses for Germanic word order (see Section 4). The coordination library was adapted to ensure correct interactions with the new word order analyses and agreement. The morphotactics library was extended to cover Dutch and Flemish interactions between word order and morphology. Finally, the lexicon and verbal case pattern implementations were extended to cover ditransitive verbs.

Both versions of word order analyses can be tweaked to include or exclude a rarely occurring variant of partial VP fronting (see Section 4.3) resulting in four distinct grammars for each of the

Vorfeld	**LB**	Mittelfeld	**RB**	Nachfeld
Der Mann	**hat**	den Jungen	**gesehen**	nach der Party
The man.nom	*has*	*the boy.acc*	*seen*	*after the party*
Der Mann	**hat**	den Jungen nach der Party	**gesehen**	
Den Jungen	**hat**	der Mann	**gesehen**	nach der Party
Nach der Party	**hat**	der Mann den Jungen	**gesehen**	
Den Jungen **gesehen**	**hat**	der Mann nach der Party		
Gesehen	**hat**	der Mann den Jungen nach der Party		
The man saw the boy after the party				

Table 1: Basic structure of German word order (not exhaustive)

languages under investigation. These 12 grammars cover Dutch, Flemish and German main clauses with up to three core arguments.[1]

3 Germanic word order

3.1 German word order

Topological fields (Erdmann, 1886; Drach, 1937) form the easiest way to describe German word order. The sentence structure for declarative main clauses, consists of five topological fields: Vorfeld ("pre-field"), Left Bracket (LB), Mittelfeld ("middle field"), Right Bracket (RB) and the Nachfeld ("after field"). A subset of permissible alternations in German are provided in Table 1. The last two sentences present an example of partial VP fronting.

The fields are defined with regard to verbal forms, which are placed in the Left and Right Brackets. Each topological field has word order restrictions of its own. The Vorfeld must contain exactly one constituent in an affirmative main clause. The Left Bracket contains the finite verb and no other elements. Other verbal forms (if not fronted to the Vorfeld) must be placed in the Right Bracket. Most non-verbal elements are placed in the Mittelfeld. When main verbs are placed in the Vorfeld, their object(s) may stay in the Mittelfeld. This kind of partial VP fronting is illustrated by the last example in Table 1. The Nachfeld typically contains subordinate clauses and sometimes adverbial phrases.

In German, the respective order between the verbs in the Right Bracket is head-final, i.e. auxiliaries follow their complements. The only exception is the auxiliary flip: under certain conditions in subordinate clauses, the finite verb precedes all other verbal forms.

3.2 Dutch word order

Dutch word order reveals the same topological fields as German. There are two main differences between the languages where word order is concerned. First, whereas the order of arguments in the German Mittelfeld allows some flexibility depending on information structure, Dutch argument order is fixed, except for the possibility of placing any argument in the Vorfeld. A related aspect is that Dutch is less flexible as to what partial VPs can be placed in the Vorfeld.

The second difference is the word order in the Right Bracket. The order of auxiliaries and their complements is less rigid in Dutch and typically auxiliary-complement, the inverse of German order. Most Dutch auxiliaries can occur in both orders, but this may be restricted according to their verb form. Four groups of auxiliary verbs can be distinguished that have different syntactic restrictions.

1. Verbs selecting for participles which may appear on either side of their complement (e.g. *hebben* ("have"), *zijn* ("be")).

2. Verbs selecting for participles which prefer to follow their complement and must do so if they are in participle form themselves (e.g. *blijven* ("remain"), *krijgen* ("get")).

3. Modals selecting for infinitives which prefer to precede their complement and must do so if they appear in infinitive form themselves.

[1]The grammar generation system also creates Danish grammars. Danish results are not presented, because the language does not pose the challenges explained in Section 4.

VF	LB	MF	RB
De man	zou	haar	kunnen hebben gezien
the man	*would*	*her.acc*	*can have seen*
De man	zou	haar	gezien kunnen hebben
%De man	zou	haar	kunnen gezien hebben
The man should have been able to see her			

Table 2: Variations of Dutch auxiliary order

4. Verbs selecting for "to infinitives" which must precede their complement.

While there is some variation among speakers, the generalizations above are robust. The permitted variations assuming a verb of the 3rd and 1st category in the right bracket are presented in Table 2.[2]

The variant %*De man zou haar kunnen gezien hebben* is typical of speakers from Belgium (Haeseryn, 1997); speakers from the Netherlands tend to regard such structures as ungrammatical. Our system can both generate a Flemish grammar accepting all of the above and a (Northern) Dutch grammar, rejecting the third variant.

4 Alternative auxiliary approaches

This section presents the alternative analyses for auxiliary-verb structures in Germanic languages compared in this study. For reasons of space, I limit my description to an explanation of the differences and relevance of the compared analyses.[3]

4.1 Argument-composition

The standard analysis for German and Dutch auxiliaries in HPSG is a so-called "argument-composition" analysis (Hinrichs and Nakazawa, 1994), which I will explain through the following Dutch example:[4]

(1) Ik zou het boek willen lezen.
I would the book want read.
"I would like to read the book."

In the sentence above, the auxiliary *willen* "want" separates the verb *lezen* "read" from its object *het boek* "the book". A parser respecting surface order can thus not combine *lezen* and *het boek* before combining *willen* and *lezen*.

Figure 1: Standard Auxiliary Subcategorization

The argument-composition analysis was introduced to make sure that *het boek* can be picked up as the object of the embedded verb *lezen*. The subcategorization of an auxiliary under this analysis is presented in Figure 1. The subject of the auxiliary is identical to the subject of the auxiliary's complement. Its complement list consists of the concatenation of the verbal complement and any complement this verbal complement may select for. In the sentence above, *willen* will add the subject and the object of *lezen* to its own subcatorization lists.[5] This standard solution for auxiliary-verb structures is (with minor differences) also what is provided by the Matrix customization system.

Argument-composition can capture the grammatical behavior of auxiliaries in German and Dutch. However, grammaticality and coverage is not all that matters for grammars of natural language. Efficiency remains an important factor, and argument-composition has some undesirable properties on this level. The problem lies in the fact that lexical entries of auxiliaries have underspecified elements on their subcategorization lists. With the current chart parsing and chart generation algorithms (Carroll and Oepen, 2005), an auxiliary in a language with flexible word order will speculatively add edges to the chart for potential analyses with the adjacent constituent as subject or complement. Because the length of the lists are underspecified as well, it can continue wrongly combining with all elements in the string. In the worse case scenario, the number of edges created by an auxiliary grows exponentially in the number of words and constituents in the string. The efficiency problem is even worse for generation: while the parser is restricted by the surface order of

[2] Note that the same orders as in the Right Brackets may also occur in the Vorfeld (with or without the object).

[3] Details of the implementations can be found by using the metagrammar, which can be found on my homepage.

[4] Hinrichs and Nakazawa (1994) present an analysis for the German auxiliary flip. The relevant observations are the same.

[5] In the semantic representation, both arguments will be directly related to the main verb exclusively.

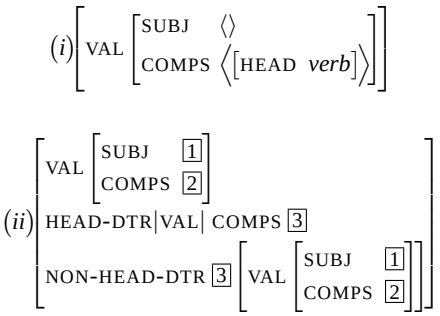

Figure 2: Auxiliary lexical type (*i*) and Auxiliary+verb construction (*ii*) under alternative analysis

the string, the generator will attempt to combine all lexical items suggested by the input semantics, as well as lexical items with empty semantics, in random order.

4.2 Aux+verb construction

Bender (Bender, 2010)[6] presents an alternative approach to auxiliary-verb structures for the Australian language Wambaya. The analysis introduces auxiliaries that only subcategorize for one verbal complement, not raising any of the complement's arguments or its subject. Auxiliaries combine with their complement using a special auxiliary+verb rule. Figure 2 presents this alternative solution. In principle, the new analysis uses the same technique as argument composition. The difference is that the auxiliary now starts out with only one element in its subcategorization lists and can only combine with potential verbal complements that are appropriately constrained. The structure that combines the auxiliary with its complement places the remaining elements on the complement's SUBJ and COMPS lists on the respective lists of the newly formed phrase, as can be seen in Figure 2 (*ii*). The constraints on raised arguments are known when the construction applies. The efficiency problem sketched above is thus avoided.

4.3 A small wrinkle: partial VP fronting

In its basic form, the auxiliary+verb structure cannot handle partial VP fronting where the main verb is placed in first position leaving one or more verbal forms in the verbal cluster, as illustrated in (2) for Dutch:

(2) Gezien zou de man haar kunnen hebben.
Seen should the man her can have
"The man should have been able to **see** her."

The problem is that *hebben* "have" cannot combine with *gezien* "seen", because they are separated by the head of the clause. Because the verb *hebben* cannot combine with its complement, it cannot raise its complement's arguments either: the auxiliary+verb analysis only permits raising when auxiliary and complement combine.

This shortcoming is no reason to immediately dismiss the proposal. Structures such as (2) are extremely rare. The difference in coverage of a parser that can and a parser that cannot handle such structures is likely to be tiny, if present at all, nor is it vital for a sentence generator to be able to produce them. However, a correct grammar should be able to analyze and produce all grammatical structures.

I implemented an additional version of the auxiliary+verb construction using two rather complex rules that capture examples such as (2). Because the structure in (2) also presented difficulties for the argument-composition analysis in Dutch, I tested both of the analyses with and without the inclusion of these structures. In the ideal case, the full coverage version will remain efficient enough as the grammar grows. But if this turns out not to be the case, the decision can be made to exclude the additional rule from the grammar or to use it as a robustness rule that is only called when regular rules fail. Given the metagrammar engineering approach, it will be straightforward to decide at a later point to exclude the special rule, if corpus studies reveal this is favourable.

5 Grammars and evaluation

5.1 Experimental set-up

As described above, the Germanic metagrammar is a branch of the customization system. As such, it takes a choices file as input to create a grammar. The basic choices files for Dutch and German were created through the LinGO Grammar Matrix web inter-

[6] Bender credits the key idea behind this analysis to Dan Flickinger (Bender, 2010).

	Complete Set		Reduced Set		
	Positive	Total	Positive	Total	Av.
	s	s	s	s	w/s
Du	177	14654	138	14591	6.61
Fl	195	14654	156	14606	6.61
Ge	116	6926	84	6914	6.65

Table 3: Number of test examples (s) used in evaluation and average words per sentence (w/s)

face.[7] The choices files defined artificial grammars with a dummy vocabulary. The system can produce real fragments of the languages, but strings representing syntactic properties through dummy vocabulary were used to give better control over ambiguity facilitating the evaluation of coverage and overgeneration of the grammars. The grammars have a lexicon of 9-10 unambiguous dummy words.

The created choices files were extended offline to define those properties that the Germanic metagrammar captures, but are not incorporated in the Matrix customization system. This included word order of the auxiliary and complement, fixed or free argument order, influence of inflection on word order, a more elaborate case hierarchy, ditransitive verbs, and the choice of auxiliary/verb analysis. Four choices files with different combinations of analyses were created for each language, resulting in 12 choices files in total.

A basic test suite was developed that covers intransitive, transitive and ditransitive main clauses with up to three auxiliaries. The German set was based on a description provided by Kathol (2000), Dutch and Flemish were based on Haeseryn (1997). For each verb and auxiliary combination, all permissible word orders were defined based on descriptive resources. In order to make sure the grammars do not reveal unexpected forms of overgeneration, all possible ungrammatical orders were automatically generated. Table 3 provides the sizes of the test suites. Each language has both a complete set for the 6 grammars that provide full coverage, and a reduced set for the 6 grammars that can not handle split verbal clusters (see Section 4.3 for the motivation to test grammars that do not have full coverage).

[7] `http://www.delph-in.net/matrix/customize/`

Each grammar was created using the metagrammar, ensuring that all components except the competing analyses were held constant among compared grammars. The [incr tsdb()] competence and performance profiling environment (Oepen, 2001) was used in combination with the LKB to evaluate parsing performance of the individual grammars on the test suites. For each grammar, the number of required parsing tasks, memory (space) and CPU time per sentence, as well as the number of passive edges created during an average parse were compared. Performance on language generation was evaluated using the LKB.

5.2 Parsing results

Table 4 presents the results from the parsing experiment. Note that all directly compared grammars have the same empirical coverage (100% coverage and 0% overgeneration on the phenomena included in the test suites). The comparison therefore addresses the effect on efficiency of the alternative analyses. Three tests per grammar were carried out: one on positive data, one on negative data and one on the complete dataset. Results were similar for all three sets, with slightly larger differences in efficiency for negative examples. For reasons of space, only the results on positive examples are presented, which are more relevant for most applications involving parsing. The results show that the auxiliary+verb (aux+v) leads to a more efficient grammar according to all measures used. There is an average reduction of 73.2% in performed tasks, 56.3% in produced passive edges and 32.9% in memory when parsing grammatical examples using the auxiliary+verb structure compared to argument-composition. CPU-time per sentence also improved significantly, but, due to the short average sentence length (5-10 words) the value is too small for exact comparison with [incr tsdb()].

5.3 Sentence generation evaluation

The complete coverage versions of Dutch and German were used to create the exhaustive set of sentences with an intransitive, transitive and ditransitive verb combined with none, one or two auxiliaries but rapidly loses ground when one or more auxiliaries[8]

[8] All auxiliaries in the grammars contribute an ep.

Table 4: Parsing results positive examples

from a total of 18 MRSs. The input MRSs were obtained by parsing a sentence with canonical word order. Both versions provide the same set of sentences as output, confirming their identical empirical coverage. Table 5 presents the number of edges required by the generator to produce the full set of generated sentences from a given MRS. The cells with no number represent conditions under which the LKB generator reaches the maximum limit of edges, set at 40,000, without completing its exhaustive search.

The grammar using argument-composition is slightly more efficient when there are no auxiliaries, are added, in particular when sentence length increases: For ditransitive verbs (dv), the Dutch argument-composition grammar maxes out the 40,000 edge limit with two auxiliaries, whereas the auxiliary+verb grammar creates 910 edges, a manageable number. Due to the more liberal order of arguments, results are even worse for German: the argument-composition grammar reaches its limit with the first auxiliary for ditransitive verbs. These results indicate that the auxiliary+verb analysis is

strongly preferable where natural language generation is concerned.

5.4 In summary

The results of the experiment presented above show that avoiding underspecified subcategorization lists, as found in the standard argument-composition analysis, significantly increases the efficiency of the grammar for both parsing and generation. On average, they show a reduction of 73.2% in performed tasks, 56.3% in produced passive edges and 32.9% in memory for parsing. In generation experiments, results are even more impressive: the reduction of edges for German sentences with one auxiliary and a ditransitve verb is at least 98.5%. These results show that the auxiliary+verb alternative should be considered seriously as an alternative to the HPSG standard analysis of argument-composition, though further investigation in a larger context is needed before final conclusions can be drawn.

Future work will focus on increasing the coverage of the grammars, as well as the number of alternative options explored. In particular, both approaches for auxiliaries should be compared using alternative analyses for verb-second word order found in other HPSG-based grammars, such as the GG (Müller and Kasper, 2000; Crysmann, 2005), Grammix (Müller, 2009; Müller, 2008) and Cheetah (Cramer and Zhang, 2009) for German, and Alpino (Bouma et al., 2001) for Dutch. These grammars may use approaches that somewhat reduce the problem of argument-composition, leading to less significant differences between the auxiliary+verb and argument-composition analyses. On the other hand, planned extensions that cover modification and sub-

ordinate clauses will increase local ambiguities. The advantage of the auxiliary+verb analysis is likely to become more important as a result.

In addition to providing a clearer picture of auxiliary structures, these extensions will also lead to a better insight into efforts involved in using grammar generation to explore alternative versions of a grammar over time. In particular, it should provide an indication of the feasibility of maintaining a higher number of competing analyses as the grammar grows. After providing background on related metagrammar projects and their goals, I will elaborate on the importance of systematic exploration of grammars in the discussion.

6 Related work

Metagrammars (or grammar generators) have been established in the field for over a decade. This section provides an overview of the goals and set-up of some of the most notable projects.

The MetaGrammar project (Candito, 1998; de la Clergerie, 2005; Kinyon et al., 2006) started as an effort to encode syntactic knowledge in an abstract class hierarchy. The hierarchy can contain cross-linguistically invariable properties and syntactic properties that hold across frameworks (Kinyon et al., 2006). The factorized descriptions of MetaGrammar support Tree-Adjoining Grammars (Joshi et al., 1975, TAG) as well as Lexical Functional Grammars (Bresnan, 2001, LFG). The eXtensible MetaGrammar (Crabbé, 2005, XMG) defines its MetaGrammar as classes that are part of a multiple inheritance hierarchy. Kinyon et al. (Kinyon et al., 2006) use XMG to perform a cross-linguistic comparison of verb-second structures. Their study focuses on code-sharing between the languages, but does not address the problem of competing analyses investigated in this paper.

The GF Resource Grammar Library (Ranta, 2009) is a multi-lingual linguistic resource that contains a set of syntactic analyses implemented in GF (Grammatical Framework). The purpose of the library is to allow engineers working on NLP applications to write simple grammar rules that can call more complex syntactic implementations from the grammar library. The grammar library is written by researchers with linguistic expertise. It makes extensive use of code sharing: general categories and constructions that are used by all languages are implemented in a core syntax grammar. Each language[9] has its own lexicon and morphology, as well as a set of language specific syntactic structures. Code sharing also takes place between the subset of languages explored, in particular by means of common modules for Romance languages and for Scandanavian languages.

PAWS creates PC-PATR (McConnel, 1995) grammars based on field linguists' input. The main purpose of PAWS lies in descriptive grammar writing and "computer-assisted related language adaptation", where the grammar is used to map words from a text in a source language to a target language. PAWS differs from the other projects discussed here, because grammar engineering or syntactic research are not the main focus of the project.

The LinGO Grammar Matrix, described in Section 2.1, is most closely related to the work presented in this paper. Like the other projects reviewed here, the Grammar Matrix does not offer alternative analyses for the same phenomenon. Moreover, starter grammars created by the Grammar Matrix are developed manually and individually after their creation. The approach taken in this paper differs from the original goal of the Grammar Matrix in that it continues the development of new grammars within the system, introducing a novel application for metagrammars. By using a metagrammar to store alternative analyses, grammars can be explored systematically over time. As such, the paper introduces a novel methodology for grammar engineering. The discussion and conclusion will elaborate on the advantages of the approach.

7 Discussion and conclusion

7.1 The challenge of choosing the right analysis

As mentioned in the introduction, most phenomena in natural languages can be accounted for by more than one formal analysis. An engineer may implement alternative solutions and test the impact on the grammar concerning interaction with other phenomena (Bierwisch, 1963; Müller, 1999; Bender, 2008; Bender et al., 2011) and efficiency to decide between analyses.

[9] Ranta (Ranta, 2009) reports that GF is developed for fourteen languages, and more are under development.

However, it is not feasible to carry out comparative tests by manually creating different versions of a grammar every time a decision about an implementation is made. Moreover, even if such a study were carried out at each stage, only the interaction with the current state of the grammar would be tested. This has two undesirable consequences. First, options may be rejected that would have worked perfectly well if different decisions had been made in the past. Second, because each decision is only based on the current state of the grammar, the resulting grammar is partially (or even largely) a product of the order in which phenomena are treated.[10]

For grammar engineers with practical applications in mind, this is undesirable because the resulting grammar may end up far from optimal. For grammar writers that use engineering to find valid linguistic analyses, the problem is even more serious: if there is a truth in a declarative grammar, surely, this should not depend on the order in which phenomena are treated.

7.2 Metagrammar engineering

This paper proposes to systematically explore analyses throughout the development of a grammar by writing a metagrammar (or grammar generator), rather than directly implementing the grammar. A metagrammar can contain several different analyses for the same phenomenon. After adding a new phenomenon to the metagrammar, the engineer can automatically generate versions of the grammar containing different combinations of previous analyses. As a result, the engineer can not only systematically explore how alternative analyses interact with the current grammar, but also continue to explore interactions with phenomena added in the future. Especially for alternative approaches to basic properties of the language, such as the auxiliary-verb structures examined in this study, parallel analyses may prevent the cumbersome scenario of changing a deeply embedded property of a large grammar.

An additional advantage is that the engineer can use the methodology to make different versions of the grammar depending on its intended application. For instance, it is possible to develop a highly restricted version for grammar checking that provides detailed feedback on detected errors (Bender et al., 2004), next to a version with fewer constraints to parse open text.

As far as finding optimal solutions is concerned, it must be noted that this approach does not guarantee a perfect result, partially because there is no guarantee the grammar engineer will think of the perfect solution for each phenomenon, but mainly because it is not maintainable to implement all possible alternatives for each phenomenon and make them interact correctly with all other variations in the grammar. The grammar engineer still needs to decide which alternatives are the most promising and therefore the most important to implement and maintain. The resulting grammar therefore partially remains a result of the order in which phenomena are implemented. Nevertheless, the grammar engineer can keep and try out solutions in parallel for a longer time, increasing the possibility of exploring more alternative versions of the grammar. These additional investigations allow for better informed decisions to stop exploring certain analyses. In addition, by breaking up analyses into possible alternatives, chances are that the resulting metagrammar will be more modular than a directly written grammar would have been, which facilitates exploring alternatives further.

In sum, even though metagrammar engineering does not completely solve the challenge of complete explorations of a grammar's possibilities, it does facilitate this process so that finding optimal solutions becomes more likely, leading to better supported choices among alternatives and a more scientific approach to grammar development.

Acknowledgments.

The work described in this paper has been supported by the project TAKE (Technologies for Advanced Knowledge Extraction), funded under contract 01IW08003 by the German Federal Ministry of Education and Research. Emily M. Bender, Laurie Poulson, Christoph Zwirello, Bart Cramer, Kim Gerdes and three anonymous reviewers provided valuable feedback that resulted in significant improvement of the paper. Naturally, all remaining errors are my own.

[10] It is, of course, possible to go back and change old analyses based on new evidence. In practice, the large effort involved will only be undertaken if the advantages are apparent beforehand.

Simple Unsupervised Grammar Induction from Raw Text with Cascaded Finite State Models

Elias Ponvert, Jason Baldridge and Katrin Erk

Abstract

We consider a new subproblem of unsupervised parsing from raw text, unsupervised partial parsing—the unsupervised version of text chunking. We show that addressing this task directly, using probabilistic finite-state methods, produces better results than relying on the local predictions of a current best unsupervised parser, Seginer's (2007) CCL. These finite-state models are combined in a cascade to produce more general (full-sentence) constituent structures; doing so outperforms CCL by a wide margin in unlabeled PARSEVAL scores for English, German and Chinese. Finally, we address the use of phrasal punctuation as a heuristic indicator of phrasal boundaries, both in our system and in CCL.

1 Introduction

Unsupervised grammar induction has been an active area of research in computational linguistics for over twenty years (Lari and Young, 1990; Pereira and Schabes, 1992; Charniak, 1993). Recent work (Headden III et al., 2009; Cohen and Smith, 2009; Hänig, 2010; Spitkovsky et al., 2010) has largely built on the dependency model with valence of Klein and Manning (2004), and is characterized by its reliance on gold-standard part-of-speech (POS) annotations: the models are trained on and evaluated using sequences of POS tags rather than raw tokens. This is also true for models which are not successors of Klein and Manning (Bod, 2006; Hänig, 2010).

An exception which learns from raw text and makes no use of POS tags is the *common cover links* parser (CCL, Seginer 2007). CCL established state-of-the-art results for unsupervised *constituency* parsing from raw text, and it is also incremental and extremely fast for both learning and parsing. Unfortunately, CCL is a non-probabilistic algorithm based on a complex set of inter-relating heuristics and a non-standard (though interesting) representation of constituent trees. This makes it hard to extend. Note that although Reichart and Rappoport (2010) improve on Seginer's results, they do so by selecting training sets to best match the particular test sentences—CCL itself is used without modification.

Ponvert et al. (2010) explore an alternative strategy of *unsupervised partial parsing*: directly predicting low-level constituents based solely on word co-occurrence frequencies. Essentially, this means segmenting raw text into multiword constituents. In that paper, we show—somewhat surprisingly—that CCL's performance is mostly dependent on its effectiveness at identifying low-level constituents. In fact, simply extracting non-hierarchical multiword constituents from CCL's output and putting a right-branching structure over them actually works *better* than CCL's own higher level predictions. This result suggests that improvements to low-level constituent prediction will ultimately lead to further gains in overall constituent parsing.

Here, we present such an improvement by using probabilistic finite-state models for phrasal segmentation from raw text. The task for these models is chunking, so we evaluate performance on identification of multiword chunks of all constituent types as well as only noun phrases. Our unsupervised chunkers extend straightforwardly to a cascade that predicts higher levels of constituent structure, similar to the supervised approach of Brants (1999). This forms an overall unsupervised parsing system that outperforms CCL by a wide margin.

2 Data

We use the standard data sets for unsupervised constituency parsing research: for **English**, the Wall Street Journal subset of the Penn Treebank-3 (WSJ, Marcus et al. 1999); for **German**, the Negra corpus v2 (Krenn et al., 1998); for **Chinese**, the Penn Chinese Treebank v5.0 (CTB, Palmer et al., 2006). We lower-case text but otherwise do not alter the raw text of the corpus. Sentence segmentation and tokenization from the treebank is used. As in previous work, punctuation is not used for evaluation.

In much unsupervised parsing work the test sentences are included in the training material. Like Cohen and Smith, Headden III et al., Spitkovsky et al., we depart from this experimental setup and keep the evaluation sets blind to the models during training. For English (WSJ) we use sections 00-22 for training, section 23 for test and we develop using section 24; for German (Negra) we use the first 18602 sentences for training, the last 1000 sentences for development and the penultimate 1000 sentences for testing; for Chinese (CTB) we adopt the data-split of Duan et al. (2007).

3 Tasks and Benchmark

Evaluation. By **unsupervised partial parsing**, or simply **unsupervised chunking**, we mean the segmentation of raw text into (non-overlapping) multiword constituents. The models are intended to capture local constituent structure – the lower branches of a constituent tree. For this reason we evaluate

CTB	Chunks	32.5	55.4
	NPs	19.8	42.9

Table 2: Percentage of gold standard constituents and words under constituent chunks and base NPs.

using what we call *constituent chunks*, the subset of gold standard constituents which are i) branching (multiword) but ii) non-hierarchical (do not contain subconstituents). We also evaluate our models based on their performance at identifying base noun phrases, NPs that do not contain nested NPs.

Examples of constituent chunks extracted from treebank constituent trees are in Fig. 1. In English newspaper text, constituent chunks largely correspond with base NPs, but this is less the case with Chinese and German. Moreover, the relationship between NPs and constituent chunks is not a subset relation: some base NPs do have internal constituent structure. The numbers of constituent chunks and NPs for the training datasets are in Table 1. The percentage of constituents in these datasets which fall under these definitions, and the percentage of words under these constituents, are in Table 2.

For parsing, the standard unsupervised parsing metric is unlabeled PARSEVAL. It measures precision and recall on constituents produced by a parser as compared to gold standard constituents.

CCL benchmark. We use Seginer's CCL as a benchmark for several reasons. First, there is a free/open-source implementation facilitating exper-

imental replication and comparison.[1] More importantly, until recently it was the only unsupervised raw text constituent parser to produce results competitive with systems which use gold POS tags (Klein and Manning, 2002; Klein and Manning, 2004; Bod, 2006) – and the recent improved raw-text parsing results of Reichart and Rappoport (2010) make direct use of CCL without modification. There are other raw-text parsing systems of note, EMILE (Adriaans et al., 2000), ABL (van Zaanen, 2000) and ADIOS (Solan et al., 2005); however, there is little consistent treebank-based evaluation of these models. One study by Cramer (2007) found that none of the three performs particularly well under treebank evaluation. Finally, CCL outperforms most published POS-based models when those models are trained on unsupervised word classes rather than gold POS tags. The only exception we are aware of is Hänig's (2010) unsuParse+, which outperforms CCL on Negra, though this is shown only for sentences with ten or fewer words.

Phrasal punctuation. Though punctuation is usually entirely ignored in unsupervised parsing research, Seginer (2007) departs from this in one key aspect: the use of *phrasal punctuation* – punctuation symbols that often mark phrasal boundaries within a sentence. These are used in two ways: i) they impose a hard constraint on constituent spans, in that no constituent (other than sentence root) may extend over a punctuation symbol, and ii) they contribute to the model, specifically in terms of the statistics of words seen adjacent to a phrasal boundary. We follow this convention and use the following set:

. ? ! ; , -- 。 、

The last two are ideographic full-stop and comma.[2]

4 Unsupervised partial parsing

We learn partial parsers as constrained sequence models over tags encoding local constituent structure (Ramshaw and Marcus, 1995). A simple tagset is unlabeled BIO, which is familiar from supervised chunking and named-entity recognition: the tag *B* denotes the beginning of a chunk, *I* denotes membership in a chunk and *O* denotes exclusion from any chunk. In addition we use the tag *STOP* for sentence boundaries and phrasal punctuation.

HMMs and PRLGs. The models we use for unsupervised partial parsing are hidden Markov models, and a generalization we refer to as probabilistic right linear grammars (PRLGs). An HMM models a sequence of observed states (words) $\mathbf{x} = \{x_1, x_2, \ldots, x_N\}$ and a corresponding set of hidden states $\mathbf{y} = \{y_1, y_2, \ldots, y_N\}$. HMMs may be thought of as a special case of probabilistic context-free grammars, where the non-terminal symbols are the hidden state space, terminals are the observed states and rules are of the form NONTERM $\rightarrow$ TERM NONTERM (assuming y_1 and y_N are fixed and given). So, the emission and transition emanating from y_n would be characterized as a PCFG rule $y_n \rightarrow x_n\ y_{n+1}$. HMMs factor rule probabilities into emission and transition probabilities:

$$\begin{aligned} P(y_n \rightarrow x_n\ y_{n+1}) &= P(x_n, y_{n+1}|y_n) \\ &\approx P(x_n|y_n)\ P(y_{n+1}|y_n). \end{aligned}$$

However, without making this independence assumption, we can model right linear rules directly:

$$P(x_n, y_{n+1}|y_n) = P(x_n|y_n, y_{n+1})\ P(y_{n+1}|y_n).$$

So, when we condition emission probabilities on both the current state y_n and the next state y_{n+1}, we have an exact model. This direct modeling of the right linear grammar rule $y_n \rightarrow x_n\ y_{n+1}$ is what we call a probabilistic right-linear grammar. To be clear, a PRLG is just an HMM without the independence of emissions and transitions. See Smith and Johnson (2007) for a discussion, where they refer to PRLGs as Mealy HMMs.

We use expectation maximization to estimate model parameters. For the E step, the forward-backward algorithm (Rabiner, 1989) works identically for the HMM and PRLG. For the M step, we use maximum likelihood estimation with additive smoothing on the emissions probabilities. So, for the HMM and PRLG models respectively, for words

[1] http://www.seggu.net/ccl

[2] This set is essentially that of Seginer (2007). While it is clear from our analysis of CCL that it does make use of phrasal punctuation in Chinese, we are not certain whether ideographic comma is included.

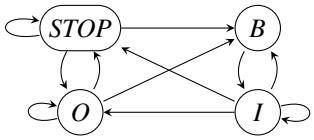

Fig. 2: Possible tag transitions as a state diagram.

	STOP	*B*	*I*	*O*
STOP	.33	.33		.33
B			1	
I	.25	.25	.25	.25
O	.33	.33		.33

Fig. 3: Uniform initialization of transition probabilities subject to the constraints in Fig. 2: rows correspond to antecedent state, columns to following state.

w and tags s, t:

$$\hat{P}(w|t) = \frac{C(t,w) + \lambda}{C(t) + \lambda V}$$
$$\hat{P}(w|s,t) = \frac{C(t,w,s) + \lambda}{C(t,s) + \lambda V}$$

where C are the soft counts of emissions $C(t,w)$, rules $C(t,w,s) = C(t \rightarrow w\ s)$, tags $C(t)$ and transitions $C(t,s)$ calculated during the E step; V is the number of terms w, and λ is a smoothing parameter. We fix $\lambda = .1$ for all experiments; more sophisticated smoothing could avoid dependence on λ.

We do not smooth transition probabilities (so $\hat{P}(s|t) = C(t,s)/C(t)$) for two reasons. First, with four tags, there is no data-sparsity concern with respect to transitions. Second, the nature of the task imposes certain constraints on transition probabilities: because we are only interested in multiword chunks, we expressly do not want to generate a *B* following a *B* – in other words $P(B|B) = 0$.

These constraints boil down to the observation that the *B* and *I* states will only be seen in *BII** sequences. This may be expressed via the state transition diagram in Fig. 2. The constraints of also dictate the initial model input to the EM process. We use uniform probability distributions subject to the constraints of Fig. 2. So, initial model transition probabilities are given in Fig. 3. In EM, if a parameter is equal to zero, subsequent iterations of the EM process will not "unset" this parameter; thus, this form of initialization is a simple way of encoding constraints on model parameters. We also experimented with random initial models (subject to the constraints in Fig. 2). Uniform initialization usually works slightly better; also, uniform initialization does not require multiple runs of each experiment, as random initialization does.

Motivating the HMM and PRLG. This approach – encoding a chunking problem as a tagging problem and learning to tag with HMMs – goes back to Ramshaw and Marcus (1995). For unsupervised learning, the expectation is that the model will learn to generalize on phrasal boundaries. That is, the models will learn to associate terms like *the* and *a*, which often occur at the beginnings of sentences and rarely at the end, with the tag *B*, which cannot occur at the end of a sentence. Likewise common nouns like *company* or *asset*, which frequently occur at the ends of sentences, but rarely at the beginning, will come to be associated with the *I* tag, which cannot occur at the beginning.

The basic motivation for the PRLG is the assumption that information is lost due to the independence assumption characteristic of the HMM. With so few states, it is feasible to experiment with the more fine-grained PRLG model.

Evaluation. Using the low-level predictions of CCL as as benchmark, we evaluate the HMM and PRLG chunkers on the tasks of constituent chunk and base NP identification. Models were initialized uniformly as illustrated in Fig. 3. Sequence models learn via EM. We report accuracy only after convergence, that is after the change in full dataset perplexity (log inverse probability) is less than %.01 between iterations. Precision, recall and *F*-score are reported for full constituent identification – brackets which do not match the gold standard exactly are false positives.

Model performance results on held-out test datasets are reported in Table 3. 'CCL' refers to the lowest-level constituents extracted from full CCL output, as a benchmark chunker. The sequence models outperform the CCL benchmark at both tasks and on all three datasets. In most cases, the PRLG sequence model performs better than the HMM; the exception is CTB, where the PRLG model is behind the HMM in evaluation, as well as behind CCL.

As the lowest-level constituents of CCL were not specifically designed to describe chunks, we also

checked the recall of *all* brackets generated by CCL against gold-standard constituent chunks. The results are given in Table 4. Even compared to this, the sequence models' recall is almost always higher.

The sequence models, as well as the CCL benchmark, show relatively low precision on the Negra corpus. One possible reason for this lies in the design decision of Negra to use relatively flat tree structures. As a result, many structures that in other treebanks would be prepositional phrases with embedded noun phrases – and thus non-local constituents – are flat prepositional phrases here. Examples include "auf die Wiesbadener Staatsanwaelte" (on Wiesbaden's district attorneys) and "in Hannovers Nachbarstadt" (in Hannover's neighbor city).

In fact, in Negra, the sequence model chunkers often find NPs embedded in PPs, which are not annotated as such. For instance, in the PP "hinter den Kulissen" (behind the scenes), both the PRLG and HMM chunkers identify the internal NP, though this is not identified in Negra and thus considered a false positive. The fact that the HMM and PRLG have higher recall on NP identification on Negra than precision is further evidence towards this.

Comparing the HMM and PRLG. To outline some of the factors differentiating the HMM and PRLG, we focus on NP identification in WSJ.

The PRLG has higher precision than the HMM, while the two models are closer in recall. Comparing the predictions directly, the two models often have the same correct predictions and often miss the same gold standard constituents. The improved results of the PRLG are based mostly on the fewer overall brackets predicted, and thus fewer false positives: for WSJ the PRLG incorrectly predicts 2241 NP constituents compared to 6949 for the HMM. Table 5 illustrates the top 5 POS sequences of the false positives predicted by the HMM.[3] (Recall that we use gold standard POS *only* for post-experiment results analysis—the model itself does not have access to them.) By contrast, the sequence representing the largest class of errors of the PRLG is DT NN, with 165 errors – this sequence represents the largest class of predictions for both models.

Two of the top classes of errors, MD VB and TO VB, represent verb phrase constituents, which are often predicted by the HMM chunker, but not by the PRLG. The class represented by NNP NNP corresponds with the tendency of the HMM chunker to split long proper names: for example, it systematically splits *new york stock exchange* into two chunks, (*new york*) (*stock exchange*), whereas the PRLG chunker predicts a single four-word chunk.

The most interesting class is DT JJ, which represents the difficulty the HMM chunker has at dis-

[3] For the Penn Treebank tagset, see Marcus et al. (1993).

		NPs		PPs	
		Lev 1	Lev 2	Lev 1	Lev 2
WSJ	HMM	66.5	68.1	20.6	70.2
	PRLG	77.5	78.3	9.1	77.6
Negra	HMM	54.7	62.3	24.8	48.1
	PRLG	61.6	65.2	40.3	44.0
CTB	HMM	33.3	35.4	34.6	38.4
	PRLG	30.9	33.6	31.6	47.1

Table 7: NP and PP recall at cascade levels 1 and 2. The level 1 NP numbers differ from the NP chunking numbers from Table 3 since they include root-level constituents which are often NPs.

tinguishing determiner-adjective from determiner-noun pairs. The PRLG chunker systematically gets DT JJ NN trigrams as chunks. The greater context provided by right branching rules allows the model to explicitly estimate separate probabilities for $P(I \rightarrow \textit{recent I})$ versus $P(I \rightarrow \textit{recent O})$. That is, *recent* within a chunk versus ending a chunk. Bigrams like *the acquisition* allow the model to learn rules $P(B \rightarrow \textit{the I})$ and $P(I \rightarrow \textit{acquisition O})$. So, the PRLG is better able to correctly pick out the trigram chunk (*the recent acquisition*).

5 Constituent parsing with a cascade of chunkers

We use cascades of chunkers for full constituent parsing, building hierarchical constituents bottom-up. After chunking is performed, all multiword constituents are collapsed and represented by a single pseudoword. We use an extremely simple, but effective, way to create pseudoword for a chunk: pick the term in the chunk with the highest corpus frequency, and mark it as a pseudoword. The sentence is now a string of symbols (normal words and pseudowords), to which a subsequent unsupervised chunking model is applied. This process is illustrated in Fig. 4.

Each chunker in the cascade chunks the raw text, then regenerates the dataset replacing chunks with pseudowords; this process is iterated until no new chunks are found. The separate chunkers in the cascade are referred to as *levels*. In our experiments the cascade process took a minimum of 5 levels, and a maximum of 7. All chunkers in the cascade have the same settings in terms of smoothing, the tagset and initialization.

Evaluation. Table 6 gives the unlabeled PARSEVAL scores for CCL and the two finite-state models. PRLG achieves the highest F-score for all datasets, and does so by a wide margin for German and Chinese. CCL does achieve higher recall for English.

While the first level of constituent analysis has high precision and recall on NPs, the second level often does well finding prepositional phrases (PPs), especially in WSJ; see Table 7. This is illustrated in Fig. 5. This example also illustrates a PP attachment error, which are a common problem for these models.

We also evaluate using short – 10-word or less – sentences. That said, we maintain the training/test split from before. Also, making use of the open

source implementation by F. Luque,[4] we compare on WSJ and Negra to the *constituent context model* (CCM) of Klein and Manning (2002). CCM learns to predict a set of brackets over a string (in practice, a string of POS tags) by jointly estimating constituent and distituent strings and contexts using an iterative EM-like procedure (though, as noted by Smith and Eisner (2004), CCM is deficient as a generative model). Note that this comparison is methodologically problematic in two respects. On the one hand, CCM is evaluated using gold standard POS sequences as input, so it receives a major source of supervision not available to the other models. On the other hand, the other models use punctuation as an indicator of constituent boundaries, but all punctuation is dropped from the input to CCM. Also, note that CCM performs better when trained on short sentences, so here CCM is trained only on the 10-word-or-less subsets of the training datasets.[5]

The results from the cascaded PRLG chunker are near or better than the best performance by CCL or CCM in these experiments. These and the full-length parsing results suggest that the cascaded chunker strategy generalizes better to longer sentences than does CCL. CCM does very poorly on longer sentences, but does not have the benefit of using punctuation, as do the raw text models; unfortunately, further exploration of this trade-off is beyond the scope of this paper. Finally, note that CCM has higher recall, and lower precision, generally, than the raw text models. This is due, in part, to the chart structure used by CCM in the calculation of constituent and distituent probabilities: as in CKY parsing, the chart structure entails the trees predicted will be binary-branching. CCL and the cascaded models can predict higher-branching constituent structures, so fewer constituents are predicted overall.

6 Phrasal punctuation revisited

Up to this point, the proposed models for chunking and parsing use phrasal punctuation as a phrasal separator, like CCL. We now consider how well these models perform in absence of this constraint.

Table 9a provides comparison of the sequence models' performance on the constituent chunking task without using phrasal punctuation in training and evaluation. The table shows absolute improvement (+) or decline (−) in precision and recall when phrasal punctuation is removed from the data. The punctuation constraint seems to help the chunkers some, but not very much; ignoring punctuation seems to *improve* chunker results for the HMM on Chinese. Overall, the effect of phrasal punctuation on the chunker models' performance is not clear.

The results for cascaded parsing differ strongly from those for chunking, as Table 9b indicates. Using phrasal punctuation to constrain bracket prediction has a larger impact on cascaded parsing re-

b) (Cascade) Parsing

Table 9: Effects of dropping phrasal punctuation in unsupervised chunking and parsing evaluations relative to Tables 3 and 6.

sults almost across the board. This is not surprising: while performing unsupervised partial parsing from raw text, the sequence models learn two general patterns: i) they learn to chunk rare sequences, such as named entities, and ii) they learn to chunk high-frequency function words next to lower frequency content words, which often correlate with NPs headed by determiners, PPs headed by prepositions and VPs headed by auxiliaries. When these patterns are themselves replaced with pseudowords (see Fig. 4), the models have fewer natural cues to identify constituents. However, within the degrees of freedom allowed by punctuation constraints as described, the chunking models continue to find relatively good constituents.

While CCL makes use of phrasal punctuation in previously reported results, the open source implementation allows it to be evaluated without this constraint. We did so, and report results in Table 9b. CCL is, in fact, very sensitive to phrasal punctuation. Comparing CCL to the cascaded chunkers when none of them use punctuation constraints, the cascaded chunkers (both HMMs and PRLGs) outperform CCL for each evaluation and dataset.

For the CTB dataset, best chunking performance and cascaded parsing performance flips from the HMM to the PRLG. More to the point, the PRLG is actually with worst performing model at the constituent chunking task, but the best performing cascade parser; also, this model has the most serious degrade in performance when phrasal punctuation is dropped from input. To investigate, we track the performance of the chunkers on the development dataset over iterations of EM. This is illustrated in Fig. 6 with the PRLG model. First of all, Fig. 6a reveals the average length of the constituents predicted by the PRLG model increases over the course of EM. However, the average constituent chunk length is 2.22. So, the PRLG chunker is predicting constituents that are longer than the ones targeted in the constituent chunking task: regardless of whether they are legitimate constituents or not, often they will likely be counted as false positives in this evaluation. This is confirmed by observing the constituent chunking precision in Fig. 6b, which peaks when the average predicted constituent length is about the same the actual average length of those in the evaluation. The question, then, is whether the longer chunks predicted correspond to actual constituents or not. Fig. 6c shows that the PRLG, when constrained by phrasal punctuation, does continue to improve its constituent prediction accuracy over the course of EM. These correctly predicted constituents are not counted as such in the constituent chunking or base NP evaluations, but they factor directly into

improved accuracy when this model is part of a cascade.

7 Related work

Our task is the unsupervised analogue of chunking (Abney, 1991), popularized by the 1999 and 2000 Conference on Natural Language Learning shared tasks (Tjong et al., 2000). In fact, our models follow Ramshaw and Marcus (1995), treating structure prediction as sequence prediction using BIO tagging.

In addition to Seginer's CCL model, the unsupervised parsing model of Gao and Suzuki (2003) and Gao et al. (2004) also operates on raw text. Like us, their model gives special treatment to local constituents, using a language model to characterize phrases which are linked via a dependency model. Their output is not evaluated directly using treebanks, but rather applied to several information retrieval problems.

In the supervised realm, Hollingshead et al. (2005) compare context-free parsers with finite-state partial parsing methods. They find that full parsing maintains a number of benefits, in spite of the greater training time required: they can train on less data more effectively than chunkers, and are more robust to shifts in textual domain.

Brants (1999) reports a supervised cascaded chunking strategy for parsing which is strikingly similar to the methods proposed here. In both, Markov models are used in a cascade to predict hierarchical constituent structure; and in both, the parameters for the model at each level are estimated independently. There are major differences, though: the models here are learned from raw text without tree annotations, using EM to train parameters; Brants' cascaded Markov models use supervised maximum likelihood estimation. Secondly, between the separate levels of the cascade, we collapse constituents into symbols which are treated as tokens in subsequent chunking levels; the Markov models in the higher cascade levels in Brants' work actually emit constituent structure. A related approach is that of Schuler et al. (2010), who report a supervised hierarchical hidden Markov model which uses a right-corner transform. This allows the model to predict more complicated trees with fewer levels than in Brants' work or this paper.

8 Conclusion

In this paper we have introduced a new subproblem of unsupervised parsing: unsupervised partial parsing, or unsupervised chunking. We have proposed a model for unsupervised chunking from raw text that is based on standard probabilistic finite-state methods. This model produces better local constituent predictions than the current best unsupervised parser, CCL, across datasets in English, German, and Chinese. By extending these probabilistic finite-state methods in a cascade, we obtain a general unsupervised parsing model. This model outperforms CCL in PARSEVAL evaluation on English, German, and Chinese.

Like CCL, our models operate from raw (albeit segmented) text, and like it our models decode very quickly; however, unlike CCL, our models are based on standard and well-understood computational linguistics technologies (hidden Markov models and related formalisms), and may benefit from new research into these core technologies. For instance, our models may be improved by the application of (unsupervised) discriminative learning techniques with features (Berg-Kirkpatrick et al., 2010); or by incorporating topic models and document information (Griffiths et al., 2005; Moon et al., 2010).

UPPARSE, the software used for the experiments in this paper, is available under an open-source license to facilitate replication and extensions.[6]

Abstract

We propose an automatic method of extracting paraphrases from definition sentences, which are also automatically acquired from the Web. We observe that a huge number of concepts are defined in Web documents, and that the sentences that define the same concept tend to convey mostly the same information using different expressions and thus contain many paraphrases. We show that a large number of paraphrases can be automatically extracted with high precision by regarding the sentences that define the same concept as parallel corpora. Experimental results indicated that with our method it was possible to extract about 300,000 paraphrases from 6×10^8 Web documents with a precision rate of about 94%.

1 Introduction

Natural language allows us to express the same information in many ways, which makes natural language processing (NLP) a challenging area. Accordingly, many researchers have recognized that automatic paraphrasing is an indispensable component of intelligent NLP systems (Iordanskaja et al., 1991; McKeown et al., 2002; Lin and Pantel, 2001; Ravichandran and Hovy, 2002; Kauchak and Barzilay, 2006; Callison-Burch et al., 2006) and have tried to acquire a large amount of paraphrase knowledge, which is a key to achieving robust automatic paraphrasing, from corpora (Lin and Pantel, 2001; Barzilay and McKeown, 2001; Shinyama et al., 2002; Barzilay and Lee, 2003).

We propose a method to extract phrasal paraphrases from pairs of sentences that define the same concept. The method is based on our observation that two sentences defining the same concept can be regarded as a parallel corpus since they largely convey the same information using different expressions. Such definition sentences abound on the Web. This suggests that we may be able to extract a large amount of phrasal paraphrase knowledge from the definition sentences on the Web.

For instance, the following two sentences, both of which define the same concept "osteoporosis", include two pairs of phrasal paraphrases, which are indicated by underlines ① and ②, respectively.

(1) a. Osteoporosis is a disease that ① decreases the quantity of bone and ② makes bones fragile.
b. Osteoporosis is a disease that ① reduces bone mass and ② increases the risk of bone fracture.

We define *paraphrase* as a pair of expressions between which entailment relations of both directions hold. (Androutsopoulos and Malakasiotis, 2010).

Our objective is to extract phrasal paraphrases from pairs of sentences that define the same concept. We propose a supervised method that exploits various kinds of lexical similarity features and contextual features. Sentences defining certain concepts are acquired automatically on a large scale from the Web by applying a quite simple supervised method.

Previous methods most relevant to our work used parallel corpora such as multiple translations of the same source text (Barzilay and McKeown, 2001) or automatically acquired parallel news texts (Shinyama et al., 2002; Barzilay and Lee, 2003; Dolan et al., 2004). The former requires a large amount of manual labor to translate the same texts

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1087–1097,
Portland, Oregon, June 19-24, 2011.

in several ways. The latter would suffer from the fact that it is not easy to automatically retrieve large bodies of parallel news text with high accuracy. On the contrary, recognizing definition sentences for the same concept is quite an easy task at least for Japanese, as we will show, and we were able to find a huge amount of definition sentence pairs from normal Web texts. In our experiments, about 30 million definition sentence pairs were extracted from 6×10^8 Web documents, and the estimated number of paraphrases recognized in the definition sentences using our method was about 300,000, for a precision rate of about 94%. Also, our experimental results show that our method is superior to well-known competing methods (Barzilay and McKeown, 2001; Koehn et al., 2007) for extracting paraphrases from definition sentence pairs.

Our evaluation is based on bidirectional checking of entailment relations between paraphrases that considers the context dependence of a paraphrase.

Note that using definition sentences is only the beginning of our research on paraphrase extraction. We have a more general hypothesis that sentences fulfilling the same *pragmatic* function (e.g. definition) for the same topic (e.g. osteoporosis) convey mostly the same information using different expressions. Such functions other than definition may include the usage of the same Linux command, the recipe for the same cuisine, or the description of related work on the same research issue.

Section 2 describes related works. Section 3 presents our proposed method. Section 4 reports on evaluation results. Section 5 concludes the paper.

2 Related Work

The existing work for paraphrase extraction is categorized into two groups. The first involves a distributional similarity approach pioneered by Lin and Pantel (2001). Basically, this approach assumes that two expressions that have a large distributional similarity are paraphrases. There are also variants of this approach that address entailment acquisition (Geffet and Dagan, 2005; Bhagat et al., 2007; Szpektor and Dagan, 2008; Hashimoto et al., 2009). These methods can be applied to a normal monolingual corpus, and it has been shown that a large number of paraphrases or entailment rules could be extracted. However, the precision of these methods has been relatively low. This is due to the fact that the evidence, i.e., distributional similarity, is just indirect evidence of paraphrase/entailment. Accordingly, these methods occasionally mistake antonymous pairs for paraphrases/entailment pairs, since an expression and its antonymous counterpart are also likely to have a large distributional similarity. Another limitation of these methods is that they can find only paraphrases consisting of frequently observed expressions since they must have *reliable* distributional similarity values for expressions that constitute paraphrases.

The second category is a parallel corpus approach (Barzilay and McKeown, 2001; Shinyama et al., 2002; Barzilay and Lee, 2003; Dolan et al., 2004). Our method belongs to this category. This approach aligns expressions between two sentences in parallel corpora, based on, for example, the overlap of words/contexts. The aligned expressions are assumed to be paraphrases. In this approach, the expressions do not need to appear frequently in the corpora. Furthermore, the approach rarely mistakes antonymous pairs for paraphrases/entailment pairs. However, its limitation is the difficulty in preparing a large amount of parallel corpora, as noted before. We avoid this by using definition sentences, which can be easily acquired on a large scale from the Web, as parallel corpora.

Murata et al. (2004) used definition sentences in two manually compiled dictionaries, which are considerably fewer in the number of definition sentences than those on the Web. Thus, the coverage of their method should be quite limited. Furthermore, the precision of their method is much poorer than ours as we report in Section 4.

For a more extensive survey on paraphrasing methods, see Androutsopoulos and Malakasiotis (2010) and Madnani and Dorr (2010).

3 Proposed method

Our method, targeting the Japanese language, consists of two steps: definition sentence acquisition and paraphrase extraction. We describe them below.

3.1 Definition sentence acquisition

We acquire sentences that define a concept (definition sentences) as in Example (2), which defines "骨

粗鬆症" (osteoporosis), from the 6×10^8 Web pages (Akamine et al., 2010) and the Japanese Wikipedia.

(2) 骨粗鬆症**とは、**骨がもろくなってしまう病気だ。
(Osteoporosis is a disease that makes bones fragile.)

Fujii and Ishikawa (2002) developed an unsupervised method to find definition sentences from the Web using 18 sentential templates and a language model constructed from an encyclopedia. On the other hand, we developed a supervised method to achieve a higher precision.

We use one sentential template and an SVM classifier. Specifically, we first collect definition sentence candidates by a template "^NP **とは**.*", where ^ is the beginning of sentence and NP is the noun phrase expressing the concept to be defined followed by a particle sequence, "**と**" (comitative) and "**は**" (topic) (and optionally followed by comma), as exemplified in (2). As a result, we collected 3,027,101 sentences. Although the particle sequence tends to mark the topic of the definition sentence, it can also appear in interrogative sentences and normal assertive sentences in which a topic is strongly emphasized. To remove such non-definition sentences, we classify the candidate sentences using an SVM classifier with a polynominal kernel ($d = 2$).[1] Since Japanese is a head-final language and we can judge whether a sentence is interrogative or not from the last words in the sentence, we included morpheme N-grams and bag-of-words (with the window size of N) at the end of sentences in the feature set. The features are also useful for confirming that the head verb is in the present tense, which definition sentences should be. Also, we added the morpheme N-grams and bag-of-words right after the particle sequence in the feature set since we observe that non-definition sentences tend to have interrogative related words like "何" (what) or "一体" ((what) on earth) right after the particle sequence. We chose 5 as N from our preliminary experiments.

Our training data was constructed from 2,911 sentences randomly sampled from all of the collected sentences. 61.1% of them were labeled as positive. In the 10-fold cross validation, the classifier's accuracy, precision, recall, and F1 were 89.4, 90.7, 92.2, and 91.4, respectively. Using the classifier, we acquired 1,925,052 positive sentences from all of the collected sentences. After adding definition sentences from Wikipedia articles, which are typically the first sentence of the body of each article (Kazama and Torisawa, 2007), we obtained a total of 2,141,878 definition sentence candidates, which covered 867,321 concepts ranging from weapons to rules of baseball. Then, we coupled two definition sentences whose defined concepts were the same and obtained 29,661,812 definition sentence pairs.

Obviously, our method is tailored to Japanese. For a language-independent method of definition acquisition, see Navigli and Velardi (2010) as an example.

3.2 Paraphrase extraction

Paraphrase extraction proceeds as follows. First, each sentence in a pair is parsed by the dependency parser KNP[2] and dependency tree fragments that constitute linguistically well-formed constituents are extracted. The extracted dependency tree fragments are called *candidate phrases* hereafter. We restricted candidate phrases to predicate phrases that consist of at least one dependency relation, do not contain demonstratives, and in which all the leaf nodes are nominal and all of the constituents are consecutive in the sentence. KNP indicates whether each candidate phrase is a predicate based on the POS of the head morpheme. Then, we check all the pairs of candidate phrases between two definition sentences to find paraphrase pairs.[3] In (1), repeated in (3), candidate phrase pairs to be checked include (① decreases the quantity of bone, ① reduces bone mass), (① decreases the quantity of bone, ② increases the risk of bone fracture), (② makes bones fragile, ① reduces bone mass), and (② makes bones fragile, ② increases the risk of bone fracture).

(3) a. Osteoporosis is a disease that ① decreases the quantity of bone and ② makes bones fragile.
b. Osteoporosis is a disease that ① reduces bone mass and ② increases the risk of bone fracture.

[1] We use SVM^{light} available at `http://svmlight.joachims.org/`.

[2] `http://nlp.kuee.kyoto-u.ac.jp/nl-resource/knp.html`.

[3] Our method discards candidate phrase pairs in which one subsumes the other in terms of their character string, or the difference is only one proper noun like "toner cartridges that Apple Inc. made" and "toner cartridges that Xerox made." Proper nouns are recognized by KNP.

f1	The ratio of the number of morphemes shared between two candidate phrases to the number of all of the morphemes in the two phrases.
f2	The ratio of the number of a candidate phrase's morphemes, for which there is a morpheme with small edit distance (1 in our experiment) in another candidate phrase, to the number of all of the morphemes in the two phrases. Note that Japanese has many orthographical variations and edit distance is useful for identifying them.
f3	The ratio of the number of a candidate phrase's morphemes, for which there is a morpheme with the same pronunciation in another candidate phrase, to the number of all of the morphemes in the two phrases. Pronunciation is also useful for identifying orthographic variations. Pronunciation is given by KNP.
f4	The ratio of the number of morphemes of a shorter candidate phrase to that of a longer one.
f5	The identity of the inflected form of the head morpheme between two candidate phrases: 1 if they are identical, 0 otherwise.
f6	The identity of the POS of the head morpheme between two candidate phrases: 1 or 0.
f7	The identity of the inflection (conjugation) of the head morpheme between two candidate phrases: 1 or 0.
f8	The ratio of the number of morphemes that appear in a candidate phrase segment of a definition sentence s_1 and in a segment that is NOT a part of the candidate phrase of another definition sentence s_2 to the number of all of the morphemes of s_1's candidate phrase, i.e. how many extra morphemes are incorporated into s_1's candidate phrase.
f9	The reversed ($s_1 \leftrightarrow s_2$) version of **f8**.
f10	The ratio of the number of parent dependency tree fragments that are shared by two candidate phrases to the number of all of the parent dependency tree fragments of the two phrases. Dependency tree fragments are represented by the pronunciation of their component morphemes.
f11	A variation of **f10**; tree fragments are represented by the base form of their component morphemes.
f12	A variation of **f10**; tree fragments are represented by the POS of their component morphemes.
f13	The ratio of the number of unigrams (morphemes) that appear in the child context of both candidate phrases to the number of all of the child context morphemes of both candidate phrases. Unigrams are represented by the pronunciation of the morpheme.
f14	A variation of **f13**; unigrams are represented by the base form of the morpheme.
f15	A variation of **f14**; the numerator is the number of child context unigrams that are adjacent to both candidate phrases.
f16	The ratio of the number of trigrams that appear in the child context of both candidate phrases to the number of all of the child context morphemes of both candidate phrases. Trigrams are represented by the pronunciation of the morpheme.
f17	Cosine similarity between two definition sentences from which a candidate phrase pair is extracted.

Table 1: Features used by paraphrase classifier.

The paraphrase checking of candidate phrase pairs is performed by an SVM classifier with a linear kernel that classifies each pair of candidate phrases into a paraphrase or a non-paraphrase.[4] Candidate phrase pairs are ranked by their distance from the SVM's hyperplane. Features for the classifier are based on our observation that two candidate phrases tend to be paraphrases if the candidate phrases themselves are sufficiently similar and/or their surrounding contexts are sufficiently similar. Table 1 lists the features used by the classifier.[5] Basically, they represent either the similarity of candidate phrases (**f1-9**) or that of their contexts (**f10-17**). We think that they have various degrees of discriminative power, and thus we use the SVM to adjust their weights. Figure 1 illustrates features **f8-12**, for which you may need supplemental remarks. English is used for ease of explanation. In the figure, **f8** has a positive value since the candidate phrase of s_1 contains morphemes "of bone", which do not appear in the candidate phrase of s_2 but do appear in the other part of s_2, i.e. they are extra morphemes for s_1's candidate phrase. On the other hand, **f9** is zero since there is no such extra morpheme in s_2's candidate phrase. Also, features **f10-12** have positive values since the two candidate phrases share two parent dependency tree fragments, *(that increases)* and *(of fracture)*.

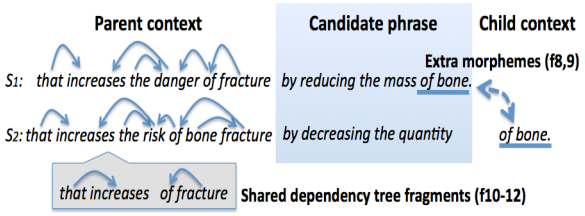

Figure 1: Illustration of features **f8-12**.

We have also tried the following features, which we do not detail due to space limitation: the similarity of candidate phrases based on semantically similar nouns (Kazama and Torisawa, 2008), entailing/entailed verbs (Hashimoto et al., 2009), and the identity of the pronunciation and base form of the head morpheme; N-grams (N=1,2,3) of child and parent contexts represented by either the inflected form, base form, pronunciation, or POS of mor-

[4] We use SVM^{perf} available at `http://svmlight.joachims.org/svm_perf.html`.

[5] In the table, the parent context of a candidate phrase consists of expressions that appear in ancestor nodes of the candidate phrase in terms of the dependency structure of the sentence. Child contexts are defined similarly.

Original definition sentence pair (s_1, s_2)	Paraphrased definition sentence pair (s'_1, s'_2)
s_1: Osteoporosis is a disease that **reduces bone mass** and makes bones fragile.	s'_1: Osteoporosis is a disease that **decreases the quantity of bone** and makes bones fragile.
s_2: Osteoporosis is a disease that **decreases the quantity of bone** and increases the risk of bone fracture.	s'_2: Osteoporosis is a disease that **reduces bone mass** and increases the risk of bone fracture.

Figure 2: Bidirectional checking of entailment relation ($\rightarrow$) of $p_1 \rightarrow p_2$ and $p_2 \rightarrow p_1$. p_1 is "**reduces bone mass**" in s_1 and p_2 is "**decreases the quantity of bone**" in s_2. p_1 and p_2 are exchanged between s_1 and s_2 to generate corresponding paraphrased sentences s'_1 and s'_2. $p_1 \rightarrow p_2$ ($p_2 \rightarrow p_1$) is verified if $s_1 \rightarrow s'_1$ ($s_2 \rightarrow s'_2$) holds. In this case, both of them hold. English is used for ease of explanation.

pheme; parent/child dependency tree fragments represented by either the inflected form, base form, pronunciation, or POS; adjacent versions (cf. **f15**) of N-gram features and parent/child dependency tree features. These amount to 78 features, but we eventually settled on the 17 features in Table 1 through ablation tests to evaluate the discriminative power of each feature.

The ablation tests were conducted using training data that we prepared. In preparing the training data, we faced the problem that the completely random sampling of candidate paraphrase pairs provided us with only a small number of positive examples. Thus, we automatically collected candidate paraphrase pairs that were expected to have a high likelihood of being positive as examples to be labeled. The likelihood was calculated by simply summing all of the 78 feature values that we have tried, since they indicate the likelihood of a given candidate paraphrase pair's being a paraphrase. Note that values of the features f8 and f9 are weighted with -1, since they indicate the unlikelihood. Specifically, we first randomly sampled 30,000 definition sentence pairs from the 29,661,812 pairs, and collected 3,000 candidate phrase pairs that had the highest likelihood from them. The manual labeling of each candidate phrase pair (p_1, p_2) was based on bidirectional checking of entailment relation, $p_1 \rightarrow p_2$ and $p_2 \rightarrow p_1$, with p_1 and p_2 embedded in contexts.

This scheme is similar to the one proposed by Szpektor et al. (2007). We adopt this scheme since paraphrase judgment might be unstable between annotators unless they are given a particular context based on which they make a judgment. As described below, we use definition sentences as contexts. We admit that annotators might be biased by this in some unexpected way, but we believe that this is a more stable method than that without contexts. The labeling process is as follows. First, from each candidate phrase pair (p_1, p_2) and its source definition sentence pair (s_1, s_2), we create two paraphrase sentence pairs (s'_1, s'_2) by exchanging p_1 and p_2 between s_1 and s_2. Then, annotators check if s_1 entails s'_1 and s_2 entails s'_2 so that entailment relations of both directions $p_1 \rightarrow p_2$ and $p_2 \rightarrow p_1$ are checked. Figure 2 shows an example of bidirectional checking. In this example, both entailment relations, $s_1 \rightarrow s'_1$ and $s_2 \rightarrow s'_2$, hold, and thus the candidate phrase pair (p_1, p_2) is judged as positive. We used (p_1, p_2), for which entailment relations of both directions held, as positive examples (1,092 pairs) and the others as negative ones (1,872 pairs).[6]

We built the paraphrase classifier from the training data. As mentioned, candidate phrase pairs were ranked by the distance from the SVM's hyperplane.

4 Experiment

In this paper, our claims are twofold.

I. Definition sentences on the Web are a treasure trove of paraphrase knowledge (Section 4.2).

II. Our method of paraphrase acquisition from definition sentences is more accurate than well-known competing methods (Section 4.1).

We first verify claim II by comparing our method with that of Barzilay and McKeown (2001) (BM method), Moses[7] (Koehn et al., 2007) (SMT method), and that of Murata et al. (2004) (Mrt method). The first two methods are well known for accurately extracting semantically equivalent phrase pairs from parallel corpora.[8] Then, we verify claim

[6] The remaining 36 pairs were discarded as they contained garbled characters of Japanese.

[7] `http://www.statmt.org/moses/`

[8] As anonymous reviewers pointed out, they are unsupervised methods and thus unable to be adapted to definition sen-

I by comparing definition sentence pairs with sentence pairs that are acquired from the Web using Yahoo!JAPAN API[9] as a paraphrase knowledge source. In the latter data set, two sentences of each pair are expected to be semantically similar regardless of whether they are definition sentences. Both sets contain 100,000 pairs.

Three annotators (not the authors) checked evaluation samples. Fleiss' kappa (Fleiss, 1971) was 0.69 (substantial agreement (Landis and Koch, 1977)).

4.1 Our method vs. competing methods

In this experiment, paraphrase pairs are extracted from 100,000 definition sentence pairs that are randomly sampled from the 29,661,812 pairs. Before reporting the experimental results, we briefly describe the BM, SMT, and Mrt methods.

BM method Given parallel sentences like multiple translations of the same source text, the BM method works iteratively as follows. First, it collects from the parallel sentences identical word pairs and their contexts (POS N-grams with indices indicating corresponding words between paired contexts) as positive examples and those of different word pairs as negative ones. Then, each context is ranked based on the frequency with which it appears in positive (negative) examples. The most likely K positive (negative) contexts are used to extract positive (negative) paraphrases from the parallel sentences. Extracted positive (negative) paraphrases and their morpho-syntactic patterns are used to collect additional positive (negative) contexts. All the positive (negative) contexts are ranked, and additional paraphrases and their morpho-syntactic patterns are extracted again. This iterative process finishes if no further paraphrase is extracted or the number of iterations reaches a predefined threshold T. In this experiment, following Barzilay and McKeown (2001), K is 10 and N is 1 to 3. The value of T is not given in their paper. We chose 3 as its value based on our preliminary experiments. Note that paraphrases extracted by this method are not ranked.

SMT method Our SMT method uses Moses (Koehn et al., 2007) and extracts a phrase table, a set of two phrases that are *translations* of each other, given a set of two sentences that are *translations* of each other. If you give Moses *monolingual* parallel sentence pairs, it should extract a set of two phrases that are *paraphrases* of each other. In this experiment, default values were used for all parameters. To rank extracted phrase pairs, we assigned each of them the product of two phrase translation probabilities of both directions that were given by Moses. For other SMT methods, see Quirk et al. (2004) and Bannard and Callison-Burch (2005) among others.

Mrt method Murata et al. (2004) proposed a method to extract paraphrases from two manually compiled dictionaries. It simply regards a difference between two definition sentences of the same word as a paraphrase candidate. Paraphrase candidates are ranked according to an unsupervised scoring scheme that implements their assumption. They assume that a paraphrase candidate tends to be a valid paraphrase if it is surrounded by infrequent strings and/or if it appears multiple times in the data.

In this experiment, we evaluated the unsupervised version of our method in addition to the supervised one described in Section 3.2, in order to compare it fairly with the other methods. The unsupervised method works in the same way as the supervised one, except that it ranks candidate phrase pairs by the sum of all 17 feature values, instead of the distance from the SVM's hyperplane. In other words, no supervised learning is used. All the feature values are weighted with 1, except for f8 and f9, which are weighted with -1 since they indicate the unlikelihood of a candidate phrase pair being paraphrases. BM, SMT, Mrt, and the two versions of our method were used to extract paraphrase pairs from the same 100,000 definition sentence pairs.

Evaluation scheme Evaluation of each paraphrase pair (p_1, p_2) was based on bidirectional checking of entailment relations $p_1 \rightarrow p_2$ and $p_2 \rightarrow p_1$ in a way similar to the labeling of the training data. The difference is that contexts for evaluation are two sentences that are retrieved from the Web and contain p_1 and p_2, instead of definition sentences from which p_1 and p_2 are extracted. This

tences. Nevertheless, we believe that comparing these methods with ours is very informative, since they are known to be accurate and have been influential.

[9] http://developer.yahoo.co.jp/webapi/

is intended to check whether extracted paraphrases are also valid for contexts other than those from which they are extracted. The evaluation proceeds as follows. For the top m paraphrase pairs of each method (in the case of the BM method, randomly sampled m pairs were used, since the method does not rank paraphrase pairs), we retrieved a sentence pair (s_1, s_2) for each paraphrase pair (p_1, p_2) from the Web, such that s_1 contains p_1 and s_2 contains p_2. In doing so, we make sure that neither s_1 nor s_2 are the definition sentences from which p_1 and p_2 are extracted. For each method, we randomly sample n samples from all of the paraphrase pairs (p_1, p_2) for which both s_1 and s_2 are retrieved. Then, from each (p_1, p_2) and (s_1, s_2), we create two paraphrase sentence pairs (s'_1, s'_2) by exchanging p_1 and p_2 between s_1 and s_2. All samples, each consisting of (p_1, p_2), (s_1, s_2), and (s'_1, s'_2), are checked by three human annotators to determine whether s_1 entails s'_1 and s_2 entails s'_2 so that entailment relations of both directions are verified. In advance of evaluation annotation, all the evaluation samples are shuffled so that the annotators cannot find out which sample is given by which method for fairness. We regard each paraphrase pair as correct if at least two annotators judge that entailment relations of both directions hold for it. You may wonder whether only one pair of sentences (s_1, s_2) is enough for evaluation since a correct (wrong) paraphrase pair might be judged as wrong (correct) accidentally. Nevertheless, we suppose that the final evaluation results are reliable if the number of evaluation samples is sufficient. In this experiment, m is 5,000 and n is 200. We use Yahoo!JAPAN API to retrieve sentences.

Graph (a) in Figure 3 shows a precision curve for each method. *Sup* and *Uns* respectively indicate the supervised and unsupervised versions of our method. The figure indicates that *Sup* outperforms all the others and shows a high precision rate of about 94% at the top 1,000. Remember that this is the result of using 100,000 definition sentence pairs. Thus, we estimate that *Sup* can extract about 300,000 paraphrase pairs with a precision rate of about 94%, if we use all 29,661,812 definition sentence pairs that we acquired.

Furthermore, we measured precision after trivial paraphrase pairs were discarded from the evaluation samples of each method. A candidate phrase pair (p_1, p_2) is regarded as trivial if the pronunciation is the same between p_1 and p_2,[10] or all of the content words contained in p_1 are the same as those of p_2. Graph (b) gives a precision curve for each method. Again, *Sup* outperforms the others too, and maintains a precision rate of about 90% until the top 1,000. These results support our claim II.

Definition sentence pairs	Sup	Uns	BM	SMT	Mrt
with trivial	1,381,424		24,049	9,562	18,184
without trivial	1,377,573		23,490	7,256	18,139
Web sentence pairs	Sup	Uns	BM	SMT	Mrt
with trivial	277,172		5,101	4,586	4,978
without trivial	274,720		4,399	2,342	4,958

Table 2: Number of extracted paraphrases.

The upper half of Table 2 shows the number of extracted paraphrases with/without trivial pairs for each method.[11] *Sup* and *Uns* extracted many more paraphrases. It is noteworthy that *Sup* performed the best in terms of both precision rate and the number of extracted paraphrases.

Table 3 shows examples of correct and incorrect outputs of *Sup*. As the examples indicate, many of the extracted paraphrases are not specific to definition sentences and seem very reusable. However, there are few paraphrases involving metaphors or idioms in the outputs due to the nature of definition sentences. In this regard, we do not claim that our method is almighty. We agree with Sekine (2005) who claims that several different methods are required to discover a wider variety of paraphrases.

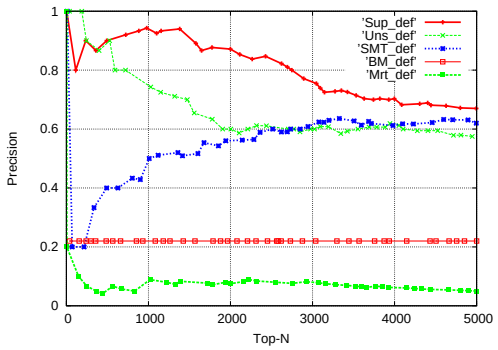
In graphs (a) and (b), the precision of the SMT method goes up as rank goes down. This strange behavior is due to the scoring by Moses that worked poorly for the data; it gave 1.0 to 82.5% of all the samples, 38.8% of which were incorrect. We suspect SMT methods are poor at monolingual alignment for paraphrasing or entailment tasks since, in the tasks, data is much noisier than that used for SMT. See MacCartney et al. (2008) for similar discussion.

4.2 Definition pairs vs. Web sentence pairs

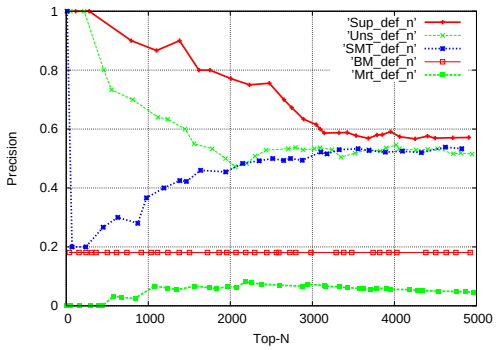
To collect Web sentence pairs, first, we randomly sampled 1.8 million sentences from the Web corpus.

[10] There are many kinds of orthographic variants in Japanese, which can be identified by their pronunciation.

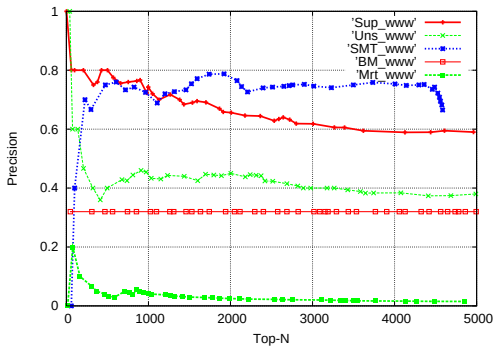
[11] We set no threshold for candidate phrase pairs of each method, and counted all the candidate phrase pairs in Table 2.



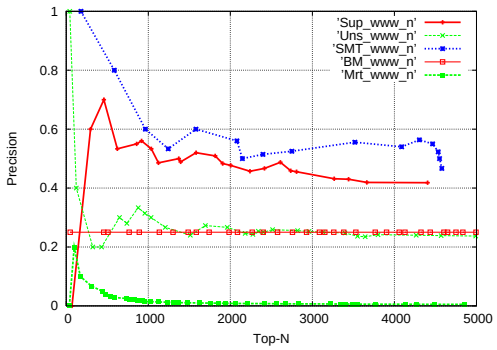
(a) Definition sentence pairs with trivial paraphrases



(b) Definition sentence pairs without trivial paraphrases



(c) Web sentence pairs with trivial paraphrases



(d) Web sentence pairs without trivial paraphrases

Figure 3: Precision curves of paraphrase extraction.

	Rank	Paraphrase pair
Correct	13	メールアドレスにメールを送る (send a message to the e-mail address) ⇔ メールアドレスに電子メールを送る (send an e-mail message to the e-mail address)
	19	お客様の依頼による (requested by a customer) ⇔ お客様の委託による (commissioned by a customer)
	70	企業の財政状況を表す (describe the fiscal condition of company) ⇔ 企業の財政状態を示す (indicate the fiscal state of company)
	112	インフォメーションを得る (get information) ⇔ ニュースを得る (get news)
	656	きまりのことです (it is a convention) ⇔ ルールのことです (it is a rule)
	841	地震のエネルギー規模をあらわす (represent the energy scale of earthquake) ⇔ 地震の規模を表す (represent the scale of earthquake)
	929	細胞を酸化させる (cause the oxidation of cells) ⇔ 細胞を老化させる (cause cellular aging)
	1,553	角質を取り除く (remove dead skin cells) ⇔ 角質をはがす (peel off dead skin cells)
	2,243	胎児の発育に必要だ (required for the development of fetus) ⇔ 胎児の発育成長に必要不可欠だ (indispensable for the growth and development of fetus)
	2,855	視力を矯正する (correct eyesight) ⇔ 視力矯正を行う (perform eyesight correction)
	2,931	チャラにしてもらう (call it even) ⇔ 帳消しにしてもらう (call it quits)
	3,667	ハードディスク上に蓄積される (accumulated on a hard disk) ⇔ ハードディスクドライブに保存される (stored on a hard disk drive)
	4,870	有害物質を排泄する (excrete harmful substance) ⇔ 有害毒素を排出する (discharge harmful toxin)
	5,501	１つのＣＰＵの内部に２つのプロセッサコアを搭載する (mount two processor cores on one CPU) ⇔ １つのパッケージに２つのプロセッサコアを集積する (build two processor cores into one package)
	10,675	外貨を売買する (trade foreign currencies) ⇔ 通貨を交換する (exchange one currency for another)
	112,819	派遣先企業の社員になる (become a regular staff member of the company where (s)he has worked as a temp) ⇔ 派遣先に直接雇用される (employed by the company where (s)he has worked as a temp)
	193,553	Ｗｅｂサイトにアクセスする (access Web sites) ⇔ WWWサイトを訪れる (visit WWW sites)
Incorrect	903	ブラウザに送信される (send to a Web browser) ⇔ パソコンに送信される (send to a PC)
	2,530	調和をはかる (intend to balance) ⇔ リフレッシュを図る (intend to refresh)
	3,008	消化酵素では消化できない (unable to digest with digestive enzymes) ⇔ 消化酵素で消化され難い (hard to digest with digestive enzymes)

Table 3: Examples of correct and incorrect paraphrases extracted by our supervised method with their rank.

We call them sampled sentences. Then, using Yahoo!JAPAN API, we retrieved up to 20 snippets relevant to each sampled sentence using all of the nouns in each sentence as a query. After that, each snippet was split into sentences, which we call snippet sentences. We paired a sampled sentence and a snippet sentence that was the most similar to the sampled sentence. Similarity is the number of nouns shared by the two sentences. Finally, we randomly sampled 100,000 pairs from all the pairs.

Paraphrase pairs were extracted from the Web sentence pairs by using BM, SMT, Mrt and the supervised and unsupervised versions of our method. The features used with our methods were selected from all of the 78 features mentioned in Section 3.2 so that they performed well for Web sentence pairs. Specifically, the features were selected by ablation tests using training data that was tailored to Web sentence pairs. The training data consisted of 2,741 sentence pairs that were collected in the same way as the Web sentence pairs and was labeled in the same way as described in Section 3.2.

Graph (c) of Figure 3 shows precision curves. We also measured precision without trivial pairs in the same way as the previous experiment. Graph (d) shows the results. The lower half of Table 2 shows the number of extracted paraphrases with/without trivial pairs for each method.

Note that precision figures of our methods in graphs (c) and (d) are lower than those of our methods in graphs (a) and (b). Additionally, none of the methods achieved a precision rate of 90% using Web sentence pairs.[12] We think that a precision rate of at least 90% would be necessary if you apply automatically extracted paraphrases to NLP tasks without manual annotation. Only the combination of *Sup* and definition sentence pairs achieved that precision.

Also note that, for all of the methods, the numbers of extracted paraphrases from Web sentence pairs are fewer than those from definition sentence pairs.

From all of these results, we conclude that our claim I is verified.

[12]Precision of SMT is unexpectedly good. We found some Web sentence pairs consisting of two mostly identical sentences on rare occasions. The method worked relatively well for them.

5 Conclusion

We proposed a method of extracting paraphrases from definition sentences on the Web. From the experimental results, we conclude that the following two claims of this paper are verified.

1. Definition sentences on the Web are a treasure trove of paraphrase knowledge.

2. Our method extracts many paraphrases from the definition sentences on the Web accurately; it can extract about 300,000 paraphrases from 6×10^8 Web documents with a precision rate of about 94%.

Our future work is threefold. First, we will release extracted paraphrases from all of the 29,661,812 definition sentence pairs that we acquired, after human annotators check their validity. The result will be available through the ALAGIN forum.[13]

Second, we plan to induce paraphrase *rules* from paraphrase *instances*. Though our method can extract a variety of paraphrase *instances* on a large scale, their coverage might be insufficient for real NLP applications since some paraphrase phenomena are highly productive. Therefore, we need paraphrase *rules* in addition to paraphrase *instances*. Barzilay and McKeown (2001) induced simple POS-based paraphrase rules from paraphrase instances, which can be a good starting point.

Finally, as mentioned in Section 1, the work in this paper is only the beginning of our research on paraphrase extraction. We are trying to extract far more paraphrases from a set of sentences fulfilling the same *pragmatic* function (e.g. definition) for the same topic (e.g. osteoporosis) on the Web. Such functions other than definition may include the usage of the same Linux command, the recipe for the same cuisine, or the description of related work on the same research issue.

Abstract

We analyze collective discourse, a collective human behavior in content generation, and show that it exhibits diversity, a property of general collective systems. Using extensive analysis, we propose a novel paradigm for designing summary generation systems that reflect the diversity of perspectives seen in real-life collective summarization. We analyze 50 sets of summaries written by human about the same story or artifact and investigate the diversity of perspectives across these summaries. We show how different summaries use various phrasal information units (i.e., *nuggets*) to express the same atomic semantic units, called *factoids*. Finally, we present a ranker that employs *distributional similarities* to build a network of words, and captures the diversity of perspectives by detecting communities in this network. Our experiments show how our system outperforms a wide range of other document ranking systems that leverage diversity.

1 Introduction

In sociology, the term *collective behavior* is used to denote mass activities that are not centrally coordinated (Blumer, 1951). Collective behavior is different from group behavior in the following ways: (a) it involves limited social interaction, (b) membership is fluid, and (c) it generates weak and unconventional norms (Smelser, 1963). In this paper, we focus on the computational analysis of *collective discourse*, a collective behavior seen in interactive content contribution and text summarization in online social media. In collective discourse each individual's behavior is largely independent of that of other individuals.

In social media, discourse (Grosz and Sidner, 1986) is often a *collective reaction* to an event. One scenario leading to collective reaction to a well-defined subject is when an event occurs (a movie is released, a story occurs, a paper is published) and people independently write about it (movie reviews, news headlines, citation sentences). This process of content generation happens over time, and each person chooses the aspects to cover. Each event has an onset and a time of death after which nothing is written about it. Tracing the generation of content over many instances will reveal temporal patterns that will allow us to make sense of the text generated around a particular event.

To understand collective discourse, we are interested in behavior that happens over a short period of time. We focus on topics that are relatively well-defined in scope such as a particular event or a single news event that does not evolve over time. This can eventually be extended to events and issues that are evolving either in time or scope such as elections, wars, or the economy.

In social sciences and the study of complex systems a lot of work has been done to study such collective systems, and their properties such as self-organization (Page, 2007) and diversity (Hong and Page, 2009; Fisher, 2009). However, there is little work that studies a collective system in which members individually write summaries.

In most of this paper, we will be concerned with developing a complex systems view of the set of collectively written summaries, and give evidence of

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1098–1108,
Portland, Oregon, June 19-24, 2011.

the diversity of perspectives and its cause. We believe that out experiments will give insight into new models of text generation, which is aimed at modeling the process of producing natural language texts, and is best characterized as the process of making choices between alternate linguistic realizations, also known as lexical choice (Elhadad, 1995; Barzilay and Lee, 2002; Stede, 1995).

2 Prior Work

In summarization, a number of previous methods have focused on diversity. (Mei et al., 2010) introduce a diversity-focused ranking methodology based on reinforced random walks in information networks. Their random walk model introduces the rich-gets-richer mechanism to PageRank with reinforcements on transition probabilities between vertices. A similar ranking model is the *Grasshopper* ranking model (Zhu et al., 2007), which leverages an absorbing random walk. This model starts with a regular time-homogeneous random walk, and in each step the node with the highest weight is set as an absorbing state. The multi-view point summarization of opinionated text is discussed in (Paul et al., 2010). Paul et al. introduce *Comparative LexRank*, based on the LexRank ranking model (Erkan and Radev, 2004). Their random walk formulation is to score sentences and pairs of sentences from opposite viewpoints (clusters) based on both their representativeness of the collection as well as their contrastiveness with each other. Once a lexical similarity graph is built, they modify the graph based on cluster information and perform LexRank on the modified cosine similarity graph.

The most well-known paper that address diversity in summarization is (Carbonell and Goldstein, 1998), which introduces Maximal Marginal Relevance (MMR). This method is based on a greedy algorithm that picks sentences in each step that are the least similar to the summary so far. There are a few other diversity-focused summarization systems like C-LexRank (Qazvinian and Radev, 2008), which employs document clustering. These papers try to increase diversity in summarizing documents, but do not explain the type of the diversity in their inputs. In this paper, we give an insightful discussion on the nature of the diversity seen in collective discourse, and will explain why some of the mentioned methods may not work under such environments.

In prior work on evaluating independent contributions in content generation, Voorhees (Voorhees, 1998) studied IR systems and showed that relevance judgments differ significantly between humans but relative rankings show high degrees of stability across annotators. However, perhaps the closest work to this paper is (van Halteren and Teufel, 2004) in which 40 Dutch students and 10 NLP researchers were asked to summarize a BBC news report, resulting in 50 different summaries. Teufel and van Halteren also used 6 DUC[1]-provided summaries, and annotations from 10 student participants and 4 additional researchers, to create 20 summaries for another news article in the DUC datasets. They calculated the Kappa statistic (Carletta, 1996; Krippendorff, 1980) and observed high agreement, indicating that the task of atomic semantic unit (factoid) extraction can be robustly performed in naturally occurring text, without any copy-editing.

The diversity of perspectives and the unprecedented growth of the factoid inventory also affects evaluation in text summarization. Evaluation methods are either extrinsic, in which the summaries are evaluated based on their quality in performing a specific task (Spärck-Jones, 1999) or intrinsic where the quality of the summary itself is evaluated, regardless of any applied task (van Halteren and Teufel, 2003; Nenkova and Passonneau, 2004). These evaluation methods assess the information content in the summaries that are generated automatically.

Finally, recent research on analyzing online social media shown a growing interest in mining news stories and headlines because of its broad applications ranging from "meme" tracking and spike detection (Leskovec et al., 2009) to text summarization (Barzilay and McKeown, 2005). In similar work on blogs, it is shown that detecting topics (Kumar et al., 2003; Adar et al., 2007) and sentiment (Pang and Lee, 2004) in the blogosphere can help identify influential bloggers (Adar et al., 2004; Java et al., 2006) and mine opinions about products (Mishne and Glance, 2006).

3 Data Annotation

The datasets used in our experiments represent two completely different categories: news headlines, and scientific citation sentences. The *headlines* datasets consist of 25 clusters of news headlines collected from Google News[2], and the *citations* datasets have 25 clusters of citations to specific scientific papers from the ACL Anthology Network (AAN)[3]. Each cluster consists of a number of unique summaries (headlines or citations) about the same artifact (non-evolving news story or scientific paper) written by different people. Table 1 lists some of the clusters with the number of summaries in them.

ID	type	Name	Story/Title	#
1	hdl	miss	Miss Venezuela wins miss universe'09	125
2	hdl	typhoon	Second typhoon hit philippines	100
3	hdl	russian	Accident at Russian hydro-plant	101
4	hdl	redsox	Boston Red Sox win world series	99

Table 1: Some of the annotated datasets and the number of summaries in each of them (hdl = headlines; cit = citations)

3.1 Nuggets vs. Factoids

We define an annotation task that requires explicit definitions that distinguish between phrases that represent the same or different information units. Unfortunately, there is little consensus in the literature on such definitions. Therefore, we follow (van Halteren and Teufel, 2003) and make the following distinction. We define a *nugget* to be a phrasal information unit. Different nuggets may all represent the same atomic semantic unit, which we call as a *factoid*. In the following headlines, which are randomly extracted from the `redsox` dataset, nuggets are manually underlined.

red sox win 2007 world series
boston red sox blank rockies to clinch world series
boston fans celebrate world series win; 37 arrests reported

These 3 headlines contain 9 nuggets, which represent 5 factoids or classes of equivalent nuggets.

f_1 : {red sox, boston, boston red sox}
f_2 : {2007 world series, world series win, world series}
f_3 : {rockies}
f_4 : {37 arrests}
f_5 : {fans celebrate}

This example suggests that different headlines on the *same story* written independently of one another use different phrases (nuggets) to refer to the same semantic unit (e.g., "red sox" vs. "boston" vs. "boston red sox") or to semantic units corresponding to different aspects of the story (e.g., "37 arrests" vs. "rockies"). In the former case different nuggets are used to represent the same factoid, while in the latter case different nuggets are used to express different factoids. This analogy is similar to the definition of factoids in (van Halteren and Teufel, 2004).

The following citation sentences to Koehn's work suggest that a similar phenomenon also happens in citations.

We also compared our model with pharaoh (Koehn et al, 2003).
Koehn et al (2003) find that phrases longer than three words improve performance little.
Koehn et al (2003) suggest limiting phrase length to three words or less.
For further information on these parameter settings, confer (koehn et al, 2003).

where the first author mentions "pharaoh" as a contribution of Koehn et al, but the second and third use different nuggets to represent the same contribution: use of trigrams. However, as the last citation shows, a citation sentence, unlike news headlines, may cover no information about the target paper.

The use of phrasal information as nuggets is an essential element to our experiments, since some headline writers often try to use uncommon terms to refer to a factoid. For instance, two headlines from the `redsox` cluster are:

Short wait for bossox this time
Soxcess started upstairs

[2]news.google.com
[3]http://clair.si.umich.edu/clair/anthology/

Following these examples, we asked two annotators to annotate all $1,390$ headlines, and 926 citations. The annotators were asked to follow precise guidelines in nugget extraction. Our guidelines instructed annotators to extract non-overlapping phrases from each headline as nuggets. Therefore, each nugget should be a substring of the headline that represents a semantic unit[4].

Previously (Lin and Hovy, 2002) had shown that information overlap judgment is a difficult task for human annotators. To avoid such a difficulty, we enforced our annotators to extract non-overlapping nuggets from a summary to make sure that they are mutually independent and that information overlap between them is minimized.

Finding agreement between annotated well-defined nuggets is straightforward and can be calculated in terms of Kappa. However, when nuggets themselves are to be extracted by annotators, the task becomes less obvious. To calculate the agreement, we annotated 10 randomly selected headline clusters twice and designed a simple evaluation scheme based on Kappa[5]. For each n-gram, w, in a given headline, we look if w is part of any nugget in either human annotations. If w occurs in both or neither, then the two annotators agree on it, and otherwise they do not. Based on this agreement setup, we can formalize the κ statistic as $\kappa = \frac{\Pr(a)-\Pr(e)}{1-\Pr(e)}$ where $Pr(a)$ is the relative observed agreement among annotators, and $Pr(e)$ is the probability that annotators agree by chance if each annotator is randomly assigning categories.

Table 2 shows the unigram, bigram, and trigram-based average κ between the two human annotators (**Human1**, **Human2**). These results suggest that human annotators can reach substantial agreement when bigram and trigram nuggets are examined, and has reasonable agreement for unigram nuggets.

4 Diversity

We study the diversity of ways with which human summarizers talk about the same story or event and explain why such a diversity exists.

[4]Before the annotations, we lower-cased all summaries and removed duplicates

[5]Previously (Qazvinian and Radev, 2010) have shown high agreement in human judgments in a similar task on citation annotation

	Average κ		
	unigram	bigram	trigram
Human1 vs. Human2			
	0.76 ± 0.4	0.80 ± 0.4	0.89 ± 0.3

Table 2: Agreement between different annotators in terms of average Kappa in 25 headline clusters.

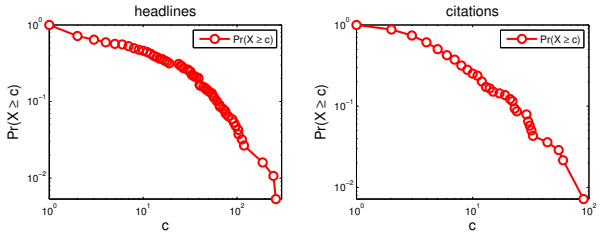

Figure 1: The cumulative probability distribution for the frequency of factoids (i.e., the probability that a factoid will be mentioned in c different summaries) across in each category.

4.1 Skewed Distributions

Our first experiment is to analyze the popularity of different factoids. For each factoid in the annotated clusters, we extract its count, X, which is equal to the number of summaries it has been mentioned in, and then we look at the distribution of X. Figure 1 shows the cumulative probability distribution for these counts (i.e., the probability that a factoid will be mentioned in at least c different summaries) in both categories.

These highly skewed distributions indicate that a large number of factoids (more than 28%) are only mentioned once across different clusters (e.g., "poor pitching of colorado" in the `redsox` cluster), and that a few factoids are mentioned in a large number of headlines (likely using different nuggets). The large number of factoids that are only mentioned in one headline indicates that different summarizers increase diversity by focusing on different aspects of a story or a paper. The set of nuggets also exhibit similar skewed distributions. If we look at individual nuggets, the `redsox` set shows that about 63 (or 80%) of the nuggets get mentioned in only one headline, resulting in a right-skewed distribution.

The factoid analysis of the datasets reveals two main causes for the content diversity seen in headlines: (1) writers focus on different aspects of the story and therefore write about different factoids

(e.g., "celebrations" vs. "poor pitching of colorado"). (2) writer use different nuggets to represent the same factoid (e.g., "redsox" vs. "bosox"). In the following sections we analyze the extent at which each scenario happens.

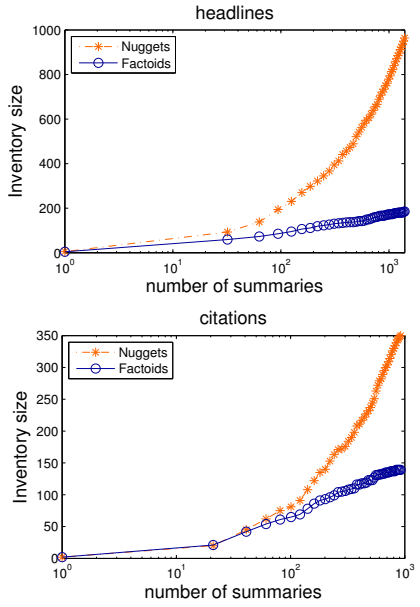

Figure 2: The number of unique factoids and nuggets observed by reading n random summaries in all the clusters of each category

4.2 Factoid Inventory

The emergence of diversity in covering different factoids suggests that looking at more summaries will capture a larger number of factoids. In order to analyze the growth of the factoid inventory, we perform a simple experiment. We shuffle the set of summaries from all 25 clusters in each category, and then look at the number of unique factoids and nuggets seen after reading n^{th} summary. This number shows the amount of information that a randomly selected subset of n writers represent. This is important to study in order to find out whether we need a large number of summaries to capture all aspects of a story and build a complete factoid inventory. The plot in Figure 4.1 shows, at each n, the number of unique factoids and nuggets observed by reading n random summaries from the 25 clusters in each category. These curves are plotted on a semi-log scale to emphasize the difference between the growth patterns of the nugget inventories and the factoid inventories[6].

This finding numerically confirms a similar observation on human summary annotations discussed in (van Halteren and Teufel, 2003; van Halteren and Teufel, 2004). In their work, van Halteren and Teufel indicated that more than 10-20 human summaries are needed for a full factoid inventory. However, our experiments with nuggets of nearly $2,400$ independent human summaries suggest that neither the nugget inventory nor the number of factoids will be likely to show asymptotic behavior. However, these plots show that the nugget inventory grows at a much faster rate than factoids. This means that a lot of the diversity seen in human summarization is a result of the so called different *lexical choices* that represent the same semantic units or factoids.

4.3 Summary Quality

In previous sections we gave evidence for the diversity seen in human summaries. However, a more important question to answer is whether these summaries all cover important aspects of the story. Here, we examine the quality of these summaries, study the distribution of information coverage in them, and investigate the number of summaries required to build a complete factoid inventory.

The information covered in each summary can be determined by the set of factoids (and not nuggets) and their frequencies across the datasets. For example, in the `redsox` dataset, "red sox", "boston", and "boston red sox" are nuggets that all represent the same piece of information: the red sox team. Therefore, different summaries that use these nuggets to refer to the red sox team should not be seen as very different.

We use the Pyramid model (Nenkova and Passonneau, 2004) to value different summary factoids. Intuitively, factoids that are mentioned more frequently are more salient aspects of the story. Therefore, our pyramid model uses the normalized frequency at which a factoid is mentioned across a dataset as its weight. In the pyramid model, the individual factoids fall in tiers. If a factoid appears in more summaries, it falls in a higher tier. In principle, if the term w_i appears $|w_i|$ times in the set of

[6]Similar experiment using individual clusters exhibit similar behavior

headlines it is assigned to the tier $T_{|w_i|}$. The pyramid score that we use is computed as follows. Suppose the pyramid has n tiers, T_i, where tier T_n is the top tier and T_1 is the bottom. The weight of the factoids in tier T_i will be i (i.e. they appeared in i summaries). If $|T_i|$ denotes the number of factoids in tier T_i, and D_i is the number of factoids in the summary that appear in T_i, then the total factoid weight for the summary is $D = \sum_{i=1}^{n} i \times D_i$. Additionally, the optimal pyramid score for a summary is $Max = \sum_{i=1}^{n} i \times |T_i|$. Finally, the pyramid score for a summary can be calculated as

$$P = \frac{D}{Max}$$

Based on this scoring scheme, we can use the annotated datasets to determine the quality of individual headlines. First, for each set we look at the variation in pyramid scores that individual summaries obtain in their set. Figure 3 shows, for each cluster, the variation in the pyramid scores (25th to 75th percentile range) of individual summaries evaluated against the factoids of that cluster. This figure indicates that the pyramid score of almost all summaries obtain values with high variations in most of the clusters For instance, individual headlines from `redsox` obtain pyramid scores as low as 0.00 and as high as 0.93. This high variation confirms the previous observations on diversity of information coverage in different summaries.

Additionally, this figure shows that headlines generally obtain higher values than citations when considered as summaries. One reason, as explained before, is that a citation may not cover any important contribution of the paper it is citing, when headlines generally tend to cover some aspects of the story.

High variation in quality means that in order to capture a larger information content we need to read a greater number of summaries. But how many headlines should one read to capture a desired level of information content? To answer this question, we perform an experiment based on drawing random summaries from the pool of all the clusters in each category. We perform a Monte Carlo simulation, in which for each n, we draw n random summaries, and look at the pyramid score achieved by reading these headlines. The pyramid score is calculated using the factoids from all 25 clusters in each category[7]. Each experiment is repeated $1,000$ times to find the statistical significance of the experiment and the variation from the average pyramid scores.

Figure 4.3 shows the average pyramid scores over different n values in each category on a log-log scale. This figure shows how pyramid score grows and approaches 1.00 rapidly as more randomly selected summaries are seen.

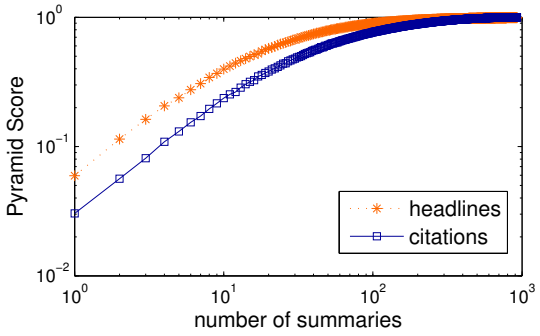

Figure 4: Average pyramid score obtained by reading n random summaries shows rapid asymptotic behavior.

5 Diversity-based Ranking

In previous sections we showed that the diversity seen in human summaries could be according to different nuggets or phrases that represent the same factoid. Ideally, a summarizer that seeks to increase diversity should capture this phenomenon and avoid covering redundant nuggets. In this section, we use different state of the art summarization systems to rank the set of summaries in each cluster with respect to information content and diversity. To evaluate each system, we cut the ranked list at a constant length (in terms of the number of words) and calculate the pyramid score of the remaining text.

5.1 Distributional Similarity

We have designed a summary ranker that will produce a ranked list of documents with respect to the diversity of their contents. Our model works based on ranking individual words and using the ranked list of words to rank documents that contain them.

In order to capture the nuggets of equivalent semantic classes, we use a *distributional similarity* of

[7] Similar experiment using individual clusters exhibit similar results

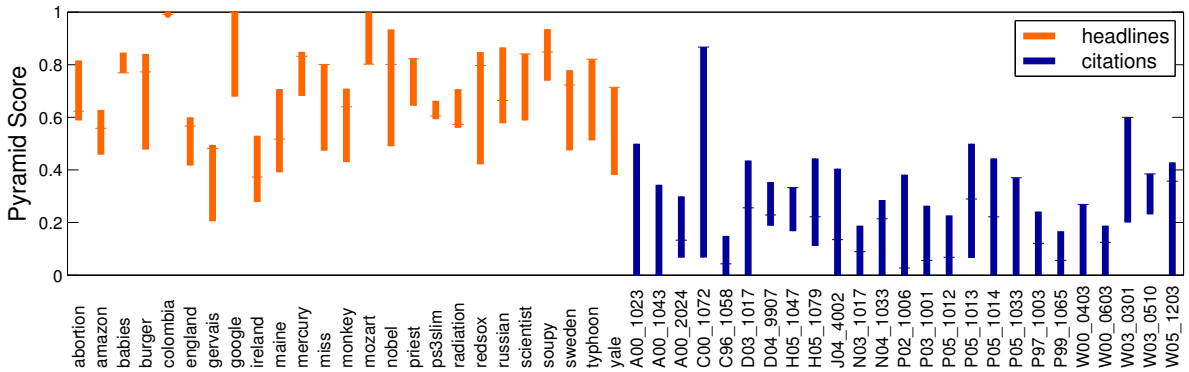

Figure 3: The 25th to 75th percentile pyramid score range in individual clusters

words that is inspired by (Lee, 1999). We represent each word by its context in the cluster and find the similarity of such contexts. Particularly, each word w_i is represented by a bag of words, ℓ_i, that have a surface distance of 3 or smaller to w_i anywhere in the cluster. In other words, ℓ_i contains any word that co-occurs with w_i in a 4-gram in the cluster. This *bag of words* representation of words enables us to find the word-pair similarities.

$$sim(w_i, w_j) = \frac{\vec{\ell_i} \cdot \vec{\ell_j}}{\sqrt{|\vec{\ell_i}||\vec{\ell_j}|}} \quad (1)$$

We use the pair-wise similarities of words in each cluster, and build a network of words and their similarities. Intuitively, words that appear in similar contexts are more similar to each other and will have a stronger edge between them in the network. Therefore, similar words, or words that appear in similar contexts, will form communities in this graph. Ideally, each community in the word similarity network would represent a factoid. To find the communities in the word network we use (Clauset et al., 2004), a hierarchical agglomeration algorithm which works by greedily optimizing the modularity in a linear running time for sparse graphs.

The community detection algorithm will assign to each word w_i, a community label C_i. For each community, we use LexRank to rank the words using the similarities in Equation 1, and assign a score to each word w_i as $S(w_i) = \frac{R_i}{|C_i|}$, where R_i is the rank of w_i in its community, and $|C_i|$ is the number of words that belong to C_i. Figure 5.1 shows part

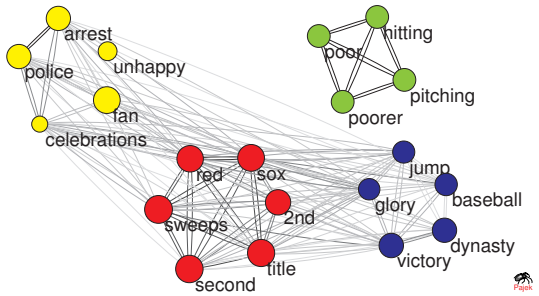

Figure 5: Part of the word similarity graph in the redsox cluster

of the word similarity graph in the `redsox` cluster, in which each node is color-coded with its community. This figure illustrates how words that are semantically related to the same aspects of the story fall in the same communities (e.g., "police" and "arrest"). Finally, to rank sentences, we define the score of each document D_j as the sum of the scores of its words.

$$p_{ds}(D_j) = \sum_{w_i \in D_j} S(w_i)$$

Intuitively, sentences that contain higher ranked words in highly populated communities will have a smaller score. To rank the sentences, we sort them in an ascending order, and cut the list when its size is greater than the length limit.

5.2 Other Methods

5.2.1 Random

For each cluster in each category (citations and headlines), this method simply gets a random per-

mutations of the summaries. In the headlines datasets, where most of the headlines cover some factoids about the story, we expect this method to perform reasonably well since randomization will increase the chances of covering headlines that focus on different factoids. However, in the citations dataset, where a citing sentence may cover no information about the cited paper, randomization has the drawback of selecting citations that have no valuable information in them.

5.2.2 LexRank

LexRank (Erkan and Radev, 2004) works by first building a graph of all the documents (D_i) in a cluster. The edges between corresponding nodes (d_i) represent the cosine similarity between them is above a threshold (0.10 following (Erkan and Radev, 2004)). Once the network is built, the system finds the most central sentences by performing a random walk on the graph.

$$p(d_j) = (1-\lambda)\frac{1}{|D|} + \lambda \sum_{d_i} p(d_i) P(d_i \rightarrow d_j) \qquad (2)$$

5.2.3 MMR

Maximal Marginal Relevance (MMR) (Carbonell and Goldstein, 1998) uses the pairwise cosine similarity matrix and greedily chooses sentences that are the least similar to those already in the summary. In particular,

$MMR = \arg\min_{D_i \in D-A} \left[\max_{D_j \in A} Sim(D_i, D_j) \right]$

where A is the set of documents in the summary, initialized to $A = \emptyset$.

5.2.4 DivRank

Unlike other time-homogeneous random walks (e.g., PageRank), DivRank does not assume that the transition probabilities remain constant over time. DivRank uses a *vertex-reinforced random walk* model to rank graph nodes based on a diversity based centrality. The basic assumption in DivRank is that the transition probability from a node to other is reinforced by the number of previous visits to the target node (Mei et al., 2010). Particularly, let's assume $p_T(u, v)$ is the transition probability from any node u to node v at time T. Then,

$$p_T(d_i, d_j) = (1-\lambda).p^*(d_j) + \lambda.\frac{p_0(d_i, d_j).N_T(d_j)}{D_T(d_i)} \qquad (3)$$

where $N_T(d_j)$ is the number of times the walk has visited d_j up to time T and

$$D_T(d_i) = \sum_{d_j \in V} p_0(d_i, d_j) N_T(d_j) \qquad (4)$$

Here, $p^*(d_j)$ is the prior distribution that determines the preference of visiting vertex d_j. We try two variants of this algorithm: **DivRank**, in which $p^*(d_j)$ is uniform, and **DivRank with priors** in which $p^*(d_j) \propto l(D_j)^{-\beta}$, where $l(D_j)$ is the number of the words in the document D_j and β is a parameter ($\beta = 0.8$).

5.2.5 C-LexRank

C-LexRank is a clustering-based model in which the cosine similarities of document pairs are used to build a network of documents. Then the the network is split into communities, and the most salient documents in each community are selected (Qazvinian and Radev, 2008). C-LexRank focuses on finding communities of documents using their cosine similarity. The intuition is that documents that are more similar to each other contain similar factoids. We expect C-LexRank to be a strong ranker, but incapable of capturing the diversity caused by using different phrases to express the same meaning. The reason is that different nuggets that represent the same factoid often have no words in common (e.g., "victory" and "glory") and won't be captured by a lexical measure like cosine similarity.

5.3 Experiments

We use each of the systems explained above to rank the summaries in each cluster. Each ranked list is then cut at a certain length (50 words for headlines, and 150 for citations) and the information content in the remaining text is examined using the pyramid score.

Table 3 shows the average pyramid score achieved by different methods in each category. The method based on the distributional similarities of words outperforms other methods in the citations category. All methods show similar results in the headlines category, where most headlines cover at least 1 factoid about the story and a random ranker performs reasonably well. Table 4 shows top 3 headlines from 3 rankers: word distributional similarity (WDS), C-LexRank, and MMR. In this example, the first 3

Method	headlines		citations		Mean
	pyramid	95% C.I.	pyramid	95% C.I.	
R	0.928	[0.896, 0.959]	0.716	[0.625, 0.807]	0.822

WDS	0.931	[0.905, 0.958]	0.813	[0.738, 0.887]	**0.872**

R=Random; LR=LexRank; DR=DivRank; DR(p)=DivRank with Priors; C-LR=C-LexRank; WDS=Word Distributional Similarity; C.I.=Confidence Interval

Table 3: Comparison of different ranking systems

Method	Top 3 headlines
WDS	1: how sweep it is 2: fans celebrate red sox win 3: red sox take title
C-LR	1: world series: red sox sweep rockies 2: red sox take world series 3: red sox win world series
MMR	1:red sox scale the rockies 2: boston sweep colorado to win world series 3: rookies respond in first crack at the big time

C-LR=C-LexRank; WDS=Word Distributional Similarity

Table 4: Top 3 ranked summaries of the redsox cluster using different methods

headlines produced by WDS cover two important factoids: "red sox winning the title" and "fans celebrating". However, the second factoid is absent in the other two.

6 Conclusion and Future Work

Our experiments on two different categories of human-written summaries (headlines and citations) showed that a lot of the diversity seen in human summarization comes from different nuggets that may actually represent the same semantic information (i.e., factoids). We showed that the factoids exhibit a skewed distribution model, and that the size of the nugget inventory asymptotic behavior even with a large number of summaries. We also showed high variation in summary quality across different summaries in terms of pyramid score, and that the information covered by reading n summaries has a rapidly growing asymptotic behavior as n increases. Finally, we proposed a ranking system that employs word distributional similarities to identify semantically equivalent words, and compared it with a wide range of summarization systems that leverage diversity.

In the future, we plan to move to content from other collective systems on Web. In order to generalize our findings, we plan to examine blog comments, online reviews, and tweets (that discuss the same URL). We also plan to build a generation system that employs the Yule model (Yule, 1925) to determine the importance of each aspect (e.g. who, when, where, etc.) in order to produce summaries that include diverse aspects of a story.

Our work has resulted in a publicly available dataset [8] of 25 annotated news clusters with nearly $1,400$ headlines, and 25 clusters of citation sentences with more than 900 citations. We believe that this dataset can open new dimensions in studying diversity and other aspects of automatic text generation.

Ordering Prenominal Modifiers with a Reranking Approach

Abstract

In this work, we present a novel approach to the generation task of ordering prenominal modifiers. We take a maximum entropy reranking approach to the problem which admits arbitrary features on a permutation of modifiers, exploiting hundreds of thousands of features in total. We compare our error rates to the state-of-the-art and to a strong Google n-gram count baseline. We attain a maximum error reduction of 69.8% and average error reduction across all test sets of 59.1% compared to the state-of-the-art and a maximum error reduction of 68.4% and average error reduction across all test sets of 41.8% compared to our Google n-gram count baseline.

1 Introduction

Speakers rarely have difficulty correctly ordering modifiers such as adjectives, adverbs, or gerunds when describing some noun. The phrase "beautiful blue Macedonian vase" sounds very natural, whereas changing the modifier ordering to "blue Macedonian beautiful vase" is awkward (see Table 1 for more examples). In this work, we consider the task of ordering an unordered set of prenominal modifiers so that they sound fluent to native language speakers. This is an important task for natural language generation systems.

Much linguistic research has investigated the semantic constraints behind prenominal modifier orderings. One common line of research suggests that modifiers can be organized by the underlying semantic property they describe and that there is an ordering on semantic properties which in turn restricts modifier orderings. For instance, Sproat and Shih (1991) contend that the *size* property precedes the *color* property and thus "small black cat" sounds more fluent than "black small cat". Using $>$ to denote precedence of semantic groups, some commonly proposed orderings are: *quality* $>$ *size* $>$ *shape* $>$ *color* $>$ *provenance* (Sproat and Shih, 1991), *age* $>$ *color* $>$ *participle* $>$ *provenance* $>$ *noun* $>$ *denominal* (Quirk et al., 1974), and *value* $>$ *dimension* $>$ *physical property* $>$ *speed* $>$ *human propensity* $>$ *age* $>$ *color* (Dixon, 1977). However, correctly classifying modifiers into these groups can be difficult and may be domain dependent or constrained by the context in which the modifier is being used. In addition, these methods do not specify how to order modifiers within the same class or modifiers that do not fit into any of the specified groups.

d. the small black beautiful purse

Table 1: Examples of restrictions on modifier orderings from Teodorescu (2006). The most natural sounding ordering is in bold, followed by other possibilities that may only be appropriate in certain situations.

There have also been a variety of corpus-based, computational approaches. Mitchell (2009) uses

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1109–1116,
Portland, Oregon, June 19-24, 2011.

a class-based approach in which modifiers are grouped into classes based on which positions they prefer in the training corpus, with a predefined ordering imposed on these classes. Shaw and Hatzivassiloglou (1999) developed three different approaches to the problem that use counting methods and clustering algorithms, and Malouf (2000) expands upon Shaw and Hatzivassiloglou's work.

This paper describes a computational solution to the problem that uses relevant features to model the modifier ordering process. By mapping a set of features across the training data and using a maximum entropy reranking model, we can learn optimal weights for these features and then order each set of modifiers in the test data according to our features and the learned weights. This approach has not been used before to solve the prenominal modifier ordering problem, and as we demonstrate, vastly outperforms the state-of-the-art, especially for sequences of longer lengths.

Section 2 of this paper describes previous computational approaches. In Section 3 we present the details of our maximum entropy reranking approach. Section 4 covers the evaluation methods we used, and Section 5 presents our results. In Section 6 we compare our approach to previous methods, and in Section 7 we discuss future work and improvements that could be made to our system.

2 Related Work

Mitchell (2009) orders sequences of at most 4 modifiers and defines nine classes that express the broad positional preferences of modifiers, where position 1 is closest to the noun phrase (NP) head and position 4 is farthest from it. Classes 1 through 4 comprise those modifiers that prefer only to be in positions 1 through 4, respectively. Class 5 through 7 modifiers prefer positions 1-2, 2-3, and 3-4, respectively, while class 8 modifiers prefer positions 1-3, and finally, class 9 modifiers prefer positions 2-4. Mitchell counts how often each word type appears in each of these positions in the training corpus. If any modifier's probability of taking a certain position is greater than a uniform distribution would allow, then it is said to prefer that position. Each word type is then assigned a class, with a global ordering defined over the nine classes.

Given a set of modifiers to order, if the entire set has been seen at training time, Mitchell's system looks up the class of each modifier and then orders the sequence based on the predefined ordering for the classes. When two modifiers have the same class, the system picks between the possibilities randomly. If a modifier was not seen at training time and thus cannot be said to belong to a specific class, the system favors orderings where modifiers whose classes are known are as close to their classes' preferred positions as possible.

Shaw and Hatzivassiloglou (1999) use corpus-based counting methods as well. For a corpus with w word types, they define a $w \times w$ matrix where $Count[A, B]$ indicates how often modifier A precedes modifier B. Given two modifiers a and b to order, they compare $Count[a, b]$ and $Count[b, a]$ in their training data. Assuming a null hypothesis that the probability of either ordering is 0.5, they use a binomial distribution to compute the probability of seeing the ordering $< a, b >$ for $Count[a, b]$ number of times. If this probability is above a certain threshold then they say that a precedes b. Shaw and Hatzivassiloglou also use a transitivity method to fill out parts of the *Count* table where bigrams are not actually seen in the training data but their counts can be inferred from other entries in the table, and they use a clustering method to group together modifiers with similar positional preferences.

These methods have proven to work well, but they also suffer from sparsity issues in the training data. Mitchell reports a prediction accuracy of 78.59% for NPs of all lengths, but the accuracy of her approach is greatly reduced when two modifiers fall into the same class, since the system cannot make an informed decision in those cases. In addition, if a modifier is not seen in the training data, the system is unable to assign it a class, which also limits accuracy. Shaw and Hatzivassiloglou report a highest accuracy of 94.93% and a lowest accuracy of 65.93%, but since their methods depend heavily on bigram counts in the training corpus, they are also limited in how informed their decisions can be if modifiers in the test data are not present at training time.

In this next section, we describe our maximum entropy reranking approach that tries to develop a more comprehensive model of the modifier ordering process to avoid the sparsity issues that previous ap-

proaches have faced.

3 Model

We treat the problem of prenominal modifier ordering as a reranking problem. Given a set B of prenominal modifiers and a noun phrase head H which B modifies, we define $\pi(B)$ to be the set of all possible permutations, or orderings, of B. We suppose that for a set B there is some $x^* \in \pi(B)$ which represents a "correct" natural-sounding ordering of the modifiers in B.

At test time, we choose an ordering $x \in \pi(B)$ using a maximum entropy reranking approach (Collins and Koo, 2005). Our distribution over orderings $x \in \pi(B)$ is given by:

$$P(x|H, B, W) = \frac{\exp\{W^T \phi(B, H, x)\}}{\sum_{x' \in \pi(B)} \exp\{W^T \phi(B, H, x')\}}$$

where $\phi(B, H, x)$ is a feature vector over a particular ordering of B and W is a learned weight vector over features. We describe the set of features in section 3.1, but note that we are free under this formulation to use arbitrary features on the full ordering x of B as well as the head noun H, which we implicitly condition on throughout. Since the size of the set of prenominal modifiers B is typically less than six, enumerating $\pi(B)$ is not expensive.

At training time, our data consists of sequences of prenominal orderings and their corresponding nominal heads. We treat each sequence as a training example where the labeled ordering $x^* \in \pi(B)$ is the one we observe. This allows us to extract any number of 'labeled' examples from part-of-speech text. Concretely, at training time, we select W to maximize:

$$\mathcal{L}(W) = \left(\prod_{(B,H,x^*)} P(x^*|H, B, W) \right) - \frac{\|W\|^2}{2\sigma^2}$$

where the first term represents our observed data likelihood and the second the ℓ_2 regularization, where σ^2 is a fixed hyperparameter; we fix the value of σ^2 to 0.5 throughout. We optimize this objective using standard L-BFGS optimization techniques.

The key to the success of our approach is using the flexibility afforded by having arbitrary features $\phi(B, H, x)$ to capture all the salient elements of the prenominal ordering data. These features can be used to create a richer model of the modifier ordering process than previous corpus-based counting approaches. In addition, we can encapsulate previous approaches in terms of features in our model. Mitchell's class-based approach can be expressed as a binary feature that tells us whether a given permuation satisfies the class ordering constraints in her model. Previous counting approaches can be expressed as a real-valued feature that, given all n-grams generated by a permutation of modifiers, returns the count of all these n-grams in the original training data.

3.1 Feature Selection

Our features are of the form $\phi(B, H, x)$ as expressed in the model above, and we include both indicator features and real-valued numeric features in our model. We attempt to capture aspects of the modifier permutations that may be significant in the ordering process. For instance, perhaps the majority of words that end with *-ly* are adverbs and should usually be positioned farthest from the head noun, so we can define an indicator function that captures this feature as follows:

$$\phi(B, H, x) = \begin{cases} 1 & \text{if the modifier in position } i \\ & \text{of ordering } x \text{ ends in -}ly \\ 0 & \text{otherwise} \end{cases}$$

We create a feature of this form for every possible modifier position i from 1 to 4.

We might also expect permutations that contain n-grams previously seen in the training data to be more natural sounding than other permutations that generate n-grams that have not been seen before. We can express this as a real-valued feature:

$$\phi(B, H, x) = \begin{cases} \text{count in training data of all} \\ n\text{-grams present in } x \end{cases}$$

See Table 2 for a summary of our features. Many of the features we use are similar to those in Dunlop et al. (2010), which uses a feature-based multiple sequence alignment approach to order modifiers.

Numeric Features	
n-gram Count	If N is the set of all n-grams present in the permutation, returns the sum of the counts of each element of N in the training data. A separate feature is created for 2-gms through 5-gms.
Count of Head Noun and Closest Modifier	Returns the count of $< M, H >$ in the training data where H is the head noun and M is the modifier closest to H.
Length of Modifier*	Returns the length of modifier in position i
Indicator Features	
Hyphenated*	Modifier in position i contains a hyphen.
Is Word *w**	Modifier in position i is word $w \epsilon W$, where W is the set of all word types in the training data.
Ends In *e**	Modifier in position i ends in suffix $e \epsilon E$, where E = {*-al -ble -ed -er -est -ic -ing -ive -ly -ian*}
Is A Color*	Modifier in position i is a color, where we use a list of common colors
Starts With a Number*	Modifier in position i starts with a number
Is a Number*	Modifier in position i is a number
Satisfies Mitchell Class Ordering	The permutation's class ordering satisfies the Mitchell class ordering constraints

Table 2: Features Used In Our Model. Features with an asterisk (*) are created for all possible modifier positions i from 1 to 4.

4 Experiments

4.1 Data Preprocessing and Selection

We extracted all noun phrases from four corpora: the Brown, Switchboard, and Wall Street Journal corpora from the Penn Treebank, and the North American Newswire corpus (NANC). Since there were very few NPs with more than 5 modifiers, we kept those with 2-5 modifiers and with tags *NN* or *NNS* for the head noun. We also kept NPs with only 1 modifier to be used for generating <*modifier, head noun*> bigram counts at training time. We then filtered all these NPs as follows: If the NP contained a *PRP*, *IN*, *CD*, or *DT* tag and the corresponding modifier was farthest away from the head noun, we removed this modifier and kept the rest of the NP. If the modifier was not the farthest away from the head noun, we discarded the NP. If the NP contained a *POS* tag we only kept the part of the phrase up to this tag. Our final set of NPs had tags from the following list: *JJ*, *NN*, *NNP*, *NNS*, *JJS*, *JJR*, *VBG*, *VBN*, *RB*, *NNPS*, *RBS*. See Table 3 for a summary of the number of NPs of lengths 1-5 extracted from the four corpora.

Our system makes several passes over the data during the training process. In the first pass, we collect statistics about the data, to be used later on when calculating our numeric features. To collect the statistics, we take each NP in the training data and consider all possible 2-gms through 5-gms that are present in the NP's modifier sequence, allowing for non-consecutive n-grams. For example, the NP "the beautiful blue Macedonian vase" generates the following bigrams: <*beautiful blue*>, <*blue Macedonian*>, and <*beautiful Macedonian*>, along with the 3-gram <*beautiful blue Macedonian*>. We keep a table mapping each unique n-gram to the number of times it has been seen in the training data. In addition, we also store a table that keeps track of bigram counts for $< M, H >$, where H is the head noun of an NP and M is the modifier closest to it. In the example "the beautiful blue Macedonian vase," we would increment the count of $< Macedonian, vase >$ in the table. The n-gram and $< M, H >$ counts are used to compute numeric fea-

Number of Sequences (Token)

	1	2	3	4	5	Total
Brown	11,265	1,398	92	8	2	12,765
WSJ	36,313	9,073	1,399	229	156	47,170

Table 3: Number of NPs extracted from our data for NP sequences with 1 to 5 modifiers.

ture values.

4.2 Google n-gram Baseline

The Google n-gram corpus is a collection of n-gram counts drawn from public webpages with a total of one trillion tokens – around 1 billion each of unique 3-grams, 4-grams, and 5-grams, and around 300,000 unique bigrams. We created a Google n-gram baseline that takes a set of modifiers B, determines the Google n-gram count for each possible permutation in $\pi(B)$, and selects the permutation with the highest n-gram count as the winning ordering x^*. We will refer to this baseline as GOOGLE N-GRAM.

4.3 Mitchell's Class-Based Ordering of Prenominal Modifiers (2009)

Mitchell's original system was evaluated using only three corpora for both training and testing data: Brown, Switchboard, and WSJ. In addition, the evaluation presented by Mitchell's work considers a prediction to be correct if the ordering of classes in that prediction is the same as the ordering of classes in the original test data sequence, where a class refers to the positional preference groupings defined in the model. We use a more stringent evaluation as described in the next section.

We implemented our own version of Mitchell's system that duplicates the model and methods but allows us to scale up to a larger training set and to apply our own evaluation techniques. We will refer to this baseline as CLASS BASED.

4.4 Evaluation

To evaluate our system (MAXENT) and our baselines, we partitioned the corpora into training and testing data. For each NP in the test data, we generated a set of modifiers and looked at the predicted orderings of the MAXENT, CLASS BASED, and GOOGLE N-GRAM methods. We considered a predicted sequence ordering to be correct if it matches the original ordering of the modifiers in the corpus. We ran four trials, the first holding out the Brown corpus and using it as the test set, the second holding out the WSJ corpus, the third holding out the Switchboard corpus, and the fourth holding out a randomly selected tenth of the NANC. For each trial we used the rest of the data as our training set.

5 Results

The MAXENT model consistently outperforms CLASS BASED across all test corpora and sequence lengths for both tokens and types, except when testing on the Brown and Switchboard corpora for modifier sequences of length 5, for which neither approach is able to make any correct predictions. However, there are only 3 sequences total of length 5 in the Brown and Swichboard corpora combined.

Test Corpus		Token Accuracy (%)					Type Accuracy (%)				
		2	**3**	**4**	**5**	**Total**	**2**	**3**	**4**	**5**	**Total**

Test Corpus	Number of Features Used In MaxEnt Model
Brown	655,536
WSJ	654,473
Switchboard	655,791
NANC	565,905

Table 4: Token and type prediction accuracies for the GOOGLE N-GRAM, MAXENT, and CLASS BASED approaches for modifier sequences of lengths 2-5. Our data consisted of four corpuses: Brown, Switchboard, WSJ, and NANC. The test data was held out and each approach was trained on the rest of the data. Winning scores are in bold. The number of features used during training for the MAXENT approach for each test corpus is also listed.

MAXENT also outperforms the GOOGLE N-GRAM baseline for almost all test corpora and sequence lengths. For the Switchboard test corpus token and type accuracies, the GOOGLE N-GRAM baseline is more accurate than MAXENT for sequences of length 2 and overall, but the accuracy of MAXENT is competitive with that of GOOGLE N-GRAM.

If we examine the error reduction between MAXENT and CLASS BASED, we attain a maximum error reduction of 69.8% for the WSJ test corpus across modifier sequence tokens, and an average error reduction of 59.1% across all test corpora for tokens. MAXENT also attains a maximum error reduction of 68.4% for the WSJ test corpus and an average error reduction of 41.8% when compared to GOOGLE N-GRAM.

It should also be noted that on average the MAXENT model takes three hours to train with several hundred thousand features mapped across the training data (the exact number used during each test run is listed in Table 4) – this tradeoff is well worth the increase we attain in system performance.

6 Analysis

MAXENT seems to outperform the CLASS BASED baseline because it learns more from the training data. The CLASS BASED model classifies each modifier in the training data into one of nine broad categories, with each category representing a different set of positional preferences. However, many of the modifiers in the training data get classified to the same category, and CLASS BASED makes a random choice when faced with orderings of modifiers all in the same category. When applying CLASS BASED

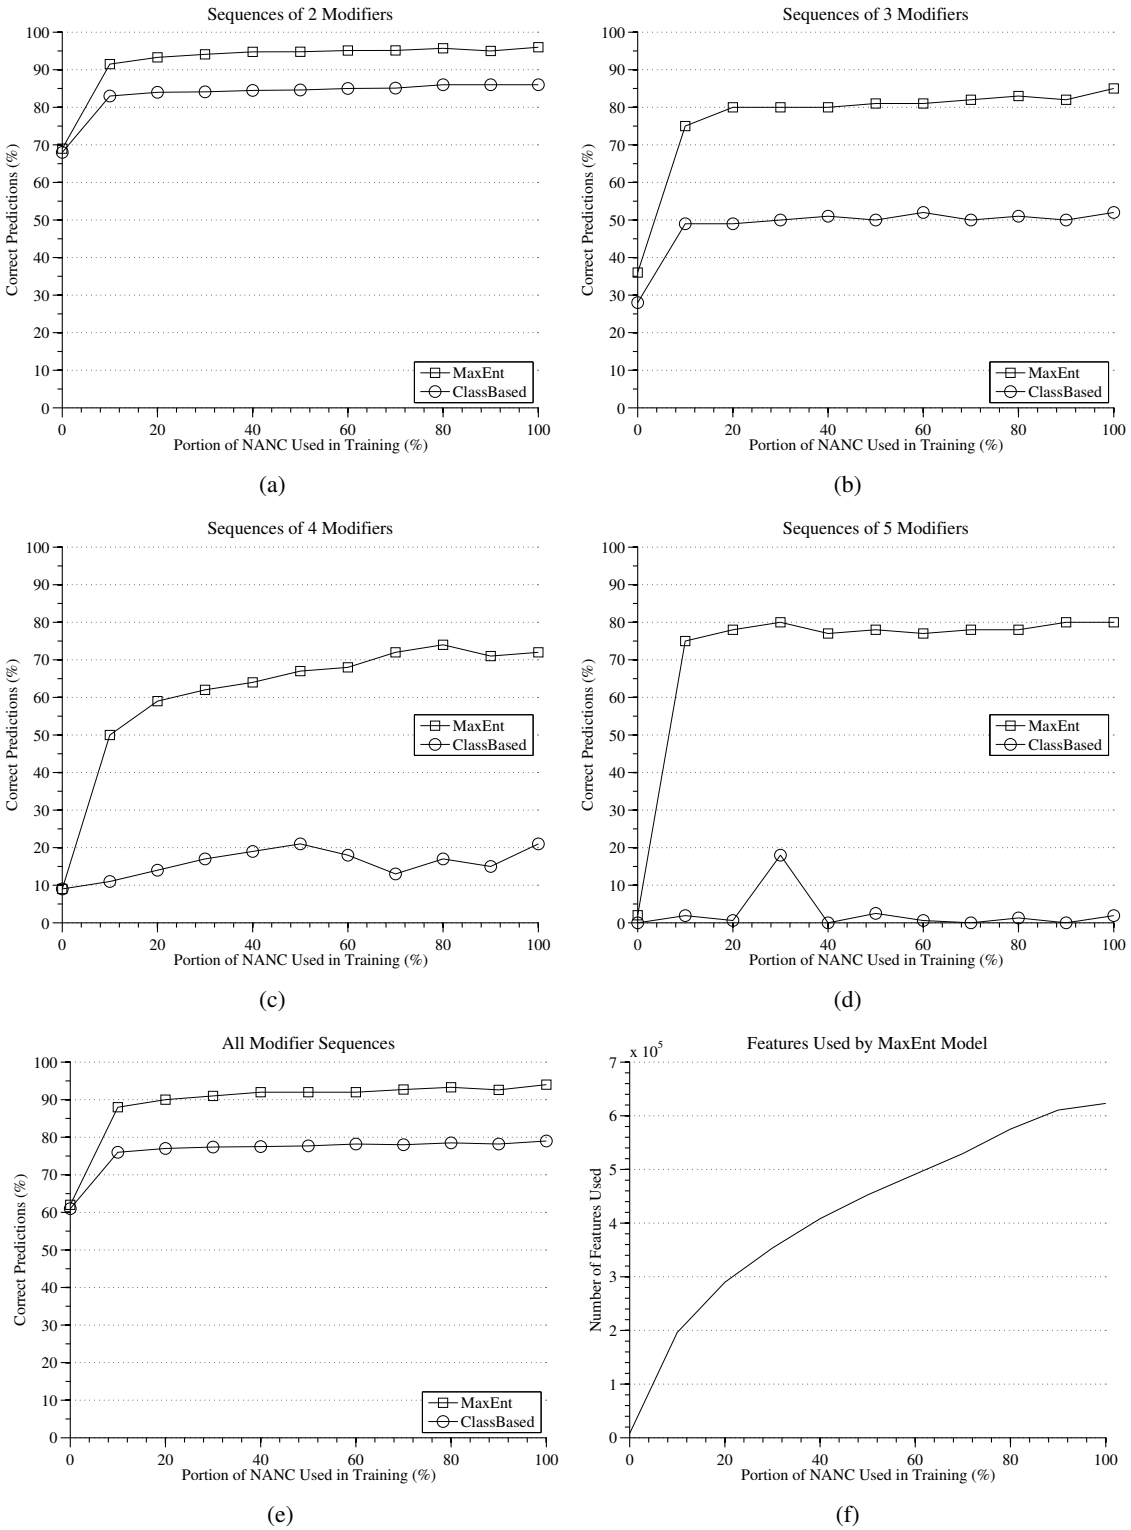

Figure 1: Learning curves for the MAXENT and CLASS BASED approaches. We start by training each approach on just the Brown and Switchboard corpora while testing on WSJ. We incrementally add portions of the NANC corpus. Graphs (a) through (d) break down the total correct predictions by the number of modifiers in a sequence, while graph (e) gives accuracies over modifier sequences of all lengths. Prediction percentages are for sequence tokens. Graph (f) shows the number of features active in the MaxEnt model as the training data scales up.

to WSJ as the test data and training on the other corpora, 74.7% of the incorrect predictions contained at least 2 modifiers that were of the same positional preferences class. In contrast, MAXENT allows us to learn much more from the training data. As a result, we see much higher numbers when trained and tested on the same data as CLASS BASED.

The GOOGLE N-GRAM method does better than the CLASS BASED approach because it contains n-gram counts for more data than the WSJ, Brown, Switchboard, and NANC corpora combined. However, GOOGLE N-GRAM suffers from sparsity issues as well when testing on less common modifier combinations. For example, our data contains rarely heard sequences such as "Italian, state-owned, holding company" or "armed Namibian nationalist guerrillas." While MAXENT determines the correct ordering for both of these examples, none of the permutations of either example show up in the Google n-gram corpus, so the GOOGLE N-GRAM method is forced to randomly select from the six possibilities. In addition, the Google n-gram corpus is composed of sentence fragments that may not necessarily be NPs, so we may be overcounting certain modifier permutations that can function as different parts of a sentence.

We also compared the effect that increasing the amount of training data has when using the CLASS BASED and MAXENT methods by initially training each system with just the Brown and Switchboard corpora and testing on WSJ. Then we incrementally added portions of NANC, one tenth at a time, until the training set included all of it. The results (see Figure 1) show that we are able to benefit from the additional data much more than the CLASS BASED approach can, since we do not have a fixed set of classes limiting the amount of information the model can learn. In addition, adding the first tenth of NANC made the biggest difference in increasing accuracy for both approaches.

7 Conclusion

The straightforward maximum entropy reranking approach is able to significantly outperform previous computational approaches by allowing for a richer model of the prenominal modifier ordering process. Future work could include adding more features to the model and conducting ablation testing. In addition, while many sets of modifiers have stringent ordering requirements, some variations on orderings, such as "former famous actor" vs. "famous former actor," are acceptable in both forms and have different meanings. It may be beneficial to extend the model to discover these ambiguities.

Abstract

In this paper we describe an unsupervised method for semantic role induction which holds promise for relieving the data acquisition bottleneck associated with supervised role labelers. We present an algorithm that iteratively splits and merges clusters representing semantic roles, thereby leading from an initial clustering to a final clustering of better quality. The method is simple, surprisingly effective, and allows to integrate linguistic knowledge transparently. By combining role induction with a rule-based component for argument identification we obtain an unsupervised end-to-end semantic role labeling system. Evaluation on the CoNLL 2008 benchmark dataset demonstrates that our method outperforms competitive unsupervised approaches by a wide margin.

1 Introduction

Recent years have seen increased interest in the *shallow semantic analysis* of natural language text. The term is most commonly used to describe the automatic identification and labeling of the semantic roles conveyed by sentential constituents (Gildea and Jurafsky, 2002). Semantic roles describe the relations that hold between a predicate and its arguments, abstracting over surface syntactic configurations. In the example sentences below. *window* occupies different syntactic positions — it is the object of *broke* in sentences (1a,b), and the subject in (1c) — while bearing the same semantic role, i.e., the physical object affected by the breaking event. Analogously, *rock* is the instrument of *break* both when realized as a prepositional phrase in (1a) and as a subject in (1b).

(1) a. [Joe]$_{A0}$ **broke** the [window]$_{A1}$ with a [rock]$_{A2}$.
b. The [rock]$_{A2}$ **broke** the [window]$_{A1}$.
c. The [window]$_{A1}$ **broke**.

The semantic roles in the examples are labeled in the style of PropBank (Palmer et al., 2005), a broad-coverage human-annotated corpus of semantic roles and their syntactic realizations. Under the PropBank annotation framework (which we will assume throughout this paper) each predicate is associated with a set of core roles (named *A*0, *A*1, *A*2, and so on) whose interpretations are specific to that predicate[1] and a set of adjunct roles (e.g., *location* or *time*) whose interpretation is common across predicates. This type of semantic analysis is admittedly shallow but relatively straightforward to automate and useful for the development of broad coverage, domain-independent language understanding systems. Indeed, the analysis produced by existing semantic role labelers has been shown to benefit a wide spectrum of applications ranging from information extraction (Surdeanu et al., 2003) and question answering (Shen and Lapata, 2007), to machine translation (Wu and Fung, 2009) and summarization (Melli et al., 2005).

Since both argument identification and labeling can be readily modeled as classification tasks, most state-of-the-art systems to date conceptualize se-

[1] More precisely, *A*0 and *A*1 have a common interpretation across predicates as *proto-agent* and *proto-patient* in the sense of Dowty (1991).

Portland, Oregon, June 19-24, 2011.

mantic role labeling as a supervised learning problem. Current approaches have high performance — a system will recall around 81% of the arguments correctly and 95% of those will be assigned a correct semantic role (see Màrquez et al. (2008) for details), however only on languages and domains for which large amounts of role-annotated training data are available. For instance, systems trained on PropBank demonstrate a marked decrease in performance (approximately by 10%) when tested on out-of-domain data (Pradhan et al., 2008).

Unfortunately, the reliance on role-annotated data which is expensive and time-consuming to produce for every language and domain, presents a major bottleneck to the widespread application of semantic role labeling. Given the data requirements for supervised systems and the current paucity of such data, unsupervised methods offer a promising alternative. They require no human effort for training thus leading to significant savings in time and resources required for annotating text. And their output can be used in different ways, e.g., as a semantic preprocessing step for applications that require broad coverage understanding or as training material for supervised algorithms.

In this paper we present a simple approach to *unsupervised* semantic role labeling. Following common practice, our system proceeds in two stages. It first identifies the semantic arguments of a predicate and then assigns semantic roles to them. Both stages operate over syntactically analyzed sentences without access to any data annotated with semantic roles. Argument identification is carried out through a small set of linguistically-motivated rules, whereas role induction is treated as a clustering problem. In this setting, the goal is to assign argument instances to clusters such that each cluster contains arguments corresponding to a specific semantic role and each role corresponds to exactly one cluster. We formulate a clustering algorithm that executes a series of *split* and *merge* operations in order to transduce an initial clustering into a final clustering of better quality. Split operations leverage syntactic cues so as to create "pure" clusters that contain arguments of the same role whereas merge operations bring together argument instances of a particular role located in different clusters. We test the effectiveness of our induction method on the CoNLL 2008 benchmark dataset and demonstrate improvements over competitive unsupervised methods by a wide margin.

2 Related Work

As mentioned earlier, much previous work has focused on building supervised SRL systems (Màrquez et al., 2008). A few semi-supervised approaches have been developed within a framework known as *annotation projection*. The idea is to combine labeled and unlabeled data by projecting annotations from a labeled source sentence onto an unlabeled target sentence within the same language (Fürstenau and Lapata, 2009) or across different languages (Padó and Lapata, 2009). Outwith annotation projection, Gordon and Swanson (2007) attempt to increase the coverage of PropBank by leveraging existing labeled data. Rather than annotating new sentences that contain previously unseen verbs, they find syntactically similar verbs and use their annotations as surrogate training data.

Swier and Stevenson (2004) induce role labels with a bootstrapping scheme where the set of labeled instances is iteratively expanded using a classifier trained on previously labeled instances. Their method is unsupervised in that it starts with a dataset containing no role annotations at all. However, it requires significant human effort as it makes use of VerbNet (Kipper et al., 2000) in order to identify the arguments of predicates and make initial role assignments. VerbNet is a broad coverage lexicon organized into verb classes each of which is explicitly associated with argument realization and semantic role specifications.

Abend et al. (2009) propose an algorithm that identifies the arguments of predicates by relying only on part of speech annotations, without, however, assigning semantic roles. In contrast, Lang and Lapata (2010) focus solely on the role induction problem which they formulate as the process of detecting alternations and finding a canonical syntactic form for them. Verbal arguments are then assigned roles, according to their position in this canonical form, since each position references a specific role. Their model extends the logistic classifier with hidden variables and is trained in a manner that makes use of the close relationship between syntactic functions and semantic roles. Grenager and Manning

(2006) propose a directed graphical model which relates a verb, its semantic roles, and their possible syntactic realizations. Latent variables represent the semantic roles of arguments and role induction corresponds to inferring the state of these latent variables.

Our own work also follows the unsupervised learning paradigm. We formulate the induction of semantic roles as a clustering problem and propose a split-merge algorithm which iteratively manipulates clusters representing semantic roles. The motivation behind our approach was to design a conceptually simple system, that allows for the incorporation of linguistic knowledge in a straightforward and transparent manner. For example, arguments occurring in similar syntactic positions are likely to bear the same semantic role and should therefore be grouped together. Analogously, arguments that are lexically similar are likely to represent the same semantic role. We operationalize these notions using a scoring function that quantifies the compatibility between arbitrary cluster pairs. Like Lang and Lapata (2010) and Grenager and Manning (2006) our method operates over syntactically parsed sentences, without, however, making use of any information pertaining to semantic roles (e.g., in form of a lexical resource or manually annotated data). Performing role-semantic analysis without a treebank-trained parser is an interesting research direction, however, we leave this to future work.

3 Learning Setting

We follow the general architecture of supervised semantic role labeling systems. Given a sentence and a designated verb, the SRL task consists of identifying the arguments of the verbal predicate (argument identification) and labeling them with semantic roles (role induction).

In our case neither argument identification nor role induction relies on role-annotated data or other semantic resources although we assume that the input sentences are syntactically analyzed. Our approach is not tied to a specific syntactic representation — both constituent- and dependency-based representations could be used. However, we opted for a dependency-based representation, as it simplifies argument identification considerably and is consistent with the CoNLL 2008 benchmark dataset used for evaluation in our experiments.

Given a dependency parse of a sentence, our system identifies argument instances and assigns them to clusters. Thereafter, argument instances can be labeled with an identifier corresponding to the cluster they have been assigned to, similar to PropBank core labels (e.g., *A*0, *A*1).

4 Argument Identification

In the supervised setting, a classifier is employed in order to decide for each node in the parse tree whether it represents a semantic argument or not. Nodes classified as arguments are then assigned a semantic role. In the unsupervised setting, we slightly reformulate argument identification as the task of discarding as many non-semantic arguments as possible. This means that the argument identification component does not make a final positive decision for any of the argument candidates; instead, this decision is deferred to role induction. The rules given in Table 1 are used to discard or select argument candidates. They primarily take into account the parts of speech and the syntactic relations encountered when traversing the dependency tree from predicate to argument. For each candidate, the first matching rule is applied.

We will exemplify how the argument identification component works for the predicate *expect* in the sentence "*The company said it expects its sales to remain steady*" whose parse tree is shown in Figure 1. Initially, all words save the predicate itself are treated as argument candidates. Then, the rules from Table 1 are applied as follows. Firstly, words *the* and *to* are discarded based on their part of speech (rule (1)); then, *remain* is discarded because the path ends with the relation IM and *said* is discarded as the path ends with an upward-leading OBJ relation (rule (2)). Rule (3) does not match and is therefore not applied. Next, *steady* is discarded because there is a downward-leading OPRD relation along the path and the words *company* and *its* are discarded because of the OBJ relations along the path (rule (4)). Rule (5) does not apply but words *it* and *sales* are kept as likely arguments (rule (6)). Finally, rule (7) does not apply, because there are no candidates left.

1. Discard a candidate if it is a determiner, infinitival marker, coordinating conjunction, or punctuation.
2. Discard a candidate if the path of relations from predicate to candidate ends with coordination, subordination, etc. (see the Appendix for the full list of relations).
3. Keep a candidate if it is the closest subject (governed by the subject-relation) to the left of a predicate and the relations from predicate p to the governor g of the candidate are all upward-leading (directed as $g \rightarrow p$).
4. Discard a candidate if the path between the predicate and the candidate, excluding the last relation, contains a subject relation, adjectival modifier relation, etc. (see the Appendix for the full list of relations).
5. Discard a candidate if it is an auxiliary verb.
6. Keep a candidate if the predicate is its parent.
7. Keep a candidate if the path from predicate to candidate leads along several verbal nodes (verb chain) and ends with arbitrary relation.
8. Discard all remaining candidates.

Table 1: Argument identification rules.

5 Split-Merge Role Induction

We treat role induction as a clustering problem with the goal of assigning argument instances (i.e., specific arguments occurring in an input sentence) to clusters such that these represent semantic roles. In accordance with PropBank, we induce a separate set of clusters for each verb and each cluster thus represents a verb-specific role.

Our algorithm works by iteratively splitting and merging clusters of argument instances in order to arrive at increasingly accurate representations of semantic roles. Although splits and merges could be arbitrarily interleaved, our algorithm executes a single split operation (split phase), followed by a series of merges (merge phase). The split phase partitions the seed cluster containing all argument instances of a particular verb into more fine-grained (sub-)clusters. This initial split results in a clustering with high purity but low collocation, i.e., argument instances in each cluster tend to belong to the same role but argument instances of a particular role are located in many clusters. The degree of dislocation is reduced in the consecutive merge phase, in which clusters that are likely to represent the same role are merged.

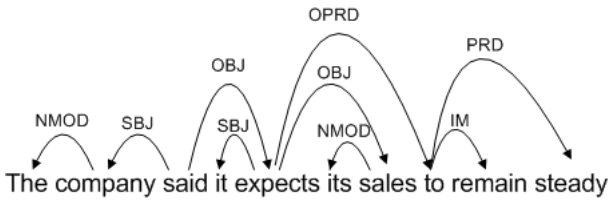

Figure 1: A sample dependency parse with dependency labels SBJ (subject), OBJ (object), NMOD (nominal modifier), OPRD (object predicative complement), PRD (predicative complement), and IM (infinitive marker). See Surdeanu et al. (2008) for more details on this variant of dependency syntax.

5.1 Split Phase

Initially, all arguments of a particular verb are placed in a single cluster. The goal then is to partition this cluster in such a way that the split-off clusters have high purity, i.e., contain argument instances of the same role. Towards this end, we characterize each argument instance by a key, formed by concatenating the following syntactic cues:

- verb voice (active/passive);
- argument linear position relative to predicate (left/right);
- syntactic relation of argument to its governor;
- preposition used for argument realization.

A cluster is allocated for each key and all argument instances with a matching key are assigned to that cluster. Since each cluster encodes fine-grained syntactic distinctions, we assume that arguments occurring in the same position are likely to bear the same semantic role. The assumption is largely supported by our empirical results (see Section 7); the clusters emerging from the initial split phase have a purity of approximately 90%. While the incorporation of additional cues (e.g., indicating the part of speech of the subject or transitivity) would result in even greater purity, it would also create problematically small clusters, thereby negatively affecting the successive merge phase.

5.2 Merge Phase

The split phase creates clusters with high purity, however, argument instances of a particular role are often scattered amongst many clusters resulting in a cluster assignment with low collocation. The goal of the merge phase is to improve collocation by executing a series of merge steps. At each step, pairs of clusters are considered for merging. Each pair is scored by a function that reflects how likely the two clusters are to contain arguments of the same role and the best scoring pair is chosen for merging. In the following, we will specify which pairs of clusters are considered (candidate search), how they are scored, and when the merge phase terminates.

5.2.1 Candidate Search

In principle, we could simply enumerate and score all possible cluster pairs at each iteration. In practice however, such a procedure has a number of drawbacks. Besides being inefficient, it requires a scoring function with comparable scores for arbitrary pairs of clusters. For example, let a, b, c, and d denote clusters. Then, $score(a,b)$ and $score(c,d)$ must be comparable. This is a stronger requirement than demanding that only scores involving some common cluster (e.g., $score(a,b)$ and $score(a,c)$) be comparable. Moreover, it would be desirable to exclude pairings involving small clusters (i.e., with few instances) as scores for these tend to be unreliable. Rather than considering all cluster pairings, we therefore select a specific cluster at each step and score merges between this cluster and certain other clusters. If a sufficiently good merge is found, it is executed, otherwise the clustering does not change. In addition, we prioritize merges between large clusters and avoid merges between small clusters.

Algorithm 1 implements our merging procedure. Each pass through the inner loop (lines 4–12) selects a different cluster to consider at that step. Then, merges between the selected cluster and all larger clusters are considered. The highest-scoring merge is executed, unless all merges are ruled out, i.e., have a score below the threshold α. After each completion of the inner loop, the thresholds contained in the scoring function (discussed below) are adjusted and this is repeated until some termination criterion is met (discussed in Section 5.2.3).

Algorithm 1: Cluster merging procedure. Operation $merge(L_i, L_j)$ merges cluster L_i into cluster L_j and removes L_i from the list L.

```
1  while not done do
2      L ← a list of all clusters sorted by number
       of instances in descending order
3      i ← 1
4      while i < length(L) do
5          j ← arg max_{0≤j'<i} score(L_i, L_j')
6          if score(L_i, L_j) ≥ α then
7              merge(L_i, L_j)
8          end
9          else
10             i ← i + 1
11         end
12     end
13     adjust thresholds
14 end
```

5.2.2 Scoring Function

Our scoring function quantifies whether two clusters are likely to contain arguments of the same role and was designed to reflect the following criteria:

1. whether the arguments found in the two clusters are lexically similar;
2. whether clause-level constraints are satisfied, specifically the constraint that all arguments of a particular clause have different semantic roles, i.e., are assigned to different clusters;
3. whether the arguments present in the two clusters have similar parts of speech.

Qualitatively speaking, criteria (2) and (3) provide negative evidence in the sense that they can be used to rule out incorrect merges but not to identify correct ones. For example, two clusters with drastically different parts of speech are unlikely to represent the same role. However, the converse is not necessarily true as part of speech similarity does not imply role-semantic similarity. Analogously, the fact that clause-level constraints are not met provides evidence against a merge, but the fact that these are satisfied is not reliable evidence in favor of a merge. In contrast, lexical similarity implies that the clus-

ters are likely to represent the same semantic role. It is reasonable to assume that due to selectional restrictions, verbs will be associated with lexical units that are semantically related and assume similar syntactic positions (e.g., *eat* prefers as an object edible things such as *apple, biscuit, meat*), thus bearing the same semantic role. Unavoidably, lexical similarity will be more reliable for arguments with overt lexical content as opposed to pronouns, however this should not impact the scoring of sufficiently large clusters.

Each of the criteria mentioned above is quantified through a separate score and combined into an overall similarity function, which scores two clusters c and c' as follows:

$$score(c,c') = \begin{cases} 0 & \text{if } pos(c,c') < \beta, \\ 0 & \text{if } cons(c,c') < \gamma, \\ lex(c,c') & \text{otherwise.} \end{cases} \quad (2)$$

The particular form of this function is motivated by the distinction between positive and negative evidence. When the part-of-speech similarity (*pos*) is below a certain threshold β or when clause-level constraints (*cons*) are satisfied to a lesser extent than threshold γ, the score takes value zero and the merge is ruled out. If this is not the case, the lexical similarity score (*lex*) determines the magnitude of the overall score. In the remainder of this section we will explain how the individual scores (*pos*, *cons*, and *lex*) are defined and then move on to discuss how the thresholds β and γ are adjusted.

Lexical Similarity We measure lexical similarity between two clusters through cosine similarity. Specifically, each cluster is represented as a vector whose components correspond to the occurrence frequencies of the argument head words in the cluster. The similarity on such vectors x and y is then quantified as:

$$lex(x,y) = cossim(x,y) = \frac{x \cdot y}{\|x\| \|y\|} \quad (3)$$

Clause-Level Constraints Arguments occurring in the same clause cannot bear the same role. Therefore, clusters should not merge if the resulting cluster contains (many) arguments of the same clause. For two clusters c and c' we assess how well they satisfy this clause-level constraint by computing:

$$cons(c,c') = 1 - \frac{2 * viol(c,c')}{NC + NC'} \quad (4)$$

where $viol(c,c')$ refers to the number of pairs of instances $(d,d') \in c \times c'$ for which d and d' occur in the same clause (each instance can participate in at most one pair) and NC and NC' are the number of instances in clusters c and c', respectively.

Part-of-speech Similarity Part-of-speech similarity is also measured through cosine-similarity (equation (3)). Clusters are again represented as vectors x and y whose components correspond to argument part-of-speech tags and values to their occurrence frequency.

5.2.3 Threshold Adaptation and Termination

As mentioned earlier the thresholds β and γ which parametrize the scoring function are adjusted at each iteration. The idea is to start with a very restrictive setting (high values) in which the negative evidence rules out merges more strictly, and then to gradually relax the requirement for a merge by lowering the threshold values. This procedure prioritizes reliable merges over less reliable ones.

More concretely, our threshold adaptation procedure starts with β and γ both set to value 0.95. Then β is lowered by 0.05 at each step, leaving γ unchanged. When β becomes zero, γ is lowered by 0.05 and β is reset to 0.95. Then β is iteratively decreased again until it becomes zero, after which γ is decreased by another 0.05. This is repeated until γ becomes zero, at which point the algorithm terminates. Note that the termination criterion is not tied explicitly to the number of clusters, which is therefore determined automatically.

6 Experimental Setup

In this section we describe how we assessed the performance of our system. We discuss the dataset on which our experiments were carried out, explain how our system's output was evaluated and present the methods used for comparison with our approach.

Data For evaluation purposes, the system's output was compared against the CoNLL 2008 shared task dataset (Surdeanu et al., 2008) which provides

	Syntactic Function			Lang and Lapata			Split-Merge

Table 2: Clustering results with our split-merge algorithm, the unsupervised model proposed in Lang and Lapata (2010) and a baseline that assigns arguments to clusters based on their syntactic function.

PropBank-style gold standard annotations. The dataset was taken from the Wall Street Journal portion of the Penn Treebank corpus and converted into a dependency format (Surdeanu et al., 2008). In addition to gold standard dependency parses, the dataset also contains automatic parses obtained from the MaltParser (Nivre et al., 2007). Although the dataset provides annotations for verbal and nominal predicate-argument constructions, we only considered the former, following previous work on semantic role labeling (Màrquez et al., 2008).

Evaluation Metrics For each verb, we determine the extent to which argument instances in a cluster share the same gold standard role (purity) and the extent to which a particular gold standard role is assigned to a single cluster (collocation).

More formally, for each group of verb-specific clusters we measure the purity of the clusters as the percentage of instances belonging to the majority gold class in their respective cluster. Let N denote the total number of instances, G_j the set of instances belonging to the j-th gold class and C_i the set of instances belonging to the i-th cluster. Purity can then be written as:

$$PU = \frac{1}{N}\sum_i \max_j |G_j \cap C_i| \quad (5)$$

Collocation is defined as follows. For each gold role, we determine the cluster with the largest number of instances for that role (the role's *primary* cluster) and then compute the percentage of instances that belong to the primary cluster for each gold role as:

$$CO = \frac{1}{N}\sum_j \max_i |G_j \cap C_i| \quad (6)$$

The per-verb scores are aggregated into an overall score by averaging over all verbs. We use the micro-average obtained by weighting the scores for individual verbs proportionately to the number of instances for that verb.

Finally, we use the harmonic mean of purity and collocation as a single measure of clustering quality:

$$F_1 = \frac{2 \times CO \times PU}{CO + PU} \quad (7)$$

Comparison Models We compared our split-merge algorithm against two competitive approaches. The first one assigns argument instances to clusters according to their syntactic function (e.g., subject, object) as determined by a parser. This baseline has been previously used as point of comparison by other unsupervised semantic role labeling systems (Grenager and Manning, 2006; Lang and Lapata, 2010) and shown difficult to outperform. Our implementation allocates up to $N = 21$ clusters[2] for each verb, one for each of the 20 most frequent functions in the CoNLL dataset and a default cluster for all other functions. The second comparison model is the one proposed in Lang and Lapata (2010) (see Section 2). We used the same model settings (with 10 latent variables) and feature set proposed in that paper. Our method's only parameter is the threshold α which we heuristically set to 0.1. On average our method induces 10 clusters per verb.

7 Results

Our results are summarized in Table 2. We report cluster purity (PU), collocation (CO) and their harmonic mean (F1) for the baseline (Syntactic Function), Lang and Lapata's (2010) model and our split-merge algorithm (Split-Merge) on four

Table 4: Clustering results for individual semantic roles with our split-merge algorithm and the syntactic function baseline.

datasets. These result from the combination of automatic parses with automatically identified arguments (auto/auto), gold parses with automatic arguments (gold/auto), automatic parses with gold arguments (auto/gold) and gold parses with gold arguments (gold/gold). Bold-face is used to highlight the best performing system under each measure on each dataset (e.g., auto/auto, gold/auto and so on).

On all datasets, our method achieves the highest purity and outperforms both comparison models by a wide margin which in turn leads to a considerable increase in F1. On the auto/auto dataset the split-merge algorithm results in 9% higher purity than the baseline and increases F1 by 2.8%. Lang and Lapata's (2010) logistic classifier achieves higher collocation but lags behind our method on the other two measures.

Not unexpectedly, we observe an increase in performance for all models when using gold standard parses. On the gold/auto dataset, F1 increases by 2.7% for the split-merge algorithm, 2.7% for the logistic classifier, and 5.5% for the syntactic function baseline. Split-Merge maintains the highest purity and levels the baseline in terms of F1. Performance also increases if gold standard arguments are used instead of automatically identified arguments. Consequently, each model attains its best scores on the gold/gold dataset.

We also assessed the argument identification component on its own (settings auto/auto and gold/auto). It obtained a precision of 88.1% (percentage of semantic arguments out of those identified) and recall of 87.9% (percentage of identified arguments out of all gold arguments). However, note that these figures are not strictly comparable to those reported for supervised systems, due to the fact that our argument identification component only discards non-argument candidates.

Tables 3 and 4 shows how performance varies across verbs and roles, respectively. We compare the syntactic function baseline and the split-merge system on the auto/auto dataset. Table 3 presents results for 12 verbs which we selected so as to exhibit varied occurrence frequencies and alternation patterns. As can be seen, the macroscopic result — increase in F1 (shown in bold face) and purity — also holds across verbs. Some caution is needed in interpreting the results in Table 4[3] since core roles A0–A3 are defined on a per-verb basis and do not necessarily have a uniform corpus-wide interpretation. Thus, conflating scores across verbs is only meaningful to the extent that these labels actually signify the same

[3]Results are shown for four core roles (A0–A3) and all subtypes of the ArgM role, i.e., adjuncts denoting general purpose (ADV), cause (CAU), direction (DIR), extent (EXT), location (LOC), manner (MNR), and time (TMP), modal verbs (MOD), negative markers (NEG), and discourse connectives (DIS).

role (which is mostly true for A0 and A1). Furthermore, the purity scores given here represent the average purity of those clusters for which the specified role is the majority role. We observe that for most roles shown in Table 4 the split-merge algorithm improves upon the baseline with regard to F1, whereas this is uniformly the case for purity.

What are the practical implications of these results, especially when considering the collocation-purity tradeoff? If we were to annotate the clusters induced by our system, low collocation would result in higher annotation effort while low purity would result in poorer data quality. Our system improves purity substantially over the baselines, without affecting collocation in a way that would massively increase the annotation effort. As an example, consider how our system could support humans in labeling an unannotated corpus. (The following numbers are derived from the CoNLL dataset[4] in the auto/auto setting.) We might decide to annotate all induced clusters with more than 10 instances. This means we would assign labels to 74% of instances in the dataset (excluding those discarded during argument identification) and attain a role classification with 79.4% precision (purity).[5] However, instead of labeling all 165,662 instances contained in these clusters individually we would only have to assign labels to 2,869 clusters. Since annotating a cluster takes roughly the same time as annotating a single instance, the annotation effort is reduced by a factor of about 50.

8 Conclusions

In this paper we presented a novel approach to unsupervised role induction which we formulated as a clustering problem. We proposed a split-merge algorithm that iteratively manipulates clusters representing semantic roles whilst trading off cluster purity with collocation. The split phase creates "pure" clusters that contain arguments of the same role whereas the merge phase attempts to increase collocation by merging clusters which are likely to represent the same role. The approach is simple, intuitive and requires no manual effort for training. Coupled with a rule-based component for automatically identifying argument candidates our split-merge algorithm forms an end-to-end system that is capable of inducing role labels without any supervision.

Our approach holds promise for reducing the data acquisition bottleneck for supervised systems. It could be usefully employed in two ways: (a) to create preliminary annotations, thus supporting the "annotate automatically, correct manually" methodology used for example to provide high volume annotation in the Penn Treebank project; and (b) in combination with supervised methods, e.g., by providing useful out-of-domain data for training. An important direction for future work lies in investigating how the approach generalizes across languages as well as reducing our system's reliance on a treebank-trained parser.

Using Cross-Entity Inference to Improve Event Extraction

Abstract

Event extraction is the task of detecting certain specified types of events that are mentioned in the source language data. The state-of-the-art research on the task is transductive inference (e.g. cross-event inference). In this paper, we propose a new method of event extraction by well using cross-entity inference. In contrast to previous inference methods, we regard entity-type consistency as key feature to predict event mentions. We adopt this inference method to improve the traditional sentence-level event extraction system. Experiments show that we can get 8.6% gain in trigger (event) identification, and more than 11.8% gain for argument (role) classification in ACE event extraction.

1 Introduction

The event extraction task in ACE (Automatic Content Extraction) evaluation involves three challenging issues: distinguishing events of different types, finding the participants of an event and determining the roles of the participants.

The recent researches on the task show the availability of transductive inference, such as that of the following methods: cross-document, cross-sentence and cross-event inferences. Transductive inference is a process to use the known instances to predict the attributes of unknown instances. As an example, given a target event, the cross-event inference can predict its type by well using the related events co-occurred with it within the same document. From the sentence:

*(1)He **left** the company.*

it is hard to tell whether it is a *Transport* event in ACE, which means that he left the place; or an *End-Position* event, which means that he retired from the company. But cross-event inference can use a related event "*Then he went shopping*" within the same document to identify it as a *Transport* event correctly.

As the above example might suggest, the availability of transductive inference for event extraction relies heavily on the known evidences of an event occurrence in specific condition. However, the evidence supporting the inference is normally unclear or absent. For instance, the relation among events is the key clue for cross-event inference to predict a target event type, as shown in the inference process of the sentence (1). But event relation extraction itself is a hard task in Information Extraction. So cross-event inference often suffers from some false evidence (viz., misleading by unrelated events) or lack of valid evidence (viz., unsuccessfully extracting related events).

In this paper, we propose a new method of transductive inference, named cross-entity inference, for event extraction by well using the relations among entities. This method is firstly motivated by the inherent ability of entity types in revealing event types. From the sentences:

*(2)He left the **bathroom**.*
*(3)He left **Microsoft**.*

it is easy to identify the sentence (2) as a *Transport* event in ACE, which means that he left the place, because nobody would retire (*End-Position* type) from a bathroom. And compared to the entities in sentence (1) and (2), the entity "*Microsoft*" in (3) would give us more confidence to tag the "*left*" event as an *End-Position* type, because people are used to giving the full name of the place where they retired.

The cross-entity inference is also motivated by the phenomenon that the entities of the same type often attend similar events. That gives us a way to predict event type based on entity-type consistency. From the sentence:

*(4)**Obama** beats McCain.*

it is hard to identify it as an *Elect* event in ACE, which means Obama wins the Presidential Election,

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1127–1136,
Portland, Oregon, June 19-24, 2011.

or an *Attack* event, which means Obama roughs somebody up. But if we have the priori knowledge that the sentence "*Bush beats McCain*" is an *Elect* event, and "*Obama*" was a presidential contender just like "*Bush*" (strict type consistency), we have ample evidence to predict that the sentence (4) is also an *Elect* event.

Indeed above cross-entity inference for event-type identification is not the only use of entity-type consistency. As we shall describe below, we can make use of it at all issues of event extraction:

- For **event type**: the entities of the same type are most likely to attend similar events. And the events often use consistent or synonymous trigger.
- For **event argument (participant)**: the entities of the same type normally co-occur with similar participants in the events of the same type.
- For **argument role**: the arguments of the same type, for the most part, play the same roles in similar events.

With the help of above characteristics of entity, we can perform a step-by-step inference in this order:

- ***Step 1***: predicting event type and labeling trigger given the entities of the same type.
- ***Step 2***: identifying arguments in certain event given priori entity type, event type and trigger that obtained by step 1.
- ***Step 3***: determining argument roles in certain event given entity type, event type, trigger and arguments that obtained by step 1 and step 2.

On the basis, we give a blind cross-entity inference method for event extraction in this paper. In the method, we first regard entities as queries to retrieve their related documents from large-scale language resources, and use the global evidences of the documents to generate entity-type descriptions. Second we determine the type consistency of entities by measuring the similarity of the type descriptions. Finally, given the priori attributes of events in the training data, with the help of the entities of the same type, we perform the step-by-step cross-entity inference on the attributes of test events (candidate sentences).

In contrast to other transductive inference methods on event extraction, the cross-entity inference makes every effort to strengthen effects of entities in predicting event occurrences. Thus the inferential process can benefit from following aspects: 1) less false evidence, viz. less false entity-type consistency (the key clue of cross-entity inference), because the consistency can be more precisely determined with the help of fully entity-type description that obtained based on the related information from Web; 2) more valid evidence, viz. more entities of the same type (the key references for the inference), because any entity never lack its congeners.

2 Task Description

The event extraction task we addressing is that of the Automatic Content Extraction (ACE) evaluations, where an event is defined as a specific occurrence involving participants. And event extraction task requires that certain specified types of events that are mentioned in the source language data be detected. We first introduce some ACE terminology to understand this task more easily:

- **Entity**: an object or a set of objects in one of the semantic categories of interest, referred to in the document by one or more (co-referential) entity mentions.
- **Entity mention**: a reference to an entity (typically, a noun phrase).
- **Event trigger**: the main word that most clearly expresses an event occurrence (An ACE event trigger is generally a verb or a noun).
- **Event arguments**: the entity mentions that are involved in an event (viz., participants).
- **Argument roles**: the relation of arguments to the event where they participate.
- **Event mention**: a phrase or sentence within which an event is described, including trigger and arguments.

The 2005 ACE evaluation had 8 types of events, with 33 subtypes; for the purpose of this paper, we will treat these simply as 33 separate event types and do not consider the hierarchical structure among them. Besides, the ACE evaluation plan defines the following standards to determine the correctness of an event extraction:

- A trigger is correctly labeled if its event type and offset (viz., the position of the trigger word in text) match a reference trigger.
- An argument is correctly identified if its event type and offsets match any of the reference argument mentions, in other word, correctly recognizing participants in an event.
- An argument is correctly classified if its role matches any of the reference argument mentions.

Consider the sentence:

*(5) It has refused in **the last five years** to **revoke** the license of **a single doctor** for committing medical errors.*[1]

The event extractor should detect an *End-Position* event mention, along with the trigger word "*revoke*", the position "*doctor*", the person whose license should be revoked, and the time during which the event happened:

Event type	***End-Position***	
Trigger	***revoke***	
Arguments	***a single doctor***	Role=***Person***
	doctor	Role=***Position***
	the last five years	Role=***Time-within***

Table 1: Event extraction example

It is noteworthy that event extraction depends on previous phases like name identification, entity mention co-reference and classification. Thereinto, the name identification is another hard task in ACE evaluation and not the focus in this paper. So we skip the phase and instead directly use the entity labels provided by ACE.

3 Related Work

Almost all the current ACE event extraction systems focus on processing one sentence at a time (Grishman et al., 2005; Ahn, 2006; Hardyet al. 2006). However, there have been several studies using high-level information from a wider scope:

Maslennikov and Chua (2007) use discourse trees and local syntactic dependencies in a pattern-based framework to incorporate wider context to refine the performance of relation extraction. They claimed that discourse information could filter noisy dependency paths as well as increasing the reliability of dependency path extraction.

Finkel et al. (2005) used Gibbs sampling, a simple Monte Carlo method used to perform approximate inference in factored probabilistic models. By using simulated annealing in place of Viterbi decoding in sequence models such as HMMs, CMMs, and CRFs, it is possible to incorporate non-local structure while preserving tractable inference. They used this technique to augment an information extraction system with long-distance dependency models, enforcing label consistency and extraction template consistency constraints.

Ji and Grishman (2008) were inspired from the hypothesis of "One Sense Per Discourse" (Yarowsky, 1995); they extended the scope from a single document to a cluster of topic-related documents and employed a rule-based approach to propagate consistent trigger classification and event arguments across sentences and documents. Combining global evidence from related documents with local decisions, they obtained an appreciable improvement in both event and event argument identification.

Patwardhan and Riloff (2009) proposed an event extraction model which consists of two components: a model for sentential event recognition, which offers a probabilistic assessment of whether a sentence is discussing a domain-relevant event; and a model for recognizing plausible role fillers, which identifies phrases as role fillers based upon the assumption that the surrounding context is discussing a relevant event. This unified probabilistic model allows the two components to jointly make decisions based upon both the local evidence surrounding each phrase and the "peripheral vision".

Gupta and Ji (2009) used cross-event information within ACE extraction, but only for recovering implicit time information for events.

Liao and Grishman (2010) propose document level cross-event inference to improve event extraction. In contrast to Gupta's work, Liao do not limit themselves to time information for events, but rather use related events and event-type consistency to make predictions or resolve ambiguities regarding a given event.

4 Motivation

In event extraction, current transductive inference methods focus on the issue that many events are missing or spuriously tagged because the local information is not sufficient to make a confident decision. The solution is to mine credible evidences of event occurrences from global information and regard that as priori knowledge to predict unknown event attributes, such as that of cross-document and cross-event inference methods.

However, by analyzing the sentence-level baseline event extraction, we found that the entities within a sentence, as the most important local information, actually contain sufficient clues for event detection. It is only based on the premise that we know the backgrounds of the entities beforehand. For instance, if we knew the entity "*vesuvius*" is an active volcano, we could easily identify

[1] Selected from the file "CNN_CF_20030304.1900.02" in ACE-2005 corpus.

the word "*erupt*", which co-occurred with the entity, as the trigger of a "*volcanic eruption*" event but not that of a "*spotty rash*".

In spite of that, it is actually difficult to use an entity to directly infer an event occurrence because we normally don't know the inevitable connection between the background of the entity and the event attributes. But we can well use the entities of the same background to perform the inference. In detail, if we first know *entity(a)* has the same background with *entity(b)*, and we also know that *entity(a)*, as a certain role, participates in a specific event, then we can predict that *entity(b)* might participtes in a similar event as the same role.

Consider the two sentences[2] from ACE corpus:

(5) ***American*** *case for* ***war*** *against* ***Saddam***.

(6) ***Bush*** *should* ***torture*** *the* ***al Qaeda chief operations officer***.

The sentences are two event mentions which have the same attributes:

(5)	Event type	***Attack***	
	Trigger	***war***	
	Arguments	***American***	Role=***Attacker***
		Saddam	Role=***Target***
(6)	Event type	***Attack***	
	Trigger	***torture***	
	Arguments	***Bush***	Role=***Attacker***
		...Qaeda chief ...	Role=***Target***

Table 2: Cross-entity inference example

From the sentences, we can find that the entities "*Saddam*" and "*Qaeda chief*" have the same background (viz., terrorist leader), and they are both the arguments of *Attack* events as the role of *Target*. So if we previously know any of the event mentions, we can infer another one with the help of the entities of the same background.

In a word, the cross-entity inference, we proposed for event extraction, bases on the hypothesis:

Entities of the consistent type normally participate in similar events as the same role.

As we will introduce below, some statistical data from ACE training corpus can support the hypothesis, which show the consistency of event type and role in event mentions where entities of the same type occur.

4.1 Entity Consistency and Distribution

Within the ACE corpus, there is a strong entity consistency: if one entity mention appears in a type of event, other entity mentions of the same type will appear in similar events, and even use the same word to trigger the events. To see this we calculated the conditional probability (in the ACE corpus) of a certain entity type appearing in the 33 ACE event subtypes.

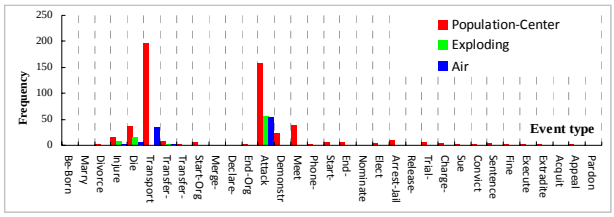

Figure 1. Conditional probability of a certain entity type appearing in the 33 ACE event subtypes (Here only the probabilities of *Population-Center*, *Exploding* and *Air* entities as examples)

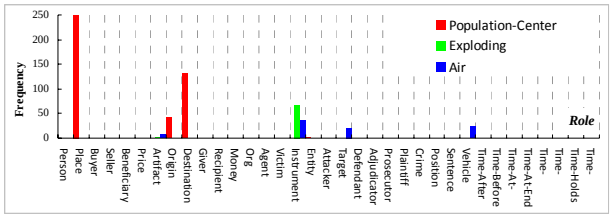

Figure 2. Conditional probability of an entity type appearing as the 34 ACE role types (Here only the probabilities of *Population-Center*, *Exploding* and *Air* entities as examples)

As there are 33 event subtypes and 43 entity types, there are potentially 33*43=1419 entity-event combinations. However, only a few of these appear with substantial frequency. For example, the *Population-Center* entities only occur in 4 types of event mentions with the conditional probability more than 0.05. From Table 3, we can find that only *Attack* and *Transport* events co-occur frequently with *Population-Center* entities (see Figure 1 and Table 3).

Event	**Cond.Prob.**	**Freq.**
Transport	0.368	197
Attack	0.295	158
Meet	0.073	39
Die	0.069	37

Table 3: Events co-occurring with *Population-Center* with the conditional probability > 0.05

Actually we find that most entity types appear in more restricted event mentions than *Population-Center* entity. For example, *Air* entity only co-occurs with 5 event types (*Attack*, *Transport*, *Die*, *Transfer-Ownership* and *Injure*), and *Exploding*

2 They are extracted from the files "CNN_CF_20030305.1900.00-1" and "CNN_CF_20030303.1900.06-1" respectively.

entity co-occurs with 4 event types (see Figure 1). Especially, they only co-occur with one or two event types with the conditional probability more than 0.05.

	Evnt.<=5	5<Evnt.<=10	Evnt.>10
Freq. > 0	24	7	12
Freq. >10	37	4	2
Freq. >50	41	1	1

Table 4: Distribution of entity-event combination corresponding to different co-occurrence frequency

Table 4 gives the distributions of whole ACE entity types co-occurring with event types. We can find that there are 37 types of entities (out of 43 in total) appearing in less than 5 types of event mentions when entity-event co-occurrence frequency is larger than 10, and only 2 (e.g. *Individual*) appearing in more than 10 event types. And when the frequency is larger than 50, there are 41 (95%) entity types co-occurring with less than 5 event types. These distributions show the fact that most instances of a certain entity type normally participate in events of the same type. And the distributions might be good predictors for event type detection and trigger determination.

Air (Entity type)	
Attack event	***Fighter plane*** (subtype 1): "*MiGs*" "*enemy planes*" "*warplanes*" "*allied aircraft*" "*U.S. jets*" "*a-10 tank killer*" "*b-1 bomber*" "*a-10 warthog*" "*f-14 aircraft*" "*apache helicopter*"
Transport event	***Spacecraft*** (subtype 2): "*russian soyuz capsule*" "*soyuz*"
	Civil aviation (subtype 3): "*airliners*" "*the airport*" "*Hooters Air executive*"
	Private plane (subtype 4): "*Marine One*" "*commercial flight*" "*private plane*"

Table 5: Event types co-occurred with *Air* entities

Besides, an ACE entity type actually can be divided into more cohesive subtypes according to similarity of background of entity, and such a subtype nearly always co-occur with unique event type. For example, the *Air* entities can be roughly divided into 4 subtypes: *Fighter plane*, *Spacecraft*, *Civil aviation* and *Private plane*, within which the *Fighter plane* entities all appear in *Attack* event mentions, and other three subtypes all co-occur with *Transport* events (see Table 5). This consistency of entities in a subtype is helpful to improve the precision of the event type predictor.

4.2 Role Consistency and Distribution

The same thing happens for entity-role combinations: entities of the same type normally play the same role, especially in the event mentions of the same type. For example, the *Population-Center* entities occur in ACE corpus as only 4 role types: *Place*, *Destination*, *Origin* and *Entity* respectively with conditional probability 0.615, 0.289, 0.093, 0.002 (see Figure 2). And They mainly appear in *Transport* event mentions as *Place*, and in *Attack* as *Destination*. Particularly the *Exploding* entities only occur as *Instrument* and *Artifact* respectively with the probability 0.986 and 0.014. They almost entirely appear in *Attack* events as *Instrument*.

	Evnt.<=5	5<Evnt.<=10	Evnt.>10
Freq. > 0	32	5	6
Freq. >10	38	3	2
Freq. >50	42	1	0

Table 6: Distribution of entity-role combination corresponding to different co-occurrence frequency

Table 6 gives the distributions of whole entity-role combinations in ACE corpus. We can find that there are 38 entity types (out of 43 in total) occur as less than 5 role types when the entity-role co-occurrence frequency is larger than 10. There are 42 (98%) when the frequency is larger than 50, and only 2 (e.g. *Individual*) when larger than 10. The distributions show that the instances of an entity type normally occur as consistent role, which is helpful for cross-entity inference to predict roles.

5 Cross-entity Approach

In this section we present our approach to using blind cross-entity inference to improve sentence-level ACE event extraction.

Our event extraction system extracts events independently for each sentence, because the definition of event mention constrains them to appear in the same sentence. Every sentence that at least involves one entity mention will be regarded as a candidate event mention, and a randomly selected entity mention from the candidate will be the staring of the whole extraction process. For the entity mention, information retrieval is used to mine its background knowledge from Web, and its type is determined by comparing the knowledge with those in training corpus. Based on the entity type, the extraction system performs our step-by-step cross-entity inference to predict the attributes of

the candidate event mention: trigger, event type, arguments, roles and whether or not being an event mention. The main frame of our event extraction system is shown in Figure 3, which includes both training and testing processes.

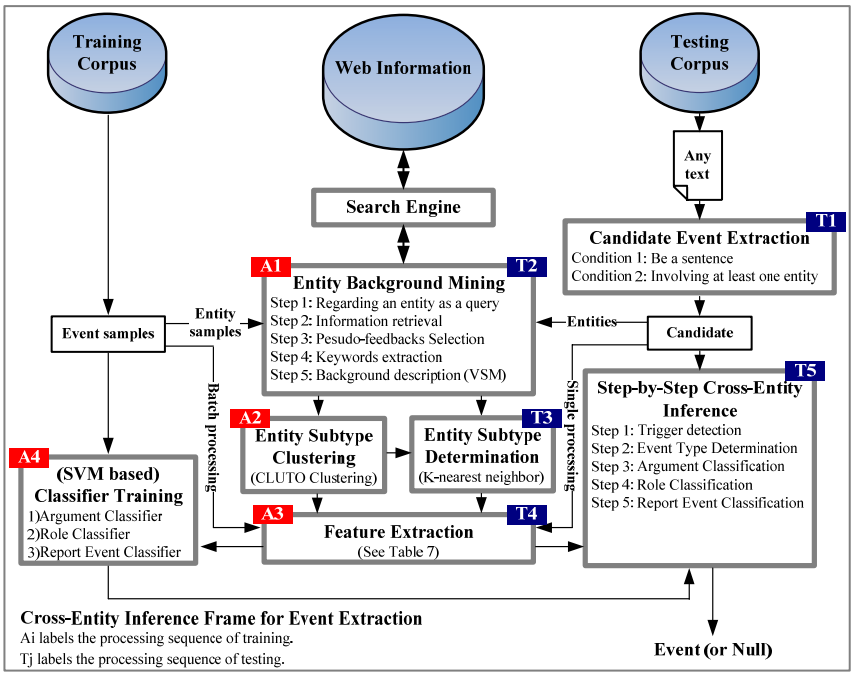

Figure 3. The frame of cross-entity inference for event extraction (including training and testing processes)

In the training process, for every entity type in the ACE training corpus, a clustering technique (CLUTO toolkit)[3] is used to divide it into different cohesive subtypes, each of which only contains the entities of the same background. For instance, the *Air* entities will be divided into *Fighter plane*, *Spacecraft*, *Civil aviation*, *Private plane*, etc (see Table 5). And for each subtype, we mine event mentions where this type of entities appear from ACE training corpus, and extract all the words which trigger the events to establish corresponding trigger list. Besides, a set of support vector machine (SVM) based classifiers are also trained:

- Argument Classifier: to distinguish arguments of a potential trigger from non-arguments[4];
- Role Classifier: to classify arguments by argument role;
- Reportable-Event Classifier (Trigger Classifier): Given entity types, a potential trigger, an event type, and a set of arguments, to determine whether there is a reportable event mention.

In the test process, for each candidate event mention, our event extraction system firstly predicts its triggers and event types: given an randomly selected entity mention from the candidate, the system determines the entity subtype it belonging to and the corresponding trigger list, and then all non-entity words in the candidate are scanned for a instance of triggers from the list. When an instance is found, the system tags the candidate as the event type that the most frequently co-occurs with the entity subtype in the events that triggered by the instance. Secondly the argument classifier is applied to the remaining mentions in the candidate; for any argument passing that classifier, the role classifier is used to assign a role to it. Finally, once all arguments have been assigned, the reportable-event classifier is applied to the candidate; if the result is successful, this event mention is reported.

5.1 Further Division of Entity Type

One of the most important pretreatments before our blind cross-entity inference is to divide the ACE entity type into more cohesive subtype. The greater consistency among backgrounds of entities in such a subtype might be good to improve the precision of cross-entity inference.

[3]http://oai.dtic.mil/oai/oai?verb=getRecord&metadataPrefix=html&identifier=ADA439508

[4] It is noteworthy that a sentence may include more than one event (more than one trigger). So it is necessary to distinguish arguments of a potential trigger from that of others.

For each ACE entity type, we collect all entity mentions of the type from training corpus, and regard each such mention as a query to retrieve the 50 most relevant documents from Web. Then we select 50 key words that the most weighted by TFIDF in the documents to roughly describe background of entity. After establishing the vector space model (VSM) for each entity mention of the type, we adopt a clustering toolkit (CLUTO) to further divide the mentions into different subtypes. Finally, for each subtype, we describe its centroid by using 100 key words which the most frequently occurred in relevant documents of entities of the subtype.

In the test process, for an entity mention in a candidate event mention, we determine its type by comparing its background against all centroids of subtypes in training corpus, and the subtype whose centroid has the most Cosine similarity with the background will be assigned to the entity. It is noteworthy that global information from the Web is only used to measure the entity-background consistency and not directly in the inference process. Thus our event extraction system actually still performs a sentence-level inference based on local information.

5.2 Cross-Entity Inference

Our event extraction system adopts a step-by-step cross-entity inference to predict event. As discussed above, the first step is to determine the trigger in a candidate event mention and tag its event type based on consistency of entity type. Given the domain of event mention that restrained by the known trigger, event type and entity subtype, the second step is to distinguish the most probable arguments that co-occurring in the domain from the non-arguments. Then for each of the arguments, the third step can use the co-occurring arguments in the domain as important contexts to predict its role. Finally, the inference process determines whether the candidate is a reportable event mention according to a confidence coefficient. In the following sections, we focus on introducing the three classifiers: argument classifier, role classifier and reportable-event classifier.

5.2.1 Cross-Entity Argument Classifier

For a candidate event mention, the first step gives its event type, which roughly restrains the domain of event mentions where the arguments of the candidate might co-occur. On the basis, given an entity mention in the candidate and its type (see the pretreatment process in section 5.1), the argument classifier could predict whether other entity mentions co-occur with it in such a domain, if yes, all the mentions will be the arguments of the candidate. In other words, if we know an entity of a certain type participates in some event, we will think of what entities also should participate in the event. For instance, when we know a *defendant* goes on trial, we can conclude that the *judge*, *lawyer* and *witness* should appear in *court*.

Argument Classifier
Feature 1: an event type (an event-mention domain)
Feature 2: an entity subtype
Feature 3: entity-subtype co-occurrence in domain
Feature 4: distance to trigger
Feature 5: distances to other arguments
Feature 6: co-occurrence with trigger in clause
Role Classifier
Feature 1 and ***Feature 2***
Feature 7: entity-subtypes of arguments
Reportable-Event Classifier
Feature 1
Feature 8: confidence coefficient of trigger in domain
Feature 9: confidence coefficient of role in domain

Table 7: Features selected for SVM-based cross-entity classifiers

A SVM-based argument classifier is used to determine arguments of candidate event mention. Each feature of this classifier is the conjunction of:

- The subtype of an entity
- The event type we are trying to assign an argument to
- A binary indicator of whether this entity subtype co-occurs with other subtypes in such an event type (There are 266 entity subtypes, and so 266 features for each instance)

Some minor features, such as another binary indicator of whether arguments co-occur with trigger in the same clause (see Table 7).

5.2.2 Cross-Entity Role Classifier

For a candidate event mention, the arguments that given by the second step (argument classifier) provide important contextual information for predicting what role the local entity (also one of the arguments) takes on. For instance, when *citizens* (Arg1) co-occur with *terrorist* (Arg2), most likely the role of Arg1 is *Victim*. On the basis, with the help of event type, the prediction might be more

precise. For instance, if the Arg1 and Arg2 co-occur in an *Attack* event mention, we will have more confidence in the *Victim* role of Arg1.

Besides, as discussed in section 4, entities of the same type normally take on the same role in similar events, especially when they co-occur with similar arguments in the events (see Table 2). Therefore, all instances of co-occurrence model {entity subtype, event type, arguments} in training corpus could provide effective evidences for predicting the role of argument in the candidate event mention. Based on this, we trained a SVM-based role classifier which uses following features:

- Feature 1 and Feature 2 (see Table 7)
- Given the event domain that restrained by the entity and event types, an indicator of what subtypes of arguments appear in the domain. (266 entity subtypes make 266 features for each instance)

5.2.3 Reportable-Event Classifier

At this point, there are still two issues need to be resolved. First, some triggers are common words which often mislead the extraction of candidate event mention, such as "*it*", "*this*", "*what*", etc. These words only appear in a few event mentions as trigger, but when they once appear in trigger list, a large quantity of noisy sentences will be regarded as candidates because of their commonness in sentences. Second, some arguments might be tagged as more than one role in specific event mentions, but as ACE event guideline, one argument only takes on one role in a sentence. So we need to remove those with low confidence.

A confidence coefficient is used to distinguish the correct triggers and roles from wrong ones. The coefficient calculate the frequency of a trigger (or a role) appearing in specific domain of event mentions and that in whole training corpus, then combines them to represent its confidence degree, just like TFIDF algorithm. Thus, the more typical triggers (or roles) will be given high confidence. Based on the coefficient, we use a SVM-based classifier to determine the reportable events. Each feature of this classifier is the conjunction of:

- An event type (domain of event mentions)
- Confidence coefficients of triggers in domain
- Confidence coefficients of roles in the domain.

6 Experiments

We followed Liao (2010)'s evaluation and randomly select 10 newswire texts from the ACE 2005 training corpus as our development set, which is used for parameter tuning, and then conduct a blind test on a separate set of 40 ACE 2005 newswire texts. We use the rest of the ACE training corpus (549 documents) as training data for our event extraction system.

To compare with the reported work on cross-event inference (Liao, 2010) and its sentence-level baseline system, we cross-validate our method on 10 separate sets of 40 ACE texts, and report the optimum, worst and mean performances (see Table 8) on the data by using Precision (P), Recall (R) and F-measure (F). In addition, we also report the performance of two human annotators on 40 ACE newswire texts (a random blind test set): one knows the rules of event extraction; the other knows nothing about it.

6.1 Main Results

From the results presented in Table 8, we can see that using the cross-entity inference, we can improve the F score of sentence-level event extraction for trigger classification by 8.59%, argument classification by 11.86%, and role classification by 11.9% (mean performance). Compared to the cross-event inference, we gains 2.87% improvement for argument classification, and 3.81% for role classification (mean performance). Especially, our worst results also have better performances than cross-event inference.

Nonetheless, the cross-entity inference has worse F score for trigger determination. As we can see, the low Recall score weaken its F score (see Table 8). Actually, we select the sentence which at least includes one entity mention as candidate event mention, but lots of event mentions in ACE never include any entity mention. Thus we have missed some mentions at the starting of inference process.

In addition, the annotator who knows the rules of event extraction has a similar performance trend with systems: high for trigger classification, middle for argument classification, and low for role classification (see Table 8). But the annotator who never works in this field obtains a different trend: higher performance for argument classification. This phenomenon might prove that the step-by-step inference is not the only way to predicate event mention because human can determine arguments without considering triggers and event types.

Performance / System/Human	Trigger (%)			Argument (%)			Role (%)		
	P	R	F	P	R	F	P	R	F
Sentence-level baseline	67.56	53.54	59.74	46.45	37.15	41.29	41.02	32.81	36.46
Cross-event inference	**68.71**	**68.87**	**68.79**	**50.85**	**49.72**	**50.28**	**45.06**	**44.05**	**44.55**
Cross-entity inference (optimum)	73.4	66.2	69.61	56.96	55.1	56	49.3	46.59	47.9
Cross-entity inference (worst)	71.3	64.17	66.1	51.28	50.3	50.78	46.3	44.3	45.28
Cross-entity inference (mean)	**72.9**	**64.3**	**68.33**	**53.4**	**52.9**	**53.15**	**51.6**	**45.5**	**48.36**
Human annotation 1 (blind)	58.9	59.1	59.0	62.6	65.9	64.2	50.3	57.69	53.74
Human annotation 2 (know rules)	74.3	76.2	75.24	68.5	75.8	71.97	61.3	68.8	64.86

Table 8: Overall performance on blind test data

6.2 Influence of Clustering on Inference

A main part of our blind inference system is the entity-type consistency detection, which relies heavily on the correctness of entity clustering and similarity measurement. In training, we used CLUTO clustering toolkit to automatically generate different types of entities based on their background-similarities. In testing, we use K-nearest neighbor algorithm to determine entity type.

Fighter plane (subtype 1 in ***Air*** entities): "*warplanes*" "*allied aircraft*" "*U.S. jets*" "*a-10 tank killer*" "*b-1 bomber*" "*a-10 warthog*" "*f-14 aircraft*" "*apache helicopter*" ***"terrorist" "Saddam" "Saddam Hussein" "Baghdad"…***

Table 9: Noises in subtype 1 of "*Air*" entities (The blod fonts are noises)

We obtained 129 entity subtypes from training set. By randomly inspecting 10 subtypes, we found nearly every subtype involves no less than 19.2% noises. For example, the subtype 1 of "*Air*" in Table 5 lost the entities of "*MiGs*" and "*enemy planes*", but involved "*terrorist*", "*Saddam"*, etc (See Table 9). Therefore, we manually clustered the subtypes and retry the step-by-step cross-entity inference. The results (denoted as "Visible 1") are shown in Table 10, within which, we additionally show the performance of the inference on the rough entity types provided by ACE (denoted as "Visible 2"), such as the type of "*Air*", "*Population-Center*", "*Exploding*", etc., which normally can be divided into different more cohesive subtypes. And the "Blind" in Table 10 denotes the performances on our subtypes obtained by CLUTO.

It is surprised that the performances (see Table 10, F-score) on "Visible 1" entity subtypes are just a little better than "Blind" inference. So it seems that the noises in our blind entity types (CLUTO clusters) don't hurt the inference much. But by re-inspecting the "Visible 1" subtypes, we found that their granularities are not enough small: the 89 manual entity clusters actually can be divided into more cohesive subtypes. So the improvements of inference on noise-free "Visible 1" subtypes are partly offset by loss on weakly consistent entities in the subtypes. It can be proved by the poor performances on "Visible 2" subtypes which are much more general than "Visible 1". Therefore, a reasonable clustering method is important in our inference process.

F-score	Trigger	Argument	Role
Blind	68.33	53.15	48.36
Visible 1	69.15	53.65	48.83
Visible 2	51.34	43.40	39.95

Table 10: Performances on visible VS blind

7 Conclusions and Future Work

We propose a blind cross-entity inference method for event extraction, which well uses the consistency of entity mention to achieve sentence-level trigger and argument (role) classification. Experiments show that the method has better performance than cross-document and cross-event inferences in ACE event extraction.

The inference presented here only considers the helpfulness of entity types of arguments to role classification. But as a superior feature, contextual roles can provide more effective assistance to role determination of local argument. For instance, when an *Attack* argument appears in a sentence, a *Target* might be there. So if we firstly identify simple roles, such as the condition that an argument has only a single role, and then use the roles as priori knowledge to classify hard ones, may be able to further improve performance.

Peeling Back the Layers: Detecting Event Role Fillers in Secondary Contexts

Abstract

The goal of our research is to improve event extraction by learning to identify secondary role filler contexts in the absence of event keywords. We propose a multi-layered event extraction architecture that progressively "zooms in" on relevant information. Our extraction model includes a document genre classifier to recognize event narratives, two types of sentence classifiers, and noun phrase classifiers to extract role fillers. These modules are organized as a pipeline to gradually zero in on event-related information. We present results on the MUC-4 event extraction data set and show that this model performs better than previous systems.

1 Introduction

Event extraction is an information extraction (IE) task that involves identifying the role fillers for events in a particular domain. For example, the Message Understanding Conferences (MUCs) challenged NLP researchers to create event extraction systems for domains such as terrorism (e.g., to identify the perpetrators, victims, and targets of terrorism events) and management succession (e.g., to identify the people and companies involved in corporate management changes).

Most event extraction systems use either a learning-based classifier to label words as role fillers, or lexico-syntactic patterns to extract role fillers from pattern contexts. Both approaches, however, generally tackle event recognition and role filler extraction at the same time. In other words, most event extraction systems primarily recognize contexts that explicitly refer to a relevant event. For example, a system that extracts information about murders will recognize expressions associated with murder (e.g., "killed", "assassinated", or "shot to death") and extract role fillers from the surrounding context. But many role fillers occur in contexts that do not explicitly mention the event, and those fillers are often overlooked. For example, the perpetrator of a murder may be mentioned in the context of an arrest, an eyewitness report, or speculation about possible suspects. Victims may be named in sentences that discuss the aftermath of the event, such as the identification of bodies, transportation of the injured to a hospital, or conclusions drawn from an investigation. We will refer to these types of sentences as "secondary contexts" because they are generally not part of the main event description. Discourse analysis is one option to explicitly link these secondary contexts to the event, but discourse modelling is itself a difficult problem.

The goal of our research is to improve event extraction by learning to identify secondary role filler contexts in the absence of event keywords. We create a set of classifiers to recognize *role-specific contexts* that suggest the presence of a likely role filler regardless of whether a relevant event is mentioned or not. For example, our model should recognize that a sentence describing an arrest probably includes a reference to a perpetrator, even though the crime itself is reported elsewhere.

Extracting information from these secondary contexts can be risky, however, unless we know that the larger context is discussing a relevant event. To

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1137–1147,
Portland, Oregon, June 19-24, 2011.

address this, we adopt a two-pronged strategy for event extraction that handles *event narrative* documents differently from other documents. We define an event narrative as an article whose main purpose is to report the details of an event. We apply the *role-specific sentence classifiers* only to event narratives to aggressively search for role fillers in these stories. However, other types of documents can mention relevant events too. The MUC-4 corpus, for example, includes interviews, speeches, and terrorist propaganda that contain information about terrorist events. We will refer to these documents as *fleeting reference* texts because they mention a relevant event somewhere in the document, albeit briefly. To ensure that relevant information is extracted from all documents, we also apply a conservative extraction process to every document to extract facts from explicit event sentences.

Our complete event extraction model, called TIER, incorporates both document genre and role-specific context recognition into 3 layers of analysis: document analysis, sentence analysis, and noun phrase (NP) analysis. At the top level, we train a text genre classifier to identify event narrative documents. At the middle level, we create two types of sentence classifiers. *Event sentence classifiers* identify sentences that are associated with relevant events, and *role-specific context classifiers* identify sentences that contain possible role fillers irrespective of whether an event is mentioned. At the lowest level, we use *role filler extractors* to label individual noun phrases as role fillers. As documents pass through the pipeline, they are analyzed at different levels of granularity. All documents pass through the event sentence classifier, and event sentences are given to the role filler extractors. Documents identified as event narratives additionally pass through role-specific sentence classifiers, and the role-specific sentences are also given to the role filler extractors. This multi-layered approach creates an event extraction system that can discover role fillers in a variety of different contexts, while maintaining good precision.

In the following sections, we position our research with respect to related work, present the details of our multi-layered event extraction model, and show experimental results for five event roles using the MUC-4 data set.

2 Related Work

Some event extraction data sets only include documents that describe relevant events (e.g., well-known data sets for the domains of corporate acquisitions (Freitag, 1998b; Freitag and McCallum, 2000; Finn and Kushmerick, 2004), job postings (Califf and Mooney, 2003; Freitag and McCallum, 2000), and seminar announcements (Freitag, 1998b; Ciravegna, 2001; Chieu and Ng, 2002; Finn and Kushmerick, 2004; Gu and Cercone, 2006). But many IE data sets present a more realistic task where the IE system must determine whether a relevant event is present in the document, and if so, extract its role fillers. Most of the Message Understanding Conference data sets represent this type of event extraction task, containing (roughly) a 50/50 mix of relevant and irrelevant documents (e.g., MUC-3, MUC-4, MUC-6, and MUC-7 (Hirschman, 1998)). Our research focuses on this setting where the event extraction system is not assured of getting only relevant documents to process.

Most event extraction models can be characterized as either pattern-based or classifier-based approaches. Early event extraction systems used handcrafted patterns (e.g., (Appelt et al., 1993; Lehnert et al., 1991)), but more recent systems generate patterns or rules automatically using supervised learning (e.g., (Kim and Moldovan, 1993; Riloff, 1993; Soderland et al., 1995; Huffman, 1996; Freitag, 1998b; Ciravegna, 2001; Califf and Mooney, 2003)), weakly supervised learning (e.g., (Riloff, 1996; Riloff and Jones, 1999; Yangarber et al., 2000; Sudo et al., 2003; Stevenson and Greenwood, 2005)), or unsupervised learning (e.g., (Shinyama and Sekine, 2006; Sekine, 2006)). In addition, many classifiers have been created to sequentially label event role fillers in a sentence (e.g., (Freitag, 1998a; Chieu and Ng, 2002; Finn and Kushmerick, 2004; Li et al., 2005; Yu et al., 2005)). Research has also been done on relation extraction (e.g., (Roth and Yih, 2001; Zelenko et al., 2003; Bunescu and Mooney, 2007)), but that task is different from event extraction because it focuses on isolated relations rather than template-based event analysis.

Most event extraction systems scan a text and search small context windows using patterns or a classifier. However, recent work has begun to ex-

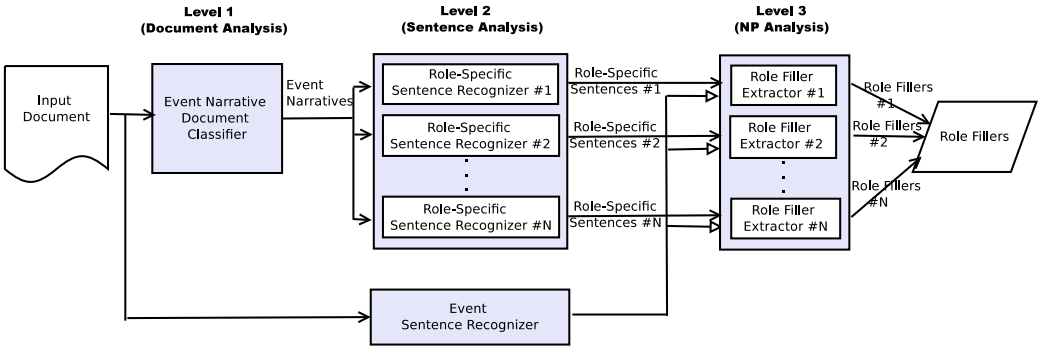

Figure 1: TIER: A Multi-Layered Architecture for Event Extraction

plore more global approaches. (Maslennikov and Chua, 2007) use discourse trees and local syntactic dependencies in a pattern-based framework to incorporate wider context. Ji and Grishman (2008) enforce event role consistency across different documents. (Liao and Grishman, 2010) use cross-event inference to help with the extraction of role fillers shared across events. And there have been several recent IE models that explore the idea of identifying relevant sentences to gain a wider contextual view and then extracting role fillers. (Gu and Cercone, 2006) created HMMs to first identify relevant sentences, but their research focused on eliminating redundant extractions and worked with seminar announcements, where the system was only given relevant documents. (Patwardhan and Riloff, 2007) developed a system that learns to recognize event sentences and uses patterns that have a *semantic affinity* for an event role to extract role fillers. GLACIER (Patwardhan and Riloff, 2009) jointly considers sentential evidence and phrasal evidence in a unified probabilistic framework. Our research follows in the same spirit as these approaches by performing multiple levels of text analysis. But our event extraction model includes two novel contributions: (1) we develop a set of *role-specific* sentence classifiers to learn to recognize *secondary contexts* associated with each type of event role , and (2) we exploit text genre to incorporate a third level of analysis that enables the system to aggressively hunt for role fillers in documents that are event narratives. In Section 5, we compare the performance of our model with both the GLACIER system and Patwardhan & Riloff's semantic affinity model.

3 A Multi-Layered Approach to Event Extraction

The main idea behind our approach is to analyze documents at multiple levels of granularity in order to identify role fillers that occur in different types of contexts. Our event extraction model progressively "zooms in" on relevant information by first identifying the document type, then identifying sentences that are likely to contain relevant information, and finally analyzing individual noun phrases to identify role fillers. The key advantage of this architecture is that it allows us to search for information using two different principles: (1) we look for contexts that directly refer to the event, as per most traditional event extraction systems, and (2) we look for secondary contexts that are often associated with a specific type of role filler. Identifying these *role-specific contexts* can root out important facts would have been otherwise missed. Figure 1 shows the multi-layered pipeline of our event extraction system.

An important aspect of our model is that two different strategies are employed to handle documents of different types. The event extraction task is to find any description of a relevant event, even if the event is not the topic of the article.[1] Consequently, all documents are given to the event sentence recognizers and their mission is to identify any sentence that mentions a relevant event. This path through the pipeline is conservative because information is extracted only from event sentences, but all documents are processed, including stories that contain only a fleeting reference to a relevant event.

[1]Per the MUC-4 task definition (MUC-4 Proceedings, 1992).

The second path through the pipeline performs additional processing for documents that belong to the event narrative text genre. For event narratives, we assume that most of the document discusses a relevant event so we can more aggressively hunt for event-related information in secondary contexts.

In this section, we explain how we create the two types of sentence classifiers and the role filler extractors. We will return to the issue of document genre and the event narrative classifier in Section 4.

3.1 Sentence Classification

We have argued that event role fillers commonly occur in two types of contexts: event contexts and role-specific secondary contexts. For the purposes of this research, we use sentences as our definition of a "context", although there are obviously many other possible definitions. An *event context* is a sentence that describes the actual event. A *secondary context* is a sentence that provides information related to an event but in the context of other activities that precede or follow the event.

For both types of classifiers, we use exactly the same feature set, but we train them in different ways. The MUC-4 corpus used in our experiments includes a training set consisting of documents and answer keys. Each document that describes a relevant event has answer key templates with the role fillers (*answer key strings*) for each event. To train the event sentence recognizer, we consider a sentence to be a positive training instance if it contains one or more answer key strings from any of the event roles. This produced 3,092 positive training sentences. All remaining sentences that do not contain any answer key strings are used as negative instances. This produced 19,313 negative training sentences, yielding a roughly 6:1 ratio of negative to positive instances.

There is no guarantee that a classifier trained in this way will identify event sentences, but our hypothesis was that training across all of the event roles together would produce a classifier that learns to recognize general event contexts. This approach was also used to train GLACIER's sentential event recognizer (Patwardhan and Riloff, 2009), and they demonstrated that this approach worked reasonably well when compared to training with event sentences labelled by human judges.

The main contribution of our work is introducing additional *role-specific sentence classifiers* to seek out role fillers that appear in less obvious secondary contexts. We train a set of role-specific sentence classifiers, one for each type of event role. Every sentence that contains a role filler of the appropriate type is used as a positive training instance. Sentences that do not contain any answer key strings are negative instances.[2] In this way, we force each classifier to focus on the contexts specific to its particular event role. We expect the role-specific sentence classifiers to find some secondary contexts that the event sentence classifier will miss, although some sentences may be classified as both.

Using all possible negative instances would produce an extremely skewed ratio of negative to positive instances. To control the skew and keep the training set-up consistent with the event sentence classifier, we randomly choose from the negative instances to produce a 6:1 ratio of negative to positive instances.

Both types of classifiers use an SVM model created with SVMlin (Keerthi and DeCoste, 2005), and exactly the same features. The feature set consists of the unigrams and bigrams that appear in the training texts, the semantic class of each noun phrase[3], plus a few additional features to represent the tense of the main verb phrase in the sentence and whether the document is long (> 35 words) or short (< 5 words). All of the feature values are binary.

3.2 Role Filler Extractors

Our extraction model also includes a set of role filler extractors, one per event role. Each extractor receives a sentence as input and determines which noun phrases (NPs) in the sentence are fillers for the event role. To train an SVM classifier, noun phrases corresponding to answer key strings for the event role are positive instances. We randomly choose among all noun phrases that are not in the answer keys to create a 10:1 ratio of negative to positive instances.

[2] We intentionally do not use sentences that contain fillers for competing event roles as negative instances because sentences often contain multiple role fillers of different types (e.g., a weapon may be found near a body). Sentences without any role fillers are certain to be irrelevant contexts.

[3] We used the Sundance parser (Riloff and Phillips, 2004) to identify noun phrases and assign semantic class labels.

The feature set for the role filler extractors is much richer than that of the sentence classifiers because they must carefully consider the local context surrounding a noun phrase. We will refer to the noun phrase being labelled as the *targeted NP*. The role filler extractors use three types of features:

Lexical features: we represent four words to the left and four words to the right of the targeted NP, as well as the head noun and modifiers (adjectives and noun modifiers) of the targeted NP itself.

Lexico-syntactic patterns: we use the AutoSlog pattern generator (Riloff, 1993) to automatically create lexico-syntactic patterns around each noun phrase in the sentence. These patterns are similar to dependency relations in that they typically represent the syntactic role of the NP with respect to other constituents (e.g., subject-of, object-of, and noun arguments).

Semantic features: we use the Stanford NER tagger (Finkel et al., 2005) to determine if the targeted NP is a named entity, and we use the Sundance parser (Riloff and Phillips, 2004) to assign semantic class labels to each NP's head noun.

4 Event Narrative Document Classification

One of our goals was to explore the use of *document genre* to permit more aggressive strategies for extracting role fillers. In this section, we first present an analysis of the MUC-4 data set which reveals the distribution of event narratives in the corpus, and then explain how we train a classifier to automatically identify event narrative stories.

4.1 Manual Analysis

We define an *event narrative* as an article whose main focus is on reporting the details of an event. For the purposes of this research, we are only concerned with events that are relevant to the event extraction task (i.e., terrorism). An *irrelevant document* is an article that does not mention any relevant events. In between these extremes is another category of documents that briefly mention a relevant event, but the event is not the focus of the article. We will refer to these documents as *fleeting reference* documents. Many of the fleeting reference documents in the MUC-4 corpus are transcripts of interviews, speeches, or terrorist propaganda communiques that refer to a terrorist event and mention at least one role filler, but within a discussion about a different topic (e.g., the political ramifications of a terrorist incident).

To gain a better understanding of how we might create a system to automatically distinguish event narrative documents from fleeting reference documents, we manually labelled the 116 relevant documents in our tuning set. This was an informal study solely to help us understand the nature of these texts.

	# of Event Narratives	# of Fleeting Ref. Docs	Acc
Gold Standard	54	62	
Heuristics	40	55	.82

Table 1: Manual Analysis of Document Types

The first row of Table 1 shows the distribution of event narratives and fleeting references based on our "gold standard" manual annotations. We see that more than half of the relevant documents (62/116) are *not* focused on reporting a terrorist event, even though they contain information about a terrorist event somewhere in the document.

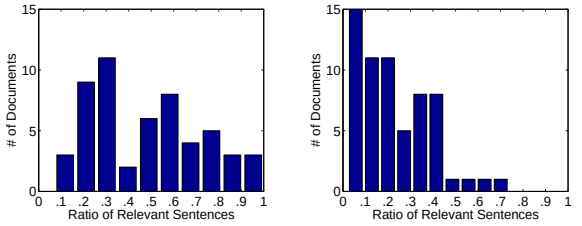
4.2 Heuristics for Event Narrative Identification

Our goal is to train a document classifier to automatically identify event narratives. The MUC-4 answer keys reveal which documents are relevant and irrelevant with respect to the terrorism domain, but they do not tell us which relevant documents are event narratives and which are fleeting reference stories. Based on our manual analysis of the tuning set, we developed several heuristics to help separate them.

We observed two types of clues: the location of the relevant information, and the density of relevant information. First, we noticed that event narratives tend to mention relevant information within the first several sentences, whereas fleeting reference texts usually mention relevant information only in the middle or end of the document. Therefore our first heuristic requires that an event narrative mention a role filler within the first 7 sentences.

Second, event narratives generally have a higher density of relevant information. We use several criteria to estimate information density because a single criterion was inadequate to cover different sce-

narios. For example, some documents mention role fillers throughout the document. Other documents contain a high concentration of role fillers in some parts of the document but no role fillers in other parts. We developed three density heuristics to account for different situations. All of these heuristics count distinct role fillers. The first density heuristic requires that more than 50% of the sentences contain at least one role filler ($\frac{|RelSents|}{|AllSents|} > 0.5$) . Figure 2 shows histograms for different values of this ratio in the event narrative (a) vs. the fleeting reference documents (b). The histograms clearly show that documents with a high ($> 50\%$) ratio are almost always event narratives.



(a) (b)

Figure 2: Histograms of Density Heuristic #1 in Event Narratives (a) vs. Fleeting References (b).

A second density heuristic requires that the ratio of different *types* of roles filled to sentences be $>$ 50% ($\frac{|Roles|}{|AllSents|} > 0.5$). A third density heuristic requires that the ratio of distinct role *fillers* to sentences be $> 70\%$ ($\frac{|RoleFillers|}{|AllSents|} > 0.7$). If any of these three criteria are satisfied, then the document is considered to have a high density of relevant information.[4]

We use these heuristics to label a document as an event narrative if: (1) it has a high density of relevant information, and (2) it mentions a role filler within the first 7 sentences.

The second row of Table 1 shows the performance of these heuristics on the tuning set. The heuristics correctly identify $\frac{40}{54}$ event narratives and $\frac{55}{62}$ fleeting reference stories, to achieve an overall accuracy of 82%. These results are undoubtedly optimistic because the heuristics were derived from analysis of the tuning set. But we felt confident enough to move forward with using these heuristics to generate training data for an event narrative classifier.

4.3 Event Narrative Classifier

The heuristics above use the answer keys to help determine whether a story belongs to the event narrative genre, but our goal is to create a classifier that can identify event narrative documents without the benefit of answer keys. So we used the heuristics to automatically create training data for a classifier by labelling each relevant document in the training set as an event narrative or a fleeting reference document. Of the 700 relevant documents, 292 were labeled as event narratives. We then trained a document classifier using the 292 event narrative documents as positive instances and all irrelevent training documents as negative instances. The 308 relevant documents that were not identified as event narratives were discarded to minimize noise (i.e., we estimate that our heuristics fail to identify 25% of the event narratives). We then trained an SVM classifier using bag-of-words (unigram) features.

Table 2 shows the performance of the event narrative classifier on the manually labeled tuning set. The classifier identified 69% of the event narratives with 63% precision. Overall accuracy was 81%.

Recall	Precision	Accuracy
.69	.63	.81

Table 2: Event Narrative Classifier Results

At first glance, the performance of this classifier is mediocre. However, these results should be interpreted loosely because there is not always a clear dividing line between event narratives and other documents. For example, some documents begin with a specific event description in the first few paragraphs but then digress to discuss other topics. Fortunately, it is not essential for TIER to have a perfect event narrative classifier since all documents will be processed by the event sentence recognizer anyway. The recall of the event narrative classifier means that nearly 70% of the event narratives will get additional scrutiny, which should help to find additional role fillers. Its precision of 63% means that some documents that are not event narratives will also get additional scrutiny, but information will be extracted only if both the role-specific sentence recognizer and NP extractors believe they have found

[4]Heuristic #1 covers most of the event narratives.

Table 3: Experimental results, reported as Precision/Recall/F-score

something relevant.

4.4 Domain-relevant Document Classifier

For comparison's sake, we also created a document classifier to identify *domain-relevant* documents. That is, we trained a classifier to determine whether a document is relevant to the domain of terrorism, irrespective of the style of the document. We trained an SVM classifier with the same bag-of-words feature set, using all relevant documents in the training set as positive instances and all irrelevant documents as negative instances. We use this classifier for several experiments described in the next section.

5 Evaluation

5.1 Data Set and Metrics

We evaluated our approach on a standard benchmark collection for event extraction systems, the MUC-4 data set (MUC-4 Proceedings, 1992). The MUC-4 corpus consists of 1700 documents with associated answer key templates. To be consistent with previously reported results on this data set, we use the 1300 DEV documents for training, 200 documents (TST1+TST2) as a tuning set and 200 documents (TST3+TST4) as the test set. Roughly half of the documents are relevant (i.e., they mention at least 1 terrorist event) and the rest are irrelevant.

We evaluate our system on the five MUC-4 "string-fill" event roles: *perpetrator individuals*, *perpetrator organizations*, *physical targets*, *victims* and *weapons*. The complete IE task involves template generation, which is complex because many documents have multiple templates (i.e., they discuss multiple events). Our work focuses on extracting individual facts and not on template generation per se (e.g., we do not perform coreference resolution or event tracking). Consequently, our evaluation follows that of other recent work and evaluates the accuracy of the extractions themselves by matching the head nouns of extracted NPs with the head nouns of answer key strings (e.g., "armed guerrillas" is considered to match "guerrillas")[5]. Our results are reported as Precision/Recall/F(1)-score for each event role separately. We also show an overall average for all event roles combined.[6]

5.2 Baselines

As baselines, we compare the performance of our IE system with three other event extraction systems. The first baseline is AutoSlog-TS (Riloff, 1996), which uses domain-specific extraction patterns. AutoSlog-TS applies its patterns to every sentence in every document, so does not attempt to explicitly identify relevant sentences or documents. The next two baselines are more recent systems: the (Patwardhan and Riloff, 2007) *semantic affinity* model and the (Patwardhan and Riloff, 2009) GLACIER system. The *semantic affinity* approach

[5]Pronouns were discarded since we do not perform coreference resolution. Duplicate extractions with the same head noun were counted as one hit or one miss.

[6]We generated the Average scores ourselves by macro-averaging over the scores reported for the individual event roles.

explicitly identifies event sentences and uses patterns that have a semantic affinity for an event role to extract role fillers. GLACIER is a probabilistic model that incorporates both phrasal and sentential evidence jointly to label role fillers.

The first 3 rows in Table 3 show the results for each of these systems on the MUC-4 data set. They all used the same evaluation criteria as our results.

5.3 Experimental Results

The lower portion of Table 3 shows the results of a variety of event extraction models that we created using different components of our system. The **AllSent** row shows the performance of our Role Filler Extractors when applied to every sentence in every document. This system produced high recall, but precision was consistently low.

The **EventSent** row shows the performance of our Role Filler Extractors applied only to the *event sentences* identified by our event sentence classifier. This boosts precision across all event roles, but with a sharp reduction in recall. We see a roughly 20 point swing from recall to precision. These results are similar to GLACIER's results on most event roles, which isn't surprising because GLACIER also incorporates event sentence identification.

The **RoleSent** row shows the results of our Role Filler Extractors applied only to the *role-specific sentences* identified by our classifiers. We see a 12-13 point swing from recall to precision compared to the **AllSent** row. This result is consistent with our hypothesis that many role fillers exist in role-specific contexts that are not event sentences. As expected, extracting facts from role-specific contexts that do not necessarily refer to an event is less reliable. The **EventSent+RoleSent** row shows the results when information is extracted from both types of sentences. We see slightly higher recall, which confirms that one set of extractions is not a strict subset of the other, but precision is still relatively low.

The next set of experiments incorporates document classification as the third layer of text analysis. The **DomDoc/EventSent+DomDoc/RoleSent** row shows the results of applying both types of sentence classifiers only to documents identified as domain-relevant by the Domain-relevant Document (**DomDoc**) Classifier described in Section 4.4. Extracting information only from domain-relevant documents improves precision by $+6$, but also sacrifices 8 points of recall.

The **EventSent** row reveals that information found in event sentences has the highest precision, even without relying on document classification. We concluded that evidence of an event sentence is probably sufficient to warrant role filler extraction irrespective of the style of the document. As we discussed in Section 4, many documents contain only a fleeting reference to an event, so it is important to be able to extract information from those isolated event descriptions as well. Consequently, we created a system, **EventSent+DomDoc/RoleSent**, that extracts information from event sentences in *all* documents, but extracts information from role-specific sentences only if they appear in a domain-relevant document. This architecture captured the best of both worlds: recall improved from 58% to 65% with only a one point drop in precision.

Finally, we evaluated the idea of using document *genre* as a filter instead of domain relevance. The last row, **EventSent+ENarrDoc/RoleSent**, shows the results of our final architecture which extracts information from event sentences in all documents, but extracts information from role-specific sentences only in Event Narrative documents. This architecture produced the best F1 score of 56. This model increases precision by an additional 4 points and produces the best balance of recall and precision.

Overall, TIER's multi-layered extraction architecture produced higher F1 scores than previous systems on four of the five event roles. The improved recall is due to the additional extractions from secondary contexts. The improved precision comes from our two-pronged strategy of treating event narratives differently from other documents. TIER aggressively searches for extractions in event narrative stories but is conservative and extracts information only from event sentences in all other documents.

5.4 Analysis

We looked through some examples of TIER's output to try to gain insight about its strengths and limitations. TIER's role-specific sentence classifiers did correctly identify some sentences containing role fillers that were not classified as event sentences. Several examples are shown below, with the role

fillers in italics:

(1) "The victims were identified as *David Lecky*, director of the Columbus school, and *James Arthur Donnelly*."

(2) "There were *seven children*, including *four of the Vice President's children*, in the home at the time."

(3) "*The woman* fled and sought refuge inside the facilities of the Salvadoran Alberto Masferrer University, where she took a group of *students* as hostages, threatening them with *hand grenades*."

(4) "The FMLN stated that *several homes* were damaged and that animals were killed in the surrounding hamlets and villages."

The first two sentences identify victims, but the terrorist event itself was mentioned earlier in the document. The third sentence contains a perpetrator (*the woman*), victims (*students*), and weapons (*hand grenades*) in the context of a hostage situation after the main event (a bus attack), when the perpetrator escaped. The fourth sentence describes incidental damage to civilian homes following clashes between government forces and guerrillas.

However there is substantial room for improvement in each of TIER's subcomponents, and many role fillers are still overlooked. One reason is that it can be difficult to recognize acts of terrorism. Many sentences refer to a potentially relevant subevent (e.g., injury or physical damage) but recognizing that the event is part of a terrorist incident depends on the larger discourse. For example, consider the examples below that TIER did not recognize as relevant sentences:

(5) "Later, *two individuals* in a Chevrolet Opala automobile pointed AK rifles at the students, fired some shots, and quickly drove away."

(6) "Meanwhile, national police members who were dressed in civilian clothes seized university students *Hugo Martinez* and *Raul Ramirez*, who are still missing."

(7) "*All labor union offices* in San Salvador were looted."

In the first sentence, the event is described as someone pointing rifles at people and the perpetrators are referred to simply as individuals. There are no strong keywords in this sentence that reveal this is a terrorist attack. In the second sentence, police are being accused of state-sponsored terrorism when they seize civilians. The verb "seize" is common in this corpus, but usually refers to the seizing of weapons or drug stashes, not people. The third sentence describes a looting subevent. Acts of looting and vandalism are not usually considered to be terrorism, but in this article it is in the context of accusations of terrorist acts by government officials.

6 Conclusions

We have presented a new approach to event extraction that uses three levels of analysis: document genre classification to identify event narrative stories, two types of sentence classifiers, and noun phrase classifiers. A key contribution of our work is the creation of role-specific sentence classifiers that can detect role fillers in secondary contexts that do not directly refer to the event. Another important aspect of our approach is a two-pronged strategy that handles event narratives differently from other documents. TIER aggressively hunts for role fillers in event narratives, but is conservative about extracting information from other documents. This strategy produced improvements in both recall and precision over previous state-of-the-art systems.

This work just scratches the surface of using document genre identification to improve information extraction accuracy. In future work, we hope to identify additional types of document genre styles and incorporate genre directly into the extraction model. Coreference resolution and discourse analysis will also be important to further improve event extraction performance.

Abstract

In this paper we give an overview of the Knowledge Base Population (KBP) track at the 2010 Text Analysis Conference. The main goal of KBP is to promote research in discovering facts about entities and augmenting a knowledge base (KB) with these facts. This is done through two tasks, *Entity Linking* – linking names in context to entities in the KB – and *Slot Filling* – adding information about an entity to the KB. A large source collection of newswire and web documents is provided from which systems are to discover information. Attributes ("slots") derived from Wikipedia infoboxes are used to create the reference KB. In this paper we provide an overview of the techniques which can serve as a basis for a good KBP system, lay out the remaining challenges by comparison with traditional Information Extraction (IE) and Question Answering (QA) tasks, and provide some suggestions to address these challenges.

1 Introduction

Traditional information extraction (IE) evaluations, such as the Message Understanding Conferences (MUC) and Automatic Content Extraction (ACE), assess the ability to extract information from individual documents in isolation. In practice, however, we may need to gather information about a person or organization that is scattered among the documents of a large collection. This requires the ability to identify the relevant documents and to integrate facts, possibly redundant, possibly complementary, possibly in conflict, coming from these documents. Furthermore, we may want to use the extracted information to *augment* an existing data base. This requires the ability to link individuals mentioned in a document, and information about these individuals, to entries in the data base. On the other hand, traditional Question Answering (QA) evaluations made limited efforts at disambiguating entities in queries (e.g. Pizzato et al., 2006), and limited use of relation/event extraction in answer search (e.g. McNamee et al., 2008).

The Knowledge Base Population (KBP) shared task, conducted as part of the NIST Text Analysis Conference, aims to address and evaluate these capabilities, and bridge the IE and QA communities to promote research in discovering facts about entities and expanding a knowledge base with these facts. KBP is done through two separate subtasks, Entity Linking and Slot Filling; in 2010, 23 teams submitted results for one or both sub-tasks. A variety of approaches have been proposed to address both tasks with considerable success; nevertheless, there are many aspects of the task that remain unclear. What are the fundamental techniques used to achieve reasonable performance? What is the impact of each novel method? What types of problems are represented in the current KBP paradigm compared to traditional IE and QA? In which way have the current testbeds and evaluation methodology affected our perception of the task difficulty? Have we reached a performance ceiling with current state of the art techniques? What are the remaining challenges and what are the possible ways to address these challenges? In this paper we aim to answer some of these questions based on our detailed analysis of evaluation results.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1148–1158,
Portland, Oregon, June 19-24, 2011.

2 Task Definition and Evaluation Metrics

This section will summarize the tasks conducted at KBP 2010. The overall goal of KBP is to automatically identify salient and novel entities, link them to corresponding Knowledge Base (KB) entries (if the linkage exists), then discover attributes about the entities, and finally expand the KB with any new attributes.

In the Entity Linking task, given a person (PER), organization (ORG) or geo-political entity (GPE, a location with a government) query that consists of a name string and a background document containing that name string, the system is required to provide the ID of the KB entry to which the name refers; or NIL if there is no such KB entry. The background document, drawn from the KBP corpus, serves to disambiguate ambiguous name strings.

In selecting among the KB entries, a system could make use of the Wikipedia text associated with each entry as well as the structured fields of each entry. In addition, there was an optional task where the system could only make use of the structured fields; this was intended to be representative of applications where no backing text was available. Each site could submit up to three runs with different parameters.

The goal of Slot Filling is to collect from the corpus information regarding certain attributes of an entity, which may be a person or some type of organization. Each query in the Slot Filling task consists of the name of the entity, its type (person or organization), a background document containing the name (again, to disambiguate the query in case there are multiple entities with the same name), its node ID (if the entity appears in the knowledge base), and the attributes which need not be filled. Attributes are excluded if they are already filled in the reference data base and can only take on a single value. Along with each slot fill, the system must provide the ID of a document which supports the correctness of this fill. If the corpus does not provide any information for a given attribute, the system should generate a NIL response (and no document ID). KBP2010 defined 26 types of attributes for persons (such as the age, birthplace, spouse, children, job title, and employing organization) and 16 types of attributes for organizations (such as the top employees, the founder, the year founded, the headquarters location, and subsidiaries). Some of these attributes are specified as only taking a single value (e.g., birthplace), while some can take multiple values (e.g., top employees).

The reference KB includes hundreds of thousands of entities based on articles from an October 2008 dump of English Wikipedia which includes 818,741 nodes. The source collection includes 1,286,609 newswire documents, 490,596 web documents and hundreds of transcribed spoken documents.

To score Entity Linking, we take each query and check whether the KB node ID (or NIL) returned by a system is correct or not. Then we compute the Micro-averaged Accuracy, computed across all queries.

To score Slot Filling, we first pool all the system responses (as is done for information retrieval evaluations) together with a set of manually-prepared slot fills. These responses are then assessed by hand. Equivalent answers (such as "Bill Clinton" and "William Jefferson Clinton") are grouped into equivalence classes. Each system response is rated as correct, wrong, or redundant (a response which is equivalent to another response for the same slot or an entry already in the knowledge base). Given these judgments, we count

Correct = total number of non-NIL system output slots judged correct

System = total number of non-NIL system output slots

Reference = number of single-valued slots with a correct non-NIL response + number of equivalence classes for all list-valued slots

Recall = Correct / Reference

Precision = Correct / System

F-Measure = (2 × Recall × Precision) / (Recall + Precision)

3 Entity Linking: What Works

In Entity Linking, we saw a general improvement in performance over last year's results – the top system achieved 85.78% micro-averaged accuracy. When measured against a benchmark based on inter-annotator agreement, two systems' performance approached and one system exceeded the benchmark on person entities.

3.1 A General Architecture

A typical entity linking system architecture is depicted in Figure 1.

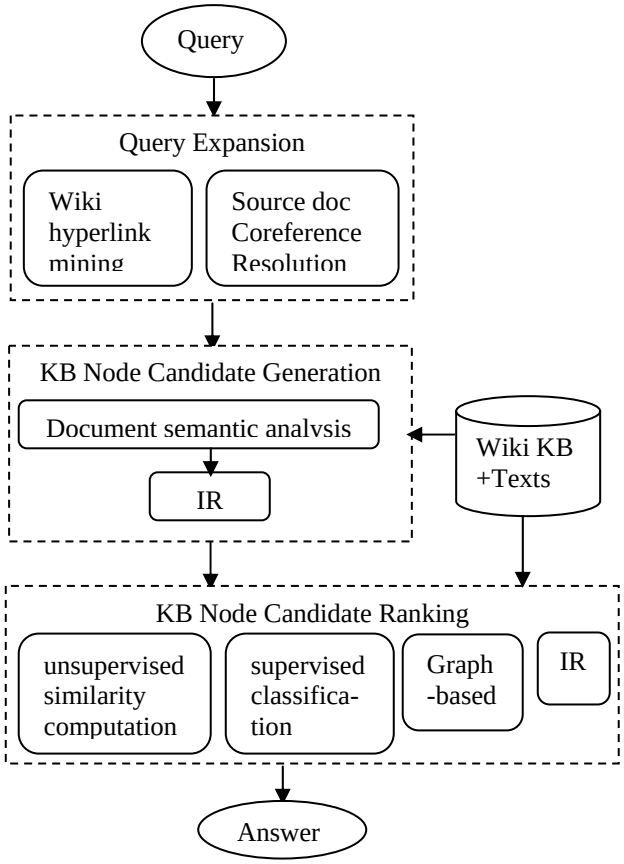

Figure 1. General Entity Linking System Architecture

It includes three steps: (1) query expansion – expand the query into a richer set of forms using Wikipedia structure mining or coreference resolution in the background document. (2) candidate generation – finding all possible KB entries that a query might link to; (3) candidate ranking – rank the probabilities of all candidates and NIL answer.

Table 1 summarizes the systems which exploited different approaches at each step. In the following subsections we will highlight the new and effective techniques used in entity linking.

3.2 Wikipedia Structure Mining

Wikipedia articles are peppered with structured information and hyperlinks to other (on average 25) articles (Medelyan et al., 2009). Such information provides additional sources for entity linking: (1). Query Expansion: For example, WebTLab (Fernandez et al., 2010) used Wikipedia link structure (source, anchors, redirects and disambiguation) to extend the KB and compute entity co-occurrence estimates. Many other teams including CUNY and Siel used redirect pages and disambiguation pages for query expansion. The Siel team also exploited bold texts from first paragraphs because they often contain nicknames, alias names and full names.

Methods		System Examples	System Ranking Range
Query Expansion	Wikipedia Hyperlink Mining	CUNY (Chen et al., 2010), NUSchime (Zhang et al., 2010), Siel (Bysani et al., 2010), SMU-SIS (Gottipati et al., 2010), USFD (Yu et al., 2010), WebTLab team (Fernandez et al., 2010)	[2, 15]
	Source document coreference resolution	CUNY (Chen et al., 2010)	9
Candidate Generation	Document semantic analysis and context modeling	ARPANI (Thomas et al., 2010), CUNY (Chen et al., 2010), LCC (Lehmann et al., 2010)	[1,14]
	IR	CUNY (Chen et al., 2010), Budapestacad (Nemeskey et al., 2010), USFD (Yu et al., 2010)	[9, 16]
Candidate Ranking	Unsupervised Similarity Computation (e.g. VSM)	CUNY (Chen et al., 2010), SMU-SIS (Gottipati et al., 2010), USFD (Yu et al., 2010)	[9, 14]
	Supervised Classification	LCC (Lehmann et al., 2010), NUSchime (Zhang et al., 2010), Stanford-UBC (Chang et al., 2010), HLTCOE (McNamee, 2010), UC3M (Pablo-Sanchez et al., 2010)	[1, 10]
	Rule-based	LCC (Lehmann et al., 2010), BuptPris (Gao et al., 2010)	[1, 8]
	Global Graph-based Ranking	CMCRC (Radford et al., 2010)	3
	IR	Budapestacad (Nemeskey et al., 2010)	16

Table 1. Entity Linking Method Comparison

(2). Candidate Ranking: Stanford-UBC used Wikipedia hyperlinks (clarification, disambiguation, title) for query re-mapping, and encoded lexical and part-of-speech features from Wikipedia articles containing hyperlinks to the queries to train a supervised classifier; they reported a significant improvement on micro-averaged accuracy, from 74.85% to 82.15%. In fact, when the mined attributes become rich enough, they can be used as an expanded query and sent into an information retrieval engine in order to obtain the relevant source documents. Budapestacad team (Nemeskey et al., 2010) adopted this strategy.

3.3 Ranking Approach Comparison

The ranking approaches exploited in the KBP2010 entity linking systems can be generally categorized into four types:

(1). Unsupervised or weakly-supervised learning, in which annotated data is minimally used to tune thresholds and parameters. The similarity measure is largely based on the unlabeled contexts.

(2). Supervised learning, in which a pair of entity and KB node is modeled as an instance for classification. Such a classifier can be learned from the annotated training data based on many different features.

(3). Graph-based ranking, in which context entities are taken into account in order to reach a global optimized solution together with the query entity.

(4). IR (Information Retrieval) approach, in which the entire background source document is considered as a single query to retrieve the most relevant Wikipedia article.

The first question we will investigate is how much higher performance can be achieved by using supervised learning? Among the 16 entity linking systems which participated in the regular evaluation, LCC (Lehmann et al., 2010), HLTCOE (McNamee, 2010), Stanford-UBC (Chang et al., 2010), NUSchime (Zhang et al., 2010) and UC3M (Pablo-Sanchez et al., 2010) have explicitly used supervised classification based on many lexical and name tagging features, and most of them are ranked in top 6 in the evaluation. Therefore we can conclude that supervised learning normally leads to a reasonably good performance. However, a high-performing entity linking system can also be implemented in an unsupervised fashion by exploiting effective characteristics and algorithms, as we will discuss in the next sections.

3.4 Semantic Relation Features

Almost all entity linking systems have used semantic relations as features (e.g. BuptPris (Gao et al., 2010), CUNY (Chen et al., 2010) and HLTCOE). The semantic features used in the BuptPris system include name tagging, infoboxes, synonyms, variants and abbreviations. In the CUNY system, the semantic features are automatically extracted from their slot filling system. The results are summarized in Table 2, showing the gains over a baseline system (using only Wikipedia title features in the case of BuptPris, using tf-idf weighted word features for CUNY). As we can see, except for person entities in the BuptPris system, all types of entities have obtained significant improvement by using semantic features in entity linking.

System	Using Semantic Features	PER	ORG	GPE	Overall
BuptPris	No	83.89	59.47	33.38	58.93
	Yes	79.09	74.13	66.62	73.29
CUNY	No	84.55	63.07	57.54	59.91
	Yes	92.81	65.73	84.10	69.29

Table 2. Impact of Semantic Features on Entity Linking (Micro-Averaged Accuracy %)

3.5 Context Inference

In the current setting of KBP, a set of target entities is provided to each system in order to simplify the task and its evaluation, because it's not feasible to require a system to generate answers for all possible entities in the entire source collection. However, ideally a fully-automatic KBP system should be able to automatically discover novel entities ("queries") which have no KB entry or few slot fills in the KB, extract their attributes, and conduct global reasoning over these attributes in order to generate the final output. At the very least, due to the semantic coherence principle (McNamara, 2001), the information of an entity depends on the information of other entities. For example, the WebTLab team and the CMCRC team extracted all entities in the context of a given query, and disambiguated all entities at the same time using a PageRank-like algorithm (Page et al., 1998) or a Graph-based Re-ranking algorithm. The SMU-SIS team (Gottipati and Jiang, 2010) re-formulated queries using contexts. The LCC team modeled

contexts using Wikipedia page concepts, and computed linkability scores iteratively. Consistent improvements were reported by the WebTLab system (from 63.64% to 66.58%).

4 Entity Linking: Remaining Challenges

4.1 Comparison with Traditional Cross-document Coreference Resolution

Part of the entity linking task can be modeled as a cross-document entity resolution problem which includes two principal challenges: the same entity can be referred to by more than one name string and the same name string can refer to more than one entity. The research on cross-document entity coreference resolution can be traced back to the Web People Search task (Artiles et al., 2007) and ACE2008 (e.g. Baron and Freedman, 2008). Compared to WePS and ACE, KBP requires linking an entity mention in a source document to a knowledge base with or without Wikipedia articles. Therefore sometimes the linking decisions heavily rely on entity profile comparison with Wikipedia infoboxes. In addition, KBP introduced GPE entity disambiguation. In source documents, especially in web data, usually few explicit attributes about GPE entities are provided, so an entity linking system also needs to conduct external knowledge discovery from background related documents or hyperlink mining.

4.2 Analysis of Difficult Queries

There are 2250 queries in the Entity Linking evaluation; for 58 of them at most 5 (out of the 46) system runs produced correct answers. Most of these queries have corresponding KB entries. For 19 queries all 46 systems produced different results from the answer key. Interestingly, the systems which perform well on the difficult queries are not necessarily those achieved top overall performance – they were ranked 13rd, 6th, 5th, 12nd, 10th, and 16th respectively for overall queries. 11 queries are highly ambiguous city names which can exist in many states or countries (e.g. "Chester"), or refer to person or organization entities. From these most difficult queries we observed the following challenges and possible solutions.

- **Require deep understanding of context entities for GPE queries**

In a document where the query entity is not a central topic, the author often assumes that the readers have enough background knowledge ('anchor' location from the news release information, world knowledge or related documents) about these entities. For 6 queries, a system would need to interpret or extract attributes for their context entities. For example, in the following passage:

> *…There are also photos of **Jake** on **IHJ** in **Brentwood**, still looking somber…*

in order to identify that the query "*Brentwood*" is located in California, a system will need to understand that "*IHJ*" is "*I heart Jake community*" and that the "*Jake*" referred to lives in Los Angeles, of which *Brentwood* is a part.

In the following example, a system is required to capture the knowledge that "*Chinese Christian man*" normally appears in "*China*" or there is a "*Mission School*" in "*Canton, China*" in order to link the query "*Canton*" to the correct KB entry. This is a very difficult query also because the more common way of spelling "*Canton*" in China is "*Guangdong*".

> *…and was from a **Mission School** in **Canton**, … but for the energetic efforts of this **Chinese Christian man** and the Refuge Matron…*

- **Require external hyperlink analysis**

Some queries require a system to conduct detailed analysis on the hyperlinks in the source document or the Wikipedia document. For example, in the source document "*…Filed under: Falcons <http://sports.aol.com/fanhouse/category/atlanta-falcons/>*", a system will need to analyze the document which this hyperlink refers to. Such cases might require new query reformulation and cross-document aggregation techniques, which are both beyond traditional entity disambiguation paradigms.

- **Require Entity Salience Ranking**

Some of these queries represent salient entities and so using web popularity rank (e.g. ranking/hit counts of Wikipedia pages from search engine) can yield correct answers in most cases (Bysani et al., 2010; Dredze et al., 2010). In fact we found that a naïve candidate ranking approach based on web popularity alone can achieve 71% micro-averaged accuracy, which is better than 24 system runs in KBP2010.

Since the web information is used as a black box (including query expansion and query log analysis) which changes over time, it's more difficult to duplicate research results. However, gazetteers with entities ranked by salience or major entities marked are worth encoding as additional features. For example, in the following passages:

> *... Tritschler brothers competed in gymnastics at the 1904 Games in **St Louis** 104 years ago*" and "*A chartered airliner carrying Democratic White House hopeful Barack Obama was forced to make an unscheduled landing on Monday in **St. Louis** after its flight crew detected mechanical problems…*

although there is little background information to decide where the query "*St Louis*" is located, a system can rely on such a major city list to generate the correct linking. Similarly, if a system knows that "*Georgia Institute of Technology*" has higher salience than "*Georgian Technical University*", it can correctly link a query "*Georgia Tech*" in most cases.

5 Slot Filling: What Works

5.1 A General Architecture

The slot-filling task is a hybrid of traditional IE (a fixed set of relations) and QA (responding to a query, generating a unified response from a large collection). Most participants met this challenge through a hybrid system which combined aspects of QA (passage retrieval) and IE (answer extraction). A few used off-the-shelf QA, either bypassing question analysis or (if QA was used as a "black box") creating a set of questions corresponding to each slot.

The basic system structure (Figure 2) involved three phases: document/passage retrieval (retrieving passages involving the queried entity), answer extraction (getting specific answers from the retrieved passages), and answer combination (merging and selecting among the answers extracted).

The solutions adopted for answer extraction reflected the range of current IE methods as well as QA answer extraction techniques (see Table 3). Most systems used one main pipeline, while CUNY and BuptPris adopted a hybrid approach of combining multiple approaches.

One particular challenge for KBP, in comparison with earlier IE tasks, was the paucity of training data. The official training data, linked to specific text from specific documents, consisted of responses to 100 queries; the participants jointly prepared responses to another 50. So traditional supervised learning, based directly on the training data, would provide limited coverage. Coverage could be improved by using the training data as seeds for a bootstrapping procedure.

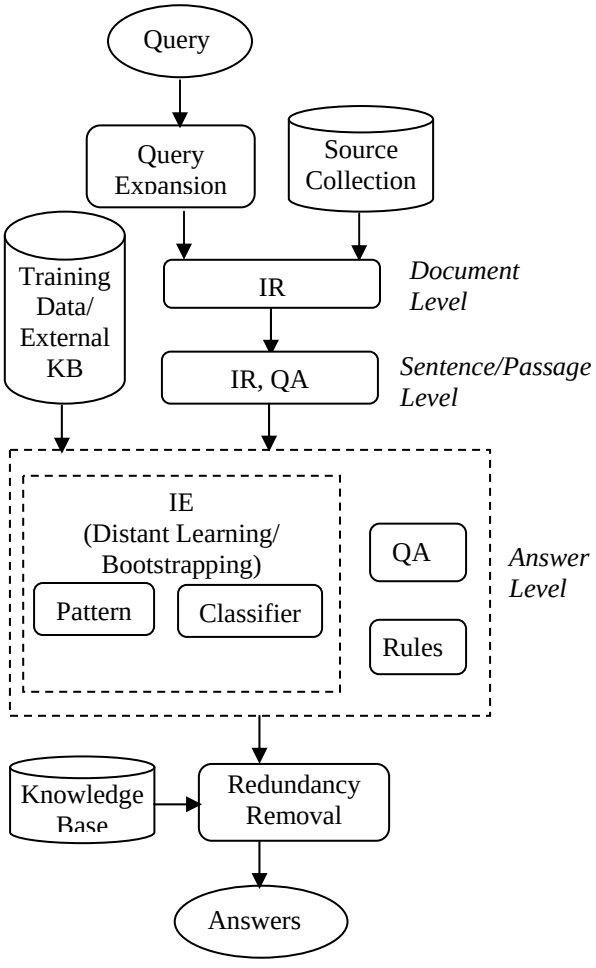

Figure 2. General Slot Filling System Architecture

Methods		System Examples	
Trained IE	Pattern Learning	Distant Learning (large seed, one iteration)	CUNY (Chen et al., 2010)
		Bootstrapping (small seed, multiple iterations)	NYU (Grishman and Min, 2010)
	Supervised Classifier	Distant Supervision	Budapestacad (Nemeskey et al., 2010), lsv (Chrupala et al., 2010), Stanford (Surdeanu et al., 2010), UBC (Intxaurrondo et al., 2010)
		Trained from KBP training data and other related tasks	BuptPris (Gao et al., 2010), CUNY (Chen et al., 2010), IBM (Castelli et al., 2010), ICL (Song et al., 2010), LCC (Lehmann et al., 2010), lsv (Chrupala et al., 2010), Siel (Bysani et al., 2010)
QA			CUNY (Chen et al., 2010), iirg (Byrne and Dunnion, 2010)
Hand-coded Heuristic Rules			BuptPris (Gao et al., 2010), USFD (Yu et al., 2010)

Table 3. Slot Filling Answer Extraction Method Comparison

On the other hand, there were a lot of 'facts' available – pairs of entities bearing a relationship corresponding closely to the KBP relations – in the form of filled Wikipedia infoboxes. These could be used for various forms of indirect or distant learning, where instances in a large corpus of such pairs are taken as (positive) training instances. However, such instances are noisy – if a pair of entities participates in more than one relation, the found instance may not be an example of the intended relation – and so some filtering of the instances or resulting patterns may be needed. Several sites used such distant supervision to acquire patterns or train classifiers, in some cases combined with direct supervision using the training data (Chrupala et al., 2010).

Several groups used and extended existing relation extraction systems, and then mapped the results into KBP slots. Mapping the ACE relations and events by themselves provided limited coverage (34% of slot fills in the training data), but was helpful when combined with other sources (e.g. CUNY). Groups with more extensive existing extraction systems could primarily build on these (e.g. LCC, IBM).

For example, IBM (Castelli et al., 2010) extended their mention detection component to cover 36 entity types which include many non-ACE types; and added new relation types between entities and event anchors. LCC and CUNY applied active learning techniques to cover non-ACE types of entities, such as “origin”, “religion”, “title”, “charge”, “web-site” and “cause-of-death”, and effectively develop lexicons to filter spurious answers.

Top systems also benefited from customizing and tightly integrating their recently enhanced extraction techniques into KBP. For example, IBM, NYU (Grishman and Min, 2010) and CUNY exploited entity coreference in pattern learning and reasoning. It is also notable that traditional extraction components trained from newswire data suffer from noise in web data. In order to address this problem, IBM applied their new robust mention detection techniques for noisy inputs (Florian et al., 2010); CUNY developed a component to recover structured forms such as tables in web data automatically and filter spurious answers.

5.2 Use of External Knowledge Base

Many instance-centered knowledge bases that have harvested Wikipedia are proliferating on the semantic web. The most well known are probably the Wikipedia derived resources, including DBpedia (Auer 2007), Freebase (Bollacker 2008) and YAGO (Suchanek et al., 2007) and Linked Open Data (http://data.nytimes.com/). The main motivation of the KBP program is to automatically distill information from news and web unstructured data instead of manually constructed knowledge bases, but these existing knowledge bases can provide a large number of seed tuples to bootstrap slot filling or guide distant learning.

Such resources can also be used in a more direct way. For example, CUNY exploited Freebase and LCC exploited DBpedia as fact validation in slot filling. However, most of these resources are manually created from single data modalities and only cover well-known entities. For example, while Freebase contains 116 million instances of

7,300 relations for 9 million entities, it only covers 48% of the slot types and 5% of the slot answers in KBP2010 evaluation data. Therefore, both CUNY and LCC observed limited gains from the answer validation approach from Freebase. Both systems gained about 1% improvement in recall with a slight loss in precision.

5.3 Cross-Slot and Cross-Query Reasoning

Slot Filling can also benefit from extracting revertible queries from the context of any target query, and conducting global ranking or reasoning to refine the results. CUNY and IBM developed recursive reasoning components to refine extraction results. For a given query, if there are no other related answer candidates available, they built "revertible" queries in the contexts, similar to (Prager et al., 2006), to enrich the inference process iteratively. For example, if *a* is extracted as the answer for org:subsidiaries of the query *q*, we can consider *a* as a new revertible query and verify that a org:parents answer of *a* is *q*. Both systems significantly benefited from recursive reasoning (CUNY F-measure on training data was enhanced from 33.57% to 35.29% and IBM F-measure was enhanced from 26% to 34.83%).

6 Slot Filling: Remaining Challenges

Slot filling remains a very challenging task; only one system exceeded 30% F-measure on the 2010 evaluation. During the 2010 evaluation data annotation/adjudication process, an initial answer key annotation was created by a manual search of the corpus (resulting in 797 instances), and then an independent adjudication pass was applied to assess these annotations together with pooled system responses. The Precision, Recall and F-measure for the initial human annotation are only about 70%, 54% and 61% respectively. While we believe the annotation consistency can be improved, in part by refinement of the annotation guidelines, this does place a limit on system performance.

Most of the shortfall in system performance reflects inadequacies in the answer extraction stage, reflecting limitations in the current state-of-the-art in information extraction. An analysis of the 2010 training data shows that cross-sentence coreference and some types of inference are critical to slot filling. In only 60.4% of the cases do the entity name and slot fill appear together in the same sentence, so a system which processes sentences in isolation is severely limited in its performance. 22.8% of the cases require cross-sentence (identity) coreference; 15% require some cross-sentence inference and 1.8% require cross-slot inference. The inferences include:

- Non-identity coreference: in the following passage: "***Lahoud*** is married to an Armenian and the couple have *three children*. Eldest *son* ***Emile Emile Lahoud*** was a member of parliament between 2000 and 2005." the semantic relation between "*children*" and "*son*" needs to be exploited in order to generate "*Emile Emile Lahoud*" as the *per:children* of the query entity "*Lahoud*";

- Cross-slot inference based on revertible queries, propagation links or even world knowledge to capture some of the most challenging cases. In the KBP slot filling task, slots are often dependent on each other, so we can improve the results by improving the "coherence" of the story (i.e. consistency among all generated answers (query profiles)). In the following example:

  "People Magazine has confirmed that actress Julia Roberts has given birth to her third child a boy named ***Henry Daniel Moder****. Henry was born Monday in Los Angeles and weighed 8? lbs. Roberts, 39, and husband* ***Danny Moder****, 38, are already parents to twins Hazel and Phinnaeus who were born in November 2006."*

  the following reasoning rules are needed to generate the answer "Henry Daniel Moder" as *per:children* of "Danny Moder":

  ChildOf ("Henry Daniel Moder", "Julia Roberts*")*
  ∧ *Coreferential (*"Julia Roberts", "Roberts*")*
  ∧ *SpouseOf (*"Roberts", "Danny Moder*")* → *ChildOf (*"Henry Daniel Moder", "Danny Moder*")*

KBP Slot Filling is similar to ACE Relation Extraction, which has been extensively studied for the past 7 years. However, the amount of training data is much smaller, forcing sites to adjust their training strategies. Also, some of the constraints of ACE relation mention extraction – notably, that both arguments are present in the same sentence – are not present, making the role of coreference and cross-sentence inference more critical.

The role of coreference and inference as limiting factors, while generally recognized, is emphasized

by examining the 163 slot values that the human annotators filled but that none of the systems were able to get correct. Many of these difficult cases involve a combination of problems, but we estimate that at least 25% of the examples involve coreference which is beyond current system capabilities, such as nominal anaphors:

"Alexandra Burke is out with the video for her second single … taken from the British artist's debut album"
"a woman charged with running a prostitution ring … her business, Pamela Martin and Associates"
(underlined phrases are coreferential).

While the types of inferences which may be required is open-ended, certain types come up repeatedly, reflecting the types of slots to be filled: systems would benefit from specialists which are able to reason about times, locations, family relationships, and employment relationships.

7 Toward System Combination

The increasing number of diverse approaches based on different resources provide new opportunities for both entity linking and slot filling tasks to benefit from system combination.

The NUSchime entity linking system trained a SVM based re-scoring model to combine two individual pipelines. Only one feature based on confidence values from the pipelines was used for re-scoring. The micro-averaged accuracy was enhanced from 79.29%/79.07% to 79.38% after combination. We also applied a voting approach on the top 9 entity linking systems and found that all combination orders achieved significant gains, with the highest absolute improvement of 4.7% in micro-averaged accuracy over the top entity linking system.

The CUNY slot filling system trained a maximum-entropy-based re-ranking model to combine three individual pipelines, based on various global features including voting and dependency relations. Significant gain in F-measure was achieved: from 17.9%, 27.7% and 21.0% (on training data) to 34.3% after combination. When we applied the same re-ranking approach to the slot filling systems which were ranked from the 2nd to 14th, we achieved 4.3% higher F-score than the best of these systems.

8 Conclusion

Compared to traditional IE and QA tasks, KBP has raised some interesting and important research issues: It places more emphasis on cross-document entity resolution which received limited effort in ACE; it forces systems to deal with redundant and conflicting answers across large corpora; it links the facts in text to a knowledge base so that NLP and data mining/database communities have a better chance to collaborate; it provides opportunities to develop novel training methods such as distant (and noisy) supervision through Infoboxes (Surdeanu et al., 2010; Chen et al., 2010).

In this paper, we provided detailed analysis of the reasons which have made KBP a more challenging task, shared our observations and lessons learned from the evaluation, and suggested some possible research directions to address these challenges which may be helpful for current and new participants, or IE and QA researchers in general.

Abstract

This paper focuses on mining the hyponymy (or is-a) relation from large-scale, open-domain web documents. A nonlinear probabilistic model is exploited to model the correlation between sentences in the aggregation of pattern matching results. Based on the model, we design a set of evidence combination and propagation algorithms. These significantly improve the result quality of existing approaches. Experimental results conducted on 500 million web pages and hypernym labels for 300 terms show over 20% performance improvement in terms of P@5, MAP and R-Precision.

1 Introduction

An important task in text mining is the automatic extraction of entities and their lexical relations; this has wide applications in natural language processing and web search. This paper focuses on mining the hyponymy (or is-a) relation from large-scale, open-domain web documents. From the viewpoint of entity classification, the problem is to automatically assign *fine-grained* class labels to terms.

There have been a number of approaches (Hearst 1992; Pantel & Ravichandran 2004; Snow et al., 2005; Durme & Pasca, 2008; Talukdar et al., 2008) to address the problem. These methods typically exploited manually-designed or automatically-learned patterns (e.g., "*NP such as NP*", "*NP like NP*", "*NP is a NP*"). Although some degree of success has been achieved with these efforts, the results are still far from perfect, in terms of both recall and precision. As will be demonstrated in this paper, even by processing a large corpus of 500 million web pages with the most popular patterns, we are not able to extract correct labels for many (especially rare) entities. Even for popular terms, incorrect results often appear in their label lists.

The basic philosophy in existing hyponymy extraction approaches (and also many other text-mining methods) is *counting*: count the number of supporting sentences. Here a *supporting sentence* of a term-label pair is a sentence from which the pair can be extracted via an extraction pattern. We demonstrate that the specific way of counting has a great impact on result quality, and that the state-of-the-art counting methods are not optimal. Specifically, we examine the problem from the viewpoint of probabilistic evidence combination and find that the probabilistic assumption behind simple counting is the statistical *independence* between the observations of supporting sentences. By assuming a *positive correlation* between supporting sentence observations and adopting properly designed nonlinear combination functions, the results precision can be improved.

It is hard to extract correct labels for rare terms from a web corpus due to the data sparseness problem. To address this issue, we propose an evidence propagation algorithm motivated by the observation that similar terms tend to share common hypernyms. For example, if we already know that 1) Helsinki and Tampere are cities, and 2) Porvoo is similar to Helsinki and Tampere, then Porvoo is

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1159–1168,
Portland, Oregon, June 19-24, 2011.

very likely also a city. This intuition, however, does not mean that the labels of a term can always be transferred to its similar terms. For example, Mount Vesuvius and Kilimanjaro are volcanoes and Lhotse is similar to them, but Lhotse is not a volcano. Therefore we should be very conservative and careful in hypernym propagation. In our propagation algorithm, we first construct some *pseudo supporting sentences* for a term from the supporting sentences of its similar terms. Then we calculate label scores for terms by performing *nonlinear* evidence combination based on the (pseudo and real) supporting sentences. Such a nonlinear propagation algorithm is demonstrated to perform better than linear propagation.

Experimental results on a publicly available collection of 500 million web pages with hypernym labels annotated for 300 terms show that our nonlinear evidence fusion and propagation significantly improve the precision and coverage of the extracted hyponymy data. This is one of the technologies adopted in our semantic search and mining system *NeedleSeek*[2].

In the next section, we discuss major related efforts and how they differ from our work. Section 3 is a brief description of the baseline approach. The probabilistic evidence combination model that we exploited is introduced in Section 4. Our main approach is illustrated in Section 5. Section 6 shows our experimental settings and results. Finally, Section 7 concludes this paper.

2 Related Work

Existing efforts for hyponymy relation extraction have been conducted upon various types of data sources, including plain-text corpora (Hearst 1992; Pantel & Ravichandran, 2004; Snow et al., 2005; Snow et al., 2006; Banko, et al., 2007; Durme & Pasca, 2008; Talukdar et al., 2008), semi-structured web pages (Cafarella et al., 2008; Shinzato & Torisawa, 2004), web search results (Geraci et al., 2006; Kozareva et al., 2008; Wang & Cohen, 2009), and query logs (Pasca 2010). Our target for optimization in this paper is the approaches that use lexico-syntactic patterns to extract hyponymy relations from plain-text corpora. Our future work will study the application of the proposed algorithms on other types of approaches.

[2] http://research.microsoft.com/en-us/projects/needleseek/ or http://needleseek.msra.cn/

The probabilistic evidence combination model that we exploit here was first proposed in (Shi et al., 2009), for combining the page in-link evidence in building a nonlinear static-rank computation algorithm. We applied it to the hyponymy extraction problem because the model takes the dependency between supporting sentences into consideration and the resultant evidence fusion formulas are quite simple. In (Snow et al., 2006), a probabilistic model was adopted to combine evidence from heterogeneous relationships to jointly optimize the relationships. The independence of evidence was assumed in their model. In comparison, we show that better results will be obtained if the evidence correlation is modeled appropriately.

Our evidence propagation is basically about using term similarity information to help instance labeling. There have been several approaches which improve hyponymy extraction with instance clusters built by distributional similarity. In (Pantel & Ravichandran, 2004), labels were assigned to the committee (i.e., representative members) of a semantic class and used as the hypernyms of the whole class. Labels generated by their approach tend to be rather coarse-grained, excluding the possibility of a term having its private labels (considering the case that one meaning of a term is not covered by the input semantic classes). In contrast to their method, our label scoring and ranking approach is applied to every single term rather than a semantic class. In addition, we also compute label scores in a nonlinear way, which improves results quality. In Snow et al. (2005), a supervised approach was proposed to improve hypernym classification using coordinate terms. In comparison, our approach is unsupervised. Durme & Pasca (2008) cleaned the set of instance-label pairs with a TF*IDF like method, by exploiting clusters of semantically related phrases. The core idea is to keep a term-label pair (T, L) only if the number of terms having the label L in the term T's cluster is above a threshold and if L is not the label of too many clusters (otherwise the pair will be discarded). In contrast, we are able to add new (high-quality) labels for a term with our evidence propagation method. On the other hand, low quality labels get smaller score gains via propagation and are ranked lower.

Label propagation is performed in (Talukdar et al., 2008; Talukdar & Pereira, 2010) based on multiple instance-label graphs. Term similarity information was not used in their approach.

Most existing work tends to utilize small-scale or private corpora, whereas the corpus that we used is publicly available and much larger than most of the existing work. We published our term sets (refer to Section 6.1) and their corresponding user judgments so researchers working on similar topics can reproduce our results.

Table 1. Patterns adopted in this paper (NP: named phrase representing an entity; NP_L: label)

3 Preliminaries

The problem addressed in this paper is corpus-based *is-a* relation mining: extracting hypernyms (as labels) for entities from a large-scale, open-domain document corpus. The desired output is a mapping from terms to their corresponding hypernyms, which can naturally be represented as a weighted bipartite graph (term-label graph). Typically we are only interested in top labels of a term in the graph.

Following existing efforts, we adopt pattern-matching as a basic way of extracting hypernymy/hyponymy relations. Two types of patterns (refer to Table 1) are employed, including the popular "Hearst patterns" (Hearst, 1992) and the IsA patterns which are exploited less frequently in existing hyponym mining efforts. One or more term-label pairs can be extracted if a pattern matches a sentence. In the baseline approach, the weight of an edge $T \rightarrow L$ (from term T to hypernym label L) in the term-label graph is computed as,

$$w(T \rightarrow L) = m \cdot \mathrm{IDF}(L) = m \cdot \log \frac{1+N}{1+\mathrm{DF}(L)} \qquad (3.1)$$

where m is the number of times the pair (T, L) is extracted from the corpus, $\mathrm{DF}(L)$ is the number of in-links of L in the graph, N is total number of terms in the graph, and IDF means the "inverse document frequency".

A term can only keep its top-k neighbors (according to the edge weight) in the graph as its final labels.

Our pattern matching algorithm implemented in this paper uses part-of-speech (POS) tagging information, without adopting a parser or a chunker. The noun phrase boundaries (for terms and labels) are determined by a manually designed POS tag list.

4 Probabilistic Label-Scoring Model

Here we model the hyponymy extraction problem from the probability theory point of view, aiming at estimating the score of a term-label pair (i.e., the score of a label w.r.t. a term) with probabilistic evidence combination. The model was studied in (Shi et al., 2009) to combine the page in-link evidence in building a nonlinear static-rank computation algorithm.

We represent the score of a term-label pair by the probability of the label being a correct hypernym of the term, and define the following events,

$A_{T,L}$: Label L is a hypernym of term T (the abbreviated form A is used in this paper unless it is ambiguous).

E_i: The observation that (T, L) is extracted from a sentence S_i via pattern matching (i.e., S_i is a supporting sentence of the pair).

Assuming that we already know m supporting sentences ($S_1 \sim S_m$), our problem is to compute $P(A|E_1,E_2,..,E_m)$, the *posterior* probability that L is a hypernym of term T, given evidence $E_1 \sim E_m$. Formally, we need to find a function f to satisfy,

$$P(A|E_1,\ldots,E_m) = f(P(A), P(A|E_1)\ldots, P(A|E_m)) \qquad (4.1)$$

For simplicity, we first consider the case of m=2. The case of m>2 is quite similar.

We start from the simple case of independent supporting sentences. That is,

$$P(E_1, E_2) = P(E_1) \cdot P(E_2) \qquad (4.2)$$

$$P(E_1, E_2|A) = P(E_1|A) \cdot P(E_2|A) \qquad (4.3)$$

By applying Bayes rule, we get,

$$\begin{aligned} P(A|E_1, E_2) &= \frac{P(E_1, E_2|A) \cdot P(A)}{P(E_1, E_2)} \\ &= \frac{P(E_1|A) \cdot P(A)}{P(E_1)} \cdot \frac{P(E_2|A) \cdot P(A)}{P(E_2)} \cdot \frac{1}{P(A)} \\ &= \frac{P(A|E_1) \cdot P(A|E_2)}{P(A)} \end{aligned} \qquad (4.4)$$

Then define

$$G(A|E) = \log \frac{P(A|E)}{P(A)} = \log(P(A|E)) - log(\mathrm{P}(A))$$

Here $G(A|E)$ represents the *log-probability-gain* of A given E, with the meaning of the *gain* in the log-probability value of A after the evidence E is observed (or known). It is a measure of the impact of evidence E to the probability of event A. With the definition of $G(A|E)$, Formula 4.4 can be transformed to,

$$G(A|E_1, E_2) = G(A|E_1) + G(A|E_2) \quad (4.5)$$

Therefore, if E_1 and E_2 are independent, the log-probability-gain of A given both pieces of evidence will exactly be the sum of the gains of A given every single piece of evidence respectively. It is easy to prove (by following a similar procedure) that the above Formula holds for the case of m>2, as long as the pieces of evidence are mutually independent.

Therefore for a term-label pair with m mutually independent supporting sentences, if we set every gain $G(A|E_i)$ to be a constant value g, the posterior gain score of the pair will be $\sum_{i=1}^{m} g = mg$. If the value g is the IDF of label L, the posterior gain will be,

$$G(A_{T,L}|E_1 \ldots, E_m) = \sum_{i=1}^{m} \mathrm{IDF}(L) = m \cdot \mathrm{IDF}(L) \quad (4.6)$$

This is exactly the Formula 3.1. By this way, we provide a probabilistic explanation of scoring the candidate labels for a term via simple counting.

	Hearst-I	**IsA-I**	**E_1: Hearst-I E_2: IsA-I**
R_A: $\frac{P(E_1,E_2\|A)}{P(E_1\|A)P(E_2\|A)}$	66.87	17.30	24.38
R: $\frac{P(E_1,E_2)}{P(E_1)P(E_2)}$	5997	1711	802.7
R_A/R	0.011	0.010	0.030

Table 2. Evidence dependency estimation for intra-pattern and inter-pattern supporting sentences

In the above analysis, we assume the statistical independence of the supporting sentence observations, which may not hold in reality. Intuitively, if we already know one supporting sentence S_1 for a term-label pair (T, L), then we have more chance to find another supporting sentence than if we do not know S_1. The reason is that, before we find S_1, we have to estimate the probability with the chance of discovering a supporting sentence for a *random* term-label pair. The probability is quite low because most term-label pairs do not have hyponymy relations. Once we have observed S_1, however, the chance of (T, L) having a hyponymy relation increases. Therefore the chance of observing another supporting sentence becomes larger than before.

Table 2 shows the rough estimation of $\frac{P(E_1,E_2|A)}{P(E_1|A)P(E_2|A)}$ (denoted as R_A), $\frac{P(E_1,E_2)}{P(E_1)P(E_2)}$ (denoted as R), and their ratios. The statistics are obtained by performing maximal likelihood estimation (MLE) upon our corpus and a random selection of term-label pairs from our term sets (see Section 6.1) together with their top labels[3]. The data verifies our analysis about the correlation between E_1 and E_2 (note that R=1 means independent). In addition, it can be seen that the conditional independence assumption of Formula 4.3 does not hold (because R_A>1). It is hence necessary to consider the correlation between supporting sentences in the model. The estimation of Table 2 also indicates that,

$$\frac{P(E_1, E_2)}{P(E_1)P(E_2)} > \frac{P(E_1, E_2|A)}{P(E_1|A)P(E_2|A)} \quad (4.7)$$

By following a similar procedure as above, with Formulas 4.2 and 4.3 replaced by 4.7, we have,

$$G(A|E_1, E_2) < G(A|E_1) + G(A|E_2) \quad (4.8)$$

This formula indicates that when the supporting sentences are positively correlated, the posterior score of label L w.r.t. term T (given both the sentences) is smaller than the sum of the gains caused by one sentence only. In the extreme case that sentence S_2 fully depends on E_1 (i.e. $P(E_2|E_1)$=1), it is easy to prove that

$$G(A|E_1, E_2) = G(A|E_1)$$

It is reasonable, since event E_2 does not bring in more information than E_1.

Formula 4.8 cannot be used directly for computing the posterior gain. What we really need is a function h satisfying

$$G(A|E_1, \ldots, E_m) = h\big(G(A|E_1), \ldots, G(A|E_m)\big) \quad (4.9)$$

and

$$h(x_1 \ldots, x_m) < \sum_{i=1}^{m} x_i \quad (4.10)$$

Shi et al. (2009) discussed other constraints to h and suggested the following nonlinear functions,

$$h_1(x_1 \ldots, x_m) = \ln(1 + \sum_{i=1}^{m} (\mathrm{e}^{x_i} - 1)) \quad (4.11)$$

[3] R_A is estimated from the labels judged as "Good"; whereas the estimation of R is from all judged labels.

$$h_2(x_1 \ldots, x_m) = \sqrt[p]{\sum_{i=1}^{m} x_i^p} \qquad (p>1) \qquad (4.12)$$

In the next section, we use the above two *h* functions as basic building blocks to compute label scores for terms.

5 Our Approach

Multiple types of patterns (Table 1) can be adopted to extract term-label pairs. For two supporting sentences the correlation between them may depend on whether they correspond to the same pattern. In Section 5.1, our nonlinear evidence fusion formulas are constructed by making specific assumptions about the correlation between intra-pattern supporting sentences and inter-pattern ones.

Then in Section 5.2, we introduce our evidence propagation technique in which the evidence of a (T, L) pair is propagated to the terms similar to *T*.

5.1 Nonlinear evidence fusion

For a term-label pair (*T*, *L*), assuming *K* patterns are used for hyponymy extraction and the supporting sentences discovered with pattern *i* are,

$$S_{i,1}, S_{i,2} \ldots, S_{i,m_i} \qquad (5.1)$$

where m_i is the number of supporting sentences corresponding to pattern *i*. Also assume the gain score of $S_{i,j}$ is $x_{i,j}$, i.e., $x_{i,j}=G(A|S_{i,j})$.

Generally speaking, supporting sentences corresponding to the same pattern typically have a higher correlation than the sentences corresponding to different patterns. This can be verified by the data in Table-2. By ignoring the inter-pattern correlations, we make the following simplified assumption:

Assumption: Supporting sentences corresponding to the same pattern are correlated, while those of different patterns are independent.

According to this assumption, our label-scoring function is,

$$score(T, L) = \sum_{i=1}^{K} h(x_{i,1}, x_{i,2} \ldots, x_{i,m_i}) \qquad (5.2)$$

In the simple case that $x_{i,j} = \mathrm{IDF}(L)$, if the *h* function of Formula 4.12 is adopted, then,

$$Score(T, L) = \left(\sum_{i=1}^{K} \sqrt[p]{m_i} \right) \cdot \mathrm{IDF}(L) \qquad (5.3)$$

We use an example to illustrate the above formula.

Example: For term *T* and label L_1, assume the numbers of the supporting sentences corresponding to the six pattern types in Table 1 are (4, 4, 4, 4, 4, 4), which means the number of supporting sentences discovered by each pattern type is 4. Also assume the supporting-sentence-count vector of label L_2 is (25, 0, 0, 0, 0, 0). If we use Formula 5.3 to compute the scores of L_1 and L_2, we can have the following (ignoring IDF for simplicity),

$Score(L_1) = 6 \cdot \sqrt{4} = 12$; $Score(L_2) = \sqrt{25} = 5$

One the other hand, if we simply count the total number of supporting sentences, the score of L_2 will be larger.

The rationale implied in the formula is: For a given term *T*, the labels supported by multiple types of patterns tend to be more reliable than those supported by a single pattern type, if they have the same number of supporting sentences.

5.2 Evidence propagation

According to the evidence fusion algorithm described above, in order to extract term labels reliably, it is desirable to have many supporting sentences of different types. This is a big challenge for rare terms, due to their low frequency in sentences (and even lower frequency in supporting sentences because not all occurrences can be covered by patterns). With evidence propagation, we aim at discovering more supporting sentences for terms (especially rare terms). Evidence propagation is motivated by the following two observations:

(I) Similar entities or coordinate terms tend to share some common hypernyms.

(II) Large term similarity graphs are able to be built efficiently with state-of-the-art techniques (Agirre et al., 2009; Pantel et al., 2009; Shi et al., 2010). With the graphs, we can obtain the similarity between two terms without their hypernyms being available.

The first observation motivates us to "*borrow*" the supporting sentences from other terms as auxiliary evidence of the term. The second observation means that *new* information is brought with the state-of-the-art term similarity graphs (in addition to the term-label information discovered with the patterns of Table 1).

Our evidence propagation algorithm contains two phases. In phase I, some *pseudo supporting sentences* are constructed for a term from the supporting sentences of its neighbors in the similarity graph. Then we calculate the label scores for terms based on their (pseudo and real) supporting sentences.

Phase I: For every supporting sentence S and every similar term T_1 of the term T, add a pseudo supporting sentence S_1 for T_1, with the gain score,

$$G(A_{T_1,L_1}|S_1) = \mu \cdot \mathrm{Sim}(T,T_1) \cdot G(A_{T,L}|S) \qquad (5.5)$$

where $\mu \in [0,1]$ is the propagation factor, and $\mathrm{Sim}(\cdot,\cdot)$ is the term similarity function taking values in [0, 1]. The formula reasonably assumes that the gain score of the pseudo supporting sentence depends on the gain score of the original real supporting sentence, the similarity between the two terms, and the propagation factor.

Phase II: The nonlinear evidence combination formulas in the previous subsection are adopted to combine the evidence of pseudo supporting sentences.

Term similarity graphs can be obtained by distributional similarity or patterns (Agirre et al., 2009; Pantel et al., 2009; Shi et al., 2010). We call the first type of graph *DS* and the second type *PB*. DS approaches are based on the distributional hypothesis (Harris, 1985), which says that terms appearing in analogous contexts tend to be similar. In a DS approach, a term is represented by a feature vector, with each feature corresponding to a context in which the term appears. The similarity between two terms is computed as the similarity between their corresponding feature vectors. In PB approaches, a list of carefully-designed (or automatically learned) patterns is exploited and applied to a text collection, with the hypothesis that the terms extracted by applying each of the patterns to a specific piece of text tend to be similar. Two categories of patterns have been studied in the literature (Heast 1992; Pasca 2004; Kozareva et al., 2008; Zhang et al., 2009): sentence lexical patterns, and HTML tag patterns. An example of sentence lexical patterns is "*T {, T}*{,} (and|or) T*". HTML tag patterns include HTML tables, drop-down lists, and other tag repeat patterns. In this paper, we generate the DS and PB graphs by adopting the best-performed methods studied in (Shi et al., 2010). We will compare, by experiments, the propagation performance of utilizing the two categories of graphs, and also investigate the performance of utilizing both graphs for evidence propagation.

6 Experiments

6.1 Experimental setup

Corpus We adopt a publicly available dataset in our experiments: ClueWeb09[4]. This is a very large dataset collected by Carnegie Mellon University in early 2009 and has been used by several tracks of the Text Retrieval Conference (TREC)[5]. The whole dataset consists of 1.04 billion web pages in ten languages while only those in English, about 500 million pages, are used in our experiments. The reason for selecting such a dataset is twofold: First, it is a corpus large enough for conducting web-scale experiments and getting meaningful results. Second, since it is publicly available, it is possible for other researchers to reproduce the experiments in this paper.

Term sets Approaches are evaluated by using two sets of selected terms: *Wiki200*, and *Ext100*. For every term in the term sets, each approach generates a list of hypernym labels, which are manually judged by human annotators. Wiki200 is constructed by first randomly selecting 400 Wikipedia[6] titles as our candidate terms, with the probability of a title T being selected to be $\log(1 + F(T))$, where $F(T)$ is the frequency of T in our data corpus. The reason of adopting such a probability formula is to balance popular terms and rare ones in our term set. Then 200 terms are manually selected from the 400 candidate terms, with the principle of maximizing the diversity of terms in terms of length (i.e., number of words) and type (person, location, organization, software, movie, song, animal, plant, etc.). Wiki200 is further divided into two subsets: *Wiki100H* and *Wiki100L*, containing respectively the 100 high-frequency and low-frequency terms. Ext100 is built by first selecting 200 *non*-Wikipedia-title terms at random from the term-label graph generated by the baseline approach (Formula 3.1), then manually selecting 100 terms.

Some sample terms in the term sets are listed in Table 3.

Table 3. Sample terms in our term sets

Annotation For each term in the term set, the top-5 results (i.e., hypernym labels) of various methods are mixed and judged by human annotators. Each annotator assigns each result item a judgment of "Good", "Fair" or "Bad". The annotators do not know the method by which a result item is generated. Six annotators participated in the labeling with a rough speed of 15 minutes per term. We also encourage the annotators to add new good results which are not discovered by any method.

The term sets and their corresponding user annotations are available for download at the following links (dataset ID=data.queryset.semcat01):

http://research.microsoft.com/en-us/projects/needleseek/
http://needleseek.msra.cn/datasets/

Evaluation We adopt the following metrics to evaluate the hypernym list of a term generated by each method. The evaluation score on a term set is the average over all the terms.

Precision@*k*: The percentage of relevant (good or fair) labels in the top-*k* results (labels judged as "Fair" are counted as 0.5)

Recall@k: The ratio of relevant labels in the top-*k* results to the total number of relevant labels

R-Precision: Precision@R where *R* is the total number of labels judged as "Good"

Mean average precision (*MAP*): The average of precision values at the positions of all good or fair results

Before annotation and evaluation, the hypernym list generated by each method for each term is preprocessed to remove *duplicate* items. Two hypernyms are called *duplicate* items if they share the same head word (e.g., "military conflict" and "conflict"). For duplicate hypernyms, only the first (i.e., the highest ranked one) in the list is kept. The goal with such a preprocessing step is to partially consider results diversity in evaluation and to make a more meaningful comparison among different methods. Consider two hypernym lists for "subway":

List-1: restaurant; chain restaurant; worldwide chain restaurant; franchise; restaurant franchise…

List-2: restaurant; franchise; transportation; company; fast food…

There are more detailed hypernyms in the first list about "subway" as a restaurant or a franchise; while the second list covers a broader range of meanings for the term. It is hard to say which is better (without considering the upper-layer applications). With this preprocessing step, we keep our focus on short hypernyms rather than detailed ones.

Term Set	Method	MAP	R-Prec	P@1	P@5
Wiki200	Linear	0.357	0.376	0.783	0.547
	Log	0.371 ↑3.92%	0.384 ↑2.13%	0.803 ↑2.55%	0.561 ↑2.56%
	PNorm	0.372 ↑4.20%	0.384 ↑2.13%	0.800 ↑2.17%	0.562 ↑2.74%

Table 4. Performance comparison among various evidence fusion methods (Term sets: Wiki200 and Wiki100H; p=2 for PNorm)

6.2 Experimental results

We first compare the evaluation results of different evidence fusion methods mentioned in Section 4.1. In Table 4, *Linear* means that Formula 3.1 is used to calculate label scores, whereas *Log* and *PNorm* represent our nonlinear approach with Formulas 4.11 and 4.12 being utilized. The performance improvement numbers shown in the table are based on the linear version; and the upward pointing arrows indicate relative percentage improvement over the baseline. From the table, we can see that the nonlinear methods outperform the linear ones on the Wiki200 term set. It is interesting to note that the performance improvement is more significant on Wiki100H, the set of high frequency terms. By examining the labels and supporting sentences for the terms in each term set, we find that for many low-frequency terms (in Wiki100L), there are only a few supporting sentences (corresponding

to one or two patterns). So the scores computed by various fusion algorithms tend to be similar. In contrast, more supporting sentences can be discovered for high-frequency terms. Much information is contained in the sentences about the hypernyms of the high-frequency terms, but the linear function of Formula 3.1 fails to make effective use of it. The two nonlinear methods achieve better performance by appropriately modeling the dependency between supporting sentences and computing the log-probability gain in a better way.

The comparison of the linear and nonlinear methods on the Ext100 term set is shown in Table 5. Please note that the terms in Ext100 do not appear in Wikipedia titles. Thanks to the scale of the data corpus we are using, even the baseline approach achieves reasonably good performance. Please note that the terms (refer to Table 3) we are using are "harder" than those adopted for evaluation in many existing papers. Again, the results quality is improved with the nonlinear methods, although the performance improvement is not big due to the reason that most terms in Ext100 are rare. Please note that the recall (R@1, R@5) in this paper is pseudo-recall, i.e., we treat the number of *known* relevant (Good or Fair) results as the total number of relevant ones.

Method	MAP	R-Prec	P@1	P@5	R@1	R@5
Linear	0.384	0.429	0.665	0.472	0.116	0.385

	↑2.86%	↑0%	↑7.52%	↑0%	↑7.76%	↑0%
PNorm	0.390	0.429	0.700	0.472	0.120	0.385
	↑1.56%	↑0%	↑5.26%	↑0%	↑3.45%	↑0%

Table 5. Performance comparison among various evidence fusion methods (Term set: Ext100; p=2 for PNorm)

The parameter p in the PNorm method is related to the degree of correlations among supporting sentences. The linear method of Formula 3.1 corresponds to the special case of p=1; while p=∞ represents the case that other supporting sentences are fully correlated to the supporting sentence with the maximal log-probability gain. Figure 1 shows that, for most of the term sets, the best performance is obtained for $p \in$[2.0, 4.0]. The reason may be that the sentence correlations are better estimated with p values in this range.

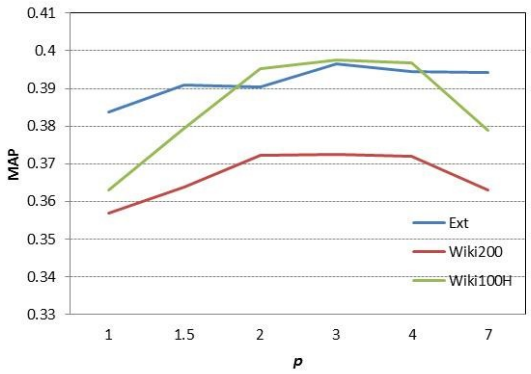

Figure 1. Performance curves of PNorm with different parameter values (Measure: MAP)

The experimental results of evidence propagation are shown in Table 6. The methods for comparison are,

Base: The linear function without propagation.

NL: Nonlinear evidence fusion (PNorm with p=2) without propagation.

LP: Linear propagation, i.e., the linear function is used to combine the evidence of pseudo supporting sentences.

NLP: Nonlinear propagation where PNorm (p=2) is used to combine the pseudo supporting sentences.

NL+NLP: The nonlinear method is used to combine both supporting sentences and pseudo supporting sentences.

Method	MAP	R-Prec	P@1	P@5	R@5
Base	0.357	0.376	0.783	0.547	0.317
NL	0.372	0.384	0.800	0.562	0.325
	↑4.20%	↑2.13%	↑2.17%	↑2.74%	↑2.52%
LP	0.357	0.376	0.783	0.547	0.317
	↑0%	↑0%	↑0%	↑0%	↑0%

	↑10.9%	↑11.2%	↑0.26%	↑10.6%	↑12.6%
NL+NLP	0.447	0.461	0.840	0.667	0.404
	↑25.2%	↑22.6%	↑7.28%	↑21.9%	↑27.4%

Table 6. Evidence propagation results (Term set: Wiki200; Similarity graph: PB; Nonlinear formula: PNorm)

In this paper, we generate the DS (distributional similarity) and PB (pattern-based) graphs by adopting the best-performed methods studied in (Shi et al., 2010). The performance improvement numbers (indicated by the upward pointing arrows) shown in tables 6~9 are relative percentage improvement

over the *base* approach (i.e., linear function without propagation). The values of parameter μ are set to maximize the MAP values.

Several observations can be made from Table 6. First, no performance improvement can be obtained with the linear propagation method (LP), while the nonlinear propagation algorithm (NLP) works quite well in improving both precision and recall. The results demonstrate the high correlation between pseudo supporting sentences and the great potential of using term similarity to improve hypernymy extraction. The second observation is that the NL+NLP approach achieves a much larger performance improvement than NL and NLP. Similar results (omitted due to space limitation) can be observed on the Ext100 term set.

Method	MAP	R-Prec	P@1	P@5	R@5
Base	0.357	0.376	0.783	0.547	0.317
NL+NLP (PB)	0.415 ↑16.2%	0.439 ↑16.8%	0.830 ↑6.00%	0.633 ↑15.7%	0.379 ↑19.6%
NL+NLP (DS)	0.456 ↑27.7%	0.469 ↑24.7%	0.843 ↑7.66%	0.673 ↑23.0%	0.406 ↑28.1%
NL+NLP (PB+DS)	0.473 ↑32.5%	0.487 ↑29.5%	0.860 ↑9.83%	0.700 ↑28.0%	0.434 ↑36.9%

Table 7. Combination of PB and DS graphs for evidence propagation (Term set: Wiki200; Nonlinear formula: Log)

Method	MAP	R-Prec	P@1	P@5	R@5
Base	0.351	0.370	0.760	0.467	0.317
NL+NLP (PB)	0.411 ↑17.1%	0.448 ↑21.1%	0.770 ↑1.32%	0.564 ↑20.8%	0.401 ↑26.5%
NL+NLP (DS)	0.469 ↑33.6%	0.490 ↑32.4%	0.815 ↑7.24%	0.622 ↑33.2%	0.438 ↑38.2%
NL+NLP (PB+DS)	0.491 ↑39.9%	0.513 ↑38.6%	0.860 ↑13.2%	0.654 ↑40.0%	0.479 ↑51.1%

Table 8. Combination of PB and DS graphs for evidence propagation (Term set: Wiki100L)

Now let us study whether it is possible to combine the PB and DS graphs to obtain better results. As shown in Tables 7, 8, and 9 (for term sets Wiki200, Wiki100L, and Ext100 respectively, using the *Log* formula for fusion and propagation), utilizing both graphs really yields additional performance gains. We explain this by the fact that the information in the two term similarity graphs tends to be complimentary. The performance improvement over Wiki100L is especially remarkable. This is reasonable because rare terms do not have adequate information in their supporting sentences due to data sparseness. As a result, they benefit the most from the pseudo supporting sentences propagated with the similarity graphs.

Method	MAP	R-Prec	P@1	P@5	R@5
Base	0.384	0.429	0.665	0.472	0.385
NL+NLP (PB)	0.454 ↑18.3%	0.479 ↑11.7%	0.745 ↑12.0%	0.550 ↑16.5%	0.456 ↑18.4%

Table 9. Combination of PB and DS graphs for evidence propagation (Term set: Ext100)

7 Conclusion

We demonstrated that the way of aggregating supporting sentences has considerable impact on results quality of the hyponym extraction task using lexico-syntactic patterns, and the widely-used counting method is not optimal. We applied a series of nonlinear evidence fusion formulas to the problem and saw noticeable performance improvement. The data quality is improved further with the combination of nonlinear evidence fusion and evidence propagation. We also introduced a new evaluation corpus with annotated hypernym labels for 300 terms, which were shared with the research community.

Acknowledgments

We would like to thank Matt Callcut for reading through the paper. Thanks to the annotators for their efforts in judging the hypernym labels. Thanks to Yueguo Chen, Siyu Lei, and the anonymous reviewers for their helpful comments and suggestions. Abstract

This paper presents a supervised pronoun anaphora resolution system based on factorial hidden Markov models (FHMMs). The basic idea is that the hidden states of FHMMs are an explicit short-term memory with an antecedent buffer containing recently described referents. Thus an observed pronoun can find its antecedent from the hidden buffer, or in terms of a generative model, the entries in the hidden buffer generate the corresponding pronouns. A system implementing this model is evaluated on the ACE corpus with promising performance.

1 Introduction

Pronoun anaphora resolution is the task of finding the correct antecedent for a given pronominal anaphor in a document. It is a subtask of coreference resolution, which is the process of determining whether two or more linguistic expressions in a document refer to the same entity. Adopting terminology used in the Automatic Context Extraction (ACE) program (NIST, 2003), these expressions are called mentions. Each mention is a reference to some entity in the domain of discourse. Mentions usually fall into three categories – proper mentions (proper names), nominal mentions (descriptions), and pronominal mentions (pronouns). There is a great deal of related work on this subject, so the descriptions of other systems below are those which are most related or which the current model has drawn insight from.

Pairwise models (Yang et al., 2004; Qiu et al., 2004) and graph-partitioning methods (McCallum and Wellner, 2003) decompose the task into a collection of pairwise or mention set coreference decisions. Decisions for each pair or each group of mentions are based on probabilities of features extracted by discriminative learning models. The aforementioned approaches have proven to be fruitful; however, there are some notable problems. Pairwise modeling may fail to produce coherent partitions. That is, if we link results of pairwise decisions to each other, there may be conflicting coreferences. Graph-partitioning methods attempt to reconcile pairwise scores into a final coherent clustering, but they are combinatorially harder to work with in discriminative approaches.

One line of research aiming at overcoming the limitation of pairwise models is to learn a mention-ranking model to rank preceding mentions for a given anaphor (Denis and Baldridge, 2007) This approach results in more coherent coreference chains.

Recent years have also seen the revival of interest in generative models in both machine learning and natural language processing. Haghighi and Klein (2007), proposed an unsupervised non-parametric Bayesian model for coreference resolution. In contrast to pairwise models, this fully generative model produces each mention from a combination of global entity properties and local attentional state. Ng (2008) did similar work using the same unsupervised generative model, but relaxed head generation as head-index generation, enforced agreement constraints at the global level, and assigned salience only to pronouns.

Another unsupervised generative model was recently presented to tackle only pronoun anaphora

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1169–1178,
Portland, Oregon, June 19-24, 2011.

resolution (Charniak and Elsner, 2009). The expectation-maximization algorithm (EM) was applied to learn parameters automatically from the parsed version of the North American News Corpus (McClosky et al., 2008). This model generates a pronoun's person, number and gender features along with the governor of the pronoun and the syntactic relation between the pronoun and the governor. This inference process allows the system to keep track of multiple hypotheses through time, including multiple different possible histories of the discourse.

Haghighi and Klein (2010) improved their nonparametric model by sharing lexical statistics at the level of abstract entity types. Consequently, their model substantially reduces semantic compatibility errors. They report the best results to date on the complete end-to-end coreference task. Further, this model functions in an online setting at mention level. Namely, the system identifies mentions from a parse tree and resolves resolution with a left-to-right sequential beam search. This is similar to Luo (2005) where a Bell tree is used to score and store the searching path.

In this paper, we present a supervised pronoun resolution system based on Factorial Hidden Markov Models (FHMMs). This system is motivated by human processing concerns, by operating incrementally and maintaining a limited short term memory for holding recently mentioned referents. According to Clark and Sengul (1979), anaphoric definite NPs are much faster retrieved if the antecedent of a pronoun is in immediately previous sentence. Therefore, a limited short term memory should be good enough for resolving the majority of pronouns. In order to construct an operable model, we also measured the average distance between pronouns and their antecedents as discussed in next sections and used distances as important salience features in the model.

Second, like Morton (2000), the current system essentially uses prior information as a discourse model with a time-series manner, using a dynamic programming inference algorithm. Third, the FHMM described here is an integrated system, in contrast with (Haghighi and Klein, 2010). The model generates part of speech tags as simple structural information, as well as related semantic information at each time step or word-by-word step. While the framework described here can be extended to deeper structural information, POS tags alone are valuable as they can be used to incorporate the binding features (described below).

Although the system described here is evaluated for pronoun resolution, the framework we describe can be extended to more general coreference resolution in a fairly straightforward manner. Further, as in other HMM-based systems, the system can be either supervised or unsupervised. But extensions to unsupervised learning are left for future work.

The final results are compared with a few supervised systems as the mention-ranking model (Denis and Baldridge, 2007) and systems compared in their paper, and Charniak and Elsner's (2009) unsupervised system, emPronouns. The FHMM-based pronoun resolution system does a better job than the global ranking technique and other approaches. This is a promising start for this novel FHMM-based pronoun resolution system.

2 Model Description

This work is based on a graphical model framework called Factorial Hidden Markov Models (FHMMs). Unlike the more commonly known Hidden Markov Model (HMM), in an FHMM the hidden state at each time step is expanded to contain more than one random variable (as shown in Figure 1). This allows for the use of more complex hidden states by taking advantage of conditional independence between substates. This conditional independence allows complex hidden states to be learned with limited training data.

2.1 Factorial Hidden Markov Model

Factorial Hidden Markov Models are an extension of HMMs (Ghahramani and Jordan, 1997). HMMs represent sequential data as a sequence of hidden states generating observation states (words in this case) at corresponding time steps t. A most likely sequence of hidden states can then be hypothesized given any sequence of observed states, using Bayes Law (Equation 2) and Markov independence assumptions (Equation 3) to define a full probability as the product of a Transition Model (Θ_T) prior probability and an Observation Model (Θ_O) likelihood

probability.

$$\hat{h}_{1..T} \stackrel{\text{def}}{=} \underset{h_{1..T}}{\text{argmax}}\ \mathsf{P}(h_{1..T} \mid o_{1..T}) \quad (1)$$

$$\stackrel{\text{def}}{=} \underset{h_{1..T}}{\text{argmax}}\ \mathsf{P}(h_{1..T}) \cdot \mathsf{P}(o_{1..T} \mid h_{1..T}) \quad (2)$$

$$\stackrel{\text{def}}{=} \underset{h_{1..T}}{\text{argmax}} \prod_{t=1}^{T} \mathsf{P}_{\Theta_T}(h_t \mid h_{t-1}) \cdot \mathsf{P}_{\Theta_O}(o_t \mid h_t) \quad (3)$$

For a simple HMM, the hidden state corresponding to each observation state only involves one variable. An FHMM contains more than one hidden variable in the hidden state. These hidden substates are usually layered processes that jointly generate the evidence. In the model described here, the substates are also coupled to allow interaction between the separate processes. As Figure 1 shows, the hidden states include three sub-states, op, cr and pos which are short forms of *operation*, *coreference feature* and *part-of-speech*. Then, the transition model expands the left term in (3) to (4).

$$\begin{aligned}\mathsf{P}_{\Theta_T}(h_t \mid h_{t-1}) \stackrel{\text{def}}{=} & \mathsf{P}(op_t \mid op_{t-1}, pos_{t-1}) \\ & \cdot \mathsf{P}(cr_t \mid cr_{t-1}, op_{t-1}) \\ & \cdot \mathsf{P}(pos_t \mid op_t, pos_{t-1})\end{aligned} \quad (4)$$

The observation model expands from the right term in (3) to (5).

$$\mathsf{P}_{\Theta_O}(o_t \mid h_t) \stackrel{\text{def}}{=} \mathsf{P}(o_t \mid pos_t, cr_t) \quad (5)$$

The observation state depends on more than one hidden state at each time step in an FHMM. Each hidden variable can be further split into smaller variables. What these terms stand for and the motivations behind the above equations will be explained in the next section.

2.2 Modeling a Coreference Resolver with FHMMs

FHMMs in our model, like standard HMMs, cannot represent the hierarchical structure of a syntactic phrase. In order to partially represent this information, the head word is used to represent the whole noun phrase. After coreference is resolved, the coreferring chain can then be expanded to the whole phrase with NP chunker tools.

In this system, hidden states are composed of three main variables: a referent operation (*OP*), coreference features (*CR*) and part of speech tags (*POS*) as displayed in Figure 1. The transition model is defined as Equation 4.

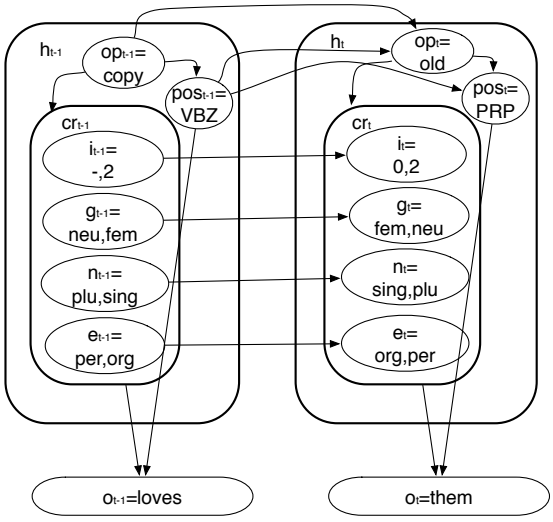

Figure 1: Factorial HMM CR Model

The starting point for the hidden state at each time step is the *OP* variable, which determines which kind of referent operations will occur at the current word. Its domain has three possible states: *none*, *new* and *old*.

The *none* state indicates that the present state will not generate a mention. All previous hidden state values (the list of previous mentions) will be passed deterministically (with probability 1) to the current time step without any changes. The *new* state signifies that there is a new mention in the present time step. In this event, a new mention will be added to the entity set, as represented by its set of feature values and position in the coreference table. The *old* state indicates that there is a mention in the present time state and that this mention refers back to some antecedent mention. In such a case, the list of entities in the buffer will be reordered deterministically, moving the currently mentioned entity to the top of the list.

Notice that op_t is defined to depend on op_{t-1} and pos_{t-1}. This is sometimes called a *switching* FHMM (Duh, 2005). This dependency can be useful, for example, if op_{t-1} is *new*, in which case op_t has a higher probability of being *none* or *old*. If

pos_{t-1} is a verb or preposition, op_t has more probability of being *old* or *new*.

One may wonder why op_t generates pos_t, and not the other way around. This model only roughly models the process of (new and old) entity generation, and either direction of causality might be consistent with a model of human entity generation, but this direction of causality is chosen to represent the effect of semantics (referents) generating syntax (POS tags). In addition, this is a joint model in which POS tagging and coreference resolution are integrated together, so the best combination of those hidden states will be computed in either case.

2.3 Coreference Features

Coreference features for this model refer to features that may help to identify co-referring entities.

In this paper, they mainly include index (*I*), named entity type (*E*), number (*N*) and gender (*G*). The index feature represents the order that a mention was encountered relative to the other mentions in the buffer. The latter three features are well known and described elsewhere, and are not themselves intended as the contribution of this work. The novel aspect of this part of the model is the fact that the features are carried forward, updated after every word, and essentially act as a discourse model. The features are just a shorthand way of representing some well known essential aspects of a referent (as pertains to anaphora resolution) in a discourse model.

Features	Values
I	positive integers from 1. . .n
G	male, female, neutral, unknown
N	singular, plural, unknown
E	person, location, organization, GPE, vehicle, company, facility

Table 1: Coreference features stored with each mention.

Unlike discriminative approaches, generative models like the FHMM described here do not have access to all observations at once. This model must then have a mechanism for jointly considering pronouns in tandem with previous mentions, as well as the features of those mentions that might be used to find matches between pronouns and antecedents.

Further, higher order HMMs may contain more accurate information about observation states. This is especially true for coreference resolution because pronouns often refer back to mentions that are far away from the present state. In this case, we would need to know information about mentions which are at least two mentions before the present one. In this sense, a higher order HMM may seem ideal for coreference resolution. However, higher order HMMs will quickly become intractable as the order increases.

In order to overcome these limitations, two strategies which have been discussed in the last section are taken: First, a switching variable called *OP* is designed (as discussed in last section); second, a memory of recently mentioned entities is maintained to store features of mentions and pass them forward incrementally.

OP is intended to model the decision to use the current word to introduce a new referent (*new*), refer to an antecedent (*old*), or neither (*none*). The entity buffer is intended to model the set of 'activated' entities in the discourse – those which could plausibly be referred to with a pronoun. These designs allow similar benefits as longer dependencies of higher-order HMMs but avoid the problem of intractability. The number of mentions maintained must be limited in order for the model to be tractable. Fortunately, human short term memory faces effectively similar limitations and thus pronouns usually refer back to mentions not very far away.

Even so, the impact of the size of the buffer on decoding time may be a concern. Since the buffer of our system will carry forward a few previous groups of coreference features plus *op* and *pos*, the computational complexity will be exorbitantly high if we keep high beam size and meanwhile if each feature interacts with others. Luckily, we have successfully reduced the intractability to a workable system in both speed and space with following methods. First, we estimate the size of buffer with a simple count of average distances between pronouns and their antecedents in the corpus. It is found that about six is enough for covering 99.2% of all pronouns.

Secondly, the coreference features we have used have the nice property of being independent from one another. One might expect English non-person entities to almost always have neutral gender, and

thus be modeled as follows:

$$\mathsf{P}(e_t, g_t \mid e_{t-1}, g_{t-1}) = \mathsf{P}(g_t \mid g_{t-1}, e_t) \cdot \mathsf{P}(e_t \mid e_{t-1}) \quad (6)$$

However, a few considerations made us reconsider. First, exceptions are found in the corpus. Personal pronouns such as *she* or *he* are used to refer to country, regions, states or organizations. Second, existing model files made by Bergsma (2005) include a large number of non-neutral gender information for non-person words. We employ these files for acquiring gender information of unknown words. If we use Equation 6, sparsity and complexity will increase. Further, preliminary experiments have shown models using an independence assumption between gender and personhood work better. Thus, we treat each coreference feature as an independent event. Hence, we can safely split coreference features into separate parts. This way dramatically reduces the model complexity. Thirdly, our HMM decoding uses the Viterbi algorithm with A-star beam search.

The probability of the new state of the coreference table $\mathsf{P}(cr_t \mid cr_{t-1}, op_t)$ is defined to be the product of probabilities of the individual feature transitions.

$$\begin{aligned} \mathsf{P}(cr_t \mid cr_{t-1}, op_t) = \mathsf{P}(i_t \mid i_{t-1}, op_t) \cdot \\ \mathsf{P}(e_t \mid e_{t-1}, i_t, op_t) \cdot \\ \mathsf{P}(g_t \mid g_{t-1}, i_t, op_t) \cdot \\ \mathsf{P}(n_t \mid n_{t-1}, i_t, op_t) \end{aligned} \quad (7)$$

This supposes that the features are conditionally independent of each other given the index variable, the operator and previous instance. Each feature only depends on the operator and the corresponding feature at the previous state, with that set of features re-ordered as specified by the index model.

2.4 Feature Passing

Equation 7 is correct and complete, but in fact the switching variable for operation type results in three different cases which simplifies the calculation of the transition probabilities for the coreference feature table.

Note the following observations about coreference features: i_t only needs a probabilistic model when op_t is *old* – in other words, only when the model must choose between several antecedents to re-refer to. g_t, e_t and n_t are deterministic except when op_t is *new*, when gender, entity type, and number information must be generated for the new entity being introduced.

When op_t is *none*, all coreference variables (entity features) will be copied over from the previous time step to the current time step, and the probability of this transition is 1.0. When op_t is *new*, i_t is changed deterministically by adding the new entity to the first position in the list and moving every other entity down one position. If the list of entities is full, the least recently mentioned entity will be discarded. The values for the top of the feature lists g_t, e_t, and n_t will then be generated from feature-specific probability distributions estimated from the training data. When op_t is *old*, i_t will probabilistically select a value $1 \ldots n$, for an entity list containing n items. The selected value will deterministically order the g_t, n_t and e_t lists. This distribution is also estimated from training data, and takes into account recency of mention. The shape of this distribution varies slightly depending on list size and noise in the training data, but in general the probability of a mention being selected is directly correlated to how recently it was mentioned.

With this understanding, coreference table transition probabilities can be written in terms of only their non-deterministic substate distributions:

$$\begin{aligned} \mathsf{P}(cr_t \mid cr_{t-1}, old) = \; & \mathsf{P}_{old}(i_t \mid i_{t-1}) \cdot \\ & \mathsf{P}_{reorder}(e_t \mid e_{t-1}, i_t) \cdot \\ & \mathsf{P}_{reorder}(g_t \mid g_{t-1}, i_t) \cdot \\ & \mathsf{P}_{reorder}(n_t \mid n_{t-1}, i_t) \end{aligned} \quad (8)$$

where the *old* model probabilistically selects the antecedent and moves it to the top of the list as described above, thus deciding how the reordering will take place. The *reorder* model actually implements the list reordering for each independent feature by moving the feature value corresponding to the selected entity in the index model to the top of that feature's list. The overall effect is simply the probabilistic reordering of entities in a list, where each entity is defined as a label and a set of features.

$$\begin{aligned} \mathsf{P}(cr_t \mid cr_{t-1}, new) = \; & \mathsf{P}_{new}(i_t \mid i_{t-1}) \cdot \\ & \mathsf{P}_{new}(g_t \mid g_{t-1}) \cdot \\ & \mathsf{P}_{new}(n_t \mid n_{t-1}) \cdot \\ & \mathsf{P}_{new}(e_t \mid e_{t-1}) \end{aligned} \quad (9)$$

where the *new* model probabilistically generates a

feature value based on the training data and puts it at the top of the list, moves every other entity down one position in the list, and removes the final item if the list is already full. Each entity in *i* takes a value from 1 to n for a list of size n. Each *g* can be one of four values – *male*, *female*, *neuter* and *unknown*; *n* one of three values – *plural*, *singular* and *unknown* and *e* around eight values.

Note that pos_t is used in both hidden states and observation states. While it is not considered a coreference feature as such, it can still play an important role in the resolving process. Basically, the system tags parts of speech incrementally while simultaneously resolving pronoun anaphora. Meanwhile, pos_{t-1} and op_{t-1} will jointly generate op_t. This point has been discussed in Section 2.2.

Importantly, the pos model can help to implement binding principles (Chomsky, 1981). It is applied when op_t is old. In training, pronouns are sub-categorised into personal pronouns, reflexive and other-pronoun. We then define a variable loc_t whose value is how far back in the list of antecedents the current hypothesis must have gone to arrive at the current value of i_t. If we have the syntax annotations or parsed trees, then, the part of speech model can be defined when op_t is *old* as $\mathsf{P}_{binding}(pos_t \,|\, loc_t, s_{loc_t})$. For example, if $pos_t \in reflexive$, $\mathsf{P}(pos_t \,|\, loc_t, s_{loc_t})$ where loc_t has smaller values (implying closer mentions to pos_t) and $s_{loc_t} = subject$ should have higher values since reflexive pronouns always refer back to subjects within its governing domains. This was what (Haghighi and Klein, 2009) did and we did this in training with the REUTERS corpus (Hasler et al., 2006) in which syntactic roles are annotated. We finally switched to the ACE corpus for the purpose of comparison with other work. In the ACE corpus, no syntactic roles are annotated. We did use the Stanford parser to extract syntactic roles from the ACE corpus. But the result is largely affected by the parsing accuracy. Again, for a fair comparison, we extract similar features to Denis and Baldridge (2007), which is the model we mainly compare with. They approximate syntactic contexts with POS tags surrounding the pronoun. Inspired by this idea, we successfully represent binding features with POS tags before anaphors. Instead of using $\mathsf{P}(pos_t \,|\, loc_t, s_{loc_t})$, we train $\mathsf{P}(pos_t \,|\, loc_t, pos_{loc_t})$ which can play the role of binding. For example, suppose the buffer size is 6 and $loc_t = 5$, $pos_{loc_t} = noun$. Then, $\mathsf{P}(pos_t = reflexive \,|\, loc_t, pos_{loc_t})$ is usually higher than $\mathsf{P}(pos_t = pronoun \,|\, loc_t, pos_{loc_t})$, since the reflexive has a higher probability of referring back to the noun located in position 5 than the pronoun.

In future work expanding to coreference resolution between any noun phrases we intend to integrate syntax into this framework as a joint model of coreference resolution and parsing.

3 Observation Model

The observation model that generates an observed state is defined as Equation 5. To expand that equation in detail, the observation state, the word, depends on its part of speech and its coreference features as well. Since FHMMs are generative, we can say part of speech and coreference features generate the word.

In actual implementation, the observed model will be very sparse, since cr_t will be split into more variables according to how many coreference features it is composed of. In order to avoid the sparsity, we transform the equation with Bayes' law as follows.

$$\mathsf{P}_{\Theta_O}(o_t \,|\, h_t) = \frac{P(o_t) \cdot \mathsf{P}(h_t \,|\, o_t)}{\sum_{o'} P(o')\mathsf{P}(h_t \,|\, o')} \tag{10}$$

$$= \frac{P(o_t) \cdot \mathsf{P}(pos_t, cr_t \,|\, o_t)}{\sum_{o'} P(o')\mathsf{P}(pos_t, cr_t \,|\, o')} \tag{11}$$

We define *pos* and *cr* to be independent of each other, so we can further split the above equation as:

$$\mathsf{P}_{\Theta_O}(o_t \,|\, h_t) \stackrel{\text{def}}{=} \frac{P(o_t) \cdot \mathsf{P}(pos_t \,|\, o_t) \cdot \mathsf{P}(cr_t \,|\, o_t)}{\sum_{o'} P(o') \cdot \mathsf{P}(pos_t \,|\, o') \cdot \mathsf{P}(cr_t \,|\, o')} \tag{12}$$

where $\mathsf{P}(cr_t \,|\, o_t) = \mathsf{P}(g_t \,|\, o_t)\mathsf{P}(n_t \,|\, o_t)\mathsf{P}(e_t \,|\, o_t)$ and $\mathsf{P}(cr_t \,|\, o') = \mathsf{P}(g_t \,|\, o')\mathsf{P}(n_t \,|\, o')\mathsf{P}(e_t \,|\, o')$.

This change transforms the FHMM to a hybrid FHMM since the observation model no longer generates the data. Instead, the observation model generates hidden states, which is more a combination of discriminative and generative approaches. This way facilitates building likelihood model files of features for given mentions from the training data. The

hidden state transition model represents prior probabilities of coreference features associated with each while this observation model factors in the probability given a pronoun.

3.1 Unknown Words Processing

If an observed word was not seen in training, the distribution of its part of speech, gender, number and entity type will be unknown. In this case, a special unknown words model is used.

The part of speech of unknown words $\mathsf{P}(pos_t \mid w_t = unkword)$ is estimated using a decision tree model. This decision tree is built by splitting letters in words from the end of the word backward to its beginning. A POS tag is assigned to the word after comparisons between the morphological features of words trained from the corpus and the strings concatenated from the tree leaves are made. This method is about as accurate as the approach described by Klein and Manning (2003).

Next, a similar model is set up for estimating $\mathsf{P}(n_t \mid w_t = unkword)$. Most English words have regular plural forms, and even irregular words have their patterns. Therefore, the morphological features of English words can often be used to determine whether a word is singular or plural.

Gender is irregular in English, so model-based predictions are problematic. Instead, we follow Bergsma and Lin (2005) to get the distribution of gender from their gender/number data and then predict the gender for unknown words.

4 Evaluation and Discussion

4.1 Experimental Setup

In this research, we used the ACE corpus (Phase 2) [1] for evaluation. The development of this corpus involved two stages. The first stage is called EDT (entity detection and tracking) while the second stage is called RDC (relation detection and characterization). All markables have named entity types such as FACILITY, GPE (geopolitical entity), PERSON, LOCATION, ORGANIZATION, PERSON, VEHICLE and WEAPONS, which were annotated in the first stage. In the second stage, relations between named entities were annotated. This corpus include three parts, composed of different genres: newspaper texts (NPAPER), newswire texts (NWIRE) and broadcasted news (BNEWS). Each of these is split into a *train* part and a *devtest* part. For the train part, there are 76, 130 and 217 articles in NPAPER, NWIRE and BNEWS respectively while for the test part, there are 17, 29 and 51 articles respectively. Though the number of articles are quite different for three genres, the total number of words are almost the same. Namely, the length of NPAPER is much longer than BNEWS (about 1200 words, 800 word and 500 words respectively for three genres). The longer articles involve longer coreference chains. Following the common practice, we used the *devtest* material only for testing. Progress during the development phase was estimated only by using cross-validation on the training set for the BNEWS section. In order to make comparisons with publications which used the same corpus, we make efforts to set up identical conditions for our experiments.

The main point of comparison is Denis and Baldridge (2007), which was similar in that it described a new type of coreference resolver using simple features.

Therefore, similar to their practice, we use all forms of personal and possessive pronouns that were annotated as ACE "markables". Namely, pronouns associated with named entity types could be used in this system. In experiments, we also used *true* ACE mentions as they did. This means that pleonastics and references to eventualities or to non-ACE entities are not included in our experiments either. In all, 7263 referential pronouns in training data set and 1866 in testing data set are found in all three genres. They have results of three different systems: SCC (single candidate classifier), TCC (twin candidate classifier) and RK (ranking). Besides the three and our own system, we also report results of emPronouns, which is an unsupervised system based on a recently published paper (Charniak and Elsner, 2009). We select this unsupervised system for two reasons. Firstly, emPronouns is a publicly available system with high accuracy in pronoun resolution. Secondly, it is necessary for us to demonstrate our system has strong empirical superiority over unsupervised ones. In testing, we also used the OPNLP Named Entity Recognizer to tag the test corpus.

[1] See `http://projects.ldc.upenn.edu/ace/annotation/previous/` for details on the corpus.

During training, besides coreference annotation itself, the part of speech, dependencies between words and named entities, gender, number and index are extracted using relative frequency estimation to train models for the coreference resolution system.

Inputs for testing are the plain text and the trained model files. The entity buffer used in these experiments kept track of only the six most recent mentions. The result of this process is an annotation of the headword of every noun phrase denoting it as a mention. In addition, this system does not do anaphoricity detection, so the antecedent operation for non-anaphora pronoun *it* is set to be *none*. Finally, the system does not yet model cataphora, about 10 cataphoric pronouns in the testing data which are all counted as wrong.

4.2 Results

The performance was evaluated using the ratio of the number of correctly resolved anaphors over the number of all anaphors as a success metrics. All the standards are consistent with those defined in Charniak and Elsner (2009).

During development, several preliminary experiments explored the effects of starting from a simple baseline and adding more features. The BNEWS corpus was employed in these development experiments. The baseline only includes part of speech tags, the index feature and and syntactic roles. Syntactic roles are extracted from the parsing results with Stanford parser. The success rate of this baseline configuration is 0.48. This low accuracy is partially due to the errors of automatic parsing. With gender and number features added, the performance jumped to 0.65. This shows that number and gender agreements play an important role in pronoun anaphora resolution. For a more standard comparison to other work, subsequent tests were performed on the gold standard ACE corpus (using the model as described with named entity features instead of syntactic role features). As shown in Denis and Baldridge (2007), they employ all features we use except syntactic roles. In these experiments, the system got better results as shown in Table 2.

The result of the first one is obtained by running the publicly available system emPronouns[2]. It is a high-accuracy unsupervised system which reported the best result in Charniak and Elsner (2009).

System	BNEWS	NPAPER	NWIRE
emPronouns	58.5	64.5	60.6
SCC	62.2	70.7	68.3
TCC	68.6	74.7	71.1
RK	72.9	76.4	72.4
FHMM	**74.9**	**79.4**	**74.5**

Table 2: Accuracy scores for emPronouns, the single-candidate classifier (SCC), the twin-candidate classifier (TCC), the ranker and FHMM

The results of the other three systems are those reported by Denis and Baldridge (2007). As Table 2 shows, the FHMM system gets the highest average results.

The emPronouns system got the lowest results partially due to the reason that we only directly run the existing system with its existing model files without retraining. But the gap between its results and results of our system is large. Thus, we may still say that our system probably can do a better job even if we train new models files for emPronouns with ACE corpus.

With almost exactly identical settings, why does our FHMM system get the highest average results? The convincing reason is that FHMM is strongly influenced by the sequential dependencies. The ranking approach ranks a set of mentions using a set of features, and it also maintains the discourse model, but it is not processing sequentially. The FHMM system always maintain a set of mentions as well as a first-order dependencies between part of speech and operator. Therefore, context can be more fully taken into consideration. This is the main reason that the FHMM approach achieved better results than the ranking approach.

From the result, one point we may notice is that NPAPER usually obtains higher results than both BNEWS and NWIRE for all systems while BNEWS lower than other two genres. In last section, we mention that articles in NPAPER are longer than other genres and also have denser coreference chains while articles in BENEWS are shorter and have sparer chains. Then, it is not hard to understand why results of NPAPER are better while those of

[2]the available system in fact only includes the testing part. Thus, it may be unfair to compare emPronouns this way with other systems.

BNEWS are poorer.

In Denis and Baldridge (2007), they also reported new results with a window of 10 sentences for RK model. All three genres obtained higher results than those when with shorter ones. They are 73.0, 77.6 and 75.0 for BNEWS, NPAPER and NWIRE respectively. We can see that except the one for NWIRE, the results are still poorer than our system. For NWIRE, the RK model got 0.5 higher. The average of the RK is 75.2 while that of the FHMM system is 76.3, which is still the best.

Since the emPronoun system can output sample-level results, it is possible to do a paired Student's t-test. That test shows that the improvement of our system on all three genres is statistically significant ($p < 0.001$). Unfortunately, the other systems only report overall results so the same comparison was not so straightforward.

4.3 Error Analysis

After running the system on these documents, we checked which pronouns fail to catch their antecedents. There are a few general reasons for errors.

First, pronouns which have antecedents very far away cannot be caught. Long-distance anaphora resolution may pose a problem since the buffer size cannot be too long considering the complexity of tracking a large number of mentions through time. During development, estimation of an acceptable size was attempted using the training data. It was found that a mention distance of fourteen would account for every case found in this corpus, though most cases fall well short of that distance. Future work will explore optimizations that will allow for larger or variable buffer sizes so that longer distance anaphora can be detected.

A second source of error is simple misjudgments when more than one candidate is waiting for selection. A simple case is that the system fails to distinguish plural personal nouns and non-personal nouns if both candidates are plural. This is not a problem for singular pronouns since gender features can tell whether pronouns are personal or not. Plural nouns in English do not have such distinctions, however. Consequently, *demands* and *Israelis* have the same probability of being selected as the antecedents for *they*, all else being equal. If *demands* is closer to *they*, *demands* will be selected as the antecedent. This may lead to the wrong choice if *they* in fact refers to *Israelis*. This may require better measures of referent salience than the "least recently used" heuristic currently implemented.

Third, these results also show difficulty resolving coordinate noun phrases due to the simplistic representation of noun phrases in the input. Consider this sentence: *President Barack Obama and his wife Michelle Obama visited China last week. They had a meeting with President Hu in Beijing*. In this example, the pronoun *they* corefers with the noun phrase *President Barack Obama and his wife Michelle Obama*. The present model cannot represent both the larger noun phrase and its contained noun phrases. Since the noun phrase is a coordinate one that includes both noun phrases, the model cannot find a head word to represent it.

Finally, while the coreference feature annotations of the ACE are valuable for learning feature models, the model training may still give some misleading results. This is brought about by missing features in the training corpus and by the data sparsity. We solved the problem with add-one smoothing and deleted interpolation in training models besides the transformation in the generation order of the observation model.

5 Conclusion and Future Work

This paper has presented a pronoun anaphora resolution system based on FHMMs. This generative system incrementally resolves pronoun anaphora with an entity buffer carrying forward mention features. The system performs well and outperforms other available models. This shows that FHMMs and other time-series models may be a valuable model to resolve anaphora.

Acknowledgments

We would like to thank the authors and maintainers of ranker models and emPronouns. We also would like to thank the three anonymous reviewers. The final version is revised based on their valuable comments. Thanks are extended to Shane Bergsma, who provided us the gender and number data distribution. In addition, Professor Jeanette Gundel and our labmate Stephen Wu also gave us support in paper editing and in theoretical discussion.

Disentangling Chat with Local Coherence Models

Abstract

We evaluate several popular models of local discourse coherence for domain and task generality by applying them to chat disentanglement. Using experiments on synthetic multiparty conversations, we show that most models transfer well from text to dialogue. Coherence models improve results overall when good parses and topic models are available, and on a constrained task for real chat data.

1 Introduction

One property of a well-written document is *coherence*, the way each sentence fits into its context– sentences should be interpretable in light of what has come before, and in turn make it possible to interpret what comes after. Models of coherence have primarily been used for text-based generation tasks: ordering units of text for multidocument summarization or inserting new text into an existing article. In general, the corpora used consist of informative writing, and the tasks used for evaluation consider different ways of reordering the same set of textual units. But the theoretical concept of coherence goes beyond both this domain and this task setting– and so should coherence models.

This paper evaluates a variety of local coherence models on the task of chat disentanglement or "threading": separating a transcript of a multiparty interaction into independent conversations[1]. Such simultaneous conversations occur in internet chat rooms, and on shared voice channels such as push-to-talk radio. In these situations, a single, correctly disentangled, conversational thread will be coherent, since the speakers involved understand the normal rules of discourse, but the transcript as a whole will not be. Thus, a good model of coherence should be able to disentangle sentences as well as order them.

There are several differences between disentanglement and the newswire sentence-ordering tasks typically used to evaluate coherence models. Internet chat comes from a different domain, one where topics vary widely and no reliable syntactic annotations are available. The disentanglement task measures different capabilities of a model, since it compares documents that are not permuted versions of one another. Finally, full disentanglement requires a large-scale search, which is computationally difficult. We move toward disentanglement in stages, carrying out a series of experiments to measure the contribution of each of these factors.

As an intermediary between newswire and internet chat, we adopt the SWITCHBOARD (SWBD) corpus. SWBD contains recorded telephone conversations with known topics and hand-annotated parse trees; this allows us to control for the performance of our parser and other informational resources. To compare the two algorithmic settings, we use SWBD for ordering experiments, and also artificially entangle pairs of telephone dialogues to create synthetic transcripts which we can disentangle. Finally, we present results on actual internet chat corpora.

On synthetic SWBD transcripts, local coherence models improve performance considerably over our baseline model, Elsner and Charniak (2008b). On

[1] A public implementation is available via https://bitbucket.org/melsner/browncoherence.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1179–1189,
Portland, Oregon, June 19-24, 2011.

internet chat, we continue to do better on a constrained disentanglement task, though so far, we are unable to apply these improvements to the full task. We suspect that, with better low-level annotation tools for the chat domain and a good way of integrating prior information, our improvements on SWBD could transfer fully to IRC chat.

2 Related work

There is extensive previous work on coherence models for text ordering; we describe several specific models below, in section 2. This study focuses on models of local coherence, which relate text to its immediate context. There has also been work on global coherence, the structure of a document as a whole (Chen et al., 2009; Eisenstein and Barzilay, 2008; Barzilay and Lee, 2004), typically modeled in terms of sequential topics. We avoid using them here, because we do not believe topic sequences are predictable in conversation and because such models tend to be algorithmically cumbersome.

In addition to text ordering, local coherence models have also been used to score the fluency of texts written by humans or produced by machine (Pitler and Nenkova, 2008; Lapata, 2006; Miltsakaki and Kukich, 2004). Like disentanglement, these tasks provide an algorithmic setting that differs from ordering, and so can demonstrate previously unknown weaknesses in models. However, the target genre is still informative writing, so they reveal little about cross-domain flexibility.

The task of disentanglement or "threading" for internet chat was introduced by Shen et al. (2006). Elsner and Charniak (2008b) created the publicly available #LINUX corpus; the best published results on this corpus are those of Wang and Oard (2009). These two studies use overlapping unigrams to measure similarity between two sentences; Wang and Oard (2009) use a message expansion technique to incorporate context beyond a single sentence. Unigram overlaps are used to model coherence, but more sophisticated methods using syntax (Lapata and Barzilay, 2005) or lexical features (Lapata, 2003) often outperform them on ordering tasks. This study compares several of these methods with Elsner and Charniak (2008b), which we use as a baseline because there is a publicly available implementation[2].

Adams (2008) also created and released a disentanglement corpus. They use LDA (Blei et al., 2001) to discover latent topics in their corpus, then measuring similarity by looking for shared topics. These features fail to improve their performance, which is puzzling in light of the success of topic modeling for other coherence and segmentation problems (Eisenstein and Barzilay, 2008; Foltz et al., 1998). The results of this study suggest that topic models can help with disentanglement, but that it is difficult to find useful topics for IRC chat.

A few studies have attempted to disentangle conversational speech (Aoki et al., 2003; Aoki et al., 2006), mostly using temporal features. For the most part, however, this research has focused on auditory processing in the context of the *cocktail party* problem, the task of attending to a specific speaker in a noisy room (Haykin and Chen, 2005). Utterance content has some influence on what the listener perceives, but only for extremely salient cues such as the listener's name (Moray, 1959), so cocktail party research does not typically use lexical models.

3 Models

In this section, we briefly describe the models we intend to evaluate. Most of them are drawn from previous work; one, the topical entity grid, is a novel extension of the entity grid. For the experiments below, we train the models on SWBD, sometimes augmented with a larger set of automatically parsed conversations from the FISHER corpus. Since the two corpora are quite similar, FISHER is a useful source for extra data; McClosky et al. (2010) uses it for this purpose in parsing experiments. (We continue to use SWBD/FISHER even for experiments on IRC, because we do not have enough disentangled training data to learn lexical relationships.)

3.1 Entity grid

The entity grid (Lapata and Barzilay, 2005; Barzilay and Lapata, 2005) is an attempt to model some principles of Centering Theory (Grosz et al., 1995) in a statistical manner. It represents a document in terms of entities and their syntactic roles: subject (S), object (O), other (X) and not present (-). In each new

[2] cs.brown.edu/~melsner

utterance, the grid predicts the role in which each entity will appear, given its history of roles in the previous sentences, plus a *salience* feature counting the total number of times the entity occurs. For instance, for an entity which is the subject of sentence 1, the object of sentence 2, and occurs four times in total, the grid predicts its role in sentence 3 according to the conditional $P(\cdot|S, O, sal = 4)$.

As in previous work, we treat each noun in a document as denoting a single entity, rather than using a coreference technique to attempt to resolve them. In our development experiments, we noticed that coreferent nouns often occur farther apart in conversation than in newswire, since they are frequently referred to by pronouns and deictics in the interim. Therefore, we extend the history to six previous utterances. For robustness with this long history, we model the conditional probabilities using multilabel logistic regression rather than maximum likelihood. This requires the assumption of a linear model, but makes the estimator less vulnerable to overfitting due to sparsity, increasing performance by about 2% in development experiments.

3.2 Topical entity grid

This model is a variant of the generative entity grid, intended to take into account topical information. To create the topical entity grid, we learn a set of topic-to-word distributions for our corpus using LDA (Blei et al., 2001)[3] with 200 latent topics. This model embeds our vocabulary in a low-dimensional space: we represent each word w as the vector of topic probabilities $p(t_i|w)$. We experimented with several ways to measure relationships between words in this space, starting with the standard cosine. However, the cosine can depend on small variations in probability (for instance, if w has most of its mass in dimension 1, then it is sensitive to the exact weight of v for topic 1, even if this essentially never happens).

To control for this tendency, we instead use the magnitude of the dimension of greatest similarity:

$$sim(w, v) = max_i \; min(w_i, v_i)$$

To model coherence, we generalize the binary history features of the standard entity grid, which detect, for example, whether entity e is the subject of the previous sentence. In the topical entity grid, we instead compute a real-valued feature which sums up the similarity between entity e and the subject(s) of the previous sentence.

These features can detect a transition like: "The House voted yesterday. The Senate will consider the bill today.". If "House" and "Senate" have a high similarity, then the feature will have a high value, predicting that "Senate" is a good subject for the current sentence. As in the previous section, we learn the conditional probabilities with logistic regression; we train in parallel by splitting the data and averaging (Mann et al., 2009). The topics are trained on FISHER, and on NANC for news.

3.3 IBM-1

The IBM translation model was first considered for coherence by Soricut and Marcu (2006), although a less probabilistically elegant version was proposed earlier (Lapata, 2003). This model attempts to generate the content words of the next sentence by translating them from the words of the previous sentence, plus a null word; thus, it will learn alignments between pairs of words that tend to occur in adjacent sentences. We learn parameters on the FISHER corpus, and on NANC for news.

3.4 Pronouns

The use of a generative pronoun resolver for coherence modeling originates in Elsner and Charniak (2008a). That paper used a supervised model (Ge et al., 1998), but we adapt a newer, unsupervised model which they also make publicly available (Charniak and Elsner, 2009)[4]. They model each pronoun as generated by an antecedent somewhere in the previous two sentences. If a good antecedent is found, the probability of the pronoun's occurrence will be high; otherwise, the probability is low, signaling that the text is less coherent because the pronoun is hard to interpret correctly.

We use the model as distributed for news text. For conversation, we adapt it by running a few iterations of their EM training algorithm on the FISHER data.

[4] bllip.cs.brown.edu/resources.shtml\#software

3.5 Discourse-newness

Building on work from summarization (Nenkova and McKeown, 2003) and coreference resolution (Poesio et al., 2005), Elsner and Charniak (2008a) use a model which recognizes discourse-new versus old NPs as a coherence model. For instance, the model can learn that "President Barack Obama" is a more likely first reference than "Obama". Following their work, we score discourse-newness with a maximum-entropy classifier using syntactic features counting different types of NP modifiers, and we use NP head identity as a proxy for coreference.

3.6 Chat-specific features

Most disentanglement models use non-linguistic information alongside lexical features; in fact, timestamps and speaker identities are usually *better* cues than words are. We capture three essential non-linguistic features using simple generative models.

The first feature is the **time** gap between one utterance and the next within the same thread. Consistent short gaps are a sign of normal turn-taking behavior; long pauses do occur, but much more rarely (Aoki et al., 2003). We round all time gaps to the nearest second and model the distribution of time gaps using a histogram, choosing bucket sizes adaptively so that each bucket contains at least four datapoints.

The second feature is **speaker** identity; conversations usually involve a small subset of the total number of speakers, and a few core speakers make most of the utterances. We model the distribution of speakers in each conversation using a Chinese Restaurant Process (CRP) (Aldous, 1985) (tuning the dispersion α to maximize development performance). The CRP's "rich-get-richer" dynamics capture our intuitions, favoring conversations dominated by a few vociferous speakers.

Finally, we model name **mentioning**. Speakers in IRC chat often use their addressee's names to coordinate the chat (O'Neill and Martin, 2003), and this is a powerful source of information (Elsner and Charniak, 2008b). Our model classifies each utterance into either the start or continuation of a conversational turn, by checking if the previous utterance had the same speaker. Given this status, it computes probabilities for three outcomes: no name mention, a mention of someone who has previously spoken in the conversation, or a mention of someone else. (The third option is extremely rare; this accounts for most of the model's predictive power). We learn these probabilities from IRC training data.

3.7 Model combination

To combine these different models, we adopt the log-linear framework of Soricut and Marcu (2006). Here, each model P_i is assigned a weight λ_i, and the combined score $P(d)$ is proportional to:

$$\sum_i \lambda_i log(P_i(d))$$

The weights λ can be learned discriminatively, maximizing the probability of d relative to a task-specific contrast set. For ordering experiments, the contrast set is a single random permutation of d; we explain the training regime for disentanglement below, in subsection 4.1.

4 Comparing orderings of SWBD

To measure the differences in performance caused by moving from news to a conversational domain, we first compare our models on an ordering task, discrimination (Barzilay and Lapata, 2005; Karamanis et al., 2004). In this task, we take an original document and randomly permute its sentences, creating an artificial incoherent document. We then test to see if our model prefers the coherent original.

For SWBD, rather than compare permutations of the individual utterances, we permute conversational turns (sets of consecutive utterances by each speaker), since turns are natural discourse units in conversation. We take documents numbered 2000–3999 as training/development and the remainder as test, yielding 505 training and 153 test documents; we evaluate 20 permutations per document. As a comparison, we also show results for the same models on WSJ, using the train-test split from Elsner and Charniak (2008a); the test set is sections 14-24, totalling 1004 documents.

Purandare and Litman (2008) carry out similar experiments on distinguishing permuted SWBD documents, using lexical and WordNet features in a model similar to Lapata (2003). Their accuracy for this task (which they call "switch-hard") is roughly 68%.

	WSJ	SWBD
EGrid	76.4‡	86.0
Topical EGrid	71.8‡	70.9‡
IBM-1	77.2‡	84.9†
Pronouns	69.6‡	71.7‡
Disc-new	72.3‡	55.0‡
Combined	81.9	88.4
-EGrid	81.0	87.5
-Topical EGrid	**82.2**	**90.5**
-IBM-1	79.0‡	88.9
-Pronouns	81.3	88.5
-Disc-new	**82.2**	88.4

Table 1: Discrimination F scores on news and dialogue. ‡ indicates a significant difference from the combined model at p=.01 and † at p=.05.

In Table 1, we show the results for individual models, for the combined model, and ablation results for mixtures without each component. WSJ is more difficult than SWBD overall because, on average, news articles are shorter than SWBD conversations. Short documents are harder, because permuting disrupts them less. The best SWBD result is 91%; the best WSJ result is 82% (both for mixtures without the topical entity grid). The WSJ result is state-of-the-art for the dataset, improving slightly on Elsner and Charniak (2008a) at 81%. We test results for significance using the non-parametric Mann-Whitney U test.

Controlling for the fact that discrimination is easier on SWBD, most of the individual models perform similarly in both corpora. The strongest models in both cases are the entity grid and IBM-1 (at about 77% for news, 85% for dialogue). Pronouns and the topical entity grid are weaker. The major outlier is the discourse-new model, whose performance drops from 72% for news to only 55%, just above chance, for conversation.

The model combination results show that all the models are quite closely correlated, since leaving out any single model does not degrade the combination very much (only one of the ablations is significantly worse than the combination). The most critical in news is IBM-1 (decreasing performance by 3% when removed); in conversation, it is the entity grid (decreasing by about 1%). The topical entity grid actually has a (nonsignificant) *negative* impact on combined performance, implying that its predictive power in this setting comes mainly from information that other models also capture, but that it is noisier and less reliable. In each domain, the combined models outperform the best single model, showing the information provided by the weaker models is not completely redundant.

Overall, these results suggest that most previously proposed local coherence models are domain-general; they work on conversation as well as news. The exception is the discourse-newness model, which benefits most from the specific conventions of a written style. Full names with titles (like "President Barack Obama") are more common in news, while conversation tends to involve fewer completely unfamiliar entities and more cases of bridging reference, in which grounding information is given implicitly (Nissim, 2006). Due to its poor performance, we omit the discourse-newness model in our remaining experiments.

5 Disentangling SWBD

We now turn to the task of disentanglement, testing whether models that are good at ordering also do well in this new setting. We would like to hold the domain constant, but we do not have any disentanglement data recorded from naturally occurring speech, so we create synthetic instances by merging pairs of SWBD dialogues. Doing so creates an artificial transcript in which two pairs of people appear to be talking simultaneously over a shared channel.

The situation is somewhat contrived in that each pair of speakers converses only with each other, never breaking into the other pair's dialogue and rarely using devices like name mentioning to make it clear who they are addressing. Since this makes speaker identity a perfect cue for disentanglement, we do not use it in this section. The only chat-specific model we use is **time**.

Because we are not using speaker information, we remove all utterances which do not contain a noun before constructing synthetic transcripts– these are mostly backchannels like "Yeah". Such utterances cannot be correctly assigned by our coherence models, which deal with content; we suspect most of them could be dealt with by associating them with the nearest utterance from the same speaker.

Once the backchannels are stripped, we can create a synthetic transcript. For each dialogue, we first simulate timestamps by sampling the number of seconds between each utterance and the next from a discretized Gaussian: $\lfloor N(0, 2.5) \rfloor$. The interleaving of the conversations is dictated by the timestamps. We truncate the longer conversation at the length of the shorter; this ensures a baseline score of 50% for the degenerate model that assigns all utterances to the same conversation.

We create synthetic instances of two types– those where the two entangled conversations had different topical prompts and those where they were the same. (Each dialogue in SWBD focuses on a preselected topic, such as *fishing* or *movies*.) We entangle dialogues from our ordering development set to use for mixture training and validation; for testing, we use 100 instances of each type, constructed from dialogues in our test set.

When disentangling, we treat each thread as independent of the others. In other words, the probability of the entire transcript is the product of the probabilities of the component threads. Our objective is to find the set of threads maximizing this. As a comparison, we use the model of Elsner and Charniak (2008b) as a baseline. To make their implementation comparable to ours, in this section we constrain it to find only two threads.

5.1 Disentangling a single utterance

Our first disentanglement task is to correctly assign a single utterance, given the true structure of the rest of the transcript. For each utterance, we compare two versions of the transcript, the original, and a version where it is swapped into the other thread. Our accuracy measures how often our models prefer the original. Unlike full-scale disentanglement, this task does not require a computationally demanding search, so it is possible to run experiments quickly. We also use it to train our mixture models for disentanglement, by construct a training example for each utterance i in our training transcripts. Since the Elsner and Charniak (2008b) model maximizes a correlation clustering objective which sums up independent edge weights, we can also use it to disentangle a single sentence efficiently.

Our results are shown in Table 2. Again, results for individual models are above the line, then our combined model, and finally ablation results for mixtures omitting a single model. The results show that, for a pair of dialogues that differ in topic, our best model can assign a single sentence with 87% accuracy. For the same topic, the accuracy is 80%. In each case, these results improve on (Elsner and Charniak, 2008b), which scores 78% and 74%.

	Different	Same	Avg.
EGrid	80.2	72.9	76.6
Topical EGrid	81.7	73.3	77.5
IBM-1	70.4	66.7	68.5
Pronouns	53.1	50.1	51.6
Time	58.5	57.4	57.9
Combined	**86.8**	**79.6**	**83.2**
-EGrid	86.0	79.1	82.6
-Topical EGrid	85.2	78.7	81.9
-IBM-1	86.2	78.7	82.4
-Pronouns	**86.8**	79.4	83.1
-Time	84.5	76.7	80.6
E+C '08	78.2	73.5	75.8

Table 2: Average accuracy for disentanglement of a single utterance on 200 synthetic multiparty conversations from SWBD test.

Changing to this new task has a substantial impact on performance. The topical model, which performed poorly for ordering, is actually stronger than the entity grid in this setting. IBM-1 underperforms either grid model (69% to 77%); on ordering, it was nearly as good (85% to 86%).

Despite their ordering performance of 72%, pronouns are essentially useless for this task, at 52%. This decline is due partly to domain, and partly to task setting. Although SWBD contains more pronominals than WSJ, many of them are first and second-person pronouns or deictics, which our model does not attempt to resolve. Since the disentanglement task involves moving only a single sentence, if moving this sentence does not sever a resolvable pronoun from its antecedent, the model will be unable to make a good decision.

As before, the ablation results show that all the models are quite correlated, since removing any single model from the mixture causes only a small decrease in performance. The largest drop (83% to 81%) is caused by removing time; though time is a weak model on its own, it is completely orthogo-

nal to the other models, since unlike them, it does not depend on the words in the sentences.

Comparing results between "different topic" and "same topic" instances shows that "same topic" is harder– by about 7% for the combined model. The IBM model has a relatively small gap of 3.7%, and in the ablation results, removing it causes a larger drop in performance for "same" than "different"; this suggests it is somewhat more robust to similarity in topic than entity grids.

Disentanglement accuracy is hard to predict given ordering performance; the two tasks plainly make different demands on models. One difference is that the models which use longer histories (the two entity grids) remain strong, while the models considering only one or two previous sentences (IBM and pronouns) do not do as well. Since the changes being considered here affect only a single sentence, while permutation affects the entire transcript, more history may help by making the model more sensitive to small changes.

5.2 Disentangling an entire transcript

We now turn to the task of disentangling an entire transcript at once. This is a practical task, motivated by applications such as search and information retrieval. However, it is more difficult than assigning only a single utterance, because decisions are interrelated– an error on one utterance may cause a cascade of poor decisions further down. It is also computationally harder.

We use tabu search (Glover and Laguna, 1997) to find a good solution. The search repeatedly finds and moves the utterance which would most improve the model score if swapped from one thread to the other. Unlike greedy search, tabu search is constrained not to repeat a solution that it has recently visited; this forces it to keep exploring when it reaches a local maximum. We run 500 iterations of tabu search (usually finding the first local maximum after about 100) and return the best solution found.

We measure performance with one-to-one overlap, which maps the two clusters to the two gold dialogues, then measures percent correct[5]. Our results (Table 3) show that, for transcripts with different topics, our disentanglement has 68% overlap with truth, extracting about two thirds of the structure correctly; this is substantially better than Elsner and Charniak (2008b), which scores 59%. Where the entangled conversations have the same topic, performance is lower, about 60%, but still better than the comparison model with 57%. Since correlations with the previous section are fairly reliable, and the disentanglement procedure is computationally intensive, we omit ablation experiments.

	Different	Same	Avg.
EGrid	60.3	57.1	58.7
Topical EGrid	62.3	56.8	59.6
IBM-1	56.5	55.2	55.9
Pronouns	54.5	54.4	54.4
Time	55.4	53.8	54.6
Combined	**67.9**	**59.8**	**63.9**
E+C '08	59.1	57.4	58.3

Table 3: One-to-one overlap between disentanglement results and truth on 200 synthetic multiparty conversations from SWBD test.

As we expect, full disentanglement is more difficult than single-sentence disentanglement (combined scores drop by about 20%), but the single-sentence task is a good predictor of relative performance. Entity grid models do best, the IBM model remains useful, but less so than for discrimination, and pronouns are very weak. The IBM model performs similarly under both metrics (56% and 57%), while other models perform worse on loc_3. This supports our suggestion that IBM's decline in performance from ordering is indeed due to its using a single sentence history; it is still capable of getting local structures right, but misses global ones.

6 IRC data

In this section, we move from synthetic data to real multiparty discourse recorded from internet chat rooms. We use two datasets: the #LINUX corpus (Elsner and Charniak, 2008b), and three larger corpora, #IPHONE, #PHYSICS and #PYTHON (Adams, 2008). We use the 1000-line "development" section of #LINUX for tuning our mixture models and the 800-line "test" section for development experiments. We reserve the Adams (2008) corpora for testing; together, they consist of 19581 lines of chat, with each section containing 500 to 1000 lines.

[5]The other popular metrics, F and loc_3, are correlated.

Chat-specific	74.0
+EGrid	**79.3**
+Topical EGrid	76.8
+IBM-1	76.3
+Pronouns	73.9
+EGrid/Topic/IBM-1	78.3
E+C '08b	76.4

Table 4: Accuracy for single utterance disentanglement, averaged over annotations of 800 lines of #LINUX data.

In order to use syntactic models like the entity grid, we parse the transcripts using (McClosky et al., 2006). Performance is bad, although the parser does identify most of the NPs; poor results are typical for a standard parser on chat (Foster, 2010). We postprocess the parse trees to retag "lol", "haha" and "yes" as UH (rather than NN, NNP and JJ).

In this section, we use all three of our chat-specific models (sec. 2.0.6; **time**, **speaker** and **mention**) as a baseline. This baseline is relatively strong, so we evaluate our other models in combination with it.

6.1 Disentangling a single sentence

As before, we show results on correctly disentangling a single sentence, given the correct structure of the rest of the transcript. We average performance on each transcript over the different annotations, then average the transcripts, weighing them by length to give each utterance equal weight.

Table 4 gives results on our development corpus, #LINUX. Our best result, for the chat-specific features plus entity grid, is 79%, improving on the comparison model, Elsner and Charniak (2008b), which gets 76%. (Although the table only presents an average over all annotations of the dataset, this model is also more accurate for each individual annotator than the comparison model.) We then ran the same model, chat-specific features plus entity grid, on the test corpora from Adams (2008). These results (Table 5) are also better than Elsner and Charniak (2008b), at an average of 93% over 89%.

As pointed out in Elsner and Charniak (2008b), the chat-specific features are quite powerful in this domain, and it is hard to improve over them. Elsner and Charniak (2008b), which has simple lexical features, mostly based on unigram overlap, increases

	#IPHONE	#PHYSICS	#PYTHON
+EGrid	**92.3**	**96.6**	**91.1**
E+C '08b	89.0	90.2	88.4

Table 5: Average accuracy for disentanglement of a single utterance for 19581 total lines from Adams (2008).

performance over baseline by 2%. Both IBM and the topical entity grid achieve similar gains. The entity grid does better, increasing performance to 79%. Pronouns, as before for SWBD, are useless.

We believe that the entity grid's good performance here is due mostly to two factors: its use of a long history, and its lack of lexicalization. The grid looks at the previous six sentences, which differentiates it from the IBM model and from Elsner and Charniak (2008b), which treats each pair of sentences independently. Using this long history helps to distinguish important nouns from unimportant ones better than frequency alone. We suspect that our lexicalized models, IBM and the topical entity grid, are hampered by poor parameter settings, since their parameters were learned on FISHER rather than IRC chat. In particular, we believe this explains why the topical entity grid, which slightly outperformed the entity grid on SWBD, is much worse here.

6.2 Full disentanglement

Running our tabu search algorithm on the full disentanglement task yields disappointing results. Accuracies on the #LINUX dataset are not only worse than previous work, but also worse than simple baselines like creating one thread for each speaker. The model finds far too many threads– it detects over 300, when the true number is about 81 (averaging over annotations). This appears to be related to biases in our chat-specific models as well as in the entity grid; the time model (which generates gaps between adjacent sentences) and the speaker model (which uses a CRP) both assign probability 1 to single-utterance conversations. The entity grid also has a bias toward short conversations, because unseen entities are empirically more likely to occur toward the beginning of a conversation than in the middle.

A major weakness in our model is that we aim only to maximize coherence of the individual conversations, with no prior on the likely length or number of conversations that will appear in the tran-

script. This allows the model to create far too many conversations. Integrating a prior into our framework is not straightforward because we currently train our mixture to maximize single-utterance disentanglement performance, and the prior is not useful for this task.

We experimented with fixing parts of the transcript to the solution obtained by Elsner and Charniak (2008b), then using tabu search to fill in the gaps. This constrains the number of conversations and their approximate positions. With this structure in place, we were able to obtain scores comparable to Elsner and Charniak (2008b), but not improvements. It appears that our performance increase on single-sentence disentanglement does not transfer to this task because of cascading errors and the necessity of using external constraints.

7 Conclusions

We demonstrate that several popular models of local coherence transfer well to the conversational domain, suggesting that they do indeed capture coherence in general rather than specific conventions of newswire text. However, their performance across tasks is not as stable; in particular, models which use less history information are worse for disentanglement.

Our results study suggest that while sophisticated coherence models can potentially contribute to disentanglement, they would benefit greatly from improved low-level resources for internet chat. Better parsing, or at least NP chunking, would help for models like the entity grid which rely on syntactic role information. Larger training sets, or some kind of transfer learning, could improve the learning of topics and other lexical parameters. In particular, our results on SWBD data confirm the conjecture of (Adams, 2008) that LDA topic modeling is in principle a useful tool for disentanglement– we believe a topic-based model could also work on IRC chat, but would require a better set of extracted topics. With better parameters for these models and the integration of a prior, we believe that our good performance on SWBD and single-utterance disentanglement for IRC can be extended to full-scale disentanglement of IRC.

Abstract

Dialogue act classification is a central challenge for dialogue systems. Although the importance of emotion in human dialogue is widely recognized, most dialogue act classification models make limited or no use of affective channels in dialogue act classification. This paper presents a novel affect-enriched dialogue act classifier for task-oriented dialogue that models facial expressions of users, in particular, facial expressions related to confusion. The findings indicate that the affect-enriched classifiers perform significantly better for distinguishing user requests for feedback and grounding dialogue acts within textual dialogue. The results point to ways in which dialogue systems can effectively leverage affective channels to improve dialogue act classification.

1 Introduction

Dialogue systems aim to engage users in rich, adaptive natural language conversation. For these systems, understanding the role of a user's utterance in the broader context of the dialogue is a key challenge (Sridhar, Bangalore, & Narayanan, 2009). Central to this endeavor is dialogue act classification, which categorizes the intention behind the user's move (e.g., asking a question, providing declarative information). Automatic dialogue act classification has been the focus of a large body of research, and a variety of approaches, including sequential models (Stolcke et al., 2000), vector-based models (Sridhar, Bangalore, & Narayanan, 2009), and most recently, feature-enhanced latent semantic analysis (Di Eugenio, Xie, & Serafin, 2010), have shown promise. These models may be further improved by leveraging regularities of the dialogue from both linguistic and extra-linguistic sources. Users' expressions of emotion are one such source.

Human interaction has long been understood to include rich phenomena consisting of verbal and nonverbal cues, with facial expressions playing a vital role (Knapp & Hall, 2006; McNeill, 1992; Mehrabian, 2007; Russell, Bachorowski, & Fernandez-Dols, 2003; Schmidt & Cohn, 2001). While the importance of emotional expressions in dialogue is widely recognized, the majority of dialogue act classification projects have focused either peripherally (or not at all) on emotion, such as by leveraging acoustic and prosodic features of spoken utterances to aid in online dialogue act classification (Sridhar, Bangalore, & Narayanan, 2009). Other research on emotion in dialogue has involved detecting affect and adapting to it within a dialogue system (Forbes-Riley, Rotaru, Litman, & Tetreault, 2009; López-Cózar, Silovsky, & Griol, 2010), but this work has not explored leveraging affect information for automatic user dialogue act classification. Outside of dialogue, sentiment analysis within discourse is an active area of research (López-Cózar et al., 2010), but it is generally lim-

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1190–1199,
Portland, Oregon, June 19-24, 2011.

ited to modeling textual features and not multimodal expressions of emotion such as facial actions. Such multimodal expressions have only just begun to be explored within corpus-based dialogue research (Calvo & D'Mello, 2010; Cavicchio, 2009).

This paper presents a novel affect-enriched dialogue act classification approach that leverages knowledge of users' facial expressions during computer-mediated textual human-human dialogue. Intuitively, the user's affective state is a promising source of information that may help to distinguish between particular dialogue acts (e.g., a *confused* user may be more likely to ask a question). We focus specifically on occurrences of students' confusion-related facial actions during task-oriented tutorial dialogue.

Confusion was selected as the focus of this work for several reasons. First, confusion is known to be prevalent within tutoring, and its implications for student learning are thought to run deep (Graesser, Lu, Olde, Cooper-Pye, & Whitten, 2005). Second, while identifying the "ground truth" of emotion based on any external display by a user presents challenges, prior research has demonstrated a correlation between particular facial action units and confusion during learning (Craig, D'Mello, Witherspoon, Sullins, & Graesser, 2004; D'Mello, Craig, Sullins, & Graesser, 2006; McDaniel et al., 2007). Finally, automatic facial action recognition technologies are developing rapidly, and confusion-related facial action events are among those that can be reliably recognized automatically (Bartlett et al., 2006; Cohn, Reed, Ambadar, Xiao, & Moriyama, 2004; Pantic & Bartlett, 2007; Zeng, Pantic, Roisman, & Huang, 2009). This promising development bodes well for the feasibility of automatic real-time confusion detection within dialogue systems.

2 Background and Related Work

2.1 Dialogue Act Classification

Because of the importance of dialogue act classification within dialogue systems, it has been an active area of research for some time. Early work on automatic dialogue act classification modeled discourse structure with hidden Markov models, experimenting with lexical and prosodic features, and applying the dialogue act model as a constraint to aid in automatic speech recognition (Stolcke et al., 2000). In contrast to this sequential modeling approach, which is best suited to offline processing, recent work has explored how lexical, syntactic, and prosodic features perform for online dialogue act tagging (when only partial dialogue sequences are available) within a maximum entropy framework (Sridhar, Bangalore, & Narayanan, 2009). A recently proposed alternative approach involves treating dialogue utterances as documents within a latent semantic analysis framework, and applying feature enhancements that incorporate such information as speaker and utterance duration (Di Eugenio et al., 2010). Of the approaches noted above, the modeling framework presented in this paper is most similar to the vector-based maximum entropy approach of Sridhar et al. (2009). However, it takes a step beyond the previous work by including multimodal affective displays, specifically facial expressions, as features available to an affect-enriched dialogue act classification model.

2.2 Detecting Emotions in Dialogue

Detecting emotional states during spoken dialogue is an active area of research, much of which focuses on detecting frustration so that a user can be automatically transferred to a human dialogue agent (López-Cózar et al., 2010). Research on spoken dialogue has leveraged lexical features along with discourse cues and acoustic information to classify user emotion, sometimes at a coarse grain along a positive/negative axis (Lee & Narayanan, 2005). Recent work on an affective companion agent has examined user emotion classification within conversational speech (Cavazza et al., 2010). In contrast to that spoken dialogue research, the work in this paper is situated within textual dialogue, a widely used modality of communication for which a deeper understanding of user affect may substantially improve system performance.

While many projects have focused on linguistic cues, recent work has begun to explore numerous channels for affect detection including facial actions, electrocardiograms, skin conductance, and posture sensors (Calvo & D'Mello, 2010). A recent project in a map task domain investigates some of these sources of affect data within task-oriented dialogue (Cavicchio, 2009). Like that work, the current project utilizes facial action tagging, for

which promising automatic technologies exist (Bartlett et al., 2006; Pantic & Bartlett, 2007; Zeng, Pantic, Roisman, & Huang, 2009). However, we leverage the recognized expressions of emotion for the task of dialogue act classification.

2.3 Categorizing Emotions within Dialogue and Discourse

Sets of emotion taxonomies for discourse and dialogue are often application-specific, for example, focusing on the frustration of users who are interacting with a spoken dialogue system (López-Cózar et al., 2010), or on uncertainty expressed by students while interacting with a tutor (Forbes-Riley, Rotaru, Litman, & Tetreault, 2007). In contrast, the most widely utilized emotion frameworks are not application-specific; for example, Ekman's Facial Action Coding System (FACS) has been widely used as a rigorous technique for coding facial movements based on human facial anatomy (Ekman & Friesen, 1978). Within this framework, facial movements are categorized into facial action units, which represent discrete movements of muscle groups. Additionally, facial action descriptors (for movements not derived from facial muscles) and movement and visibility codes are included. Ekman's basic emotions (Ekman, 1999) have been used in recent work on classifying emotion expressed within blog text (Das & Bandyopadhyay, 2009), while other recent work (Nguyen, 2010) utilizes Russell's core affect model (Russell, 2003) for a similar task.

During tutorial dialogue, students may not frequently experience Ekman's basic emotions of *happiness*, *sadness*, *anger*, *fear*, *surprise*, and *disgust*. Instead, students appear to more frequently experience cognitive-affective states such as *flow* and *confusion* (Calvo & D'Mello, 2010). Our work leverages Ekman's facial tagging scheme to identify a particular facial action unit, Action Unit 4 (AU4), that has been observed to correlate with confusion (Craig, D'Mello, Witherspoon, Sullins, & Graesser, 2004; D'Mello, Craig, Sullins, & Graesser, 2006; McDaniel et al., 2007).

2.4 Importance of Confusion in Tutorial Dialogue

Among the affective states that students experience during tutorial dialogue, confusion is prevalent, and its implications for student learning are significant. Confusion is associated with *cognitive disequilibrium*, a state in which students' existing knowledge is inconsistent with a novel learning experience (Graesser, Lu, Olde, Cooper-Pye, & Whitten, 2005). Students may express such confusion within dialogue as *uncertainty*, to which human tutors often adapt in a context-dependent fashion (Forbes-Riley et al., 2007). Moreover, implementing adaptations to student uncertainty within a dialogue system can improve the effectiveness of the system (Forbes-Riley et al., 2009).

For tutorial dialogue, the importance of understanding student utterances is paramount for a system to positively impact student learning (Dzikovska, Moore, Steinhauser, & Campbell, 2010). The importance of frustration as a cognitive-affective state during learning suggests that the presence of student confusion may serve as a useful constraining feature for dialogue act classification of student utterances. This paper explores the use of facial expression features in this way.

3 Task-Oriented Dialogue Corpus

The corpus was collected during a textual human-human tutorial dialogue study in the domain of introductory computer science (Boyer, Phillips, et al., 2010). Students solved an introductory computer programming problem and carried on textual dialogue with tutors, who viewed a synchronized version of the students' problem-solving workspace. The original corpus consists of 48 dialogues, one per student. Each student interacted with one of two tutors. Facial videos of students were collected using built-in webcams, but were not shown to the tutors. Video quality was ranked based on factors such as obscured foreheads due to hats or hair, and improper camera position resulting in students' faces not being fully captured on the video. The highest-quality set contained 14 videos, and these videos were used in this analysis. They have a total running time of 11 hours and 55 minutes, and include dialogues with three female subjects and eleven male subjects.

3.1 Dialogue act annotation

The dialogue act annotation scheme (Table 1) was applied manually. The kappa statistic for inter-annotator agreement on a 10% subset of the corpus was κ=0.80, indicating good reliability.

Table 1. Dialogue act tags and relative frequencies across fourteen dialogues in video corpus

Student Dialogue Act	Example	Rel. Freq.
EXTRA-DOMAIN (EX)	*Little sleep deprived today*	.08
GROUNDING (G)	*Ok* or *Thanks*	.21
NEGATIVE FEEDBACK WITH ELABORATION (NE)	*I'm still confused on what this next for loop is doing.*	.02
NEGATIVE FEEDBACK (N)	*I don't see the diff.*	.04
POSITIVE FEEDBACK WITH ELABORATION (PE)	*It makes sense now that you explained it, but I never used an else if in any of my other programs*	.04
POSITIVE FEEDBACK (P)	*Second part complete.*	.11
QUESTION (Q)	*Why couldn't I have said if (i<5)*	.11
STATEMENT (S)	*i is my only index*	.07
REQUEST FOR FEEDBACK (RF)	*So I need to create a new method that sees how many elements are in my array?*	.16
RESPONSE (RSP)	*You mean not the length but the contents*	.14
UNCERTAIN FEEDBACK WITH ELABORATION (UE)	*I'm trying to remember how to copy arrays*	.008
UNCERTAIN FEEDBACK (U)	*Not quite yet*	.008

3.2 Task action annotation

The tutoring sessions were task-oriented, focusing on a computer programming exercise. The task had several subtasks consisting of programming modules to be implemented by the student. Each of those subtasks also had numerous fine-grained goals, and student task actions either contributed or did not contribute to the goals. Therefore, to obtain a rich representation of the task, a manual annotation along two dimensions was conducted (Boyer, Phillips, et al., 2010). First, the subtask structure was annotated hierarchically, and then each task action was labeled for correctness according to the requirements of the assignment. Inter-annotator agreement was computed on 20% of the corpus at the leaves of the subtask tagging scheme, and resulted in a simple kappa of κ=.56. However, the leaves of the annotation scheme feature an implicit ordering (subtasks were completed in order, and adjacent subtasks are semantically more similar than subtasks at a greater distance); therefore, a weighted kappa is also meaningful to consider for this annotation. The weighted kappa is $\kappa_{weighted}$=.80. An annotated excerpt of the corpus is displayed in Table 2.

Table 2. Excerpt from corpus illustrating annotations and interplay between dialogue and task

13:38:09	Student:	How do I know where to end? **[RF]**
13:38:26	Tutor:	Well you told me how to get how many elements in an array by using .length right?
13:38:26	Student:	**[Task action: Subtask 1-a-iv, Buggy]**
13:38:56	Tutor:	Great
13:38:56	Student:	**[Task action: Subtask 1-a-v, Correct]**
13:39:35	Student:	Well is it "array.length"? **[RF]** ****Facial Expression: AU4**
13:39:46	Tutor:	You just need to use the correct array name
13:39:46	Student:	**[Task action: Subtask 1-a-iv, Buggy]**

3.3 Lexical and Syntactic Features

In addition to the manually annotated dialogue and task features described above, syntactic features of each utterance were automatically extracted using the Stanford Parser (De Marneffe et al., 2006). From the phrase structure trees, we extracted the top-most syntactic node and its first two children. In the case where an utterance consisted of more than one sentence, only the phrase structure tree of the first sentence was considered. Individual word tokens in the utterances were further processed with the Porter Stemmer (Porter, 1980) in the NLTK package (Loper & Bird, 2004). Our prior work has shown that these lexical and syntactic features are highly predictive of dialogue acts during task-oriented tutorial dialogue (Boyer, Ha et al. 2010).

4 Facial Action Tagging

An annotator who was certified in the Facial Action Coding System (FACS) (Ekman, Friesen, & Hager, 2002) tagged the video corpus consisting of fourteen dialogues. The FACS certification process requires annotators to pass a test designed to analyze their agreement with reference coders on a set of spontaneous facial expressions (Ekman & Rosenberg, 2005). This annotator viewed the videos continuously and paused the playback whenever notable facial displays of Action Unit 4 (AU4: Brow Lowerer) were seen. This action unit was chosen for this study based on its correlations with confusion in prior research (Craig, D'Mello, Witherspoon, Sullins, & Graesser, 2004; D'Mello, Craig, Sullins, & Graesser, 2006; McDaniel et al., 2007).

To establish reliability of the annotation, a second FACS-certified annotator independently annotated 36% of the video corpus (5 of 14 dialogues), chosen randomly after stratification by gender and tutor. This annotator followed the same method as the first annotator, pausing the video at any point to tag facial action events. At any given time in the video, the coder was first identifying whether an action unit event existed, and then describing the facial movements that were present. The annotators also specified the beginning and ending time of each event. In this way, the action unit event tags spanned discrete durations of varying length, as specified by the coders. Because the two coders were not required to tag at the same point in time, but rather were permitted the freedom to stop the video at any point where they felt a notable facial action event occurred, calculating agreement between annotators required discretizing the continuous facial action time windows across the tutoring sessions. This discretization was performed at granularities of 1/4, 1/2, 3/4, and 1 second, and inter-rater reliability was calculated at each level of granularity (Table 3). Windows in which both annotators agreed that no facial action event was present were tagged by default as *neutral*. Figure 1 illustrates facial expressions that display facial Action Unit 4.

Table 3. Kappa values for inter-annotator agreement on facial action events

	Granularity			
	¼ sec	½ sec	¾ sec	1 sec
Presence of AU4 (Brow Lowerer)	*.84*	*.87*	*.86*	*.86*

Figure 1. Facial expressions displaying AU4 (Brow Lowerer)

Despite the fact that promising automatic approaches exist to identifying many facial action units (Bartlett et al., 2006; Cohn, Reed, Ambadar, Xiao, & Moriyama, 2004; Pantic & Bartlett, 2007; Zeng, Pantic, Roisman, & Huang, 2009), manual annotation was selected for this project for two reasons. First, manual annotation is more robust than automatic recognition of facial action units, and manual annotation facilitated an exploratory, comprehensive view of student facial expressions during learning through task-oriented dialogue. Although a detailed discussion of the other emotions present in the corpus is beyond the scope of this paper, Figure 2 illustrates some other spontaneous student facial expressions that differ from those associated with confusion.

Figure 2. Other facial expressions from the corpus

5 Models

The goal of the modeling experiment was to determine whether the addition of confusion-related facial expression features significantly boosts dialogue act classification accuracy for student utterances.

5.1 Features

We take a vector-based approach, in which the features consist of the following:

Utterance Features

- *Dialogue act features*: Manually annotated dialogue act for the past three utterances. These features include tutor dialogue acts, annotated with a scheme analogous to that used to annotate student utterances (Boyer et al., 2009).
- *Speaker*: Speaker for past three utterances
- *Lexical features*: Word unigrams
- *Syntactic features*: Top-most syntactic node and its first two children

Task-based Features

- *Subtask*: Hierarchical subtask structure for past three task actions (semantic programming actions taken by student)
- *Correctness*: Correctness of past three task actions taken by student
- *Preceded by task*: Indicator for whether the most recent task action immediately preceded the target utterance, or whether it was immediately preceded by the last dialogue move

Facial Expression Features

- *AU4_1sec:* Indicator for the display of the brow lowerer within 1 second prior to this utterance being sent, for the most recent three utterances
- *AU4_5sec:* Indicator for the display of the brow lowerer within 5 seconds prior to this utterance being sent, for the most recent three utterances
- *AU4_10sec:* Indicator for the display of the brow lowerer within 10 seconds prior to this utterance being sent, for the most recent three utterances

5.2 Modeling Approach

A logistic regression approach was used to classify the dialogue acts based on the above feature vectors. The Weka machine learning toolkit (Hall et al., 2009) was used to learn the models and to first perform feature selection in a best-first search. Logistic regression is a generalized maximum likelihood model that discriminates between pairs of output values by calculating a feature weight vector over the predictors.

The goal of this work is to explore the utility of confusion-related facial features in the context of particular dialogue act types. For this reason, a specialized classifier was learned by dialogue act.

5.3 Classification Results

The classification accuracy and kappa for each specialized classifier is displayed in Table 4. Note that kappa statistics adjust for the accuracy that would be expected by majority-baseline chance; a kappa statistic of zero indicates that the classifier performed equal to chance, and a positive kappa statistic indicates that the classifier performed better than chance. A kappa of 1 constitutes perfect agreement. As the table illustrates, the feature selection chose to utilize the AU4 feature for every dialogue act except STATEMENT (S). When considering the accuracy of the model across the ten folds, two of the affect-enriched classifiers exhibited statistically significantly better performance. For GROUNDING (G) and REQUEST FOR FEEDBACK (RF), the facial expression features significantly

improved the classification accuracy compared to a model that was learned without affective features.

6 Discussion

Dialogue act classification is an essential task for dialogue systems, and it has been addressed with a variety of modeling approaches and feature sets. We have presented a novel approach that treats facial expressions of students as constraining features for an affect-enriched dialogue act classification model in task-oriented tutorial dialogue. The results suggest that knowledge of the student's confusion-related facial expressions can significantly enhance dialogue act classification for two types of dialogue acts, GROUNDING and REQUEST FOR FEEDBACK.

Table 4. Classification accuracy and kappa for specialized DA classifiers. Statistically significant differences (across ten folds, one-tailed *t*-test) are shown in bold.

6.1 Features Selected for Classification

Out of more than 1500 features available during feature selection, each of the specialized dialogue act classifiers selected between 30 and 50 features in each condition (with and without affect features). To gain insight into the specific features that were useful for classifying these dialogue acts, it is useful to examine which of the AU4 history features were chosen during feature selection.

For GROUNDING, features that indicated the presence of absence of AU4 in the immediately preceding utterance, either at the 1 second or 5 second granularity, were selected. Absence of this confusion-related facial action unit was associated with a higher probability of a grounding act, such as an acknowledgement. This finding is consistent with our understanding of how students and tutors interacted in this corpus; when a student experienced confusion, she would be unlikely to then make a simple grounding dialogue move, but instead would tend to inspect her computer program, ask a question, or wait for the tutor to explain more.

For REQUEST FOR FEEDBACK, the predictive features were presence or absence of AU4 within ten seconds of the longest available history (three turns in the past), as well as the presence of AU4 within five seconds of the current utterance (the utterance whose dialogue act is being classified). This finding suggests that there may be some lag between the student experiencing confusion and then choosing to make a request for feedback, and that the confusion-related facial expressions may re-emerge as the student is making a request for feedback, since the five-second window prior to the student sending the textual dialogue message would overlap with the student's construction of the message itself.

Although the improvements seen with AU4 features for QUESTION, POSITIVE FEEDBACK, and EXTRA-DOMAIN acts were not statistically reliable, examining the AU4 features that were selected for classifying these moves points toward ways in which facial expressions may influence classification of these acts (Table 5).

Table 5. Number of features, and AU4 features selected, for specialized DA classifiers

Dialogue Act	# features selected	AU4 features selected
G	43	One utterance ago: AU4_1sec, AU4_5sec
RF	37	Three utterances ago: AU4_10sec Target utterance: AU4_5sec
EX	50	Three utterances ago: AU4_1sec
P	36	Current utterance: AU4_10sec
Q	30	One utterance ago: AU4_5sec

6.2 Implications

The results presented here demonstrate that leveraging knowledge of user affect, in particular of spontaneous facial expressions, may improve the performance of dialogue act classification models. Perhaps most interestingly, displays of confusion-related facial actions prior to a student dialogue move enabled an affect-enriched classifier to recognize requests for feedback with significantly greater accuracy than a classifier that did not have access to the facial action features. Feedback is known to be a key component of effective tutorial dialogue, through which tutors provide adaptive help (Shute, 2008). Requesting feedback also seems to be an important behavior of students, characteristically engaged in more frequently by women than men, and more frequently by students with lower incoming knowledge than by students with higher incoming knowledge (Boyer, Vouk, & Lester, 2007).

6.3 Limitations

The experiments reported here have several notable limitations. First, the time-consuming nature of manual facial action tagging restricted the number of dialogues that could be tagged. Although the highest quality videos were selected for annotation, other medium quality videos would have been sufficiently clear to permit tagging, which would have increased the sample size and likely revealed statistically significant trends. For example, the performance of the affect-enriched classifier was better for dialogue acts of interest such as positive feedback and questions, but this difference was not statistically reliable.

An additional limitation stems from the more fundamental question of which affective states are indicated by particular external displays. The field is only just beginning to understand facial expressions during learning and to correlate these facial actions with emotions. Additional research into the "ground truth" of emotion expression will shed additional light on this area. Finally, the results of manual facial action annotation may constitute upper-bound findings for applying automatic facial expression analysis to dialogue act classification.

7 Conclusions and Future Work

Emotion plays a vital role in human interactions. In particular, the role of facial expressions in human-human dialogue is widely recognized. Facial expressions offer a promising channel for understanding the emotions experienced by users of dialogue systems, particularly given the ubiquity of webcam technologies and the increasing number of dialogue systems that are deployed on webcam-enabled devices. This paper has reported on a first step toward using knowledge of user facial expressions to improve a dialogue act classification model for tutorial dialogue, and the results demonstrate that facial expressions hold great promise for distinguishing the pedagogically relevant dialogue act REQUEST FOR FEEDBACK, and the conversational moves of GROUNDING.

These early findings highlight the importance of future work in this area. Dialogue act classification models have not fully leveraged some of the techniques emerging from work on sentiment analysis. These approaches may prove particularly useful for identifying emotions in dialogue utterances. Another important direction for future work involves more fully exploring the ways in which affect expression differs between textual and spoken dialogue. Finally, as automatic facial tagging technologies mature, they may prove powerful enough to enable broadly deployed dialogue systems to feasibly leverage facial expression data in the near future.

Abstract

We develop a novel approach to the semantic analysis of short text segments and demonstrate its utility on a large corpus of Web search queries. Extracting meaning from short text segments is difficult as there is little semantic redundancy between terms; hence methods based on shallow semantic analysis may fail to accurately estimate meaning. Furthermore search queries lack explicit syntax often used to determine intent in question answering. In this paper we propose a hybrid model of semantic analysis combining explicit class-label extraction with a latent class PCFG. This *class-label correlation* (CLC) model admits a robust parallel approximation, allowing it to scale to large amounts of query data. We demonstrate its performance in terms of (1) its predicted label accuracy on polysemous queries and (2) its ability to accurately chunk queries into base constituents.

1 Introduction

Search queries are generally short and rarely contain much explicit syntax, making query understanding a purely semantic endeavor. Furthermore, as in noun-phrase understanding, shallow lexical semantics is often irrelevant or misleading; e.g., the query [*tropical breeze cleaners*] has little to do with island vacations, nor are desert birds relevant to [*1970 road runner*], which refers to a car model.

This paper introduces *class-label correlation* (CLC), a novel unsupervised approach to extracting shallow semantic content that combines class-based semantic markup (e.g., *road runner* is a *car model*) with a latent variable model for capturing weakly compositional interactions between query constituents. Constituents are tagged with IsA class labels from a large, automatically extracted lexicon, using a probabilistic context free grammar (PCFG). Correlations between the resulting label→term distributions are captured using a set of latent production rules specified by a hierarchical Dirichlet Process (Teh et al., 2006) with latent data groupings.

Concretely, the IsA tags capture the inventory of potential meanings (e.g., *jaguar* can be labeled as *european car* or *large cat*) and relevant constituent spans, while the latent variable model performs sense and theme disambiguation (e.g., [*jaguar habitat*] would lend evidence for the *large cat* label). In addition to broad sense disambiguation, CLC can distinguish closely related usages, e.g., the use of *dell* in [*dell motherboard replacement*] and [*dell stock price*].[1] Furthermore, by employing IsA class labeling as a preliminary step, CLC can account for common non-compositional phrases, such as *big apple* unlike systems relying purely on lexical semantics. Additional examples can be found later, in Figure 5.

In addition to improving query understanding, potential applications of CLC include: (1) relation extraction (Baeza-Yates and Tiberi, 2007), (2) query substitutions or broad matching (Jones et al., 2006), and (3) classifying other short textual fragments such as SMS messages or tweets.

We implement a parallel inference procedure for

Portland, Oregon, June 19-24, 2011.

CLC and evaluate it on a sample of 500M search queries along two dimensions: (1) query constituent chunking precision (i.e., how accurate are the inferred spans breaks; cf., Bergsma and Wang (2007); Tan and Peng (2008)), and (2) class label assignment precision (i.e., given the query intent, how relevant are the inferred class labels), paying particular attention to cases where queries contain ambiguous constituents. CLC compares favorably to several simpler submodels, with gains in performance stemming from coarse-graining related class labels and increasing the number of clusters used to capture between-label correlations.

(**Paper organization**): Section 2 discusses relevant background, Section 3 introduces the CLC model, Section 4 describes the experimental setup employed, Section 5 details results, Section 6 introduces areas for future work and Section 7 concludes.

2 Background

Query understanding has been studied extensively in previous literature. Li (2010) defines the semantic structure of noun-phrase queries as *intent heads* (attributes) coupled with some number of *intent modifiers* (attribute values), e.g., the query [*alice in wonderland 2010 cast*] is comprised of an intent head *cast* and two intent modifiers *alice in wonderland* and *2010*. In this work we focus on semantic class markup of query constituents, but our approach could be easily extended to account for query structure as well.

Popescu et al. (2010) describe a similar class-label-based approach for query interpretation, explicitly modeling the importance of each label for a given entity. However, details of their implementation were not publicly available, as of publication of this paper.

For simplicity, we extract class labels using the seed-based approach proposed by Van Durme and Paşca (2008) (in particular Paşca (2010)) which generalizes Hearst (1992). Talukdar and Pereira (2010) use graph-based semi-supervised learning to acquire class-instance labels; Wang et al. (2009) introduce a similar CRF-based approach but only apply it to a small number of verticals (i.e., *Computing and Electronics* or *Clothing and Shoes*). Snow et al. (2006) describe a learning approach for automatically acquiring patterns indicative of hypernym (IsA) relations. Semantic class label lexicons derived from any of these approaches can be used as input to CLC.

Several authors have studied query clustering in the context of information retrieval (e.g., Beeferman and Berger, 2000). Our approach is novel in this regard, as we cluster queries in order to capture correlations between span labels, rather than explicitly for query understanding.

Tratz and Hovy (2010) propose a taxonomy for classifying and interpreting noun-compounds, focusing specifically on the relationships holding between constituents. Our approach yields similar topical decompositions of noun-phrases in queries and is completely unsupervised.

Jones et al. (2006) propose an automatic method for *query substitution*, i.e., replacing a given query with another query with the similar meaning, overcoming issues with poor paraphrase coverage in tail queries. Correlations mined by our approach are readily useful for downstream query substitution.

Bergsma and Wang (2007) develop a supervised approach to query chunking using 500 hand-segmented queries from the AOL corpus. Tan and Peng (2008) develop a generative model of query segmentation that makes use of a language model and concepts derived from Wikipedia article titles. CLC differs fundamentally in that it learns concept label markup in addition to segmentation and uses in-domain concepts derived from queries themselves. This work also differs from both of these studies significantly in scope, training on 500M queries instead of just 500.

At the level of class-label markup, our model is related to Bayesian PCFGs (Liang et al., 2007; Johnson et al., 2007b), and is a particular realization of an *Adaptor Grammar* (Johnson et al., 2007a; Johnson, 2010).

Szpektor et al. (2008) introduce a model of *contextual preferences*, generalizing the notion of selectional preference (cf. Ritter et al., 2010) to arbitrary terms, allowing for context-sensitive inference. Our approach differs in its use of class-instance labels for generalizing terms, a necessary step for dealing with the lack of syntactic information in queries.

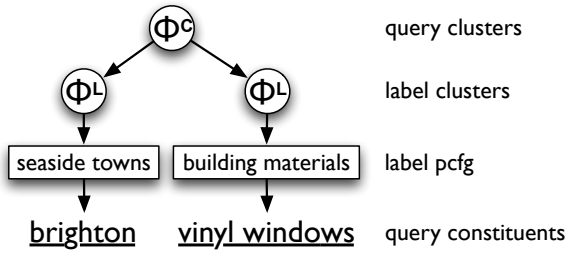

Figure 1: Overview of CLC markup generation for the query [*brighton vinyl windows*]. Arrows denote multinomial distributions.

class label→query span
recreational facilities→jacuzzi
rural areas→wales
destinations→wales
seaside towns→brighton
building materials→vinyl windows
consumer goods→european clothing

Table 1: Example production rules collected using the semi-supervised approach of Van Durme and Paşca (2008).

3 Latent Class-Label Correlation

Input to CLC consists of raw search queries and a partial grammar mapping class labels to query spans (e.g., building materials→vinyl windows). CLC infers two additional latent productions types on top of these class labels: (1) a potentially infinite set of label clusters $\phi^L_{l_k}$ coarse-graining the raw input label productions V, and (2) a finite set of query clusters $\phi^C_{c_i}$ specifying distributions over label clusters; see Figure 1 for an overview.

Operationally, CLC is implemented as a Hierarchical Dirichlet Process (HDP; Teh et al., 2006) with latent groups coupled with a Probabilistic Context Free Grammar (PCFG) likelihood function (Figure 2). We motivate our use of an HDP latent class model instead of a full PCFG with binary productions by the fact that the space of possible binary rule combinations is prohibitively large (561K base labels; 314B binary rules). The next sections discuss the three main components of CLC: §3.1 the raw IsA class labels, §3.2 the PCFG likelihood, and §3.3 the HDP with latent groupings.

3.1 IsA Label Extraction

IsA class labels (hypernyms) V are extracted from a large corpus of raw Web text using the method proposed by Van Durme and Paşca (2008) and extended by Paşca (2010). Manually specified patterns are used to extract a seed set of class labels and the resulting label lists are reranked using cluster purity measures. 561K labels for base noun phrases are collected. Table 1 shows an example set of class labels extracted for several common noun phrases. Similar repositories of IsA labels, extracted using other methods, are available for experimental purposes (Talukdar and Pereira, 2010). In addition to extracted rules, the CLC grammar is augmented with a set of *null rules*, one per unigram, ensuring that every query has a valid parse.

3.2 Class-Label PCFG

In addition to the observed class-label production rules, CLC incorporates two sets of latent production rules coupled via an HDP (Figure 1). Class label→query span productions extracted from raw text are clustered into a set of latent *label production clusters* $\mathcal{L} = \{l_1, \ldots, l_\infty\}$. Each label production cluster l_k defines a multinomial distribution over class labels V parametrized by $\phi^L_{l_k}$. Conceptually, $\phi^L_{l_k}$ captures a set of class labels with similar productions that are found in similar queries, for example the class labels *states, northeast states, u.s. states, state areas, eastern states,* and *certain states* might be included in the same coarse-grained cluster due to similarities in their productions.

Each query $q \in \mathcal{Q}$ is assigned to a latent *query cluster* $c_q \in \mathcal{C}\{c_1, \ldots, c_\infty\}$, which defines a distribution over label production clusters $\mathcal{L}$, denoted $\phi^C_{c_q}$. Query clusters capture broad correlations between label production clusters and are necessary for performing sense disambiguation and capturing selectional preference. Query clusters and label production clusters are linked using a single HDP, allowing the number of label clusters to vary over the course of Gibbs sampling, based on the variance of the underlying data (Section 3.3). Viewed as a grammar, CLC only contains unary rules mapping labels to query spans; production correlations are captured directly by the query cluster, unlike in HDP-PCFG (Liang et al., 2007), as branching parses over the en-

		Indices	Cardinality

Query cluster	$\boldsymbol{\phi}^C_i \sim \text{DP}(\boldsymbol{\alpha}^C, \boldsymbol{\beta})$	$i \in \lvert C\rvert$	$\lvert\mathcal{L}\rvert \to \infty$
Label cluster	$\boldsymbol{\phi}^L_k \sim \text{Dirichlet}(\boldsymbol{\alpha}^L)$	$k \in \lvert\mathcal{L}\rvert$	$\lvert V\rvert$
Query cluster ind	$\boldsymbol{\pi}_q \sim \text{Dirichlet}(\boldsymbol{\xi})$	$q \in \lvert\mathcal{Q}\rvert$	$\lvert C\rvert$
	$c_q \sim \boldsymbol{\pi}_q$	$q \in \lvert\mathcal{Q}\rvert$	1
Label cluster ind	$z_{q,t} \sim \boldsymbol{\phi}^C_{c_q}$	$\mathbf{t} \in q, q \in \lvert\mathcal{Q}\rvert$	1
Label ind	$l_{q,t} \sim \boldsymbol{\phi}^L_{z_{q,t}}$	$\mathbf{t} \in q, q \in \lvert\mathcal{Q}\rvert$	1

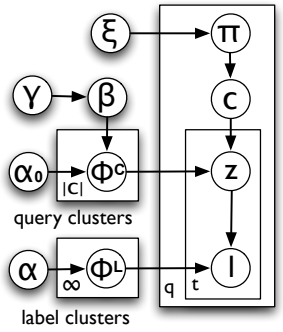

Figure 2: Generative process and graphical model for CLC. The top section of the model is the standard HDP prior; the middle section is the additional machinery necessary for modeling latent groupings and the bottom section contains the indicators for the latent class model. PCFG likelihood is not shown.

tire label sparse are intractably large.

Given a query q, a query cluster assignment c_q and a set of label production clusters $\mathcal{L}$, we define a parse of q to be a sequence of productions $\mathbf{t}_q$ forming a parse tree consuming all the tokens in q. As with Bayesian PCFGs (Johnson, 2010), the probability of a tree $\mathbf{t}_q$ is the product of the probabilities of the production rules used to construct it

$$P(\mathbf{t}_q|\boldsymbol{\phi}^L, \boldsymbol{\phi}^C, c_q) = \prod_{r \in R_q} P(r|\boldsymbol{\phi}^L_{l_r}) P(l_r|\boldsymbol{\phi}^C_{c_q})$$

where R_q is the set of production rules used to derive $\mathbf{t}_q$, $P(r|\phi^L_{l_r})$ is the probability of r given its label cluster assignment l_r, and $P(l_r|\phi^C_{c_q})$ is the probability of label cluster l_r in query cluster c.

The probability of a query q is the sum of the probabilities of the parse trees that can generate it,

$$P(q|\boldsymbol{\phi}^L, \boldsymbol{\phi}^C, c_q) = \sum_{\{\mathbf{t}|y(\mathbf{t})=q\}} P(\mathbf{t}|\boldsymbol{\phi}^L, \boldsymbol{\phi}^C, c_q)$$

where $\{\mathbf{t}|y(\mathbf{t}) = q\}$ is the set of trees with q as their *yield* (i.e., generate the string of tokens in q).

3.3 Hierarchical Dirichlet Process with Latent Groups

We complete the Bayesian generative specification of CLC with an HDP prior linking $\boldsymbol{\phi}^C$ and $\boldsymbol{\phi}^L$. The HDP is a Bayesian generative model of shared structure for grouped data (Teh et al., 2006). A set of base clusters $\boldsymbol{\beta} \sim \text{GEM}(\boldsymbol{\gamma})$ is drawn from a Dirichlet Process with base measure $\boldsymbol{\gamma}$ using the stick-breaking construction, and clusters for each group k, $\boldsymbol{\phi}^C_k \sim \text{DP}(\boldsymbol{\beta})$, are drawn from a separate Dirichlet Process with base measure $\boldsymbol{\beta}$, defined over the space of label clusters. Data in each group k are conditionally independent given $\boldsymbol{\beta}$. Intuitively, $\boldsymbol{\beta}$ defines a common "menu" of label clusters, and each query cluster $\boldsymbol{\phi}^C_k$ defines a separate distribution over the label clusters.

$\boldsymbol{\gamma}$	– HDP-LG base-measure smoother; higher values lead to more uniform mass over label clusters.
$\boldsymbol{\alpha}^C$	– Query cluster smoothing; higher values lead to more uniform mass over label clusters.
$\boldsymbol{\alpha}^L$	– Label cluster smoothing; higher values lead to more label diversity within clusters.
$\boldsymbol{\xi}$	– Query cluster assignment smoothing; higher values lead to more uniform assignment.

Table 2: CLC-HDP-LG hyperparameters.

In order to account for variable query-cluster assignment, we extend the HDP model with *latent groupings* $\boldsymbol{\pi}_q \sim \text{Dir}(\xi)$ for each query. The resulting *Hierarchical Dirichlet Process with Latent Groups* (HDP-LG) can be used to define a set of query clusters over a set of (potentially infinite) base label clusters (Figure 2). Each query cluster $\boldsymbol{\phi}^C$ (latent group) assigns weight to different subsets of the available label clusters $\boldsymbol{\phi}^L$, capturing correlations between them at the query level. Each query q maintains a distribution over query clusters $\boldsymbol{\pi}_q$, capturing its affinity for each latent group. The full generative specification of CLC is shown in Figure 2; hyperparameters are shown in Table 2.

In addition to the full joint CLC model, we evalu-

ate several simpler models:

1. CLC-BASE – no query clusters, one label per label cluster.
2. CLC-DPMM – no query clusters, DPMM($\boldsymbol{\alpha}^C$) distribution over labels.
3. CLC-HDP-LG – full HDP-LG model with $|C|$ query clusters over a potentially infinite number of query clusters.

as well as various hyperparameter settings.

3.4 Parallel Approximate Gibbs Sampler

We perform inference in CLC via Gibbs sampling, leveraging Multinomial-Dirichlet conjugacy to integrate out $\boldsymbol{\pi}$, $\boldsymbol{\phi}^C$ and $\boldsymbol{\phi}^L$ (Teh et al., 2006; Johnson et al., 2007b). The remaining indicator variables $\mathbf{c}$, $\mathbf{z}$ and $\mathbf{l}$ are sampled iteratively, conditional on all other variable assignments. Although there are an exponential number of parse trees for a given query, this space can be sampled efficiently using dynamic programming (Finkel et al., 2006; Johnson et al., 2007b)

In order to apply CLC to Web-scale data, we implement an efficient parallel approximate Gibbs sampler in the MapReduce framework Dean and Ghemawat (2004). Each Gibbs iteration consists of a single MapReduce step for sampling, followed by an additional MapReduce step for computing marginal counts. [2] Relevant assignments $\mathbf{c}$, $\mathbf{z}$ and $\mathbf{l}$ are stored locally with each query and are distributed across compute nodes. Each node is responsible only for resampling assignments for its local set of queries. Marginals are fetched opportunistically from a separate distributed hash server as they are needed by the sampler. Each Map step computes a single Gibbs step for 10% of the available data, using the marginals computed at the previous step. By resampling only 10% of the available data each iteration, we minimize the potentially negative effects of using the previous step's marginal distribution.

4 Experimental Setup

4.1 Query Corpus

Our dataset consists of a sample of 450M English queries submitted by anonymous Web users to Google. The queries have an average of 3.81 tokens per query (1.7B tokens). Single token queries are removed as the model is incapable of using context to disambiguate their meaning. Figure 3 shows the distribution of remaining queries. During training, we include 10 copies of each query (4.5B queries total), allowing an estimate of the Bayes average posterior from a single Gibbs sample.

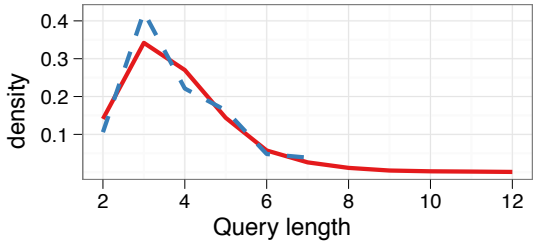

Figure 3: Distribution in the query corpus, broken down by query length (red/solid=all queries; blue/dashed=queries with ambiguous spans); most queries contain between 2-6 tokens.

4.2 Evaluations

Query markup is evaluated for phrase-chunking precision (Section 5.1) and label precision (Section 5.2) by human raters across two different samples: (1) an unbiased sample from the original corpus, and (2) a biased sample of queries containing ambiguous spans.

Two raters scored a total of 10K labels from 800 spans across 300 queries. Span labels were marked as *incorrect* (0.0), *badspan* (0.0), *ambiguous* (0.5), or *correct* (1.0), with numeric scores for label precision as indicated. Chunking precision is measured as the percentage of labels not marked as *badspan*.

We report two sets of precision scores depending on how *null* labels are handled: *Strict* evaluation treats null-labeled spans as incorrect, while *Normal* evaluation removes null-labeled spans from the precision calculation. Normal evaluation was included since the simpler models (e.g., CLC-BASE) tend to produce a significantly higher number of *null* assignments.

Model evaluations were broken down into *maximum a posteriori* (MAP) and *Bayes average* estimates. MAP estimates are calculated as the single most likely label/cluster assignment across all query copies; all assignments in the sample are averaged

[2] This approximation and architecture is similar to Smola and Narayanamurthy (2010).

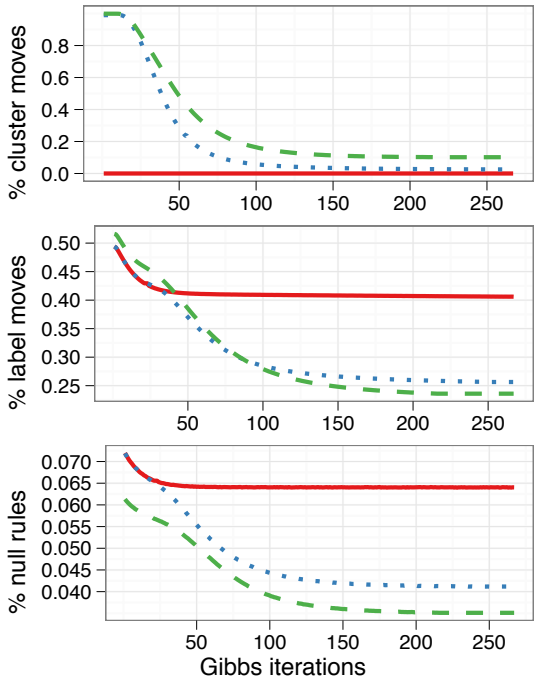

Figure 4: Convergence rates of CLC-BASE (red/solid), CLC-HDP-LG $100C$,$40L$ (green/dashed), CLC-HDP-LG $1000C$,$40L$ (blue/dotted) in terms of % of query cluster swaps, label cluster swaps and null rule assignments.

to obtain the Bayes average precision estimate.[3]

5 Results

A total of five variants of CLC were evaluated with different combinations of $|C|$ and HDP prior concentration α^C (controlling the effective number of label clusters). Referring to models in terms of their parametrizations is potentially confusing. Therefore, we will make use of the fact that models with $\boldsymbol{\alpha}^C = 1$ yielded roughly 40 label clusters on average, and models with $\boldsymbol{\alpha}^C = 0.1$ yielded roughly 200 label clusters, naming model variants simply by the number of query and label clusters: (1) CLC-BASE, (2) CLC-DPMM 1C-40L, (3) CLC-HDP-LG 100C-40L, (4) CLC-HDP-LG 1000C-40L, and (5) CLC-HDP-LG 1000C-200L. Figure 4 shows the model convergence for CLC-BASE, CLC-HDP-LG 100C-40L, and CLC-HDP-LG 1000C-40L.

[3]We calculate the Bayes average precision estimates at the top 10 (Bayes@10) and top 20 (Bayes@20) parse trees, weighted by probability.

5.1 Chunking Precision

Chunking precision scores for each model are shown in Table 3 (average % of labels not marked *badspan*). CLC-HDP-LG 1000C-40L has the highest precision across both MAP and Bayes estimates (∼93% accuracy), followed by CLC-HDP-LG 1000C-200L (∼90% accuracy) and CLC-DPMM 1C-40L (∼85%). CLC-BASE performed the worst by a significant margin (∼78%), indicating that label coarse-graining is more important than query clustering for chunking accuracy. No significant differences in label chunking accuracy were found between Bayes and MAP inference.

5.2 Predicting Span Labels

The full CLC-HDP-LG model variants obtain higher label precision than the simpler models, with CLC-HDP-LG 1000C-40L achieving the highest precision of the three (∼63% accuracy). Increasing the number of label clusters too high, however, significantly reduces precision: CLC-HDP-LG 1000C-200L obtains only ∼51% accuracy. However, comparing to CLC-DPMM 1C-40L and CLC-BASE demonstrates that the addition of label clusters and query clusters both lead to gains in label precision. These relative rankings are robust across *strict* and *normal* evaluation regimes.

The breakdown over MAP and Bayes posterior estimation is less clear when considering label precision: the simpler models CLC-BASE and CLC-DPMM 1C-40L perform significantly worse than Bayes when using MAP estimation, while in CLC-HDP-LG the reverse holds.

There is little evidence for correlation between precision and query length (weak, not statistically significant negative correlation using Spearman's ρ). This result is interesting as the relative prevalence of natural language queries increases with query length, potentially degrading performance. However, we did find a strong positive correlation between precision and the number of labels productions applicable to a query, i.e., production rule fertility is a potential indicator of semantic quality.

Finally, the *histogram* column in Table 3 shows the distribution of rater responses for each model. In general, the more precise models tend to have a significantly lower proportion of missing spans

Model	Chunking Precision	Label Precision			Ambiguous Label Precision		Spearman's ρ

Confidence intervals are standard error; sparklines show distribution of precision scores (left is zero, right is one). *Hist* shows the distribution of human rating response (log y scale): green/first is correct, blue/second is ambiguous, cyan/third is missing and red/fourth is incorrect. Spearman's ρ columns give label precision correlations with query length (weak negative correlation) and the number of applicable labels (weak to strong positive correlation); dots indicate significance.

(blue/second bar; due to null rule assignment) in additional to more correct (green/first) and fewer incorrect (red/fourth) spans.

5.3 High Polysemy Subset

We repeat the analysis of label precision on a subset of queries containing one of the manually-selected polysemous spans shown in Table 4. The CLC-HDP-LG -based models still significantly outperform the simpler models, but unlike in the broader setting, CLC-HDP-LG 100C-40L significantly outperforms CLC-HDP-LG 1000C-40L, indicating that lower query cluster granularity helps address polysemy (Table 3).

5.4 Error Analysis

Figure 5 gives examples of both high-precision and low-precision queries markups inferred by CLC-HDP-LG. In general, CLC performs well on queries with clear *intent head / intent modifier* structure (Li, 2010). More complex queries, such as [*never know until you try quotes*] or [*how old do you have to be a bartender in new york*] do not fit this model; however, expanding the set of extracted labels to also cover instances such as *never know until you try* would mitigate this problem, motivating the use of n-gram language models with semantic markup.

acapella, alamo, apple, atlas, bad, bank, batman, beloved, black forest, bravo, bush, canton, casino, champion, club, comet, concord, dallas, diamond, driver, english, ford, gamma, ion, lemon, manhattan, navy, pa, palm, port, put, resident evil, ronaldo, sacred heart, saturn, seven, solution, sopranos, sparta, supra, texas, village, wolf, young

Table 4: Samples from a list of 90 manually selected ambiguous spans used to evaluate model performance under polysemy.

A large number of mistakes made by CLC are

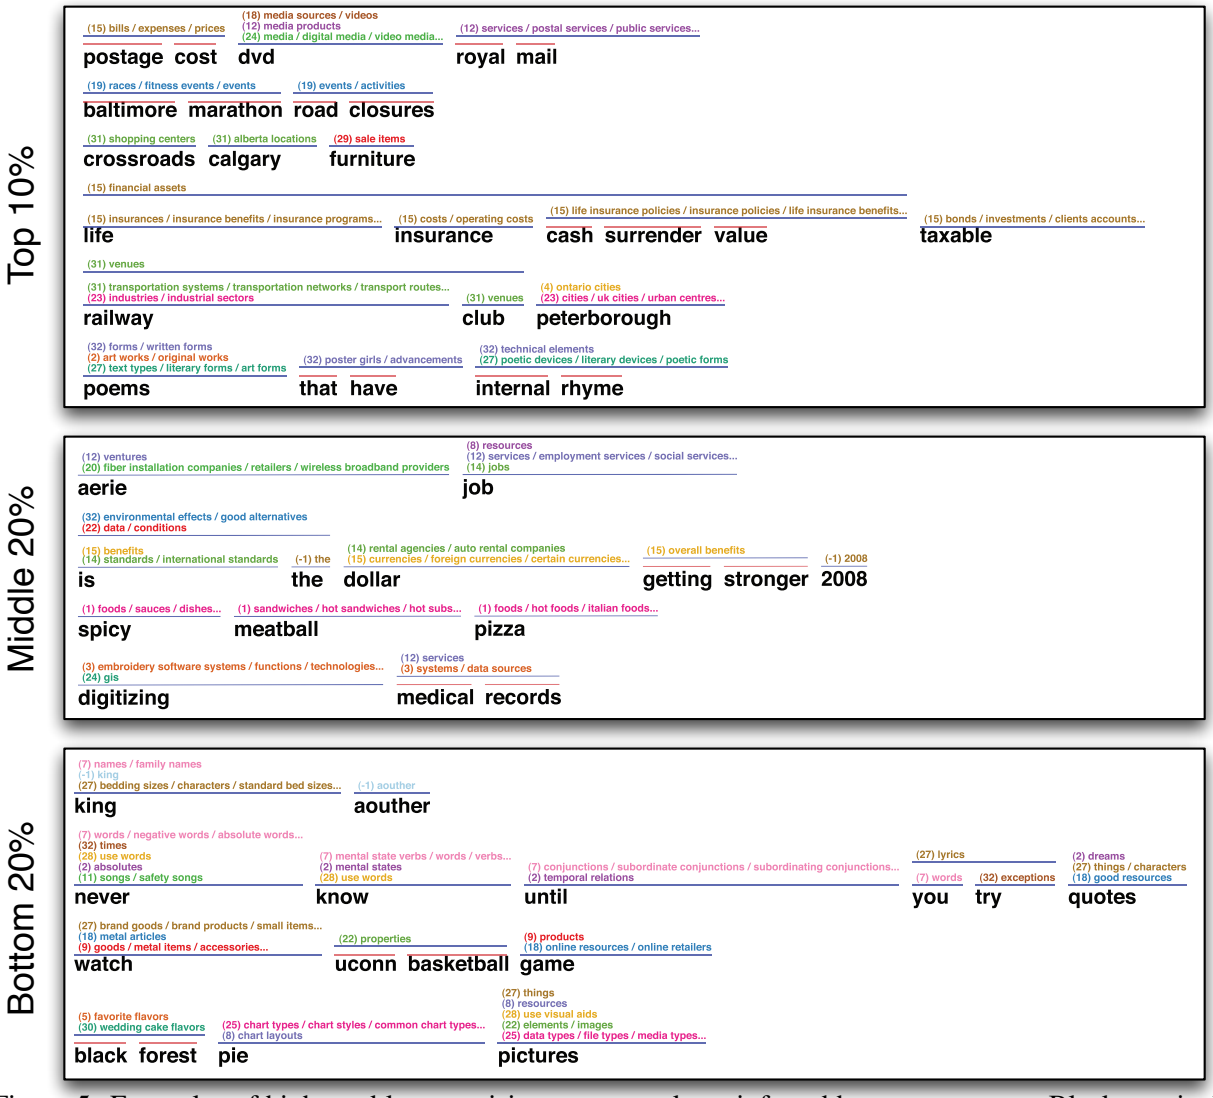

Figure 5: Examples of high- and low-precision query markups inferred by CLC-HDP-LG. Black text is the original query; lines indicate potential spans; small text shows potential labels colored and numbered by label cluster; small bar shows percentage of assignments to that label cluster.

due to named-entity categories with weak semantics such as rock bands or businesses (e.g., [*tropical breeze cleaners*], [*cosmic railroad band*] or [*sopranos cigars*]). When the named entity is common enough, it is detected by the rule set, but for the long tail of named entities this is not the case. One potential solution is to use a stronger notion of *selectional preference* and slot-filling, rather than just relying on correlation between labels.

Other examples of common errors include interpreting *weymouth* in [*weymouth train time table*] as a town in Massachusetts instead of a town in the UK (lack of domain knowledge), and using lower quality semantic labels (e.g., *neighboring countries* for *france*, or *great retailers* for *target*).

6 Discussion and Future Work

Adding both latent label clusters (DPMM) and latent query clusters (extending to HDP-LG) improve chunking and label precision over the baseline CLC-BASE system. The label clusters are important because they capture intra-group correlations between class labels, while the query clusters are important for capturing inter-group correlations. However, the algorithm is sensitive to the relative number of clusters in each case: Too many labels/label clusters rel-

ative to the number of query clusters make it difficult to learn correlations ($O(n^2)$ query clusters are required to capture pairwise interactions). Too many query clusters, on the other hand, make the model intractable computationally. The HDP automates selecting the number of clusters, but still requires manual hyperparameter setting.

(**Future Work**) Many query slots have weak semantics and hence are misleading for CLC. For example [*pacific breeze cleaners*] or [*dale hartley subaru*] should be parsed such that the type of the leading slot is determined not by its direct content, but by its context; seeing *subaru* or *cleaners* after a noun-phrase slot is a strong indicator of its type (*dealership* or *shop name*). The current CLC model only couples these slots through their correlations in query clusters, not directly through relative position or context. Binary productions in the PCFG or a discriminative learning model would help address this.

Finally, we did not measure label coverage with respect to a human evaluation set; coverage is useful as it indicates whether our inferred semantics are biased with respect to human norms.

7 Conclusions

We introduced CLC, a set of latent variable PCFG models for semantic analysis of short textual segments. CLC captures semantic information in the form of interactions between clusters of automatically extracted class-labels, e.g., finding that placenames commonly co-occur with business-names. We applied CLC to a corpus containing 500M search queries, demonstrating its scalability and straightforward parallel implementation using frameworks like MapReduce or Hadoop. CLC was able to chunk queries into spans more accurately and infer more precise labels than several sub-models even across a highly ambiguous query subset. The key to obtaining these results was coarse-graining the input class-label set and using a latent variable model to capture interactions between coarse-grained labels.

Abstract

The availability of learner corpora, especially those which have been manually error-tagged or shallow-parsed, is still limited. This means that researchers do not have a common development and test set for natural language processing of learner English such as for grammatical error detection. Given this background, we created a novel learner corpus that was manually error-tagged and shallow-parsed. This corpus is available for research and educational purposes on the web. In this paper, we describe it in detail together with its data-collection method and annotation schemes. Another contribution of this paper is that we take the first step toward evaluating the performance of existing POS-tagging/chunking techniques on learner corpora using the created corpus. These contributions will facilitate further research in related areas such as grammatical error detection and automated essay scoring.

1 Introduction

The availability of learner corpora is still somewhat limited despite the obvious usefulness of such data in conducting research on natural language processing of learner English in recent years. In particular, learner corpora tagged with grammatical errors are rare because of the difficulties inherent in learner corpus creation as will be described in Sect. 2. As shown in Table 1, error-tagged learner corpora are very few among existing learner corpora (see Leacock et al. (2010) for a more detailed discussion of learner corpora). Even if data is error-tagged, it is often not available to the public or its access is severely restricted. For example, the Cambridge Learner Corpus, which is one of the largest error-tagged learner corpora, can only be used by authors and writers working for Cambridge University Press and by members of staff at Cambridge ESOL.

Error-tagged learner corpora are crucial for developing and evaluating error detection/correction algorithms such as those described in (Rozovskaya and Roth, 2010b; Chodorow and Leacock, 2000; Chodorow et al., 2007; Felice and Pulman, 2008; Han et al., 2004; Han et al., 2006; Izumi et al., 2003b; Lee and Seneff, 2008; Nagata et al., 2004; Nagata et al., 2005; Nagata et al., 2006; Tetreault et al., 2010b). This is one of the most active research areas in natural language processing of learner English. Because of the restrictions on their availability, researchers have used their own learner corpora to develop and evaluate error detection/correction methods, which are often not commonly available to other researchers. This means that the detection/correction performance of each existing method is not directly comparable as Rozovskaya and Roth (2010a) and Tetreault et al. (2010a) point out. In other words, we are not sure which methods achieve the best performance. Commonly available error-tagged learner corpora are therefore essential to further research in this area.

For similar reasons, to the best of our knowledge, there exists no such learner corpus that is manually shallow-parsed and which is also publicly available, unlike, say, native-speaker corpora such as the Penn Treebank. Such a comparison brings up another crucial question: "Do existing POS taggers and chun-

In *Availability*, *Yes* denotes that the full texts of the corpus is available to the public. *Partially* denotes that it is accessible through specially-made interfaces such as a concordancer. The information in this table may not be consistent because many of the URLs of the corpora give only sparse information about them.

Table 1: Learner corpus list.

kers work on learner English as well as on edited text such as newspaper articles?" Nobody really knows the answer to the question. The only exception in the literature is the work by Tetreault et al. (2010b) who evaluated parsing performance in relation to prepositions. Nevertheless, a great number of researchers have used existing POS taggers and chunkers to analyze the writing of learners of English. For instance, error detection methods normally use a POS tagger and/or a chunker in the error detection process. It is therefore possible that a major cause of false positives and negatives in error detection may be attributed to errors in POS-tagging and chunking. In corpus linguistics, researchers (Aarts and Granger, 1998; Granger, 1998; Tono, 2000) use such tools to extract interesting patterns from learner corpora and to reveal learners' tendencies. However, poor performance of the tools may result in misleading conclusions.

Given this background, we describe in this paper a manually error-tagged and shallow-parsed learner corpus that we created. In Sect. 2, we discuss the difficulties inherent in learner corpus creation. Considering the difficulties, in Sect. 3, we describe our method for learner corpus creation, including its data collection method and annotation schemes. In Sect. 4, we describe our learner corpus in detail. The learner corpus is called the Konan-JIEM learner corpus (KJ corpus) and is freely available for research and educational purposes on the web[1]. Another contribution of this paper is that we take the first step toward answering the question about the performance of existing POS-tagging/chunking techniques on learner data. We report and discuss the results in Sect. 5.

2 Difficulties in Learner Corpus Creation

In addition to the common difficulties in creating any corpus, learner corpus creation has its own difficulties. We classify them into the following four categories of the difficulty in:

1. collecting texts written by learners;
2. transforming collected texts into a corpus;
3. copyright transfer; and
4. error and POS/parsing annotation.

The first difficulty concerns the problem in collecting texts written by learners. As in the case of other corpora, it is preferable that the size of a learner corpus be as large as possible where the size can be measured in several ways including the total number of texts, words, sentences, writers, topics, and texts per writer. However, it is much more difficult to create a large learner corpus than to create a

[1] http://www.gsk.or.jp/index_e.html

large native-speaker corpus. In the case of native-speaker corpora, published texts such as newspaper articles or novels can be used as a corpus. By contrast, in the case of learner corpora, we must find learners and then let them write since there are no such published texts written by learners of English (unless they are part of a learner corpus). Here, it should be emphasized that learners often do not spontaneously write but are typically obliged to write, for example, in class, or during an exam. Because of this, learners may soon become tired of writing. This in itself can affect learner corpus creation much more than one would expect especially when creating a longitudinal learner corpus. Thus, it is crucial to keep learners motivated and focused on the writing assignments.

The second difficulty arises when the collected texts are transformed into a learner corpus. This involves several time-consuming and troublesome tasks. The texts must be archived in electronic form, which requires typing every single collected text since learners normally write on paper. Besides, each text must be archived and maintained with accompanying information such as who wrote what text when and on what topic. Optionally, a learner corpus could include other pieces of information such as proficiency, first language, and age. Once the texts have been electronically archived, it is relatively easy to maintain and access them. However, this is not the case when the texts are first collected. Thus, it is better to have an efficient method for managing such information as well as the texts themselves.

The third difficulty concerning copyright is a daunting problem. The copyright for each text must be transferred to the corpus creator so that the learner corpus can be made available to the public. Consider the case when a number of learners participate in a learner corpus creation project and everyone has to sign a copyright transfer form. This issue becomes even more complicated when the writer does not actually have such a right to transfer copyright. For instance, under the Japanese law, those younger than 20 years of age do not have the right; instead their parents do. Thus, corpus creators have to ask learners' parents to sign copyright transfer forms. This is often the case since the writers in learner corpus creation projects are normally junior high school, high school, or college students.

The final difficulty is in error and POS/parsing annotation. For error annotation, several annotation schemes exist (for example, the NICT JLE scheme (Izumi et al., 2005)). While designing an annotation scheme is one issue, annotating errors is yet another. No matter how well an annotation scheme is designed, there will always be exceptions. Every time an exception appears, it becomes necessary to revise the annotation scheme. Another issue we have to remember is that there is a trade-off between the granularity of an annotation scheme and the level of the difficulty in error annotation. The more detailed an annotation scheme is, the more information it can contain and the more difficult identifying errors is, and vice versa.

For POS/parsing annotation, there are also a number of annotation schemes including the Brown tag set, the Claws tag set, and the Penn Treebank tag set. However, none of them are designed to be used for learner corpora. In other words, a variety of linguistic phenomena occur in learner corpora which the existing annotation schemes do not cover. For instance, spelling errors often appear in texts written by learners of English as in *sard year*, which should be *third year*. Grammatical errors prevent us applying existing annotation schemes, too. For instance, there are at least three possibilities for POS-tagging the word *sing* in the sentence *everyone sing together.* using the Penn Treebank tag set: sing/VB, sing/VBP, or sing/VBZ. The following example is more complicated: *I don't success cooking.* Normally, the word *success* is not used as a verb but as a noun. The instance, however, appears in a position where a verb appears. As a result, there are at least two possibilities for tagging: success/NN and success/VB. Errors in mechanics are also problematic as in *Tonight,we* and *beautifulhouse* (missing spaces)[2]. One solution is to split them to obtain the correct strings and then tag them with a normal scheme. However, this would remove the information that spaces were originally missing which we want to preserve. To handle these and other phenomena which are peculiar to learner corpora, we need to develop a novel annotation scheme.

[2]Note that the KJ corpus consists of typed essays.

3 Method

3.1 How to Collect and Maintain Texts Written by Learners

Our text-collection method is based on writing exercises. In the writing exercises, learners write essays on a blog system. This very simple idea of using a blog system naturally solves the problem of archiving texts in electronic form. In addition, the use of a blog system enables us to easily register and maintain accompanying information including who (user ID) writes when (uploaded time) and on what topic (title of blog item). Besides, once registered in the user profile, the optional pieces of information such as proficiency, first language, and age are also easy to maintain and access.

To design the writing exercises, we consulted with several teachers of English and conducted pre-experiments. Ten learners participated in the pre-experiments and were assigned five essay topics on average. Based on the experimental results, we designed the procedure of the writing exercise as shown in Table 2. In the first step, learners are assigned an essay topic. In the second step, they are given time to prepare during which they think about what to write on the given topic before they start writing. We found that this enables the students to write more. In the third step, they actually write an essay on the blog system. After they have finished writing, they submit their essay to the blog system to be registered.

The following steps were considered optional. We implemented an article error detection method (Nagata et al., 2006) in the blog system as a trial attempt to keep the learners motivated since learners are likely to become tired of doing the same exercise repeatedly. To reduce this, the blog system highlights where article errors exist after the essay has been submitted. The hope is that this might prompt the learners to write more accurately and to continue the exercises. In the pre-experiments, the detection did indeed seem to interest the learners and to provide them with additional motivation. Considering these results, we decided to include the fourth and fifth steps in the writing exercises when we created our learner corpus. At the same time, we should of course be aware that the use of error detection affects learners' writing. For example, it may change the distribution of errors. Nagata and Nakatani (2010) reported the effects in detail.

Step	Min.
1. Learner is assigned an essay topic	–
2. Learner prepares for writing	5
3. Learner writes an essay	35
4. System detects errors in the essay	5
5. Learner rewrites the essay	15

Table 2: Procedure of writing exercise.

To solve the problem of copyright transfer, we took legal professional advice but were informed that, in Japan at least, the only way to be sure is to have a copyright transfer form signed every time. We considered having it signed on the blog system, but it soon turned out that this did not work since participating learners may still be too young to have the legal right to sign the transfer. It is left for our long-term future work to devise a better solution to this legal issue.

3.2 Annotation Scheme

This subsection describes the error and POS/chunking annotation schemes. Note that errors and POS/chunking are annotated separately, meaning that there are two files for any given text. Due to space restrictions we limit ourselves to only summarizing our annotation schemes in this section. The full descriptions are available together with the annotated corpus on the web.

3.2.1 Error Annotation

We based our error annotation scheme on that used in the NICT JLE corpus (Izumi et al., 2003a), whose detailed description is readily available, for example, in Izumi et al. (2005). In that annotation scheme and accordingly in ours, errors are tagged using an XML syntax; an error is annotated by tagging a word or phrase that contains it. For instance, a tense error is annotated as follows: *I <v_tns crr="made">make</v_tns> pies last year.*

where *v_tns* denotes a tense error in a verb. It should be emphasized that the error tags contain the information on correction together with error annotation. For instance, *crr="made"* in the above example denotes the correct form of the verb is *made*. For missing word errors, error tags are placed where

a word or phrase is missing (e.g., *My friends live <prp crr="in"></prp> these places.*).

As a pilot study, we applied the NICT JLE annotation scheme to a learner corpus to reveal what modifications we needed to make. The learner corpus consisted of 455 essays (39,716 words) written by junior high and high school students[3]. The following describes the major modifications deemed necessary as a result of the pilot study.

The biggest difference between the NICT JLE corpus and our targeted corpus is that the former is spoken data and the latter is written data. This difference inevitably requires several modifications to the annotation scheme. In speech data, there are no errors in spelling and mechanics such as punctuation and capitalization. However, since such errors are not usually regarded as grammatical errors, we decided simply not to annotate them in our annotation schemes.

Another major difference is fragment errors. Fragments that do not form a complete sentence often appear in the writing of learners (e.g., *I have many books. Because I like reading.*). In written language, fragments can be regarded as a grammatical error. To annotate fragment errors, we added a new tag <f> (e.g., *I have many books.* <f>*Because I like reading.*</f>).

As discussed in Sect. 2, there is a trade-off between the granularity of an annotation scheme and the level of the difficulty in annotating errors. In our annotation scheme, we narrowed down the number of tags to 22 from 46 in the original NICT JLE tag set to facilitate the annotation; the 22 tags are shown in Appendix A. The removed tags are merged into the tag for *other*. For instance, there are only three tags for errors in nouns (number, lexis, and other) in our tag set whereas there are six in the NICT JLE corpus (inflection, number, case, countability, complement, and lexis); the *other* tag (<n_o>) covers the four removed tags.

3.2.2 POS/Chunking Annotation

We selected the Penn Treebank tag set, which is one of the most widely used tag sets, for our POS/chunking annotation scheme. Similar to the error annotation scheme, we conducted a pilot study to determine what modifications we needed to make to the Penn Treebank scheme. In the pilot study, we used the same learner corpus as in the pilot study for the error annotation scheme.

As a result of the pilot study, we found that the Penn Treebank tag set sufficed in most cases except for errors which learners made. Considering this, we determined a basic rule as follows: "Use the Penn Treebank tag set and preserve the original texts as much as possible." To handle such errors, we made several modifications and added two new POS tags (CE and UK) and another two for chunking (XP and PH), which are described below.

A major modification concerns errors in mechanics such as *Tonight,we* and *beautifulhouse* as already explained in Sect. 2. We use the symbol "-" to annotate such cases. For instance, the above two examples are annotated as follows: *Tonight,we/NN-,-PRP* and *beautifulhouse/JJ-NN*. Note that each POS tag is hyphenated. It can also be used for annotating chunks in the same manner. For instance, *Tonight,we* is annotated as *[NP-PH-NP Tonight,we/NN-,-PRP]*. Here, the tag *PH* stands for ϕ chunk label and denotes tokens which are not normally chunked (cf., [NP Tonight/NN] ,/, [NP we/PRP]).

Another major modification was required to handle grammatical errors. Essentially, POS/chunking tags are assigned according to the surface information of the word in question regardless of the existence of any errors. For example, *There is apples.* is annotated as *[NP There/EX] [VP is/VBZ] [NP apples/NNS] ./.* Additionally, we define the CE[4] tag to annotate errors in which learners use a word with a POS which is not allowed such as in *I don't success cooking.* The CE tag encodes a POS which is obtained from the surface information together with the POS which would have been assigned to the word if it were not for the error. For instance, the above example is tagged as *I don't success/CE:NN:VB cooking.* In this format, the second and third POSs are separated by ":" which denotes the POS which is obtained from the surface information and the POS which would be assigned

[3]The learner corpus had been created before this reported work started. Learners wrote their essays on paper. Unfortunately, this learner corpus cannot be made available to the public since the copyrights were not transferred to us.

[4]CE stands for cognitive error.

to the word without an error. The user can select either POS depending on his or her purposes. Note that the CE tag is compatible with the basic annotation scheme because we can retrieve the basic annotation by extracting only the second element (i.e., success/NN). If the tag is unknown because of grammatical errors or other phenomena, UK and XP[5] are used for POS and chunking, respectively.

For spelling errors, the corresponding POS and chunking tag are assigned to mistakenly spelled words if the correct forms can be guessed (e.g., [NP sird/JJ year/NN]); otherwise UK and XP are used.

4 The Corpus

We carried out a learner corpus creation project using the described method. Twenty six Japanese college students participated in the project. At the beginning, we had the students or their parents sign a conventional paper-based copyright transfer form. After that, they did the writing exercise described in Sect. 3 once or twice a week over three months. During that time, they were assigned ten topics, which were determined based on a writing textbook (Okihara, 1985). As described in Sect. 3, they used a blog system to write, submit, and rewrite their essays. Through out the exercises, they did not have access to the others' essays and their own previous essays.

As a result, 233 essays were collected; Table 3 shows the statistics on the collected essays. It turned out that the learners had no difficulties in using the blog system and seemed to focus on writing. Out of the 26 participants, 22 completed the 10 assignments while one student quit before the exercises started.

We annotated the grammatical errors of all 233 essays. Two persons were involved in the annotation. After the annotation, another person checked the annotation results; differences in error annotation were resolved by consulting the first two. The error annotation scheme was found to work well on them. The error-annotated essays can be used for evaluating error detection/correction methods.

Number of essays	233
Number of writers	25
Number of sentences	3,199
Number of words	25,537

Table 3: Statistics on the learner corpus.

[5]UK and XP stand for unknown and X phrase, respectively.

For POS/chunking annotation, we chose 170 essays out of 233. We annotated them using our POS/chunking scheme; hereafter, the 170 essays will be referred to as the shallow-parsed corpus.

5 Using the Corpus and Discussion

5.1 POS Tagging

The 170 essays in the shallow-parsed corpus was used for evaluating existing POS-tagging techniques on texts written by learners. It consisted of 2,411 sentences and 22,452 tokens.

HMM-based and CRF-based POS taggers were tested on the shallow-parsed corpus. The former was implemented using tri-grams by the author. It was trained on a corpus consisting of English learning materials (213,017 tokens). The latter was CRFTagger[6], which was trained on the WSJ corpus. Both use the Penn Treebank POS tag set.

The performance was evaluated using accuracy defined by

$$\frac{\text{number of tokens correctly POS-tagged}}{\text{number of tokens}}. \quad (1)$$

If the number of tokens in a sentence was different in the human annotation and the system output, the sentence was excluded from the calculation. This discrepancy sometimes occurred because the tokenization of the system sometimes differed from that of the human annotators. As a result, 19 and 126 sentences (215 and 1,352 tokens) were excluded from the evaluation in the HMM-based and CRF-based POS taggers, respectively.

Table 4 shows the results. The second column corresponds to accuracies on a native-speaker corpus (sect. 00 of the WSJ corpus). The third column corresponds to accuracies on the learner corpus.

As shown in Table 4, the CRF-based POS tagger suffers a decrease in accuracy as expected. Interestingly, the HMM-based POS tagger performed better on the learner corpus. This is perhaps because it

[6]"CRFTagger: CRF English POS Tagger," Xuan-Hieu Phan, `http://crftagger.sourceforge.net/`, 2006.

was trained on a corpus consisting of English learning materials whose distribution of vocabulary was expected to be relatively similar to that of the learner corpus. By contrast, it did not perform well on the native-speaker corpus because the size of the training corpus was relatively small and the distribution of vocabulary was not similar, and thus unknown words often appeared. This implies that selecting appropriate texts as a training corpus may improve the performance.

Table 5 shows the top five POSs mistakenly tagged as other POSs. An obvious cause of mistakes in both taggers is that they inevitably make errors in the POSs that are not defined in the Penn Treebank tag set, that is, UK and CE. A closer look at the tagging results revealed that phenomena which were common to the writing of learners were major causes of other mistakes. Errors in capitalization partly explain why the taggers made so many mistakes in NN (singular nouns). They often identified erroneously capitalized common nouns as proper nouns as in *This Summer/NNP Vacation/NNP*. Spelling errors affected the taggers in the same way. Grammatical errors also caused confusion between POSs. For instance, omission of a certain word often caused confusion between a verb and an adjective as in *I frightened/VBD.* which should be *I (was) frightened/JJ.* Another interesting case is expressions that learners overuse (e.g., *and/CC so/RB on/RB* and *so/JJ so/JJ*). Such phrases are not erroneous but are relatively infrequent in native-speaker corpora. Therefore, the taggers tended to identify their POSs according to the surface information on the tokens themselves when such phrases appeared in the learner corpus (e.g., *and/CC so/RB* <u>*on/IN*</u> and <u>*so/RB so/RB*</u>). We should be aware that tokenization is also problematic although failures in tokenization were excluded from the accuracies.

The influence of the decrease in accuracy on other NLP tasks is expected to be task and/or method dependent. Methods that directly use or handle sequences of POSs are likely to suffer from it. An example is the error detection method (Chodorow and Leacock, 2000), which identifies unnatural sequences of POSs as grammatical errors in the writing of learners. As just discussed above, existing techniques often fail in sequences of POSs that have a grammatical error. For instance, an existing POS tagger likely tags the sentence *I frightened.* as *I/PRP frightened/VBD ./.* as we have just seen, and in turn the error detection method cannot identify it as an error because the sequence *PRP VBD* is not unnatural; it would correctly detect it if the sentence were correctly tagged as *I/PRP frightened/JJ ./.* For the same reason, the decrease in accuracy may affect the methods (Aarts and Granger, 1998; Granger, 1998; Tono, 2000) for extracting interesting sequences of POSs from learner corpora; for example, BOS[7] PRP JJ is an interesting sequence but is never extracted unless the phrase is correctly POS-tagged. It requires further investigation to reveal how much impact the decrease has on these methods. By contrast, error detection/correction methods based on the bag-of-word features (or feature vectors) are expected to suffer less from it since mistakenly POS-tagged tokens are only one of the features. At the same time, we should notice that if the target errors are in the tokens that are mistakenly POS-tagged, the detection will likely fail (e.g., verbs should be correctly identified in tense error detection).

In addition to the above evaluation, we attempted to improve the POS taggers using the transformation-based POS-tagging technique (Brill, 1994). In the technique, transformation rules are obtained by comparing the output of a POS tagger and the human annotation so that the differences between the two are reduced. We used the shallow-

Method	Native Corpus	Learner Corpus
CRF	0.970	0.932
HMM	0.887	0.926

Table 4: POS-tagging accuracy.

HMM		CRF	
POS	Freq.	POS	Freq.
NN	259	NN	215
VBP	247	RB	166
RB	163	CE	144
CE	150	JJ	140
JJ	108	FW	86

Table 5: Top five POSs mistakenly tagged.

[7] BOS denotes a beginning of a sentence.

Method	Original	Improved
CRF	0.932	0.934
HMM	0.926	0.933

Table 6: Improvement obtained by transformation.

parsed corpus as a test corpus and the other manually POS-tagged corpus created in the pilot study described in Subsect. 3.2.1 as a training corpus. We used POS-based and word-based transformations as Brill (1994) described.

Table 6 shows the improvements together with the original accuracies. Table 6 reveals that even the simple application of Brill's technique achieves a slight improvement in both taggers. Designing the templates of the transformation for learner corpora may achieve further improvement.

5.2 Head Noun Identification

In the evaluation of chunking, we focus on head noun identification. Head noun identification often plays an important role in error detection/correction. For example, it is crucial to identify head nouns to detect errors in article and number.

We again used the shallow-parsed corpus as a test corpus. The essays contained 3,589 head nouns. We implemented an HMM-based chunker using 5-grams whose input is a sequence of POSs, which was obtained by the HMM-based POS tagger described in the previous subsection. The chunker was trained on the same corpus as the HMM-based POS tagger. The performance was evaluated by recall and precision defined by

$$\frac{\text{number of head nouns correctly identified}}{\text{number of head nouns}} \quad (2)$$

and

$$\frac{\text{number of head nouns correctly identified}}{\text{number of tokens identified as head noun}}, \quad (3)$$

respectively.

Table 7 shows the results. To our surprise, the chunker performed better than we had expected. A possible reason for this is that sentences written by learners of English tend to be shorter and simpler in terms of their structure.

The results in Table 7 also enable us to quantitatively estimate expected improvement in error detection/correction which is achieved by improving chunking. To see this, let us define the following symbols: r: Recall of head noun identification, R: recall of error detection without chunking error, $\hat{R}$ recall of error detection with chunking error. R and $\hat{R}$ are interpreted as the true recall of error detection and its observed value when chunking error exists, respectively. Here, note that $\hat{R}$ can be expressed as $\hat{R} = rR$. For instance, according to Han et al. (2006), their method achieves a recall of 0.40 (i.e., $\hat{R} = 0.4$), and thus $R = 0.44$ assuming that chunking errors exist and recall of head noun identification is $r = 0.90$ just as in this evaluation. Improving r to $r = 0.97$ would achieve $R = 0.43$ without any modification to the error detection method. Precision can also be estimated in a similar manner although it requires a more complicated calculation.

6 Conclusions

In this paper, we discussed the difficulties inherent in learner corpus creation and a method for efficiently creating a learner corpus. We described the manually error-annotated and shallow-parsed learner corpus which was created using this method. We also showed its usefulness in developing and evaluating POS taggers and chunkers. We believe that publishing this corpus will give researchers a common development and test set for developing related NLP techniques including error detection/correction and POS-tagging/chunking, which will facilitate further research in these areas.

A Error tag set

This is the list of our error tag set. It is based on the NICT JLE tag set (Izumi et al., 2005).

- n: noun
  - num: number
  - lxc: lexis
  - o: other
- v: verb
  - agr: agreement

Recall	Precision
0.903	0.907

Table 7: Performance on head noun identification.

  - tns: tense
  - lxc: lexis
  - o: other
- mo: auxiliary verb
- aj: adjective
  - lxc: lexis
  - o: other
- av: adverb
- prp: preposition
  - lxc: lexis
  - o: other
- at: article
- pn: pronoun
- con: conjunction
- rel: relative clause
- itr: interrogative
- olxc: errors in lexis in more than two words
- ord: word order
- uk: unknown error
- f: fragment error

Crowdsourcing Translation: Professional Quality from Non-Professionals

Omar F. Zaidan and **Chris Callison-Burch**
Dept. of Computer Science, Johns Hopkins University
Baltimore, MD 21218, USA
{ozaidan,ccb}@cs.jhu.edu

Abstract

Naively collecting translations by crowdsourcing the task to non-professional translators yields disfluent, low-quality results if no quality control is exercised. We demonstrate a variety of mechanisms that increase the translation quality to near professional levels. Specifically, we solicit redundant translations and edits to them, and automatically select the best output among them. We propose a set of features that model both the translations and the translators, such as country of residence, LM perplexity of the translation, edit rate from the other translations, and (optionally) calibration against professional translators. Using these features to score the collected translations, we are able to discriminate between acceptable and unacceptable translations. We recreate the NIST 2009 Urdu-to-English evaluation set with Mechanical Turk, and quantitatively show that our models are able to select translations within the range of quality that we expect from professional translators. The total cost is more than an order of magnitude lower than professional translation.

1 Introduction

In natural language processing research, translations are most often used in statistical machine translation (SMT), where systems are trained using bilingual sentence-aligned parallel corpora. SMT owes its existence to data like the Canadian Hansards (which by law must be published in both French and English). SMT can be applied to any language pair for which there is sufficient data, and it has been shown to produce state-of-the-art results for language pairs like Arabic–English, where there is ample data. However, large bilingual parallel corpora exist for relatively few languages pairs.

There are various options for creating new training resources for new language pairs. These include harvesting the web for translations or comparable corpora (Resnik and Smith, 2003; Munteanu and Marcu, 2005; Smith et al., 2010; Uszkoreit et al., 2010), improving SMT models so that they are better suited to the low resource setting (Al-Onaizan et al., 2002; Probst et al., 2002; Oard et al., 2003; Niessen and Ney, 2004), or designing models that are capable of learning translations from monolingual corpora (Rapp, 1995; Fung and Yee, 1998; Schafer and Yarowsky, 2002; Haghighi et al., 2008). Relatively little consideration is given to the idea of simply hiring translators to create parallel data, because it would seem to be prohibitively expensive. For example, Germann (2001) estimated the cost of hiring professional translators to create a Tamil-English corpus at $0.36/word. At that rate, translating enough data to build even a small parallel corpus like the LDC's 1.5 million word Urdu–English corpus would exceed half a million dollars.

In this paper we examine the idea of creating low cost translations via crowdscouring. We use Amazon's Mechanical Turk to hire a large group of non-professional translators, and have them recreate an Urdu–English evaluation set at a fraction of the cost of professional translators. The original dataset already has professionally-produced reference translations, which allows us to objectively and quantitatively compare the quality of professional and non-professional translations. Although many of the individual non-expert translators produce low-quality, disfluent translations, we show that it is possible to

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1220–1229,
Portland, Oregon, June 19-24, 2011.

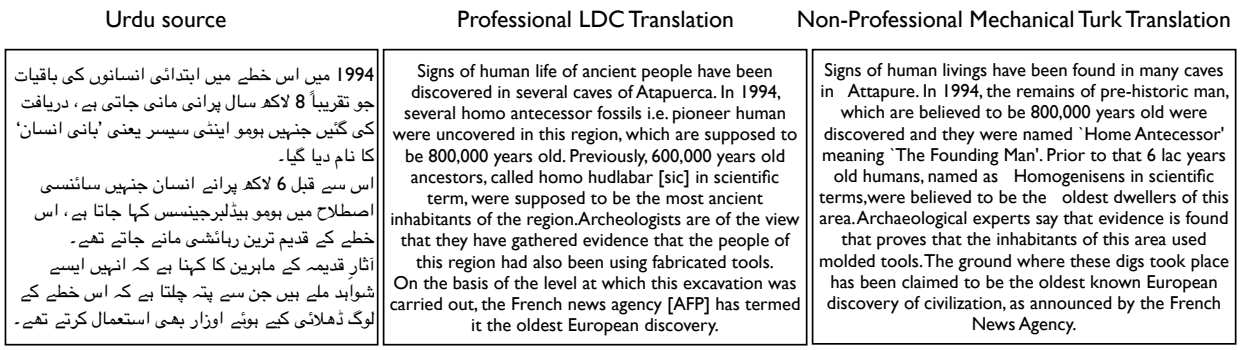

Figure 1: A comparison of professional translations provided by the LDC to non-professional translations created on Mechanical Turk.

get high quality translations in aggregate by soliciting multiple translations, redundantly editing them, and then selecting the best of the bunch.

To select the best translation, we use a machine-learning-inspired approach that assigns a score to each translation we collect. The scores discriminate acceptable translations from those that are not (and competent translators from those who are not). The scoring is based on a set of informative, intuitive, and easy-to-compute features. These include country of residence, number of years speaking English, LM perplexity of the translation, edit rate from the other translations, and (optionally) calibration against professional translators, with the weights set using a small set of gold standard data from professional translators.

2 Crowdsourcing Translation to Non-Professionals

To collect crowdsourced translations, we use Amazon's Mechanical Turk (MTurk), an online marketplace designed to pay people small sums of money to complete *Human Intelligence Tasks* (or HITs) – tasks that are difficult for computers but easy for people. Example HITs range from labeling images to moderating blog comments to providing feedback on relevance of results for search queries. Anyone with an Amazon account can either submit HITs or work on HITs that were submitted by others. Workers are referred to as "Turkers", and designers of HITs as "Requesters." A Requester specifies the reward to be paid for each completed item, sometimes as low as $0.01. Turkers are free to select whichever HITs interest them, and to bypass HITs they find uninteresting or which they deem pay too little.

The advantages of Mechanical Turk include:

- zero overhead for hiring workers
- a large, low-cost labor force
- easy micropayment system
- short turnaround time, as tasks get completed in parallel by many individuals
- access to foreign markets with native speakers of many rare languages

One downside is that Amazon does not provide any personal information about Turkers. (Each Turker is identifiable only through an anonymous ID like A23KO2TP7I4KK2.) In particular, no information is available about a worker's educational background, skills, or even native language(s). This makes it difficult to determine if a Turker is qualified to complete a translation task.

Therefore, soliciting translations from anonymous non-professionals carries a significant risk of poor translation quality. Whereas hiring a professional translator ensures a degree of quality and care, it is not very difficult to find bad translations provided by Turkers. One Urdu headline, professionally translated as *Barack Obama: America Will Adopt a New Iran Strategy*, was rendered disfluently by a Turker as *Barak* ***Obam*** *will* ***do a new policy*** *with Iran*. Another translated it with snarky sarcasm: *Barak Obama and America* ***weave new evil strategies*** *against Iran*. Figure 1 gives more typical translation examples. The translations often reflect non-native English, but are generally done conscientiously (in spite of the relatively small payment).

To improve the accuracy of noisy labels from non-experts, most existing quality control mechanisms

employ some form of voting, assuming a discrete set of possible labels. This is not the case for translations, where the 'labels' are full sentences. When dealing with such a structured output, the space of possible outputs is diverse and complex. We therefore need a different approach for quality control. That is precisely the focus of this work: to propose, and evaluate, such quality control mechanisms.

In the next section, we discuss reproducing the Urdu-to-English 2009 NIST evaluation set. We then describe a principled approach to discriminate good translations from bad ones, given a set of redundant translations for the same source sentence.

3 Datasets

3.1 The Urdu-to-English 2009 NIST Evaluation Set

We translated the Urdu side of the Urdu–English test set of the 2009 NIST MT Evaluation Workshop. The set consists of 1,792 Urdu sentences from a variety of news and online sources. The set includes four different reference translations for each source sentence, produced by professional translation agencies. NIST contracted the LDC to oversee the translation process and perform quality control.

This particular dataset, with its multiple reference translations, is very useful because we can measure the quality range for professional translators, which gives us an idea of whether or not the crowdsourced translations approach the quality of a professional translator.

3.2 Translation HIT design

We solicited English translations for the Urdu sentences in the NIST dataset. Amazon has enabled payments in rupees, which has attracted a large demographic of workers from India (Ipeirotis, 2010). Although it does not yet have s direct payment in Pakistan's local currency, we found that a large contingent of our workers are located in Pakistan.

Our HIT involved showing the worker a sequence of Urdu sentences, and asking them to provide an English translation for each one. The screen also included a brief set of instructions, and a short questionnaire section. The reward was set at $0.10 per translation, or roughly $0.005 per word.

In our first collection effort, we solicited only one translation per Urdu sentence. After confirming that the task is feasible due to the large pool of workers willing and able to provide translations, we carried out a second collection effort, this time soliciting *three* translations per Urdu sentence (from three distinct translators). The interface was also slightly modified, in the following ways:

- Instead of asking Turkers to translate a full document (as in our first pass), we instead split the data set into groups of 10 sentences per HIT.
- We converted the Urdu sentences into images so that Turkers could not cheat by copying-and-pasting the Urdu text into an MT system.
- We collected information about each worker's geographic location, using a JavaScript plugin.

The translations from the first pass were of noticeably low quality, most likely due to Turkers using automatic translation systems. That is why we used images instead of text in our second pass, which yielded significant improvements. That said, we do not discard the translations from the first pass, and we do include them in our experiments.

3.3 Post-editing and Ranking HITs

In addition to collecting four translations per source sentence, we also collected **post-edited** versions of the translations, as well as **ranking judgments** about their quality.

Figure 2 gives examples of the unedited translations that we collected in the translation pass. These typically contain many simple mistakes like misspellings, typos, and awkward word choice. We posted another MTurk task where we asked workers to edit the translations into more fluent and grammatical sentences. We restrict the task to US-based workers to increase the likelihood that they would be native English speakers.

We also asked US-based Turkers to rank the translations. We presented the translations in groups of four, and the annotator's task was to rank the sentences by fluency, from best to worst (allowing ties).

We collected redundant annotations in these two tasks as well. Each translation is edited three times (by three distinct editors). We solicited only one edit per translation from our first pass translation effort. So, in total, we had 10 post-edited translations for

Avoiding dieting to prevent from flu	abstention from dieting in order to avoid Flu	Abstain from decrease eating in order to escape from flue	In order to be safer from flu quit dieting
This research of American scientists came in front after experimenting on mice.	This research from the American Scientists have come up after the experiments on rats.	This research of American scientists was shown after many experiments on mouses.	According to the American Scientist this research has come out after much experimentations on rats.
Experiments proved that mice on a lower calorie diet had comparatively less ability to fight the flu virus.	in has been proven from experiments that rats put on diet with less calories had less ability to resist the Flu virus.	It was proved by experiments the low calories eaters mouses had low defending power for flue in ratio.	Experimentaions have proved that those rats on less calories diet have developed a tendency of not overcoming the flu virus.
research has proven this old myth wrong that its better to fast during fever.	Research disproved the old axiom that " It is better to fast during fever"	The research proved this old talk that decrease eating is useful in fever.	This Research has proved the very old saying wrong that it is good to starve while in fever.

Figure 2: We redundantly translate each source sentence by soliciting multiple translations from different Turkers. These translations are put through a subsequent editing set, where multiple edited versions are produced. We select the best translation from the set using features that predict the quality of each translation and each translator.

each source sentence (plus the four original translations). In the ranking task, we collected judgments from five distinct workers for each translation group.

3.4 Data Collection Cost

We paid a reward of \$0.10 to translate a sentence, \$0.25 to edit a set of ten sentences, and \$0.06 to rank a set of four translation groups. Therefore, we had the following costs:

- Translation cost: \$716.80
- Editing cost: \$447.50
- Ranking cost: \$134.40

(If not done redundantly, those values would be \$179.20, \$44.75, and \$26.88, respectively.)

Adding Amazon's 10% fee, this brings the grand total to under \$1,500, spent to collect 7,000+ translations, 17,000+ edited translations, and 35,000+ rank labels.[1] We also use about 10% of the existing professional references in most of our experiments (see 4.2 and 4.3). If we estimate the cost at \$0.30/word, that would roughly be an additional \$1,000.

3.5 MTurk Participation

52 different Turkers took part in the translation task, each translating 138 sentences on average. In the editing task, 320 Turkers participated, averaging 56 sentences each. In the ranking task, 245 Turkers participated, averaging 9.1 HITs each, or 146 rank labels (since each ranking HIT involved judging 16 translations, in groups of four).

[1]Data URL: `www.cs.jhu.edu/~ozaidan/RCLMT`.

4 Quality Control Model

Our approach to building a translation set from the available data is to select, for each Urdu sentence, the one translation that our model believes to be the best out of the available translations. We evaluate various selection techniques by comparing the selected Turker translations against existing professionally-produced translations. The more the selected translations resemble the professional translations, the higher the quality.

4.1 Features Used to Select Best Translations

Our model selects one of the 14 English options generated by Turkers. For a source sentence s_i, our model assigns a score to each sentence in the set of available translations $\{t_{i,1}, ...t_{i,14}\}$. The chosen translation is the highest scoring translation:

$$tr(s_i) = tr_{i,j^*} \text{ s.t. } j^* = \underset{j}{\operatorname{argmax}}\, score(t_{i,j}) \quad (1)$$

where $score(.)$ is the dot product:

$$score(t_{i,j}) \stackrel{\text{def}}{=} \vec{w} \cdot \vec{f}(t_{i,j}) \quad (2)$$

Here, $\vec{w}$ is the model's weight vector (tuned as described below in 4.2), and $\vec{f}$ is a translation's corresponding feature vector. Each feature is a function computed from the English sentence string, the Urdu sentence string, the workers (translators, editors, and rankers), and/or the rank labels. We use 21 features, categorized into the following three sets.

Sentence-level (6 features). Most of the Turkers performing our task were native Urdu speakers whose second language was English, and they do not always produce natural-sounding English sentences. Therefore, the first set of features attempt to discriminate good English sentences from bad ones.

- Language model features: each sentence is assigned a log probability and per-word perplexity score, using a 5-gram language model trained on the English Gigaword corpus.
- Sentence length features: a good translation tends to be comparable in length to the source sentence, whereas an overly short or long translation is probably bad. We add two features that are the ratios of the two lengths (one penalizes short sentences and one penalizes long ones).
- Web n-gram match percentage: we assign a score to each sentence based on the percentage of the n-grams (up to length 5) in the translation that exist in the Google N-Gram Database.
- Web n-gram geometric average: we calculate the average over the different n-gram match percentages (similar to the way BLEU is computed). We add three features corresponding to max n-gram lengths of 3, 4, and 5.
- Edit rate to other translations: a bad translation is likely not to be very similar to other translations, since there are many more ways a translation can be bad than for it to be good. So, we compute the average edit rate distance from the other translations (using the TER metric).

Worker-level (12 features). We add *worker*-level features that evaluate a translation based on *who* provided it.

- Aggregate features: for each sentence-level feature above, we have a corresponding feature computed over *all* of that worker's translations.
- Language abilities: we ask workers to provide information about their language abilities. We have a binary feature indicating whether Urdu is their native language, and a feature for how long they have spoken it. We add a pair of equivalent features for English.
- Worker location: two binary features reflect a worker's location, one to indicate if they are located in Pakistan, and one to indicate if they are located in India.

Ranking (3 features). The third set of features is based on the ranking labels we collected (see 3.3).

- Average rank: the average of the five rank labels provided for this translation.
- Is-Best percentage: how often the translation was top-ranked among the four translations.
- Is-Better percentage: how often the translation was judged as the better translation, over all pairwise comparisons extracted from the ranks.

Other features (not investigated here) could include source-target information, such as translation model scores or the number of source words translated correctly according to a bilingual dictionary.

4.2 Parameter Tuning

Once features are computed for the sentences, we must set the model's weight vector $\vec{w}$. Naturally, the weights should be chosen so that good translations get high scores, and bad translations get low scores. We optimize translation quality against a small subset (10%) of reference (professional) translations.

To tune the weight vector, we use the linear search method of Och (2003), which is the basis of Minimum Error Rate Training (MERT). MERT is an iterative algorithm used to tune parameters of an MT system, which operates by iteratively generating new candidate translations and adjusting the weights to give good translations a high score, then regenerating new candidates based on the updated weights, etc. In our work, the set of candidate translations is *fixed* (the 14 English sentences for each source sentence), and therefore iterating the procedure is not applicable. We use the Z-MERT software package (Zaidan, 2009) to perform the search.

4.3 The *Worker Calibration* Feature

Since we use a small portion of the reference translations to perform weight tuning, we can also use that data to compute another worker-specific feature. Namely, we can evaluate the competency of each worker by scoring their translations against the reference translations. We then use that feature for every translation given by that worker. The intuition

is that workers known to produce good translations are likely to continue to produce good translations, and the opposite is likely true as well.

4.4 Evaluation Strategy

To measure the quality of the translations, we make use of the existing professional translations. Since we have *four* professional translation sets, we can calculate the BLEU score (Papineni et al., 2002) for one professional translator P_1 using the other three $P_{2,3,4}$ as a reference set. We repeat the process four times, scoring each professional translator against the others, to calculate the expected range of professional quality translation. We can see how a translation set T (chosen by our model) compares to this range by calculating T's BLEU scores against the same four sets of three reference translations. We will evaluate different strategies for selecting such a set T, and see how much each improves on the BLEU score, compared to randomly picking from among the Turker translations.

We also evaluate Turker translation quality by using them as reference sets to score various submissions to the NIST MT evaluation. Specifically, we measure the correlation (using Pearson's r) between BLEU scores of MT systems measured against non-professional translations, and BLEU scores measured against professional translations. Since the main purpose of the NIST dataset was to compare MT systems against each other, this is a more direct fitness-for-task measure. We chose the middle 6 systems (in terms of performance) submitted to the NIST evaluation, out of 12, as those systems were fairly close to each other, with less than 2 BLEU points separating them.[2]

5 Experimental Results

We establish the performance of professional translators, calculate oracle upper bounds on Turker translation quality, and carry out a set of experiments that demonstrate the effectiveness of our model and that determine which features are most helpful.

Each number reported in this section is an average of four numbers, corresponding to the four possible ways of choosing 3 of the 4 reference sets. Furthermore, each of those 4 numbers is itself based on a five-fold cross validation, where 80% of the data is used to compute feature values, and 20% used for evaluation. The 80% portion is used to compute the aggregate worker-level features. For the worker calibration feature, we utilize the references for 10% of the data (which is within the 80% portion).

5.1 Translation Quality: BLEU Scores Compared to Professionals

We first evaluated the reference sets against each other, in order to quantify the concept of "professional quality". On average, evaluating one reference set against the other three gives a BLEU score of 42.38 (Figure 3). A Turker set of translations scores 28.13 on average, which highlights the loss in quality when collecting translations from amateurs. To make the gap clearer, the output of a state-of-the-art machine translation system (the syntax-based variant of Joshua; Li et al. (2010)) achieves a score of 26.91, a mere 1.22 worse than the Turkers.

We perform two oracle experiments to determine if there exist high-quality Turker translations in the first place. The first oracle operates on the segment level: for each source segment, choose from the four translations the one that scores highest against the reference sentence. The second oracle operates on the worker level: for each source segment, choose from the four translations the one provided by the worker whose translations (over all sentences) score the highest. The two oracles achieve BLEU scores of 43.75 and 40.64, respectively – well within the range of professional translators.

We examined two voting-inspired methods, since taking a majority vote usually works well when dealing with MTurk data. The first selects the translation with the minimum average TER (Snover et al., 2006) against the other three translations, since that would be a 'consensus' translation. The second method selects the translation that received the best average rank, using the rank labels assigned by other Turkers (see 3.3). These approaches achieve BLEU scores of 34.41 and 36.64, respectively.

The main set of experiments evaluated the features from 4.1 and 4.3. We applied our approach using each of the four feature types: sentence features, Turker features, rank features, and the cali-

[2]Using all 12 systems artificially inflates correlation, due to the vast differences between the systems. For instance, the top system outperforms the bottom system by **15** BLEU points!

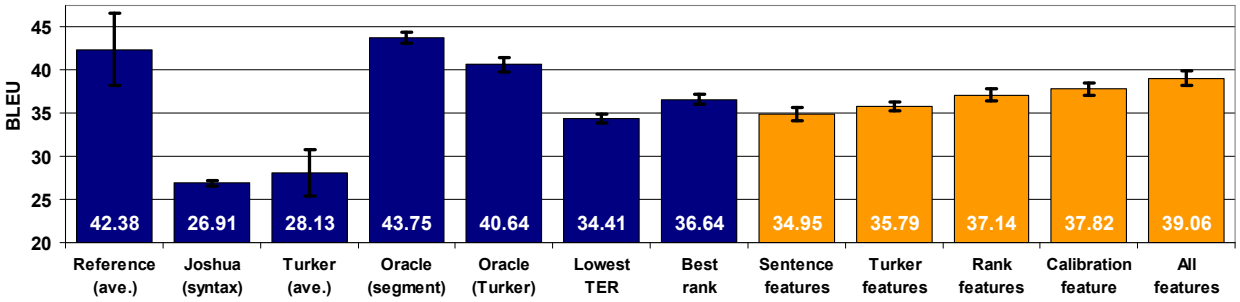

Figure 3: BLEU scores for different selection methods, measured against the reference sets. Each score is an average of four BLEU scores, each calculated against three LDC reference translations. The five right-most bars are colored in orange to indicate selection over a set that includes both original translations as well as edited versions of them.

bration feature. That yielded BLEU scores ranging from 34.95 to 37.82. With all features combined, we achieve a higher score of 39.06, which is within the range of scores for the professional translators.

5.2 Fitness for a Task: Correlation With Professionals When Ranking MT Systems

We evaluated the selection methods by measuring correlation with the references, in terms of BLEU scores assigned to outputs of MT systems. The results, in Table 1, tell a fairly similar story as evaluating with BLEU: references and oracles naturally perform very well, and the loss in quality when selecting arbitrary Turker translations is largely eliminated using our selection strategy.

Interestingly, when using the Joshua output as a reference set, the performance is quite abysmal. Even though its BLEU score is comparable to the Turker translations, it cannot be used to distinguish closely matched MT systems from each other.[3]

6 Analysis

The oracles indicate that there is usually an acceptable translation from the Turkers for any given sentence. Since the oracles select from a small group of only 4 translations per source segment, they are not overly optimistic, and rather reflect the true potential of the collected translations.

The results indicate that, although some features are more useful than others, much of the benefit from combining all the features can be obtained from any one set of features, with the benefit of adding more features being somewhat orthogonal.

[3]It should be noted that the Joshua system was not one of the six MT systems we scored in the correlation experiments.

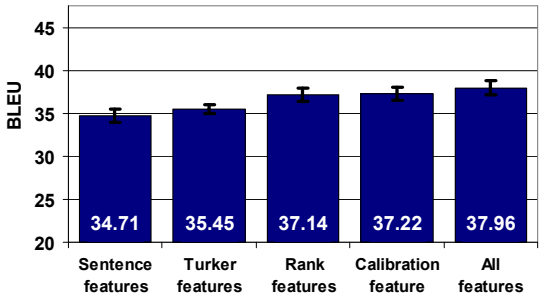

Figure 4: BLEU scores for the five right-most setups from Figure 3, constrained over the original translations.

Finally, we performed a series of experiments exploring the calibration feature, varying the amount of gold-standard references from 10% all the way up to 80%. As expected, the performance improved as more references were used to calibrate the translators (Figure 5). What's particularly important about this experiment is that it shows the added benefit of the other features: We would have to use 30%–40% of the references to get the same benefit obtained from combining the non-calibration features and only 10% for the calibration feature (dashed line in the Figure; BLEU = 39.06).

6.1 Cost Reduction

While the combined cost of our data collection effort ($2,500; see 3.4) is quite low considering the amount of collected data, it would be more attractive if the cost could be reduced further without losing much in translation quality. To that end, we investigated lowering cost along two dimensions: eliminating the need for professional translations, and decreasing the amount of edited translations.

Selection Method	Pearson's r^2
Reference (ave.)	0.81 ± 0.07
Joshua (syntax)	0.08 ± 0.09
Turker (ave.)	0.60 ± 0.17
Oracle (segment)	0.81 ± 0.09
Oracle (Turker)	0.79 ± 0.10
Lowest TER	0.50 ± 0.26
Best rank	0.74 ± 0.17
Sentence features	0.56 ± 0.21
Turker features	0.59 ± 0.19
Rank features	0.75 ± 0.14
Calibration feature	0.76 ± 0.13
All features	0.77 ± 0.11

Table 1: Correlation ($\pm$ std. dev.) for different selection methods, compared against the reference sets.

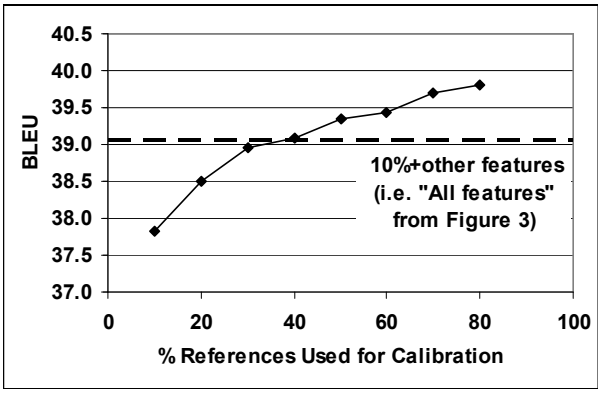

Figure 5: The effect of varying the amount of calibration data (and using only the calibration feature). The 10% point (BLEU = 37.82) and the dashed line (BLEU = 39.06) correspond to the two right-most bars of Figure 3.

The professional translations are used in our approach for computing the worker calibration feature (subsection 4.3) and for tuning the weights of the other features. We use a relatively small amount for this purpose, but we investigate a different setup whereby no professional translations are used at all. This eliminates the worker calibration feature, but, perhaps more critically, the feature weights must be set in a different fashion, since we cannot optimize BLEU on reference data anymore. Instead, we use the rank labels (from 3.3) as a proxy for BLEU, and set the weights so that better ranked translations receive higher scores.

Note that the rank features will also be excluded in this setup, since they are perfect predictors of rank labels. On the one hand, this means no rank labels need to be collected, other than for a small set used for weight tuning, further reducing the cost of data collection. However, this leads to a significant drop in performance, yielding a BLEU score of 34.86.

Another alternative for cost reduction would be to reduce the number of collected edited translations. To that end, we first investigate completely eliminating the editing phase, and considering only unedited translations. In other words, the selection will be over a group of four English sentences rather than 14 sentences. Completely eliminating the edited translations has an adverse effect, as expected (Figure 4). Another option, rather than eliminating the editing phase altogether, would be to consider the edited translations of only the translation receiving the best rank labels. This would reflect a data collection process whereby the editing task is delayed until after the rank labels are collected, with the rank labels used to determine which translations are most promising to post-edit (in addition to using the rank labels for the ranking features). Using this approach enables us to greatly reduce the number of edited translations collected, while maintaining good performance, obtaining a BLEU score of 38.67.

It is therefore our recommendation that crowdsourced translation efforts adhere to the following pipeline: collect multiple translations for each source sentence, collect rank labels for the translations, and finally collect edited versions of the top ranked translations.

7 Related Work

Dawid and Skene (1979) investigated filtering annotations using the EM algorithm, estimating annotator-specific error rates in the context of patient medical records. Snow et al. (2008) were among the first to use MTurk to obtain data for several NLP tasks, such as textual entailment and word sense disambiguation. Their approach, based on majority voting, had a component for annotator bias correction. They showed that for such tasks, a few non-expert labels usually suffice.

Whitehill et al. (2009) proposed a probabilistic model to filter labels from non-experts, in the context of an image labeling task. Their system generatively models image difficulty, as well as noisy, even

adversarial, annotators. They apply their method to simulated labels rather than real-life labels.

Callison-Burch (2009) proposed several ways to evaluate MT output on MTurk. One such method was to collect reference translations to score MT output. It was only a pilot study (50 sentences in each of several languages), but it showed the possibility of obtaining high-quality translations from non-professionals. As a followup, Bloodgood and Callison-Burch (2010) solicited a single translation of the NIST Urdu-to-English dataset we used. Their evaluation was similar to our correlation experiments, examining how well the collected translations agreed with the professional translations when evaluating three MT systems.

That paper appeared in a NAACL 2010 workshop organized by Callison-Burch and Dredze (2010), focusing on MTurk as a source of data for speech and language tasks. Two relevant papers from that workshop were by Ambati and Vogel (2010), focusing on the design of the translation HIT, and by Irvine and Klementiev (2010), who created translation lexicons between English and 42 rare languages.

Resnik et al. (2010) explore a very interesting way of creating translations on MTurk, relying only on *monolingual* speakers. Speakers of the target language iteratively identified problems in machine translation output, and speakers of the source language paraphrased the corresponding source portion. The paraphrased source would then be retranslated to produce a different translation, hopefully more coherent than the original.

8 Conclusion and Future Work

We have demonstrated that it is possible to obtain high-quality translations from non-professional translators, and that the cost is an order of magnitude cheaper than professional translation. We believe that crowdsourcing can play a pivotal role in future efforts to create parallel translation datasets. Beyond the cost and scalability, crowdsourcing provides access to languages that currently fall outside the scope of statistical machine translation research. We have begun an ongoing effort to collect translations for several low resource languages, including Tamil, Yoruba, and dialectal Arabic. We plan to:

- Investigate improvements from system combination techniques to the redundant translations.
- Modify our editing step to collect an annotated corpus of English as a second language errors.
- Calibrate against good Turkers, instead of professionals, once they have been identified.
- Predict whether it is necessary to solicit another translation instead of collecting a fixed number.
- Analyze how much quality matters if our goal is to train a statistical translation system.

A Statistical Tree Annotator and Its Applications

Xiaoqiang Luo and Bing Zhao

{xiaoluo,zhaob}@us.ibm.com

Abstract

In many natural language applications, there is a need to enrich syntactical parse trees. We present a statistical tree annotator augmenting nodes with additional information. The annotator is generic and can be applied to a variety of applications. We report 3 such applications in this paper: predicting function tags; predicting null elements; and predicting whether a tree constituent is projectable in machine translation. Our function tag prediction system outperforms significantly published results.

1 Introduction

Syntactic parsing has made tremendous progress in the past 2 decades (Magerman, 1994; Ratnaparkhi, 1997; Collins, 1997; Charniak, 2000; Klein and Manning, 2003; Carreras et al., 2008), and accurate syntactic parsing is often assumed when developing other natural language applications. On the other hand, there are plenty of language applications where basic syntactic information is insufficient. For instance, in question answering, it is highly desirable to have the semantic information of a syntactic constituent, e.g., a noun-phrase (NP) is a person or an organization; an adverbial phrase is locative or temporal. As syntactic information has been widely used in machine translation systems (Yamada and Knight, 2001; Xiong et al., 2010; Shen et al., 2008; Chiang, 2010; Shen et al., 2010), an interesting question is to predict whether or not a syntactic constituent is *projectable*[1] across a language pair.

[1]A constituent in the source language is projectable if it can be aligned to a contiguous span in the target language.

Such problems can be abstracted as adding additional annotations to an existing tree structure. For example, the English Penn treebank (Marcus et al., 1993) contains function tags and many carry semantic information. To add semantic information to the basic syntactic trees, a logical step is to predict these function tags after syntactic parsing. For the problem of predicting projectable syntactic constituent, one can use a sentence alignment tool and syntactic trees on source sentences to create training data by annotating a tree node as projectable or not. A generic tree annotator can also open the door of solving other natural language problems so long as the problem can be cast as annotating tree nodes. As one such example, we will present how to predict empty elements for the Chinese language.

Some of the above-mentioned problems have been studied before: predicting function tags were studied in (Blaheta and Charniak, 2000; Blaheta, 2003; Lintean and Rus, 2007a), and results of predicting and recovering empty elements can be found in (Dienes et al., 2003; Schmid, 2006; Campbell, 2004). In this work, we will show that these seemingly unrelated problems can be treated uniformly as adding annotations to an existing tree structure, which is the first goal of this work. Second, the proposed generic tree annotator can also be used to solve new problems: we will show how it can be used to predict projectable syntactic constituents. Third, the uniform treatment not only simplifies the model building process, but also affords us to concentrate on discovering most useful features for a particular application which often leads to improved performances, e.g, we find some features are very effective in predicting function tags and our system

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1230–1238,
Portland, Oregon, June 19-24, 2011.

has significant lower error rate than (Blaheta and Charniak, 2000; Lintean and Rus, 2007a).

The rest of the paper is organized as follows. Section 2 describes our tree annotator, which is a conditional log-linear model. Section 3 describes the features used in our system. Next, three applications of the proposed tree annotator are presented in Section 4: predicting English function tags, predicting Chinese empty elements and predicting Arabic projectable constituents. Section 5 compares our work with some related prior arts.

2 A MaxEnt Tree Annotator Model

The input to the tree annotator is a tree T. While T can be of any type, we concentrate on the syntactic parse tree in this paper. The non-terminal nodes, $N = \{n : n \in T\}$ of T are associated with an order by which they are visited so that they can be indexed as n_1, n_2, $\cdots$, $n_{|T|}$, where $|T|$ is the number of non-terminal nodes in T. As an example, Figure 1 shows a syntactic parse tree with the prefix order (i.e., the number at the up-right corner of each non-terminal node), where child nodes are visited recursively from left to right before the parent node is visited. Thus, the `NP-SBJ` node is visited first, followed by the `NP` spanning `duo action`, followed by the `PP-CLR` node etc.

With a prescribed tree visit order, our tree annotator model predicts a symbol l_i, where l_i takes value from a predefined finite set $\mathcal{L}$, for each non-terminal node n_i in a sequential fashion:

$$P(l_1, \cdots, l_{|T|}|T) = \prod_{i=1}^{|T|} P(l_i|l_1, \cdots, l_{i-1}, T) \quad (1)$$

The visit order is important since it determines what are in the conditioning of Eq. (1).

$P(l_i|l_1, \cdots, l_{i-1}, T)$ in this work is a conditional log linear (or MaxEnt) model (Berger et al., 1996):

$$P(l_i|l_1, \cdots, l_{i-1}, T) = \frac{exp\big(\sum_k \lambda_k g_k(l_1^{i-1}, T, l_i)\big)}{Z(l_1^{i-1}, T)} \quad (2)$$

where

$$Z(l_1^{i-1}, T) = \sum_{x \in \mathcal{L}} exp\big(\sum_k \lambda_k g_k(l_1^{i-1}, T, x)\big)$$

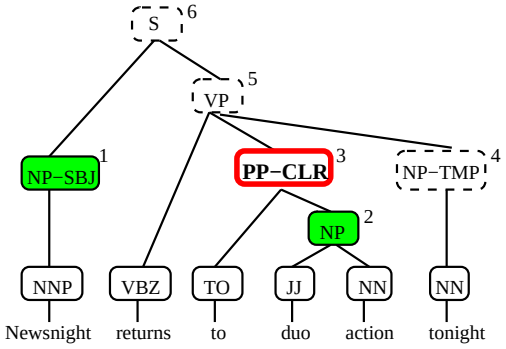

Figure 1: A sample tree: the number on the upright corner of each non-terminal node is the visit order.

is the normalizing factor to ensure that $P(l_i|l_1, \cdots, l_{i-1}, T)$ in Equation (2) is a probability and $\{g_k(l_1^{i-1}, T, l_i)\}$ are feature functions.

There are efficient training algorithms to find optimal weights relative to a labeled training data set once the feature functions $\{g_k(l_1^{i-1}, T, l_i)\}$ are selected (Berger et al., 1996; Goodman, 2002; Malouf, 2002). In our work, we use the SCGIS training algorithm (Goodman, 2002), and the features used in our systems are detailed in the next section.

Once a model is trained, at testing time it is applied to input tree nodes by the same order. Figure 1 highlights the prediction of the function tag for node 3(i.e., `PP-CLR`-node in the thickened box) after 2 shaded nodes (`NP-SBJ` node and `NP` node) are predicted. Note that by this time the predicted values are available to the system, while unvisited nodes (nodes in dashed boxes in Figure 1) can not provide such information.

3 Features

The features used in our systems are tabulated in Table 1. Numbers in the first column are the feature indices. The second column contains a brief description of each feature, and the third column contains the feature value when the feature at the same row is applied to the `PP`-node of Figure 1 for the task of predicting function tags.

Feature 1 through 8 are non-lexical features in that all of them are computed based on the labels or POS tags of neighboring nodes (e.g., Feature 4 computes the label or POS tag of the right most child), or the structure information (e.g., Feature 5 computes the number of child nodes).

Feature 9 and 10 are computed from past predicted values. When predicting the function tag for the PP-node in Figure 1, there is no predicted value for its left-sibling and any of its child node. That's why both feature values are NONE, a special symbol signifying that a node does not carry any function tag. If we were to predict the function tag for the VP-node, the value of Feature 9 would be SBJ, while Feature 10 will be instantiated twice with one value being CLR, another being TMP.

No.	Description	Value
1	current node label	PP
2	parent node label	VP
3	left-most child label/tag	TO
4	right-most child label/tag	NP
5	number of child nodes	2
6	CFG rule	PP->TO NP
7	label/tag of left sibling	VBZ
8	label/tag of right sibling	NP
9	predicted value of left-sibling	NONE
10	predicted value of child nodes	NONE
11	left-most internal word	to
12	right-most internal word	action
13	left neighboring external word	returns
14	right neighboring external word	tonight
15	head word of current node	to
16	head word of parent node	returns
17	is current node the head child	false
18	label/tag of head child	TO
19	predicted value of the head child	NONE

Table 1: Feature functions: the 2nd column contains the descriptions of each feature, and the 3rd column the feature value when it is applied to the PP-node in Figure 1.

Feature 11 to 19 are lexical features or computed from head nodes. Feature 11 and 12 compute the node-internal boundary words, while Feature 13 and 14 compute the immediate node-external boundary words. Feature 15 to 19 rely on the head information. For instance, Feature 15 computes the head word of the current node, which is to for the PP-node in Figure 1. Feature 16 computes the same for the parent node. Feature 17 tests if the current node is the head of its parent. Feature 18 and 19 compute the label or POS tag and the predicted value of the head child, respectively.

Besides the basic feature presented in Table 1, we also use conjunction features. For instance, applying the conjunction of Feature 1 and 18 to the PP-node in Figure 1 would yield a feature instance that captures the fact that the current node is a PP node and its head child's POS tag is TO.

4 Applications and Results

A wide variety of language problems can be treated as or cast into a tree annotating problem. In this section, we present three applications of the statistical tree annotator. The first application is to predict function tags of an input syntactic parse tree; the second one is to predict Chinese empty elements; and the third one is to predict whether a syntactic constituent of a source sentence is *projectable*, meaning if the constituent will have a contiguous translation on the target language.

4.1 Predicting Function Tags

In the English Penn Treebank (Marcus et al., 1993) and more recent OntoNotes data (Hovy et al., 2006), some tree nodes are assigned a function tag, which is of one of the four types: grammatical, form/function, topicalization and miscellaneous. Table 2 contains a list of function tags used in the English Penn Treebank (Bies et al., 1995). The "Grammatical" row contains function tags marking the grammatical role of a constituent, e.g., DTV for dative objects, LGS for logical subjects etc. Many tags in the "Form/function" row carry semantic information, e.g., LOC is for locative expressions, and TMP for temporal expressions.

Type	Function Tags
Grammatical (52.2%)	DTV LGS PRD PUT SBJ VOC
Form/function (36.2%)	ADV BNF DIR EXT LOC MNR NOM PRP TMP
Topicalization (2.2%)	TPC
Miscellaneous (9.4%)	CLF CLR HLN TTL

Table 2: Four types of function tags and their relative frequency

4.1.1 Comparison with Prior Arts

In order to have a direct comparison with (Blaheta and Charniak, 2000; Lintean and Rus, 2007a), we use the same English Penn Treebank (Marcus et al., 1993) and partition the data set identically: Section

2-21 of Wall Street Journal (WSJ) data for training and Section 23 as the test set. We use all features in Table 1 and build four models, each of which predicting one type of function tags. The results are tabulated in Table 3.

As can be seen, our system performs much better than both (Blaheta and Charniak, 2000) and (Lintean and Rus, 2007a). For two major categories, namely grammatical and form/function which account for 96.84% non-null function tags in the test set, our system achieves a relative error reduction of 77.1% (from (Blaheta and Charniak, 2000)'s 1.09% to 0.25%) and 46.9%(from (Blaheta and Charniak, 2000)'s 2.90% to 1.54%) , respectively. The performance improvements result from a clean learning framework and some new features we introduced: e.g., the node-external features, i.e., Feature 13 and 14 in Table 1, can capture long-range statistical dependencies in the conditional model (2) and are proved very useful (cf. Section 4.1.2). As far as we can tell, they are not used in previous work.

Type	Blaheta00	Lintean07	Ours
Grammar	98.91%	98.45%	99.75%
Form/Func	97.10%	95.15%	98.46%
topic	99.92%	99.87%	99.98%
Misc	98.65%	98.54%	99.41%

Table 3: Function tag prediction accuracies on gold parse trees: breakdown by types of function tags. The 2nd column is due to (Blaheta and Charniak, 2000) and 3rd column due to (Lintean and Rus, 2007a). Our results on the 4th column compare favorably with theirs.

4.1.2 Relative Contributions of Features

Since the English WSJ data set contains newswire text, the most recent OntoNotes (Hovy et al., 2006) contains text from a more diversified genres such as broadcast news and broadcast conversation, we decide to test our system on this data set as well. WSJ Section 24 is used for development and Section 23 for test, and the rest is used as the training data. Note that some WSJ files were not included in the OntoNotes release and Section 23 in OntoNotes contains only 1640 sentences. The OntoNotes data statistics is tabulated in Table 4. Less than 2% of nodes with non-empty function tags were assigned multiple function tags. To simplify the system building, we take the first tag in training and testing and report the aggregated accuracy only in this section.

	#-sents	#-nodes	#-funcNodes
training	71,186	1,242,747	280,755
test	1,640	31,117	6,778

Table 4: Statistics of OntoNotes: #-sents – number of sentences; #-nodes – number of non-terminal nodes; #-funcNodes – number of nodes containing non-empty function tags.

We use this data set to test relative contributions of different feature groups by incrementally adding features into the system, and the results are reported in Table 5. The dummy baseline is predicting the most likely prior – the empty function tag, which indicates that there are 78.21% of nodes without a function tag. The next line reflects the performance of a system with non-lexical features only (Feature 1 to 8 in Table 1), and the result is fairly poor with an accuracy 91.51%. The past predictions (Feature 8 and 9) helps a bit by improving the accuracy to 92.04%. Node internal lexical features (Feature 11 and 12) are extremely useful: it added more than 3 points to the accuracy. So does the node external lexical features (Feature 13 and 14) which added an additional 1.52 points. Features computed from head words (Feature 15 to 19) carry information complementary to the lexical features and it helps quite a bit by improving the accuracy by 0.64%. When all features are used, the system reached an accuracy of 97.34%.

From these results, we can conclude that, unlike syntactic parsing (Bikel, 2004), lexical information is extremely important for predicting and recovering function tags. This is not surprising since many function tags carry semantic information, and more often than not, the ambiguity can only be resolved by lexical information. E.g., whether a PP is locative or temporal PP is heavily influenced by the lexical choice of the NP argument.

4.2 Predicting Chinese Empty Elements

As is well known, Chinese is a pro-drop language. This and its lack of subordinate conjunction complementizers lead to the ubiquitous use of empty elements in the Chinese treebank (Xue et al., 2005). Predicting or recovering these empty elements is therefore important for the Chinese language pro-

Feature Set	Accuracy
prior (guess NONE)	78.21%
Non-lexical labels only	91.52%
+past prediction	92.04%
+node-internal lexical	95.17%
+node-external lexical	96.70%
+head word	**97.34%**

Table 5: Effects of feature sets: the second row contains the baseline result when always predicting NONE; Row 3 through 8 contain results by incrementally adding feature sets.

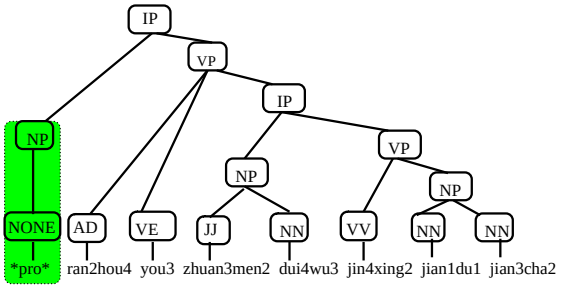
cessing. Recently, Chung and Gildea (2010) has found it useful to recover empty elements in machine translation.

Since empty elements do not have any surface string representation, we tackle the problem by attaching a pseudo function tag to an empty element's lowest non-empty parent and then removing the subtree spanning it. Figure 2 contains an example tree before and after removing the empty element *pro* and annotating the non-empty parent with a pseudo function tag NoneL. The transformation procedure is summarized in Algorithm 1.

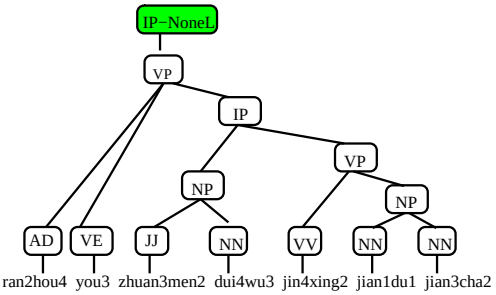
In particular, line 2 of Algorithm 1 find the lowest parent of an empty element that spans at least one non-trace word. In the example in Figure 2, it would find the top IP-node. Since *pro* is the left-most child, line 4 of Algorithm 1 adds the pseudo function tag NoneL to the top IP-node. Line 9 then removes its NP child node and all lower children (i.e., shaded subtree in Figure 2(1)), resulting in the tree in Figure 2(2).

Line 4 to 8 of Algorithm 1 indicate that there are 3 types of pseudo function tags: NoneL, NoneM, and NoneR, encoding a trace found in the left, middle or right position of its lowest non-empty parent. It's trivial to recover a trace's position in a sentence from NoneL, and NoneR, but it may be ambiguous for NoneM. The problem could be solved either using heuristics to determine the position of a middle empty element, or encoding the positional information in the pseudo function tag. Since here we just want to show that predicting empty elements can be cast as a tree annotation problem, we leave this option to future research.

With this transform, the problem of predicting a trace is cast into predicting the corresponding



(1) Original tree with a trace (the left−most child of the top IP−node)



(2) After removing trace and its parent node (shaded subtree in (1))

Figure 2: Transform of traces in a Chinese parse tree by adding pseudo function tags.

Algorithm 1 Procedure to remove empty elements and add pseudo function tags.

Input: An input tree
Output: a tree after removing traces (and their empty parents) and adding pseudo function tags to its lowest non-empty parent node
1:Foreach trace t
2: Find its lowest ancestor node p spanning at least one non-trace word
3: if t is p's left-most child
4: add pseudo tag NoneL to p
5: else if t is p's right-most child
6: add pseudo tag NoneR to p
7: else
8: add pseudo tag NoneM to p
9: Remove p's child spanning the trace t and all its children

pseudo function tag and the statistical tree annotator can thus be used to solve this problem.

4.2.1 Results

We use Chinese Treebank v6.0 (Xue et al., 2005) and the broadcast conversation data from CTB v7.0 [2]. The data set is partitioned into training, development and blind test as shown in Table 6. The partition is created so that different genres are well represented in different subsets. The training, development and test set have 32925, 3297 and 3033 sentences, respectively.

Subset	File IDs
Training	0001-0325, 0400-0454, 0600-0840 0500-0542, 2000-3000, 0590-0596 1001-1120, cctv,cnn,msnbc, phoenix 00-06
Dev	0841-0885, 0543-0548, 3001-3075 1121-1135, phoenix 07-09
Test	0900-0931,0549-0554, 3076-3145 1136-1151, phoenix 10-11

Table 6: Data partition for CTB6 and CTB 7's broadcast conversation portion

We then apply Algorithm 1 to transform trees and predict pseudo function tags. Out of 1,100,506 non-terminal nodes in the training data, 80,212 of them contain pseudo function tags. There are 94 nodes containing 2 pseudo function tags. The vast majority of pseudo tags – more then 99.7% – are attached to either `IP`, `CP`, or `VP`: 50971, 20113, 8900, respectively.

We used all features in Table 1 and achieved an accuracy of 99.70% on the development data, and 99.71% on the test data on gold trees.

To understand why the accuracies are so high, we look into the 5 most frequent labels carrying pseudo tags in the development set, and tabulate their performance in Table 7. The 2nd column contains the number of nodes in the reference; the 3rd column the number of nodes of system output; the 4th column the number of nodes with correct prediction; and the 5th column F-measure for each label.

From Table 7, it is clear that `CP-NoneL` and `IP-NoneL` are easy to predict. This is not surprising, given that the Chinese language lacks of complementizers for subordinate clauses. In other words, left-most empty elements under `CP` are almost unambiguous: if a `CP` node has an immediate `IP` child, it almost always has a left-most empty element; similarly, if an `IP` node has a `VP` node as the left-most child (i.e., without a subject), it almost always should have a left empty element (e.g., marking the dropped pro). Another way to interpret these results is as follows: when developing the Chinese treebank, there is really no point to annotate left-most traces for `CP` and `IP` when tree structures are available.

Label	numRef	numSys	numCorr	F1
CP-NoneL	1723	1724	1715	0.995
IP-NoneL	3874	3875	3844	0.992
VP-NoneR	660	633	597	0.923
IP-NoneM	440	432	408	0.936
VP-NoneL	135	107	105	0.868

Table 7: 5 most frequent labels carrying pseudo tags and their performances

On the other hand, predicting the left-most empty elements for `VP` is a lot harder: the F-measure is only 86.8% for `VP-NoneL`. Predicting the right-most empty elements under `VP` and middle empty elements under `IP` is somewhat easier: `VP-NoneR` and `IP-NoneM`'s F-measures are 92.3% and 93.6%, respectively.

4.3 Predicting Projectable Constituents

The third application is predicting projectable constituents for machine translation. State-of-the-art machine translation systems (Yamada and Knight, 2001; Xiong et al., 2010; Shen et al., 2008; Chiang, 2010; Shen et al., 2010) rely heavily on syntactic analysis. Projectable structures are important in that it is assumed in CFG-style translation rules that a source span can be translated contiguously. Clearly, not all source constituents can be translated this way, but if we can predict whether a non-terminal source node is projectable, we can avoid translation errors by bypassing or discouraging the derivation paths relying on non-projectable constituents, or using phrase-based approaches for non-projectable constituents.

We start from LDC's bilingual Arabic-English treebank with source human parse trees and alignments, and mark source constituents as either pro-

[2] Many files are missing in LDC's early 2010 release of CTB 7.0, but broadcast conversation portion is new and is used in our system.

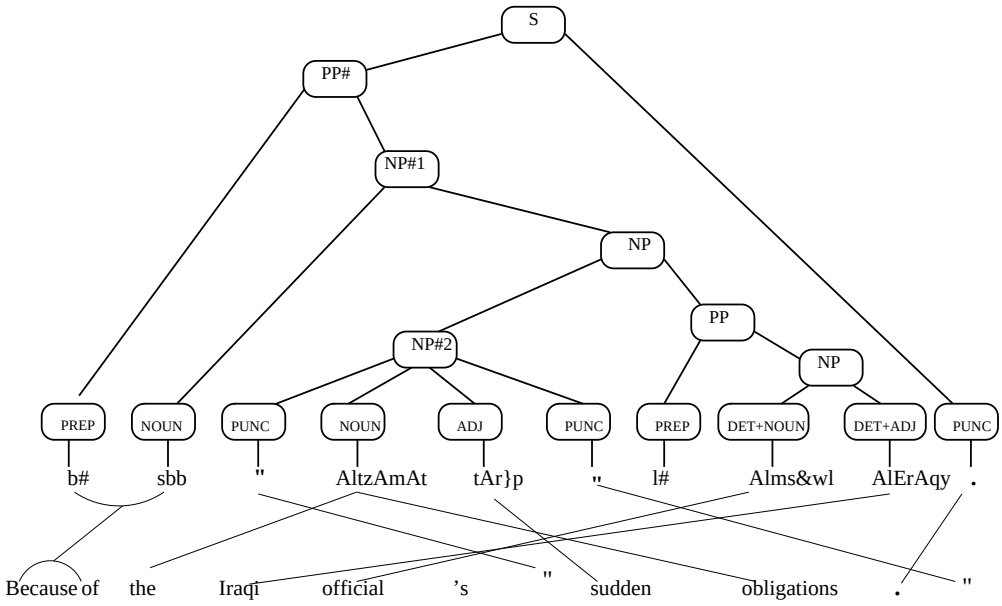


Figure 3: An example to show how a source tree is annotated with its alignment with the target sentence.

jectable or non-projectable. The binary annotations can again be treated as pseudo function tags and the proposed tree annotator can be readily applied to this problem.

As an example, the top half of Figure 3 contains an Arabic sentence with its parse tree; the bottom is its English translation with the human word-alignment. There are three non-projectable constituents marked with "#": the top `PP#` spanning the whole sentence except the final stop, and `NP#1` and `NP#2`. The `PP#` node is not projectable due to an inserted stop from outside; `NP#1` is not projectable because it is involved in a 2-to-2 alignment with the token `b#` outside `NP#1`; `NP#2` is aligned to a span `the Iraqi official 's sudden obligations .`, in which `Iraqi official` breaks the contiguity of the translation. It is clear that a CFG-like grammar will not be able to generate the translation for `NP#2`.

The LDC's Arabic-English bilingual treebank does not mark if a source node is projectable or not, but the information can be computed from word alignment. In our experiments, we processed 16,125 sentence pairs with human source trees for training, and 1,151 sentence pairs for testing. The statistics of the training and test data can be found in Table 8, where the number of sentences, the number of non-terminal nodes and the number of non-projectable nodes are listed in Column 2 through 4, respectively.

Data Set	#Sents	#nodes	#NonProj
Training	16,125	558,365	121,201
Test	1,151	40,674	8,671

Table 8: Statistics of the data for predicting projectable constituents

We get a 94.6% accuracy for predicting projectable constituents on the gold trees, and an 84.7% F-measure on the machine-generated parse trees. This component has been integrated into our machine translation system (Zhao et al., 2011).

5 Related Work

Blaheta and Charniak (2000) used a feature tree model to predict function tags. The work was later extended to use the voted perceptron (Blaheta, 2003). There are considerable overlap in terms of features used in (Blaheta and Charniak, 2000; Blaheta, 2003) and our system: for example, the label of current node, parent node and sibling nodes. However, there are some features that are unique in our work, e.g., lexical features at a constituent boundaries (node-internal and node-external words). Table 2 of (Blaheta and Charniak, 2000) contains the ac-

curacies for 4 types of function tags, and our results in Table 3 compare favorably with those in (Blaheta and Charniak, 2000). Lintean and Rus (2007a; Lintean and Rus (2007b) also studied the function tagging problem and applied naive Bayes and decision tree to it. Their accuracy results are worse than (Blaheta and Charniak, 2000). Neither (Blaheta and Charniak, 2000) nor (Lintean and Rus, 2007a; Lintean and Rus, 2007b) reported the relative usefulness of different features, while we found that the lexical features are extremely useful.

Campbell (2004) and Schmid (2006) studied the problem of predicting and recovering empty categories, but they used very different approaches: in (Campbell, 2004), a rule-based approach is used while (Schmid, 2006) used a non-lexical PCFG similar to (Klein and Manning, 2003). Chung and Gildea (2010) studied the effects of empty categories on machine translation and they found that even with noisy machine predictions, empty categories still helped machine translation. In this paper, we showed that empty categories can be encoded as pseudo function tags and thus predicting and recovering empty categories can be cast as a tree annotating problem. Our results also shed light on some empty categories can almost be determined unambiguously, given a gold tree structure, which suggests that these empty elements do not need to be annotated.

Gabbard et al. (2006) modified Collins' parser to output function tags. Since their results for predicting function tags are on system parses, they are not comparable with ours. (Gabbard et al., 2006) also contains a second stage employing multiple classifiers to recover empty categories and resolve coindexations between an empty element and its antecedent.

As for predicting projectable constituent, it is related to the work described in (Xiong et al., 2010), where they were predicting translation boundaries. A major difference is that (Xiong et al., 2010) defines projectable spans on a left-branching derivation tree solely for their phrase decoder and models, while translation boundaries in our work are defined from source parse trees. Our work uses more resources, but the prediction accuracy is higher (modulated on a different test data): we get a F-measure 84.7%, in contrast with (Xiong et al., 2010)'s 71%.

6 Conclusions and Future Work

We proposed a generic statistical tree annotator in the paper. We have shown that a variety of natural language problems can be tackled with the proposed tree annotator, from predicting function tags, predicting empty categories, to predicting projectable syntactic constituents for machine translation. Our results of predicting function tags compare favorably with published results on the same data set, possibly due to new features employed in the system. We showed that empty categories can be represented as pseudo function tags, and thus predicting empty categories can be solved with the proposed tree annotator. The same technique can be used to predict projectable syntactic constituents for machine translation.

There are several directions to expand the work described in this paper. First, the results for predicting function tags and Chinese empty elements were obtained on human-annotated trees and it would be interesting to do it on parse trees generated by system. Second, predicting projectable constituents is for improving machine translation and we are integrating the component into a syntax-based machine translation system.

Abstract

We present a discriminative learning method to improve the consistency of translations in phrase-based Statistical Machine Translation (SMT) systems. Our method is inspired by Translation Memory (TM) systems which are widely used by human translators in industrial settings. We constrain the translation of an input sentence using the most similar 'translation example' retrieved from the TM. Differently from previous research which used simple fuzzy match thresholds, these constraints are imposed using discriminative learning to optimise the translation performance. We observe that using this method can benefit the SMT system by not only producing consistent translations, but also improved translation outputs. We report a 0.9 point improvement in terms of BLEU score on English–Chinese technical documents.

1 Introduction

Translation consistency is an important factor for large-scale translation, especially for domain-specific translations in an industrial environment. For example, in the translation of technical documents, lexical as well as structural consistency is essential to produce a fluent target-language sentence. Moreover, even in the case of translation errors, consistency in the errors (e.g. repetitive error patterns) are easier to diagnose and subsequently correct by translators.

In phrase-based SMT, translation models and language models are automatically learned and/or generalised from the training data, and a translation is produced by maximising a weighted combination of these models. Given that global contextual information is not normally incorporated, and that training data is usually noisy in nature, there is no guarantee that an SMT system can produce translations in a consistent manner.

On the other hand, TM systems – widely used by translators in industrial environments for enterprise localisation by translators – can shed some light on mitigating this limitation. TM systems can assist translators by retrieving and displaying previously translated similar 'example' sentences (displayed as source-target pairs, widely called 'fuzzy matches' in the localisation industry (Sikes, 2007)). In TM systems, fuzzy matches are retrieved by calculating the similarity or the so-called 'fuzzy match score' (ranging from 0 to 1 with 0 indicating no matches and 1 indicating a full match) between the input sentence and sentences in the source side of the translation memory.

When presented with fuzzy matches, translators can then avail of useful chunks in previous translations while composing the translation of a new sentence. Most translators only consider a few sentences that are most similar to the current input sentence; this process can inherently improve the consistency of translation, given that the new translations produced by translators are likely to be similar to the target side of the fuzzy match they have consulted.

Previous research as discussed in detail in Sec-

tion 2 has focused on using fuzzy match score as a threshold when using the target side of the fuzzy matches to constrain the translation of the input sentence. In our approach, we use a more fine-grained discriminative learning method to determine whether the target side of the fuzzy matches should be used as a constraint in translating the input sentence. We demonstrate that our method can consistently improve translation quality.

The rest of the paper is organized as follows: we begin by briefly introducing related research in Section 2. We present our discriminative learning method for consistent translation in Section 3 and our feature design in Section 4. We report the experimental results in Section 5 and conclude the paper and point out avenues for future research in Section 6.

2 Related Research

Despite the fact that TM and MT integration has long existed as a major challenge in the localisation industry, it has only recently received attention in main-stream MT research. One can loosely combine TM and MT at sentence (called segments in TMs) level by choosing one of them (or both) to recommend to the translators using automatic classifiers (He et al., 2010), or simply using fuzzy match score or MT confidence measures (Specia et al., 2009).

One can also tightly integrate TM with MT at the sub-sentence level. The basic idea is as follows: given a source sentence to translate, we firstly use a TM system to retrieve the most similar 'example' source sentences together with their translations. If matched chunks between input sentence and fuzzy matches can be detected, we can directly re-use the corresponding parts of the translation in the fuzzy matches, and use an MT system to translate the remaining chunks.

As a matter of fact, implementing this idea is pretty straightforward: a TM system can easily detect the word alignment between the input sentence and the source side of the fuzzy match by retracing the paths used in calculating the fuzzy match score. To obtain the translation for the matched chunks, we just require the word alignment between source and target TM matches, which can be addressed using state-of-the-art word alignment techniques. More importantly, albeit not explicitly spelled out in previous work, this method can potentially increase the consistency of translation, as the translation of new input sentences is closely informed and guided (or constrained) by previously translated sentences.

There are several different ways of using the translation information derived from fuzzy matches, with the following two being the most widely adopted: 1) to add these translations into a phrase table as in (Biçici and Dymetman, 2008; Simard and Isabelle, 2009), or 2) to mark up the input sentence using the relevant chunk translations in the fuzzy match, and to use an MT system to translate the parts that are not marked up, as in (Smith and Clark, 2009; Koehn and Senellart, 2010; Zhechev and van Genabith, 2010). It is worth mentioning that translation consistency was not explicitly regarded as their primary motivation in this previous work. Our research follows the direction of the second strand given that consistency can no longer be guaranteed by constructing another phrase table.

However, to categorically reuse the translations of matched chunks without any differentiation could generate inferior translations given the fact that the context of these matched chunks in the input sentence could be completely different from the source side of the fuzzy match. To address this problem, both (Koehn and Senellart, 2010) and (Zhechev and van Genabith, 2010) used fuzzy match score as a threshold to determine whether to reuse the translations of the matched chunks. For example, (Koehn and Senellart, 2010) showed that reusing these translations as large rules in a hierarchical system (Chiang, 2005) can be beneficial when the fuzzy match score is above 70%, while (Zhechev and van Genabith, 2010) reported that it is only beneficial to a phrase-based system when the fuzzy match score is above 90%.

Despite being an informative measure, using fuzzy match score as a threshold has a number of limitations. Given the fact that fuzzy match score is normally calculated based on Edit Distance (Levenshtein, 1966), a low score does not necessarily imply that the fuzzy match is harmful when used to constrain an input sentence. For example, in longer sentences where fuzzy match scores tend to be low, some chunks and the corresponding translations within the sentences can still be useful. On

the other hand, a high score cannot fully guarantee the usefulness of a particular translation. We address this problem using discriminative learning.

3 Constrained Translation with Discriminative Learning

3.1 Formulation of the Problem

Given a sentence $\mathbf{e}$ to translate, we retrieve the most similar sentence $\mathbf{e}'$ from the translation memory associated with target translation $\mathbf{f}'$. The m common "phrases" $\bar{\mathbf{e}}_{\mathbf{1}}^{\mathbf{m}}$ between $\mathbf{e}$ and $\mathbf{e}'$ can be identified. Given the word alignment information between $\mathbf{e}'$ and $\mathbf{f}'$, one can easily obtain the corresponding translations $\bar{\mathbf{f}}'^{\mathbf{m}}_{\mathbf{1}}$ for each of the phrases in $\bar{\mathbf{e}}_{\mathbf{1}}^{\mathbf{m}}$. This process can derive a number of "phrase pairs" $< \bar{e}_m, \bar{f}'_m >$, which can be used to specify the translations of the matched phrases in the input sentence. The remaining words without specified translations will be translated by an MT system.

For example, given an input sentence $e_1 e_2 \cdots e_i e_{i+1} \cdots e_I$, and a phrase pair $< \bar{e}, \bar{f}' >$, $\bar{e} = e_i e_{i+1}$, $\bar{f}' = f'_j f'_{j+1}$ derived from the fuzzy match, we can mark up the input sentence as:

$e_1 e_2 \cdots$ <tm="$f'_j f'_{j+1}$"> $e_i e_{i+1}$ < /tm> $\cdots e_I$.

Our method to constrain the translations using TM fuzzy matches is similar to (Koehn and Senellart, 2010), except that the word alignment between $\mathbf{e}'$ and $\mathbf{f}'$ is the intersection of bidirectional GIZA++ (Och and Ney, 2003) posterior alignments. We use the intersected word alignment to minimise the noise introduced by word alignment of only one direction in marking up the input sentence.

3.2 Discriminative Learning

Whether the translation information from the fuzzy matches should be used or not (i.e. whether the input sentence should be marked up) is determined using a discriminative learning procedure. The translation information refers to the "phrase pairs" derived using the method described in Section 3.1. We cast this problem as a binary classification problem.

3.2.1 Support Vector Machines

SVMs (Cortes and Vapnik, 1995) are binary classifiers that classify an input instance based on decision rules which minimise the regularised error function in (1):

$$\begin{aligned} \min_{w,b,\xi} \quad & \frac{1}{2}\mathbf{w}^T\mathbf{w} + C\sum_{i=1}^{l}\xi_i \\ \text{s. t.} \quad & y_i(\mathbf{w}^T\phi(\mathbf{x}_i) + b) \geqslant 1 - \xi_i \\ & \xi_i \geqslant 0 \end{aligned} \tag{1}$$

where $(\mathbf{x}_i, y_i) \in R^n \times \{+1, -1\}$ are l training instances that are mapped by the function ϕ to a higher dimensional space. $\mathbf{w}$ is the weight vector, ξ is the relaxation variable and $C > 0$ is the penalty parameter.

Solving SVMs is viable using a kernel function K in (1) with $K(\mathbf{x}_i, \mathbf{x}_j) = \Phi(\mathbf{x}_i)^T\Phi(\mathbf{x}_j)$. We perform our experiments with the Radial Basis Function (RBF) kernel, as in (2):

$$K(\mathbf{x}_i, \mathbf{x}_j) = exp(-\gamma||\mathbf{x}_i - \mathbf{x}_j||^2), \gamma > 0 \tag{2}$$

When using SVMs with the RBF kernel, we have two free parameters to tune on: the cost parameter C in (1) and the radius parameter γ in (2).

In each of our experimental settings, the parameters C and γ are optimised by a brute-force grid search. The classification result of each set of parameters is evaluated by cross validation on the training set.

The SVM classifier will thus be able to predict the usefulness of the TM fuzzy match, and determine whether the input sentence should be marked up using relevant phrase pairs derived from the fuzzy match before sending it to the SMT system for translation. The classifier uses features such as the fuzzy match score, the phrase and lexical translation probabilities of these relevant phrase pairs, and additional syntactic dependency features. Ideally the classifier will decide to mark up the input sentence if the translations of the marked phrases are accurate when taken contextual information into account. As large-scale manually annotated data is not available for this task, we use automatic TER scores (Snover et al., 2006) as the measure for training data annotation.

We label the training examples as in (3):

$$y = \begin{cases} +1 & \text{if } TER(\text{w. markup}) < TER(\text{w/o markup}) \\ -1 & \text{if } TER(\text{w/o markup}) \geq TER(\text{w. markup}) \end{cases} \tag{3}$$

Each instance is associated with a set of features which are discussed in more detail in Section 4.

3.2.2 Classification Confidence Estimation

We use the techniques proposed by (Platt, 1999) and improved by (Lin et al., 2007) to convert classification margin to posterior probability, so that we can easily threshold our classifier (cf. Section 5.4.2).

Platt's method estimates the posterior probability with a sigmoid function, as in (4):

$$Pr(y=1|\mathbf{x}) \approx P_{A,B}(f) \equiv \frac{1}{1+exp(Af+B)} \quad (4)$$

where $f = f(\mathbf{x})$ is the decision function of the estimated SVM. A and B are parameters that minimise the cross-entropy error function F on the training data, as in (5):

$$\min_{z=(A,B)} F(z) = -\sum_{i=1}^{l}(t_i log(p_i) + (1-t_i) log(1-p_i)),$$
$$\text{where } p_i = P_{A,B}(f_i), \text{and } t_i = \begin{cases} \frac{N_+ +1}{N_+ +2} \text{ if } y_i = +1 \\ \frac{1}{N_- +2} \text{ if } y_i = -1 \end{cases} \quad (5)$$

where $z = (A, B)$ is a parameter setting, and N_+ and N_- are the numbers of observed positive and negative examples, respectively, for the label y_i. These numbers are obtained using an internal cross-validation on the training set.

4 Feature Set

The features used to train the discriminative classifier, all on the sentence level, are described in the following sections.

4.1 The TM Feature

The TM feature is the fuzzy match score, which indicates the overall similarity between the input sentence and the source side of the TM output. If the input sentence is similar to the source side of the matching segment, it is more likely that the matching segment can be used to mark up the input sentence.

The calculation of the fuzzy match score itself is one of the core technologies in TM systems, and varies among different vendors. We compute fuzzy match cost as the minimum Edit Distance (Levenshtein, 1966) between the source and TM entry, normalised by the length of the source as in (6), as most of the current implementations are based on edit distance while allowing some additional flexible matching.

$$h_{fm}(\mathbf{e}) = \min_{\mathbf{s}} \frac{EditDistance(\mathbf{e}, \mathbf{s})}{Len(\mathbf{e})} \quad (6)$$

where $\mathbf{e}$ is the sentence to translate, and $\mathbf{s}$ is the source side of an entry in the TM. For fuzzy match scores F, h_{fm} roughly corresponds to $1 - F$.

4.2 Translation Features

We use four features related to translation probabilities, i.e. the phrase translation and lexical probabilities for the phrase pairs $< \bar{e}_m, \bar{f'}_m >$ derived using the method in Section 3.1. Specifically, we use the phrase translation probabilities $p(\bar{f'}_m|\bar{e}_m)$ and $p(\bar{e}_m|\bar{f'}_m)$, as well as the lexical translation probabilities $p_{lex}(\bar{f'}_m|\bar{e}_m)$ and $p_{lex}(\bar{e}_m|\bar{f'}_m)$ as calculated in (Koehn et al., 2003). In cases where multiple phrase pairs are used to mark up one single input sentence $\mathbf{e}$, we use a unified score for each of the four features, which is an average over the corresponding feature in each phrase pair. The intuition behind these features is as follows: phrase pairs $< \bar{e}_m, \bar{f'}_m >$ derived from the fuzzy match should also be reliable with respect to statistically produced models.

We also have a count feature, i.e. the number of phrases used to mark up the input sentence, and a binary feature, i.e. whether the phrase table contains at least one phrase pair $< \bar{e}_m, \bar{f'}_m >$ that is used to mark up the input sentence.

4.3 Dependency Features

Given the phrase pairs $< \bar{e}_m, \bar{f'}_m >$ derived from the fuzzy match, and used to translate the corresponding chunks of the input sentence (cf. Section 3.1), these translations are more likely to be coherent in the context of the particular input sentence if the matched parts on the input side are syntactically and semantically related.

For matched phrases $\bar{e}_m$ between the input sentence and the source side of the fuzzy match, we define the contextual information of the input side using dependency relations between words e_m in $\bar{e}_m$ and the remaining words e_j in the input sentence $\mathbf{e}$.

We use the Stanford parser to obtain the dependency structure of the input sentence. We add a pseudo-label SYS_PUNCT to punctuation marks, whose governor and dependent are both the punctuation mark. The dependency features designed to capture the context of the matched input phrases $\bar{e}_m$ are as follows:

Coverage features measure the coverage of dependency labels on the input sentence in order to obtain a bigger picture of the matched parts in the input. For each dependency label *L*, we consider its head or modifier as *covered* if the corresponding input word e_m is covered by a matched phrase $\bar{e}_m$. Our coverage features are the frequencies of governor and dependent coverage calculated separately for each dependency label.

Position features identify whether the head and the tail of a sentence are matched, as these are the cases in which the matched translation is not affected by the preceding words (when it is the head) or following words (when it is the tail), and is therefore more reliable. The feature is set to 1 if this happens, and to 0 otherwise. We distinguish among the possible dependency labels, the head or the tail of the sentence, and whether the aligned word is the governor or the dependent. As a result, each permutation of these possibilities constitutes a distinct binary feature.

The consistency feature is a single feature which determines whether matched phrases $\bar{e}_m$ belong to a consistent dependency structure, instead of being distributed discontinuously around in the input sentence. We assume that a consistent structure is less influenced by its surrounding context. We set this feature to 1 if every word in $\bar{e}_m$ is dependent on another word in $\bar{e}_m$, and to 0 otherwise.

5 Experiments

5.1 Experimental Setup

Our data set is an English–Chinese translation memory with technical translation from Symantec, consisting of 87K sentence pairs. The average sentence length of the English training set is 13.3 words and the size of the training set is comparable to the larger TMs used in the industry. Detailed corpus statistics about the training, development and test sets for the SMT system are shown in Table 1.

The composition of test subsets based on fuzzy match scores is shown in Table 2. We can see that sentences in the test sets are longer than those in the training data, implying a relatively difficult translation task. We train the SVM classifier using the libSVM (Chang and Lin, 2001) toolkit. The SVM-

	Train	Develop	Test

CHI. VOC.	12,823	3,212	1,431

Table 1: Corpus Statistics

Scores	Sentences	Words	W/S
(0.9, 1.0)	80	1526	19.0750
(0.8, 0.9]	96	1430	14.8958
(0.7, 0.8]	110	1596	14.5091
(0.6, 0.7]	74	1031	13.9324
(0.5, 0.6]	104	1811	17.4135
(0, 0.5]	479	8972	18.7307

Table 2: Composition of test subsets based on fuzzy match scores

training and validation is on the same training sentences[1] as the SMT system with 5-fold cross validation.

The SVM hyper-parameters are tuned using the training data of the first fold in the 5-fold cross validation via a brute force grid search. More specifically, for parameter C in (1), we search in the range $[2^{-5}, 2^{15}]$, while for parameter γ (2) we search in the range $[2^{-15}, 2^{3}]$. The step size is 2 on the exponent.

We conducted experiments using a standard log-linear PB-SMT model: GIZA++ implementation of IBM word alignment model 4 (Och and Ney, 2003), the refinement and phrase-extraction heuristics described in (Koehn et al., 2003), minimum-error-rate training (Och, 2003), a 5-gram language model with Kneser-Ney smoothing (Kneser and Ney, 1995) trained with SRILM (Stolcke, 2002) on the Chinese side of the training data, and Moses (Koehn et al., 2007) which is capable of handling user-specified translations for some portions of the input during decoding. The maximum phrase length is set to 7.

5.2 Evaluation

The performance of the phrase-based SMT system is measured by BLEU score (Papineni et al., 2002) and TER (Snover et al., 2006). Significance test-

[1]We have around 87K sentence pairs in our training data. However, for 67.5% of the input sentences, our MT system produces the same translation irrespective of whether the input sentence is marked up or not.

ing is carried out using approximate randomisation (Noreen, 1989) with a 95% confidence level.

We also measure the quality of the classification by precision and recall. Let A be the set of predicted markup input sentences, and B be the set of input sentences where the markup version has a lower TER score than the plain version. We standardly define precision P and recall R as in (7):

$$P = \frac{|A \bigcap B|}{|A|}, R = \frac{|A \bigcap B|}{|B|} \quad (7)$$

5.3 Cross-fold translation

In order to obtain training samples for the classifier, we need to label each sentence in the SMT training data as to whether marking up the sentence can produce better translations. To achieve this, we translate both the marked-up versions and plain versions of the sentence and compare the two translations using the sentence-level evaluation metric TER.

We do not make use of additional training data to translate the sentences for SMT training, but instead use cross-fold translation. We create a new training corpus T by keeping 95% of the sentences in the original training corpus, and creating a new test corpus H by using the remaining 5% of the sentences. Using this scheme we make 20 different pairs of corpora (T_i, H_i) in such a way that each sentence from the original training corpus is in exactly one H_i for some $1 \leq i \leq 20$. We train 20 different systems using each T_i, and use each system to translate the corresponding H_i as well as the marked-up version of H_i using the procedure described in Section 3.1. The development set is kept the same for all systems.

5.4 Experimental Results

5.4.1 Translation Results

Table 3 contains the translation results of the SMT system when we use discriminative learning to mark up the input sentence (MARKUP-DL). The first row (BASELINE) is the result of translating plain test sets without any markup, while the second row is the result when all the test sentences are marked up. We also report the oracle scores, i.e. the upperbound of using our discriminative learning approach. As we can see from this table, we obtain significantly inferior results compared to the the Baseline system if we categorically mark up all the input sentences using phrase pairs derived from fuzzy matches. This is reflected by an absolute 1.4 point drop in BLEU score and a 1.8 point increase in TER. On the other hand, both the oracle BLEU and TER scores represent as much as a 2.5 point improvement over the baseline. Our discriminative learning method (MARKUP-DL), which automatically classifies whether an input sentence should be marked up, leads to an increase of 0.7 absolute BLEU points over the BASELINE, which is statistically significant. We also observe a slight decrease in TER compared to the BASELINE. Despite there being much room for further improvement when compared to the Oracle score, the discriminative learning method appears to be effective not only in maintaining translation consistency, but also a statistically significant improvement in translation quality.

	TER	BLEU
BASELINE	39.82	45.80
MARKUP	41.62	44.41
MARKUP-DL	39.61	46.46
ORACLE	37.27	48.32

Table 3: Performance of Discriminative Learning (%)

5.4.2 Classification Confidence Thresholding

To further analyse our discriminative learning approach, we report the classification results on the test set using the SVM classifier. We also investigate the use of classification confidence, as described in Section 3.2.2, as a threshold to boost classification precision if required. Table 4 shows the classification and translation results when we use different confidence thresholds. The default classification confidence is 0.50, and the corresponding translation results were described in Section 5.4.1. We investigate the impact of increasing classification confidence on the performance of the classifier and the translation results. As can be seen from Table 4, increasing the classification confidence up to 0.70 leads to a steady increase in classification precision with a corresponding sacrifice in recall. The fluctuation in classification performance has an impact on the translation results as measured by BLEU and TER. We can see that the best BLEU as well as TER scores are achieved when we set the classification confidence to 0.60, representing a modest improve-

	Classification Confidence						
	0.50	0.55	0.60	0.65	0.70	0.75	0.80
BLEU	46.46	46.65	**46.69**	46.59	46.34	46.06	46.00
TER	39.61	39.46	**39.32**	39.36	39.52	39.71	39.71
P	60.00	68.67	70.31	**74.47**	72.97	64.28	88.89
R	32.14	29.08	22.96	**17.86**	13.78	9.18	4.08

Table 4: The impact of classification confidence thresholding

ment over the default setting (0.50). Despite the higher precision when the confidence is set to 0.7, the dramatic decrease in recall cannot be compensated for by the increase in precision.

We can also observe from Table 4 that the recall is quite low across the board, and the classification results become unstable when we further increase the level of confidence to above 0.70. This indicates the degree of difficulty of this classification task, and suggests some directions for future research as discussed at the end of this paper.

5.4.3 Comparison with Previous Work

As discussed in Section 2, both (Koehn and Senellart, 2010) and (Zhechev and van Genabith, 2010) used fuzzy match score to determine whether the input sentences should be marked up. The input sentences are only marked up when the fuzzy match score is above a certain threshold. We present the results using this method in Table 5. From this table, we can see an inferior performance compared to the BASELINE results (cf. Table 3) when the fuzzy match score is below 0.70. A modest gain can only be achieved when the fuzzy match score is above 0.8. This is slightly different from the conclusions drawn in (Koehn and Senellart, 2010), where gains are observed when the fuzzy match score is above 0.7, and in (Zhechev and van Genabith, 2010) where gains are only observed when the score is above 0.9. Comparing Table 5 with Table 4, we can see that our classification method is more effective. This confirms our argument in the last paragraph of Section 2, namely that fuzzy match score is not informative enough to determine the usefulness of the subsentences in a fuzzy match, and that a more comprehensive set of features, as we have explored in this paper, is essential for the discriminative learning-based method to work.

	Fuzzy Match Scores				
	0.50	0.60	0.70	0.80	0.90
BLEU	45.13	45.55	45.58	45.84	45.82
TER	40.99	40.62	40.56	40.29	40.07

Table 5: Performance using fuzzy match score for classification

FM Scores	w. markup	w/o markup
[0,0.5]	37.75	62.24
(0.5,0.6]	40.64	59.36
(0.6,0.7]	40.94	59.06
(0.7,0.8]	46.67	53.33
(0.8,0.9]	54.28	45.72
(0.9,1.0]	44.14	55.86

Table 6: Percentage of training sentences with markup vs without markup grouped by fuzzy match (FM) score ranges

To further validate our assumption, we analyse the training sentences by grouping them according to their fuzzy match score ranges. For each group of sentences, we calculate the percentage of sentences where markup (and respectively without markup) can produce better translations. The statistics are shown in Table 6. We can see that for sentences with fuzzy match scores lower than 0.8, more sentences can be better translated without markup. For sentences where fuzzy match scores are within the range $(0.8, 0.9]$, more sentences can be better translated with markup. However, within the range $(0.9, 1.0]$, surprisingly, actually more sentences receive better translation without markup. This indicates that fuzzy match score is not a good measure to predict whether fuzzy matches are beneficial when used to constrain the translation of an input sentence.

5.5 Contribution of Features

We also investigated the contribution of our different feature sets. We are especially interested in the contribution of dependency features, as they re-

Example 1	
w/o markup	after policy name , type the name of the policy (it shows new host integrity policy by default) .
Translation	在 “ 策略 ” 名称 后面 ， 键入 策略 的 名称 (名称 显示 为 “ 新 主机 完整性 策略 默认 ） 。
w. markup	after policy name <tm translation=“， 键入 策略 名称 （ 默认 显示 “ 新 主机 完整性 策略 ” ） 。”>, type the name of the policy (it shows new host integrity policy by default) .< /tm>
Translation	在 “ 策略 ” 名称 后面 ， 键入 策略 名称 （ 默认 显示 “ 新 主机 完整性 策略 ” ） 。
Reference	在 “ 策略 名称 ” 后面 ， 键入 策略 名称 （ 默认 显示 “ 新 主机 完整性 策略 ” ） 。
Example 2	
w/o markup	changes apply only to the specific scan that you select .
Translation	更改 仅 适用于 特定 扫描 的 规则 。
w. markup	changes apply only to the specific scan that you select <tm translation=“。”>.< /tm>
Translation	更改 仅 适用于 您 选择 的 特定 扫描 。
Reference	更改 只 应用于 您 选择 的 特定 扫描 。

flect whether translation consistency can be captured using syntactic knowledge. The classification and translation results using different features are reported in Table 7. We observe a significant improvement in both classification precision and recall by adding dependency (DEP) features on top of TM and translation features. As a result, the translation quality also significantly improves. This indicates that dependency features which can capture structural and semantic similarities are effective in gauging the usefulness of the phrase pairs derived from the fuzzy matches. Note also that without including the dependency features, our discriminative learning method cannot outperform the BASELINE (cf. Table 3) in terms of translation quality.

	TER	BLEU	P	R
TM+TRANS	40.57	45.51	52.48	27.04
+DEP	39.61	46.46	60.00	32.14

Table 7: Contribution of Features (%)

5.6 Improved Translations

In order to pinpoint the sources of improvements by marking up the input sentence, we performed some manual analysis of the output. We observe that the improvements can broadly be attributed to two reasons: 1) the use of long phrase pairs which are missing in the phrase table, and 2) deterministically using highly reliable phrase pairs.

Phrase-based SMT systems normally impose a limit on the length of phrase pairs for storage and speed considerations. Our method can overcome this limitation by retrieving and reusing long phrase pairs on the fly. A similar idea, albeit from a different perspective, was explored by (Lopez, 2008), where he proposed to construct a phrase table on the fly for each sentence to be translated. Differently from his approach, our method directly translates part of the input sentence using fuzzy matches retrieved on the fly, with the rest of the sentence translated by the pre-trained MT system. We offer some more insights into the advantages of our method by means of a few examples.

Example 1 shows translation improvements by using long phrase pairs. Compared to the reference translation, we can see that for the underlined phrase, the translation without markup contains (i) word ordering errors and (ii) a missing right quotation mark. In Example 2, by specifying the translation of the final punctuation mark, the system correctly translates the relative clause ‘that you select’. The translation of this relative clause is missing when translating the input without markup. This improvement can be partly attributed to the reduction in search errors by specifying the highly reliable translations for phrases in an input sentence.

6 Conclusions and Future Work

In this paper, we introduced a discriminative learning method to tightly integrate fuzzy matches retrieved using translation memory technologies with phrase-based SMT systems to improve translation consistency. We used an SVM classifier to predict whether phrase pairs derived from fuzzy matches could be used to constrain the translation of an in-

put sentence. A number of feature functions including a series of novel dependency features were used to train the classifier. Experiments demonstrated that discriminative learning is effective in improving translation quality and is more informative than the fuzzy match score used in previous research. We report a statistically significant 0.9 absolute improvement in BLEU score using a procedure to promote translation consistency.

As mentioned in Section 2, the potential improvement in sentence-level translation consistency using our method can be attributed to the fact that the translation of new input sentences is closely informed and guided (or constrained) by previously translated sentences using global features such as dependencies. However, it is worth noting that the level of gains in translation consistency is also dependent on the nature of the TM itself; a self-contained coherent TM would facilitate consistent translations. In the future, we plan to investigate the impact of TM quality on translation consistency when using our approach. Furthermore, we will explore methods to promote translation consistency at document level.

Moreover, we also plan to experiment with phrase-by-phrase classification instead of sentence-by-sentence classification presented in this paper, in order to obtain more stable classification results. We also plan to label the training examples using other sentence-level evaluation metrics such as Meteor (Banerjee and Lavie, 2005), and to incorporate features that can measure syntactic similarities in training the classifier, in the spirit of (Owczarzak et al., 2007). Currently, only a standard phrase-based SMT system is used, so we plan to test our method on a hierarchical system (Chiang, 2005) to facilitate direct comparison with (Koehn and Senellart, 2010). We will also carry out experiments on other data sets and for more language pairs.

Abstract

The state-of-the-art system combination method for machine translation (MT) is based on confusion networks constructed by aligning hypotheses with regard to word similarities. We introduce a novel system combination framework in which hypotheses are encoded as a confusion forest, a packed forest representing alternative trees. The forest is generated using syntactic consensus among parsed hypotheses: First, MT outputs are parsed. Second, a context free grammar is learned by extracting a set of rules that constitute the parse trees. Third, a packed forest is generated starting from the root symbol of the extracted grammar through non-terminal rewriting. The new hypothesis is produced by searching the best derivation in the forest. Experimental results on the WMT10 system combination shared task yield comparable performance to the conventional confusion network based method with smaller space.

1 Introduction

System combination techniques take the advantages of consensus among multiple systems and have been widely used in fields, such as speech recognition (Fiscus, 1997; Mangu et al., 2000) or parsing (Henderson and Brill, 1999). One of the state-of-the-art system combination methods for MT is based on confusion networks, which are compact graph-based structures representing multiple hypotheses (Bangalore et al., 2001).

Confusion networks are constructed based on string similarity information. First, one skeleton or backbone sentence is selected. Then, other hypotheses are aligned against the skeleton, forming a lattice with each arc representing alternative word candidates. The alignment method is either model-based (Matusov et al., 2006; He et al., 2008) in which a statistical word aligner is used to compute hypothesis alignment, or edit-based (Jayaraman and Lavie, 2005; Sim et al., 2007) in which alignment is measured by an evaluation metric, such as translation error rate (TER) (Snover et al., 2006). The new translation hypothesis is generated by selecting the best path through the network.

We present a novel method for system combination which exploits the syntactic similarity of system outputs. Instead of constructing a string-based confusion network, we generate a packed forest (Billot and Lang, 1989; Mi et al., 2008) which encodes exponentially many parse trees in a polynomial space. The packed forest, or *confusion forest*, is constructed by merging the MT outputs with regard to their syntactic consensus. We employ a grammar-based method to generate the confusion forest: First, system outputs are parsed. Second, a set of rules are extracted from the parse trees. Third, a packed forest is generated using a variant of Earley's algorithm (Earley, 1970) starting from the unique root symbol. New hypotheses are selected by searching the best derivation in the forest. The grammar, a set of rules, is limited to those found in the parse trees. Spurious ambiguity during the generation step is further reduced by encoding the tree local contextual information in each non-terminal symbol, such as parent and sibling labels, using the state representation in Earley's algorithm.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1249–1257,
Portland, Oregon, June 19-24, 2011.

Experiments were carried out for the system combination task of the fifth workshop on statistical machine translation (WMT10) in four directions, {Czech, French, German, Spanish}-to-English (Callison-Burch et al., 2010), and we found comparable performance to the conventional confusion network based system combination in two language pairs, and statistically significant improvements in the others.

First, we will review the state-of-the-art method which is a system combination framework based on confusion networks (§2). Then, we will introduce a novel system combination method based on confusion forest (§3) and present related work in consensus translations (§4). Experiments are presented in Section 5 followed by discussion and our conclusion.

2 Combination by Confusion Network

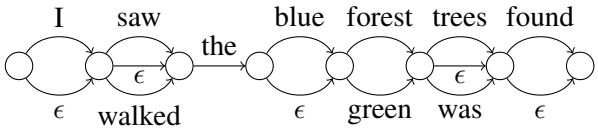
The system combination framework based on confusion network starts from computing pairwise alignment between hypotheses by taking one hypothesis as a reference. Matusov et al. (2006) employs a model based approach in which a statistical word aligner, such as GIZA++ (Och and Ney, 2003), is used to align the hypotheses. Sim et al. (2007) introduced TER (Snover et al., 2006) to measure the edit-based alignment.

Then, one hypothesis is selected, for example by employing a minimum Bayes risk criterion (Sim et al., 2007), as a skeleton, or a backbone, which serves as a building block for aligning the rest of the hypotheses. Other hypotheses are aligned against the skeleton using the pairwise alignment. Figure 1(b) illustrates an example of a confusion network constructed from the four hypotheses in Figure 1(a), assuming the first hypothesis is selected as our skeleton. The network consists of several arcs, each of which represents an alternative word at that position, including the empty symbol, ϵ.

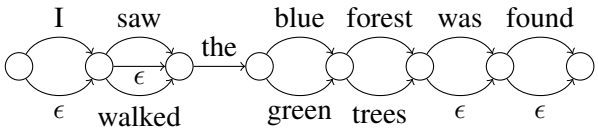
This pairwise alignment strategy is prone to spurious insertions and repetitions due to alignment errors such as in Figure 1(a) in which "green" in the third hypothesis is aligned with "forest" in the skeleton. Rosti et al. (2008) introduces an incremental method so that hypotheses are aligned incrementally to the growing confusion network, not only the skeleton hypothesis. In our example, "green trees" is aligned with "blue forest" in Figure 1(c).

*	I	saw	the		forest		
	I	walked	the	blue	forest		
	I	saw	the		green	trees	
			the		forest	was	found

(a) Pairwise alignment using the first starred hypothesis as a skeleton.



(b) Confusion network from (a)



(c) Incrementally constructed confusion network

Figure 1: An example confusion network construction

The confusion network construction is largely influenced by the skeleton selection, which determines the global word reordering of a new hypothesis. For example, the last hypothesis in Figure 1(a) has a passive voice grammatical construction while the others are active voice. This large grammatical difference may produce a longer sentence with spuriously inserted words, as in "I saw the blue trees was found" in Figure 1(c). Rosti et al. (2007b) partially resolved the problem by constructing a large network in which each hypothesis was treated as a skeleton and the multiple networks were merged into a single network.

3 Combination by Confusion Forest

The confusion network approach to system combination encodes multiple hypotheses into a compact lattice structure by using word-level consensus. Likewise, we propose to encode multiple hypotheses into a confusion forest, which is a packed forest which represents multiple parse trees in a polynomial space (Billot and Lang, 1989; Mi et al., 2008) Syntactic consensus is realized by sharing tree frag-

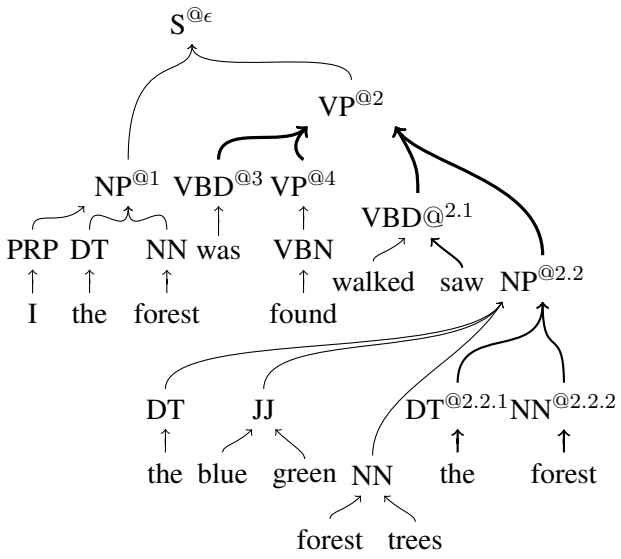


Figure 2: An example packed forest representing hypotheses in Figure 1(a).

ments among parse trees. The forest is represented as a hypergraph which is exploited in parsing (Klein and Manning, 2001; Huang and Chiang, 2005) and machine translation (Chiang, 2007; Huang and Chiang, 2007).

More formally, a hypergraph is a pair $\langle V, E\rangle$ where V is the set of nodes and E is the set of hyperedges. Each node in V is represented as $X^{@p}$ where $\mathrm{X} \in \mathcal{N}$ is a non-terminal symbol and p is an address (Shieber et al., 1995) that encapsulates each node id relative to its parent. The root node is given the address ϵ and the address of the first child of node p is given $p.1$. Each hyperedge $e \in E$ is represented as a pair $\langle head(e), tails(e)\rangle$ where $head(e) \in V$ is a head node and $tails(e) \in V^*$ is a list of tail nodes, corresponding to the left-hand side and the right-hand side of an instance of a rule in a CFG, respectively. Figure 2 presents an example packed forest for the parsed hypotheses in Figure 1(a). For example, $\mathrm{VP}^{@2}$ has two hyperedges, $\langle \mathrm{VP}^{@2}, (\mathrm{VBD}^{@3}, \mathrm{VP}^{@4})\rangle$ and $\langle \mathrm{VP}^{@2}, (\mathrm{VBD}^{@2.1}, \mathrm{NP}^{@2.2})\rangle$, leading to different derivations where the former takes the grammatical construction in passive voice while the latter in active voice.

Given system outputs, we employ the following grammar based approach for constructing a confusion forest: First, MT outputs are parsed. Second, a grammar is learned by treating each hyperedge as an instance of a CFG rule. Third, a forest is generated from the unique root symbol of the extracted grammar through non-terminal rewriting.

Initialization:

$$\frac{}{[\mathrm{TOP} \rightarrow \bullet \mathrm{S}, 0] : \bar{1}}$$

Scan:

$$\frac{[\mathrm{X} \rightarrow \alpha \bullet x\beta, h] : u}{[\mathrm{X} \rightarrow \alpha x \bullet \beta, h] : u}$$

Predict:

$$\frac{[\mathrm{X} \rightarrow \alpha \bullet \mathrm{Y}\beta, h]}{[\mathrm{Y} \rightarrow \bullet\gamma, h+1] : u} \quad \mathrm{Y} \xrightarrow{u} \gamma \in \mathcal{G}, h < H$$

Complete:

$$\frac{[\mathrm{X} \rightarrow \alpha \bullet \mathrm{Y}\beta, h] : u \quad [\mathrm{Y} \rightarrow \gamma\bullet, h+1] : v}{[\mathrm{X} \rightarrow \alpha\mathrm{Y} \bullet \beta, h] : u \otimes v}$$

Goal:

$$[\mathrm{TOP} \rightarrow \mathrm{S}\bullet, 0]$$

Figure 3: The deductive system for Earley's generation algorithm

3.1 Forest Generation

Given the extracted grammar, we apply a variant of Earley's algorithm (Earley, 1970) which can generate strings in a left-to-right manner from the unique root symbol, TOP. Figure 3 presents the deductive inference rules (Goodman, 1999) for our generation algorithm. We use capital letters $\mathrm{X} \in \mathcal{N}$ to denote non-terminals and $x \in \mathcal{T}$ for terminals. Lowercase Greek letters α, β and γ are strings of terminals and non-terminals $(\mathcal{T} \cup \mathcal{N})^*$. u and v are weights associated with each item.

The major difference compared to Earley's parsing algorithm is that we ignore the terminal span information each non-terminal covers and keep track of the height of derivations by h. The scanning step will always succeed by moving the dot to the right. Combined with the prediction and completion steps, our algorithm may potentially generate a spuriously deep forest. Thus, the height of the forest is constrained in the prediction step not to exceed H, which is empirically set to 1.5 times the maximum

height of the parsed system outputs.

3.2 Tree Annotation

The grammar compiled from the parsed trees is local in that it can represent a finite number of sentences translated from a specific input sentence. Although its coverage is limited, our generation algorithm may yield a spuriously large forest. As a way to reduce spurious ambiguities, we relabel the non-terminal symbols assigned to each parse tree before extracting rules.

Here, we replace each non-terminal symbol by the state representation of Earley's algorithm corresponding to the sequence of prediction steps starting from TOP. Figure 4(a) presents an example parse tree with each symbol replaced by the Earley's state in Figure 4(b). For example, the label for VBD is replaced by •S + NP : •VP + •VBD : NP which corresponds to the prediction steps of TOP → •S, S → NP • VP and VP → •VBD NP. The context represented in the Earley's state is further limited by the vertical and horizontal Markovization (Klein and Manning, 2003). We define the vertical order v in which the label is limited to memorize only v previous prediction steps. For instance, setting $v = 1$ yields NP : •VP + •VBD : NP in our example. Likewise, we introduce the horizontal order h which limits the number of sibling labels memorized on the left and the right of the dotted label. Limiting $h = 1$ implies that each deductive step is encoded with at most three symbols.

No limits in the horizontal and vertical Markovization orders implies memorizing of all the deductions and yields a confusion forest representing the union of parse trees through the grammar collection and the generation processes. More relaxed horizontal orders allow more reordering of subtrees in a confusion forest by discarding the sibling context in each prediction step. Likewise, constraining the vertical order generates a deeper forest by ignoring the sequence of symbols leading to a particular node.

3.3 Forest Rescoring

From the packed forest F, new k-best derivations are extracted from all possible derivations D by efficient forest-based algorithms for k-best parsing (Huang and Chiang, 2005). We use a linear combination of features as our objective function to seek for the best derivation $\hat{d}$:

$$\hat{d} = \arg\max_{d \in D} \mathbf{w}^\top \cdot \mathbf{h}(d, F) \quad (1)$$

where $\mathbf{h}(d, F)$ is a set of feature functions scaled by weight vector $\mathbf{w}$. We use cube-pruning (Chiang, 2007; Huang and Chiang, 2007) to approximately intersect with non-local features, such as n-gram language models. Then, k-best derivations are extracted from the rescored forest using algorithm 3 of Huang and Chiang (2005).

4 Related Work

Consensus translations have been extensively studied with many granularities. One of the simplest forms is a sentence-based combination in which hypotheses are simply reranked without merging (Nomoto, 2004). Frederking and Nirenburg (1994)

proposed a phrasal combination by merging hypotheses in a chart structure, while others depended on confusion networks, or similar structures, as a building block for merging hypotheses at the word level (Bangalore et al., 2001; Matusov et al., 2006; He et al., 2008; Jayaraman and Lavie, 2005; Sim et al., 2007). Our work is the first to explicitly exploit syntactic similarity for system combination by merging hypotheses into a syntactic packed forest. The confusion forest approach may suffer from parsing errors such as the confusion network construction influenced by alignment errors. Even with parsing errors, we can still take a tree fragment-level consensus as long as a parser is consistent in that similar syntactic mistakes would be made for similar hypotheses.

Rosti et al. (2007a) describe a re-generation approach to consensus translation in which a phrasal translation table is constructed from the MT outputs aligned with an input source sentence. New translations are generated by decoding the source sentence again using the newly extracted phrase table. Our grammar-based approach can be regarded as a re-generation approach in which an off-the-shelf monolingual parser, instead of a word aligner, is used to annotate syntactic information to each hypothesis, then, a new translation is generated from the merged forest, not from the input source sentence through decoding. In terms of generation, our approach is an instance of statistical generation (Langkilde and Knight, 1998; Langkilde, 2000). Instead of generating forests from semantic representations (Langkilde, 2000), we generate forests from a CFG encoding the consensus among parsed hypotheses.

Liu et al. (2009) present joint decoding in which a translation forest is constructed from two distinct MT systems, tree-to-string and string-to-string, by merging forest outputs. Their merging method is either translation-level in which no new translation is generated, or derivation-level in that the rules sharing the same left-hand-side are used in both systems. While our work is similar in that a new forest is constructed by sharing rules among systems, although their work involves no consensus translation and requires structures internal to each system such as model combinations (DeNero et al., 2010).

5 Experiments

5.1 Setup

We ran our experiments for the WMT10 system combination task usinge four language pairs, {Czech, French, German, Spanish}-to-English (Callison-Burch et al., 2010). The data is summarized in Table 1. The system outputs are retokenized to match the Penn-treebank standard, parsed by the Stanford Parser (Klein and Manning, 2003), and lower-cased.

We implemented our confusion forest system combination using an in-house developed hypergraph-based toolkit *cicada* which is motivated by generic weighted logic programming (Lopez, 2009), originally developed for a synchronous-CFG based machine translation system (Chiang, 2007). Input to our system is a collection of hypergraphs, a set of parsed hypotheses, from which rules are extracted and a new forest is generated as described in Section 3. Our baseline, also implemented in *cicada*, is a confusion network-based system combination method (§2) which incrementally aligns hypotheses to the growing network using TER (Rosti et al., 2008) and merges multiple networks into a large single network. After performing epsilon removal, the network is transformed into a forest by parsing with monotone rules of S $\rightarrow$ X, S $\rightarrow$ S X and X $\rightarrow$ x. k-best translations are extracted from the forest using the forest-based algorithms in Section 3.3.

5.2 Features

The feature weight vector $\mathbf{w}$ in Equation 1 is tuned by MERT over hypergraphs (Kumar et al., 2009).

We use three lower-cased 5-gram language mod-

els $h^i_{lm}(d)$: English Gigaword Fourth edition[1], the English side of French-English 10^9 corpus and the news commentary English data[2]. The count based features $h_t(d)$ and $h_e(d)$ count the number of terminals and the number of hyperedges in d, respectively. We employ M confidence measures $h^m_s(d)$ for M systems, which basically count the number of rules used in d originally extracted from mth system hypothesis (Rosti et al., 2007a).

Following Macherey and Och (2007), BLEU (Papineni et al., 2002) correlations are also incorporated in our system combination. Given M system outputs $\mathbf{e}_1 ... \mathbf{e}_M$, M BLEU scores are computed for d using each of the system outputs $\mathbf{e}_m$ as a reference

$$h^m_b(d) = BP(\mathbf{e}, \mathbf{e}_m) \cdot \exp\left(\frac{1}{4}\sum_{n=1}^{4} \log \rho_n(\mathbf{e}, \mathbf{e}_m)\right)$$

where $\mathbf{e} = \text{yield}(d)$ is a terminal yield of d, $BP(\cdot)$ and $\rho_n(\cdot)$ respectively denote brevity penalty and n-gram precision. Here, we use approximated unclipped n-gram counts (Dreyer et al., 2007) for computing $\rho_n(\cdot)$ with a compact state representation (Li and Khudanpur, 2009).

Our baseline confusion network system has an additional penalty feature, $h_p(m)$, which is the total edits required to construct a confusion network using the mth system hypothesis as a skeleton, normalized by the number of nodes in the network (Rosti et al., 2007b).

5.3 Results

Table 2 compares our confusion forest approach (CF) with different orders, a confusion network (CN) and max/min systems measured by BLEU (Papineni et al., 2002). We vary the horizontal orders, $h = 1, 2, \infty$ with vertical orders of $v = 3, 4, \infty$. Systems without statistically significant differences from the best result ($p < 0.05$) are indicated by bold face. Setting $v = \infty$ and $h = \infty$ achieves comparable performance to CN. Our best results in three languages come from setting $v = \infty$ and $h = 2$, which favors little reordering of phrasal structures. In general, lower horizontal and vertical order leads to lower BLEU.

Table 3: Oracle lower-case BLEU

Table 3 presents oracle BLEU achievable by each combination method. The gains achievable by the CF over simple reranking are small, at most 2-3 points, indicating that small variations are encoded in confusion forests. We also observed that a lower horizontal and vertical order leads to better BLEU potentials. As briefly pointed out in Section 3.2, the higher horizontal and vertical order implies more faithfulness to the original parse trees. Introducing new tree fragments to confusion forests leads to new phrasal translations with enlarged forests, as presented in Table 4, measured by the average number

Table 4: Hypegraph size measured by the average number of hyperedges ($h = 1$ for CF). "lattice" is the average number of edges in the original CN.

of hyperedges[3]. The larger potentials do not imply better translations, probably due to the larger search space with increased search errors. We also conjecture that syntactic variations were not captured by the n-gram like string-based features in Section 5.2, therefore resulting in BLEU loss, which will be investigated in future work.

In contrast, CN has more potential for generating better translations, with the exception of the German-to-English direction, with scores that are usually 10 points better than simple sentence-wise reranking. The low potential in German should be interpreted in the light of the extremely large confusion network in Table 4. We postulate that the divergence in German hypotheses yields wrong alignments, and therefore amounts to larger networks with incorrect hypotheses. Table 4 also shows that CN produces a forest that is an order of magnitude larger than those created by CFs. Although we cannot directly relate the runtime and the number of hyperedges in CN and CFs, since the shape of the forests are different, CN requires more space to encode the hypotheses than those by CFs.

Table 5 compares the average length of the minimum/maximum hypothesis that each method can produce. CN may generate shorter hypotheses, whereby CF prefers longer hypotheses as we decrease the vertical order. Large divergence is also observed for German, such as for hypergraph size.

6 Conclusion

We presented a confusion forest based method for system combination in which system outputs are merged into a packed forest using their syntactic similarity. The forest construction is treated as a generation from a CFG compiled from the parsed outputs. Our experiments indicate comparable performance to a strong confusion network baseline with smaller space, and statistically significant gains in some language pairs.

To our knowledge, this is the first work to directly introduce syntactic consensus to system combination by encoding multiple system outputs into a single forest structure. We believe that the confusion forest based approach to system combination has future exploration potential. For instance, we did not employ syntactic features in Section 5.2 which would be helpful in discriminating hypotheses in larger forests. We would also like to analyze the trade-offs, if any, between parsing errors and confusion forest constructions by controlling the parsing qualities. As an alternative to the grammar-based forest generation, we are investigating an edit distance measure for tree alignment, such as tree edit distance (Bille, 2005) which basically computes insertion/deletion/replacement of nodes in trees.

[3]We measure the hypergraph size before intersecting with non-local features, like n-gram language models.

Abstract

This paper presents *hypothesis mixture decoding* (HM decoding), a new decoding scheme that performs translation reconstruction using hypotheses generated by multiple translation systems. HM decoding involves two decoding stages: first, each component system decodes independently, with the explored search space kept for use in the next step; second, a new search space is constructed by composing existing hypotheses produced by all component systems using a set of rules provided by the HM decoder itself, and a new set of model independent features are used to seek the final best translation from this new search space. Few assumptions are made by our approach about the underlying component systems, enabling us to leverage SMT models based on arbitrary paradigms. We compare our approach with several related techniques, and demonstrate significant BLEU improvements in large-scale Chinese-to-English translation tasks.

1 Introduction

Besides tremendous efforts on constructing more complicated and accurate models for statistical machine translation (SMT) (Och and Ney, 2004; Chiang, 2005; Galley et al., 2006; Shen et al., 2008; Chiang 2010), many researchers have concentrated on the approaches that improve translation quality using information between hypotheses from one or more SMT systems as well.

System combination is built on top of the *N*-best outputs generated by multiple component systems (Rosti et al., 2007; He et al., 2008; Li et al., 2009b) which aligns multiple hypotheses to build confusion networks as new search spaces, and outputs the highest scoring paths as the final translations. *Consensus decoding*, on the other hand, can be based on either single or multiple systems: single system based methods (Kumar and Byrne, 2004; Tromble et al., 2008; DeNero et al., 2009; Kumar et al., 2009) re-rank translations produced by a single SMT model using either *n*-gram posteriors or expected *n*-gram counts. Because hypotheses generated by a single model are highly correlated, improvements obtained are usually small; recently, dedicated efforts have been made to extend it from single system to multiple systems (Li et al., 2009a; DeNero et al., 2010; Duan et al., 2010). Such methods select translations by optimizing consensus models over the combined hypotheses using all component systems' posterior distributions.

Although these two types of approaches have shown consistent improvements over the standard Maximum a Posteriori (MAP) decoding scheme, most of them are implemented as post-processing procedures over translations generated by MAP decoders. In this sense, the work of Li et al. (2009a) is different in that both partial and full hypotheses are re-ranked during the decoding phase directly using consensus between translations from different SMT systems. However, their method does not change component systems' search spaces.

This paper presents *hypothesis mixture decoding* (HM decoding), a new decoding scheme that performs translation reconstruction using hypotheses generated by multiple component systems. HM decoding involves two decoding stages: first, each component system decodes the source sentence independently, with the explored search space kept for use in the next step; second, a new search space is constructed by composing existing hypo-

Portland, Oregon, June 19-24, 2011.

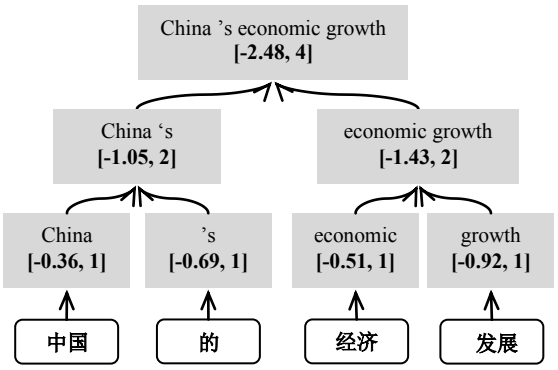

Figure 1: A decoding example of a phrase-based SMT system. Each hypothesis is annotated with a feature vector, which includes a logarithmic probability feature and a word count feature.

theses produced by all component systems using a set of rules provided by the HM decoder itself, and a new set of component model independent features are used to seek the final best translation from this new constructed search space.

We evaluate by combining two SMT models with state-of-the-art performances on the NIST Chinese-to-English translation tasks. Experimental results show that our approach outperforms the best component SMT system by up to 2.11 BLEU points. Consistent improvements can be observed over several related decoding techniques as well, including word-level system combination, collaborative decoding and model combination.

2 Hypothesis Mixture Decoding

2.1 Motivation and Overview

SMT models based on different paradigms have emerged in the last decade using fairly different levels of linguistic knowledge. Motivated by the success of system combination research, the key contribution of this work is to make more effective use of the extended search spaces from different SMT models in decoding phase directly, rather than just post-processing their final outputs. We first begin with a brief review of single system based SMT decoding, and then illustrate major challenges to this end.

Given a source sentence f, an SMT decoder seeks for a target translation e that best matches f as its translation by maximizing the following conditional probability:

$$P(e|f) = \frac{exp\{\sum_{r\in\mathcal{D}(e)}\theta\cdot\phi(r)\}}{\sum_{e'\in\mathcal{H}(f)}exp\{\sum_{r\in\mathcal{D}(e')}\theta\cdot\phi(r)\}}$$

where $\phi(\cdot)$ is the feature vector that includes a set of system specific features, θ is the weight vector, $\mathcal{D}(e)$ is a derivation that can yield e and is defined as a sequence of translation rule applications $\{r\}$. Figure 1 illustrates a decoding example, in which the final translation is generated by recursively composing partial hypotheses that cover different ranges of the source sentence until the whole input sentence is fully covered, and the feature vector of the final translation is the aggregation of feature vectors of all partial hypotheses used.[1]

However, hypotheses generated by different SMT systems cannot be combined directly to form new translations because of two major issues:

The first one is the heterogeneous structures of different SMT models. For example, a string-to-tree system cannot use hypotheses generated by a phrase-based system in decoding procedure, as such hypotheses are based on flat structures, which cannot provide any additional information needed in the syntactic model.

The second one is the incompatible feature spaces of different SMT models. For example, even if a phrase-based system can use the lexical forms of hypotheses generated by a syntax-based system without considering syntactic structures, the feature vectors of these hypotheses still cannot be aggregated together in any trivial way, because the feature sets of SMT models based on different paradigms are usually inconsistent.

To address these two issues discussed above, we propose HM decoding that performs translation reconstruction using hypotheses generated by multiple component systems.[2] Our method involves two decoding stages depicted as follows:

1. *Independent decoding* stage, in which each component system decodes input sentences independently based on its own model and search algorithm, and the explored search spaces (translation forests) are kept for use in the next stage.

[1] There are also features independent of translation derivations, such as the language model feature.

[2] In this paper, we will constrain our discussions within CKY-style decoders, in which we find translations for all spans of the source sentence. Although standard implementations of phrase-based decoders fall out of this scope, they can be still re-written to work in the CKY-style bottom-up manner at the cost of 1) only BTG-style reordering allowed, and 2) higher time complexity. As a result, any phrase-based SMT system can be used as a component in our HM decoding method.

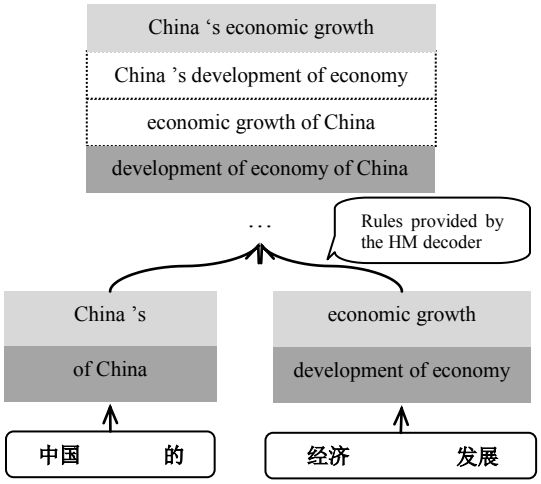

Figure 2: An example of HM decoding, in which the translations surrounded by the dotted lines are newly generated hypotheses. Hypotheses light-shaded come from a phrase-based system, and hypotheses dark-shaded come from a syntax-based system.

2. *HM decoding* stage, where a mixture search space is constructed for translation derivations by composing partial hypotheses generated by all component systems, and a new decoding model with a set of enriched feature functions are used to seek final translations from this newly generated search space.

HM decoding can use lexicalized hypotheses of arbitrary SMT models to derive translation, and a set of component model independent features are used to compute translation confidence. We discuss mixture search space construction, details of model and feature designs as well as HM decoding algorithms in Section 2.2, 2.3 and 2.4 respectively.

2.2 Mixture Search Space Construction

Let $\mathcal{M}_1, \dots, \mathcal{M}_N$ denote N component MT systems, f_i^j denote the span of a source sentence f starting at position i and ending at position j. We use $\mathcal{H}_n(f_i^j)$ denoting the search space of f_i^j predicted by $\mathcal{M}_n$, and $\mathcal{H}(f_i^j)$ denoting the mixture search space of f_i^j constructed by the HM decoder, which is defined recursively as follows:

- $\mathcal{H}_n(f_i^j) \subset \mathcal{H}(f_i^j)$. This rule adds all component systems' search spaces into the mixture search space for use in HM decoding. Thus hypotheses produced by all component systems are still available to the HM decoder.
- $r(e_{p_1}^{q_1}, \dots, e_{p_k}^{q_k}) \subset \mathcal{H}(f_i^j)$, in which $i \le p_k \le q_k \le j$ and $e_{p_k}^{q_k} \subset \mathcal{H}(f_{p_k}^{q_k})$. r is a translation rule provided by HM decoder that composes a new hypothesis using smaller hypotheses in the search spaces $\mathcal{H}(f_{p_1}^{q_1}), \dots, \mathcal{H}(f_{p_k}^{q_k})$. These rules further extend $\mathcal{H}(f_i^j)$ with hypotheses generated by the HM decoder itself.

Figure 2 shows an example of HM decoding, in which hypotheses generated by two SMT systems are used together to compose new translations. Since search space pruning is the indispensable procedure for all SMT systems, we will omit its explicit expression in the following descriptions and algorithms for convenience.

2.3 Models and Features

Following the common practice in SMT research, we use a linear model to formulate the preference of translation hypotheses in the mixture search space $\mathcal{H}(f)$. Formally, we are to find a translation $\hat{e}$ that maximizes the weighted linear combination of a set of real-valued features as follows:

$$\hat{e} = \underset{e \in \mathcal{H}(f)}{argmax} \left\{ \sum_i \lambda_i \cdot h_i(e, f) \right\}$$

where $h_i(e, f)$ is an HM decoding feature with its corresponding feature weight λ_i.

In this paper, the HM decoder does not assume the availability of any internal knowledge of the underlying component systems. The HM decoding features are independent of component models as well, which fall into two categories:

The first category contains a set of consensus-based features, which are inspired by the success of consensus decoding approaches. These features are described in details as follows:

1) $h_{\mathcal{H}_n(f)}(e, f)$: the n-gram posterior feature of e computed based on the component search space $\mathcal{H}_n(f)$ generated by $\mathcal{M}_n$:

$$h_{\mathcal{H}_n(f)}(e, f) = \sum_{\omega \in e} \#_\omega(e) p(\omega | \mathcal{H}_n(f))$$

$p(\omega | \mathcal{H}_n(f)) = \sum_{e' \in \mathcal{H}_n(f)} \delta_\omega(e') P_n(e' | f)$ is the posterior probability of an n-gram ω in $\mathcal{H}_n(f)$, $\#_\omega(e)$ is the number of times that ω occurs in e, $\delta_\omega(e)$ equals to 1 when ω occurs in e, and 0 otherwise.

2) $h_{\mathcal{H}_n^S(f)}(e^S, f)$: the stemmed *n*-gram posterior feature of e computed based on the stemmed component search space $\mathcal{H}_n^S(f)$. A word stem dictionary that includes 22,660 entries is used to convert e and $\mathcal{H}_n(f)$ into their stem forms e^S and $\mathcal{H}_n^S(f)$ by replacing each word into its stem form. This feature is computed similarly to that of $h_{\mathcal{H}_n(f)}(e, f)$.

3) $h_{\mathcal{H}(f)}(e, f)$: the *n*-gram posterior feature of e computed based on the mixture search space $\mathcal{H}(f)$ generated by the HM decoder:

$$h_{\mathcal{H}(f)}(e, f) = \sum_{\omega \in e} \#_\omega(e) p(\omega|\mathcal{H}(f))$$

$p(\omega|\mathcal{H}(f)) = \sum_{e' \in \mathcal{H}(f)} \delta_\omega(e') P(e'|f)$ is the posterior probability of an *n*-gram ω in $\mathcal{H}(f)$, $P(e'|f)$ is the posterior probability of one translation e' given f based on $\mathcal{H}(f)$.

4) $h_I(e, f)$: the length posterior feature of the specific target hypothesis with length *I* based on the mixture search space $\mathcal{H}(f)$ generated by the HM decoder:

$$h_I(e, f) = \sum_{e' \in \mathcal{H}(f), |e'| = |e| = I} P(e'|f)$$

Note here that features in $h_{\mathcal{H}(f)}(e, f)$ and $h_I(e, f)$ will be computed when the computations of all the remainder features in two categories have already finished for each e in $\mathcal{H}(f)$, and they will be used to update current HM decoding model scores.

Consensus features based on component search spaces have already shown effectiveness (Kumar et al., 2009; DeNero et al., 2010; Duan et al., 2010). We leverage consensus features based on the mixture search space newly generated in HM decoding as well. The length posterior feature (Zen and Ney, 2006) is used to adjust the preference of HM decoder for longer or shorter translations, and the stemmed *n*-gram posterior features are used to provide more discriminative power for HM decoding and to decrease the effects of morphological changes in words for more accurate computation of consensus statistics.

The second feature category contains a set of general features. Although there are more features that can be incorporated into HM decoding besides the ones we list below, we only utilize the most representative ones for convenience:

1) $h_{Length}(e, f)$: the word count feature.

2) $h_{LM}(e, f)$: the language model feature.

3) $h_{Dict}(e, f)$: the dictionary-based feature that counts how many lexicon pairs can be found in a given translation pair (e, f).

4) $h_{[\cdot]}(e, f)$ and $h_{<\cdot>}(e, f)$: reordering features that penalize the uses of straight and inverted BTG rules during the derivation of e in HM decoding. These two features are specific to BTG-based HM decoding (Section 2.4.1):

$$h_{[\cdot]}(e, f) = \sum_{r \in \mathcal{D}(e)} \delta_r([\cdot])$$

$$h_{<\cdot>}(e, f) = \sum_{r \in \mathcal{D}(e)} \delta_r(<\cdot>)$$

5) $h_{Rule}(e, f)$ and $h_{Glue}(e, f)$: reordering features that penalize the uses of hierarchical and glue rules during the derivation of e in HM decoding. These two features are specific to SCFG-based HM decoding (Section 2.4.2):

$$h_{Rule}(e, f) = \sum_{r \in \mathcal{D}(e)} \delta_r(R)$$

$$h_{Glue}(e, f) = \sum_{r \in \mathcal{D}(e)} \delta_r([\cdot])$$

R is the hierarchical rule set provided by the HM decoder itself, $\delta_r(R)$ equals to 1 when r is provided by R, and 0 otherwise.

6) $h_{New}(e, f)$: the feature that counts how many *n*-grams in e are newly generated by the HM decoder, which cannot be found in all existing component search spaces:

$$h_{New}(e, f) = \sum_{\omega \in e} \#_\omega(e) \bar{\delta}_\omega(\bigcup_{n=1}^{N} \mathcal{H}_n(f))$$

$\bar{\delta}_\omega(\cup_{n=1}^{N} \mathcal{H}_n(f))$ equals to 1 when ω does not exist in $\cup_{n=1}^{N} \mathcal{H}_n(f)$, and 0 otherwise.

The MERT algorithm (Och, 2003) is used to tune weights of HM decoding features.

2.4 Decoding Algorithms

Two CKY-style algorithms for HM decoding are presented in this subsection. The first one is based on BTG (Wu, 1997), and the second one is based on SCFG, similar to Chiang (2005).

2.4.1 BTG-based HM Decoding

The first algorithm, *BTG-HMD*, is presented in Algorithm 1, where hypotheses of two consecutive source spans are composed using two BTG rules:

- *Straight rule* $[\cdot]$. It combines translations of two consecutive blocks into a single larger block in a straight order.
- *Inverted rule* $\langle\cdot\rangle$. It combines translations of two consecutive blocks into a single larger block in an inverted order.

These two rules are used bottom-up until the whole source sentence is fully covered. We use two reordering rule penalty features, $h_{[\cdot]}(e,f)$ and $h_{\langle\cdot\rangle}(e,f)$, to penalize the uses of these two rules.

Algorithm 1: BTG-based HM Decoding

1: **for** each component model $\mathcal{M}_n$ **do**
2: output the search space $\mathcal{H}_n(f)$ for the input f
3: **end for**
4: **for** $l = 1$ to $|f| - 1$ **do**
5: **for** all i, j s.t. $j - i = l$ **do**
6: $\mathcal{H}(f_i^j) = \{\emptyset\}$
7: **for** all k s.t. $i \le k < j$ **do**
8: **for** $e_1 \in \mathcal{H}(f_i^k)$ and $e_2 \in \mathcal{H}(f_{k+1}^j)$ **do**
9: add $e = Comb_{[\cdot]}(e_1, e_2)$ to $\mathcal{H}(f_i^j)$
10: add $e = Comb_{\langle\cdot\rangle}(e_1, e_2)$ to $\mathcal{H}(f_i^j)$
11: **end for**
12: **end for**
13: **for** each hypothesis $e \in \bigcup_{n=1}^{N} \mathcal{H}_n(f_i^j)$ **do**
14: compute HM decoding features for e
15: add e to $\mathcal{H}(f_i^j)$
16: **end for**
17: **for** each hypothesis $e \in \mathcal{H}(f_i^j)$ **do**
18: compute the n-gram and length posterior features for e based on $\mathcal{H}(f_i^j)$
19: update current HM decoding score of e
20: **end for**
21: **end for**
22: **end for**
23: return $\hat{e} \in \mathcal{H}(f)$ with the maximum model score

In BTG-HMD, in order to derive translations for a source span f_i^j, we compose hypotheses of any two smaller spans f_i^k and f_{k+1}^j using two BTG rules in line 9 and 10, $Comb_r(e_1, e_2)$ denotes the operations that firstly combine e_1 and e_2 using one BTG rule r and secondly compute HM decoding features for the newly generated hypothesis e. We compute HM decoding features for hypotheses contained in all existing component search spaces $\bigcup_{n=1}^{N} \mathcal{H}_n(f_i^j)$ as well, and add them to $\mathcal{H}(f_i^j)$. From line 17 to 20, we update current HM decoding scores for all hypotheses in $\mathcal{H}(f_i^j)$ using the n-gram and length posterior features computed based on $\mathcal{H}(f_i^j)$. When the whole source sentence is fully covered, we return the hypothesis with the maximum model score as the final best translation.

2.4.2 SCFG-based HM Decoding

The second algorithm, *SCFG-HMD*, is presented in Algorithm 2. An additional rule set $\mathcal{R}$, which is provided by the HM decoder, is used to compose hypotheses. It includes hierarchical rules extracted using Chiang (2005)'s method and glue rules. Two reordering rule penalty features, $h_{Rule}(e,f)$ and $h_{Glue}(e,f)$, are used to adjust the preferences of using hierarchical rules and glue rules.

Algorithm 2: SCFG-based HM Decoding

1: **for** each component model $\mathcal{M}_n$ **do**
2: output the search space $\mathcal{H}_n(f)$ for the input f
3: **end for**
4: **for** $l = 1$ to $|f| - 1$ **do**
5: **for** all i, j s.t. $j - i = l$ **do**
6: $\mathcal{H}(f_i^j) = \{\emptyset\}$
7: **for** each rule $r \in \mathcal{R}$ that matches f_i^j **do**
8: **for** $e_1 \in \mathcal{H}(r_{\#_1})$ and $e_2 \in \mathcal{H}(r_{\#_2})$ **do**
9: add $e = Comb_r(e_1, e_2)$ to $\mathcal{H}(f_i^j)$
10: **end for**
11: **end for**
12: **for** each hypothesis $e \in \bigcup_{n=1}^{N} \mathcal{H}_n(f_i^j)$ **do**
13: compute HM decoding features for e
14: add e to $\mathcal{H}(f_i^j)$
15: **end for**
16: **for** each hypothesis $e \in \mathcal{H}(f_i^j)$ **do**
17: compute the n-gram and length posterior features for e based on $\mathcal{H}(f_i^j)$
18: update current HM decoding score of e
19: **end for**
20: **end for**
21: **end for**
22: return $\hat{e} \in \mathcal{H}(f)$ with the maximum model score

Compared to BTG-HMD, the key differences in SCFG-HMD are located from line 7 to 11, where the translation for a given span f_i^j is generated by replacing the non-terminals in a hierarchical rule $r \in \mathcal{R}$ with their corresponding target translations, $r_{\#_i}$ is the source span that is covered by the i^{th} non-terminal of r, $\mathcal{H}(r_{\#_i})$ is the search space for $r_{\#_i}$ predicted by the HM decoder.

3 Comparisons to Related Techniques

3.1 Model Combination and Mixture Model based MBR Decoding

Model combination (DeNero et al., 2010) is an approach that selects translations from a conjoint search space using information from multiple SMT component models; Duan et al. (2010) presents a similar method, which utilizes a mixture model to combine distributions of hypotheses from different systems for Bayes-risk computation, and selects final translations from the combined search spaces using MBR decoding. Both of these two methods share a common limitation: they only re-rank the combined search space, without the capability to generate new translations. In contrast, by reusing hypotheses generated by all component systems in HM decoding, translations beyond any existing search space can be generated.

3.2 Co-Decoding and Joint Decoding

Li et al. (2009a) proposes collaborative decoding, an approach that combines translation systems by re-ranking partial and full translations iteratively using *n*-gram features from the predictions of other member systems. However, in co-decoding, all member systems must work in a synchronous way, and hypotheses between different systems cannot be shared during decoding procedure; Liu et al. (2009) proposes joint-decoding, in which multiple SMT models are combined in either translation or derivation levels. However, their method relies on the correspondence between nodes in hypergraph outputs of different models. HM decoding, on the other hand, can use hypotheses from component search spaces directly without any restriction.

3.3 Hybrid Decoding

Hybrid decoding (Cui et al., 2010) resembles our approach in the motivation. This method uses the system combination technique in decoding directly to combine partial hypotheses from different SMT models. However, confusion network construction brings high computational complexity. What's more, partial hypotheses generated by confusion network decoding cannot be assigned exact feature values for future use in higher level decoding, and they only use feature values of 1-best hypothesis as an approximation. HM decoding, on the other hand, leverages a set of enriched features, which are computable for all the hypotheses generated by either component systems or the HM decoder.

4 Experiments

4.1 Data and Metric

Experiments are conducted on the NIST Chinese-to-English MT tasks. The NIST 2004 (MT04) data set is used as the development set, and evaluation results are reported on the NIST 2005 (MT05), the newswire portions of the NIST 2006 (MT06) and 2008 (MT08) data sets. All bilingual corpora available for the NIST 2008 constrained data track of Chinese-to-English MT task are used as training data, which contain 5.1M sentence pairs, 128M Chinese words and 147M English words after pre-processing. Word alignments are performed using GIZA++ with the intersect-diag-grow refinement. The English side of bilingual corpus plus Xinhua portion of the LDC English Gigaword Version 3.0 are used to train a 5-gram language model.

Translation performance is measured in terms of case-insensitive BLEU scores (Papineni et al., 2002), which compute the brevity penalty using the shortest reference translation for each segment. Statistical significance is computed using the bootstrap re-sampling approach proposed by Koehn (2004). Table 1 gives some data statistics.

Data Set	#Sentence	#Word
MT04(dev)	1,788	48,215
MT05	1,082	29,263
MT06	616	17,316
MT08	691	17,424

Table 1: Statistics on dev and test data sets

4.2 Component Systems

For convenience of comparing HM decoding with several related decoding techniques, we include two state-of-the-art SMT systems as component systems only:

- *PB*. A phrase-based system (Xiong et al., 2006) with one lexicalized reordering model based on the maximum entropy principle.
- *DHPB*. A string-to-dependency tree-based system (Shen et al., 2008), which translates source strings to target dependency trees. A target dependency language model is used as an additional feature.

Phrasal rules are extracted on all bilingual data, hierarchical rules used in DHPB and reordering rules used in SCFG-HMD are extracted from a selected data set[3]. Reordering model used in PB is trained on the same selected data set as well. A trigram dependency language model used in DHPB is trained with the outputs from Berkeley parser on all language model training data.

4.3 Contrastive Techniques

We compare HM decoding with three multiple-system based decoding techniques:

- *Word-Level System Combination* (SC). We re-implement an IHMM alignment based system combination method proposed by Li et al. (2009b). The setting of the *N*-best candidates used is the same as the original paper.
- *Co-decoding* (CD). We re-implement it based on Li et al. (2009a), with the only difference that only two models are included in our re-implementation, instead of three in theirs. For each test set, co-decoding outputs three results, two for two member systems, and one for the further system combination.
- *Model Combination* (MC). Different from co-decoding, MC produces single one output for each input sentence. We re-implement this method based on DeNero et al. (2010) with two component models included.

4.4 Comparison to Component Systems

We compared HM decoding with two component SMT systems first (in Table 2). 30 features are used to annotate each hypothesis in HM decoding, including: 8 *n*-gram posterior features computed from PB/DHPB forests for $1 \leq n \leq 4$; 8 stemmed *n*-gram posterior features computed from stemmed PB/DHPB forests for $1 \leq n \leq 4$; 4 *n*-gram posterior features and 1 length posterior feature computed from the mixture search space of HM decoder for $1 \leq n \leq 4$; 1 LM feature; 1 word count feature; 1 dictionary-based feature; 2 grammar-specified rule penalty features for either BTG-HMD or SCFG-HMD; 4 count features for newly generated *n*-grams in HM decoding for $1 \leq n \leq 4$. All *n*-gram posteriors are computed using the efficient algorithm proposed by Kumar et al. (2009).

[3] LDC2003E07, LDC2003E14, LDC2005T06, LDC2005T10, LDC2005E83, LDC2006E26, LDC2006E34, LDC2006E85 and LDC2006E92

Model	BLEU%			
	MT04	MT05	MT06	MT08
PB	38.93	38.21	33.59	29.62
DHPB	39.90	39.76	35.00	30.43
BTG-HMD	**41.24***	**41.26***	**36.76***	**31.69***
SCFG-HMD	**41.31***	**41.19***	**36.63***	**31.52***

Table 2: HM decoding vs. single component system decoding (*: significantly better than each component system with $\boldsymbol{p} < 0.01$)

From table 2 we can see, both BTG-HMD and SCFG-HMD outperform decoding results of the best component system (DHPB) with significant improvements: +1.50, +1.76, and +1.26 BLEU points on MT05, MT06, and MT08 for BTG-HMD; +1.43, +1.63 and +1.09 BLEU points on MT05, MT06, and MT08 for SCFG-HMD. We also notice that BTG-HMD performs slight better than SCFG-HMD on test sets. We think the potential reason is that more reordering rules are used in SCFG-HMD to handle phrase movements than BTG-HMD do; however, current HM decoding model lacks the ability to distinguish the qualities of different rules.

We also investigate on the effects of different HM-decoding features. For the convenience of comparison, we divide them into five categories:

- *Set-1*. 8 *n*-gram posterior features based on 2 component search spaces plus 3 commonly used features (1 LM feature, 1 word count feature and 1 dictionary-based feature).
- *Set-2*. 8 stemmed *n*-gram posterior features based on 2 stemmed component search spaces.
- *Set-3*. 4 *n*-gram posterior features and 1 length posterior feature based on the mixture search space of the HM decoder.
- *Set-4*. 2 grammar-specified reordering rule penalty features.
- *Set-5*. 4 count features for unseen *n*-grams generated by HM decoder itself.

Except for the dictionary-based feature, all the features contained in Set-1 are used by the latest multiple-system based consensus decoding techniques (DeNero et al., 2010; Duan et al., 2010). We use them as the starting point. Each time, we add one more feature set and describe the changes of performances by drawing two curves for each HM decoding algorithm on MT08 in Figure 3.

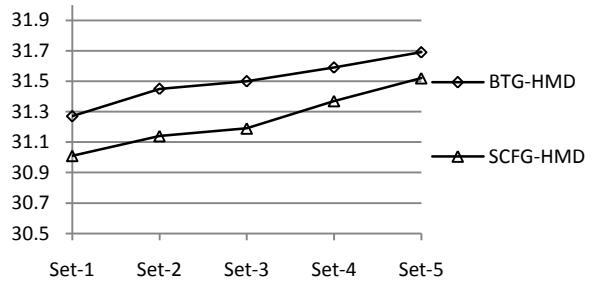

Figure 3: Effects of using different sets of HM decoding features on MT08

With Set-1 used only, HM-decoding has already outperformed the best component system, which shows the strong contributions of these features as proved in related work; small gains (+0.2 BLEU points) are achieved by using 8 stemmed *n*-gram posterior features in Set-2, which shows consensus statistics based on *n*-grams in their stem forms are also helpful; *n*-gram and length posterior features based on mixture search space bring improvements as well; reordering rule penalty features and count features for unseen *n*-grams boost newly generated hypotheses specific for HM decoding, and they contribute to the overall improvements.

4.5 Comparison to System Combination

Word-level system combination is state-of-the-art method to improve translation performance using outputs generated by multiple SMT systems. In this paper, we compare our HM decoding with the combination method proposed by Li et al. (2009b). Evaluation results are shown in Table 3.

Model	BLEU%			
	MT04	MT05	MT06	MT08
SC	41.14	40.70	36.04	31.16
BTG-HMD	**41.24**	**41.26**$^{+}$	**36.76**$^{+}$	**31.69**$^{+}$
SCFG-HMD	**41.31**$^{+}$	**41.19**$^{+}$	**36.63**$^{+}$	**31.52**$^{+}$

Table 3: HM decoding vs. system combination (+: significantly better than SC with $\boldsymbol{p} < 0.05$)

Compared to word-level system combination, both BTG-HMD and SCFG-HMD can provide significant improvements. We think the potential reason for these improvements is that, system combination can only use a small portion of the component systems' search spaces; HM decoding, on the other hand, can make full use of the entire translation spaces of all component systems.

4.6 Comparison to Consensus Decoding

Consensus decoding is another decoding technique that motivates our approach. We compare our HM decoding with two latest multiple-system based consensus decoding approaches, co-decoding and model combination. We list the comparison results in Table 4, in which CD-PB and CD-DHPB denote the translation results of two member systems in co-decoding respectively, CD-Comb denotes the results of further combination using outputs of CD-PB and CD-DHPB, MC denotes the results of model combination.

Model	BLEU%			
	MT04	MT05	MT06	MT08
CD-PB	40.39	40.34	35.20	30.39
CD-DHPB	40.81	40.56	35.73	30.87
CD-Comb	41.27	41.02	36.37	31.54
MC	41.19	40.96	36.30	31.43
BTG-HMD	**41.24**	**41.26**$^{+}$	**36.76**$^{+}$	**31.69**
SCFG-HMD	**41.31**	**41.19**	**36.63**$^{+}$	**31.52**

Table 4: HM decoding vs. consensus decoding (+: significantly better than the best result of consensus decoding methods with $\boldsymbol{p} < 0.05$)

Table 4 shows that after an additional system combination procedure, CD-Comb performs slight better than MC. Both BTG-HMD and SCFG-HMD perform consistent better than CD and MC on all blind test sets, due to its richer generative capability and usage of larger search spaces.

4.7 System Combination over BTG-HMD and SCFG-HMD Outputs

As BTG-HMD and SCFG-HMD are based on two different decoding grammars, we could perform system combination over the outputs of these two settings ($SC^{BTG+SCFG}$) for further improvements as well, just as Li et al. (2009a) did in co-decoding. We present evaluation results in Table 5.

Model	BLEU%			
	MT04	MT05	MT06	MT08
BTG-HMD	41.24	41.26	36.76	31.69
SCFG-HMD	41.31	41.19	36.63	31.52
$SC^{BTG+SCFG}$	**41.74**$^{+}$	**41.53**$^{+}$	**37.11**$^{+}$	**32.06**$^{+}$

Table 5: System combination based on the outputs of BTG-HMD and SCFG-HMD (+: significantly better than the best HM decoding algorithm (SCFG-HMD) with $\boldsymbol{p} < 0.05$)

After system combination, translation results are significantly better than all decoding approaches investigated in this paper: up to 2.11 BLEU points over the best component system (DHPB), up to 1.07 BLEU points over system combination, up to 0.74 BLEU points over co-decoding, and up to 0.81 BLEU points over model combination.

4.8 Evaluation of Oracle Translations

In the last part, we evaluate the quality of oracle translations on the *n*-best lists generated by HM decoding and all decoding approaches discussed in this paper. Oracle performances are obtained using the metric of sentence-level BLEU score proposed by Ye et al. (2007), and each decoding approach outputs its 1000-best hypotheses, which are used to extract oracle translations.

Model	BLEU%			
	MT04	MT05	MT06	MT08
PB	49.53	48.36	43.69	39.39
DHPB	50.66	49.59	44.68	40.47
SC	51.77	50.84	46.87	42.11
CD-PB	50.26	50.10	45.65	40.52
CD-DHPB	51.91	50.61	46.23	41.01
CD-Comb	52.10	51.00	46.95	42.20
MC	52.03	51.22	46.60	42.23
BTG-HMD	**52.69**$^{+}$	**51.75**$^{+}$	**47.08**	**42.71**$^{+}$
SCFG-HMD	**52.94**$^{+}$	**51.40**	**47.27**$^{+}$	**42.45**$^{+}$
$SC^{BTG+SCFG}$	**53.58**$^{+}$	**52.03**$^{+}$	**47.90**$^{+}$	**43.07**$^{+}$

Table 6: Oracle performances of different methods (+: significantly better than the best multiple-system based decoding method (CD-Comb) with $\boldsymbol{p} < 0.05$)

Results are shown in Table 6: compared to each single component system, decoding methods based on multiple SMT systems can provide significant improvements on oracle translations; word-level system combination, collaborative decoding and model combination show similar performances, in which CD-Comb performs best; BTG-HMD, SCFG-HMD and $SC^{BTG+SCFG}$ can obtain significant improvements than all the other approaches, and $SC^{BTG+SCFG}$ performs best on all evaluation sets.

5 Conclusion

In this paper, we have presented the hypothesis mixture decoding approach to combine multiple SMT models, in which hypotheses generated by multiple component systems are used to compose new translations. HM decoding method integrates the advantages of both system combination and consensus decoding techniques into a unified framework. Experimental results across different NIST Chinese-to-English MT evaluation data sets have validated the effectiveness of our approach.

In the future, we will include more SMT models and explore more features, such as syntax-based features, helping to improve the performance of HM decoding. We also plan to investigate more complicated reordering models in HM decoding.

Abstract

We present *minimum Bayes-risk system combination*, a method that integrates consensus decoding and system combination into a unified multi-system minimum Bayes-risk (MBR) technique. Unlike other MBR methods that re-rank translations of a single SMT system, MBR system combination uses the MBR decision rule and a linear combination of the component systems' probability distributions to search for the minimum risk translation among all the finite-length strings over the output vocabulary. We introduce expected BLEU, an approximation to the BLEU score that allows to efficiently apply MBR in these conditions. MBR system combination is a general method that is independent of specific SMT models, enabling us to combine systems with heterogeneous structure. Experiments show that our approach bring significant improvements to single-system-based MBR decoding and achieves comparable results to different state-of-the-art system combination methods.

1 Introduction

Once statistical models are trained, a decoding approach determines what translations are finally selected. Two parallel lines of research have shown consistent improvements over the max–derivation decoding objective, which selects the highest probability derivation. *Consensus decoding* procedures select translations for a single system with a minimum Bayes risk (MBR) (Kumar and Byrne, 2004). *System combination* procedures, on the other hand, generate translations from the output of multiple component systems by combining the best fragments of these outputs (Frederking and Nirenburg, 1994). In this paper, we present minimum Bayes risk system combination, a technique that unifies these two approaches by learning a consensus translation over multiple underlying component systems.

MBR system combination operates directly on the outputs of the component models. We perform an MBR decoding using a linear combination of the component models' probability distributions. Instead of re-ranking the translations provided by the component systems, we search for the hypothesis with the minimum expected translation error among all the possible finite-length strings in the target language. By using a loss function based on BLEU (Papineni et al., 2002), we avoid the hypothesis alignment problem that is central to standard system combination approaches (Rosti et al., 2007). MBR system combination assumes only that each translation model can produce expectations of n-gram counts; the latent derivation structures of the component systems can differ arbitrary. This flexibility allows us to combine a great variety of SMT systems.

The key contributions of this paper are three: the usage of a linear combination of distributions within the MBR decoding, which allows multiple SMT models to be involved in, and makes the computation of n-grams statistics to be more accurate; the decoding in an extended search space, which allows to find better hypotheses than the evidences provided by the component models; and the use of an expected BLEU score instead of the sentence-wise BLEU, which allows to efficiently apply MBR decoding in the huge search space under consideration.

We evaluate in a multi-source translation task obtaining improvements of up to $+2.0$ BLEU abs. over the best single system max-derivation, and state-of-the-art performance in the system combination task of the ACL 2010 workshop on SMT.

2 Related Work

MBR system combination is a multi-system generalization of MBR decoding where the space of hypotheses is not constrained to the space of evidences. We expand the space of hypotheses following some underlying ideas of system combination techniques.

2.1 Minimum Bayes risk

In SMT, MBR decoding allows to minimize the loss of the output for a single translation system. MBR is generally implemented by re-ranking an N-best list of translations produced by a first pass decoder (Kumar and Byrne, 2004). Different techniques to widen the search space have been described (Tromble et al., 2008; DeNero et al., 2009; Kumar et al., 2009; Li et al., 2009). These works extend the traditional MBR algorithms based on N-best lists to work with lattices.

The use of MBR to combine the outputs of various MT systems has also been explored previously. Duan et al. (2010) present an MBR decoding that makes use of a mixture of different SMT systems to improve translation accuracy. Our technique differs in that we use a linear combination instead of a mixture, which avoids the problem of component systems not sharing the same search space; perform the decoding in a search space larger than the outputs of the component models; and optimize an expected BLEU score instead of the linear approximation to it described in (Tromble et al., 2008).

DeNero et al. (2010) present *model combination*, a multi-system lattice MBR decoding on the conjoined evidences spaces of the component systems. Our technique differs in that we perform the search in an extended search space not restricted to the provided evidences, have fewer parameters to learn, and optimizes an expected BLEU score instead of the linear BLEU approximation.

Another MBR-related technique to combine the outputs of various MT systems was presented by González-Rubio and Casacuberta (2010). They use different median string (Fu, 1982) algorithms to combine various machine translation systems. Our approach differs in that we take into account the posterior distribution over translations instead of considering each translation equally likely, optimize the expected BLEU score instead of a sentence-wise measure such as the edit distance or the sentence-level BLEU, and take into account the quality differences by associating a tunable scaling factor to each system.

2.2 System Combination

System combination techniques in MT take as input the outputs $\{\mathbf{e}_1, \cdots, \mathbf{e}_N\}$ of N translation systems, where $\mathbf{e}_n$ is a structured translation object (or N-best lists thereof), typically viewed as a sequence of words. The dominant approach in the field chooses a primary translation $\mathbf{e}_p$ as a backbone, then finds an alignment $\mathbf{a}_n$ to the backbone for each $\mathbf{e}_n$. A new search space is constructed from these backbone-aligned outputs and then a voting procedure of feature-based model predicts a final consensus translation (Rosti et al., 2007). MBR system combination entirely avoids this alignment problem by considering hypotheses as n-gram occurrence vectors rather than word sequences. MBR system combination performs the decoding in a larger search space and includes statistics from the components' posteriors, whereas system combination techniques typically do not.

Despite these advantages, system combination may be more appropriate in some settings. In particular, MBR system combination is designed primarily for statistical systems that generate N-best or lattice outputs. MBR system combination can integrate non-statistical systems that generate either a single or an unweighted output. However, we would not expect the same strong performance from MBR system combination in these constrained settings.

3 Minimum Bayes risk Decoding

MBR decoding aims to find the candidate hypothesis that has the least expected loss under a probability model (Bickel and Doksum, 1977). We begin with a review of MBR for SMT.

SMT can be described as a mapping of a word sequence $\mathbf{f}$ in a source language to a word sequence $\mathbf{e}$ in a target language; this mapping is produced by the MT decoder $\mathcal{D}(\mathbf{f})$. If the reference translation $\mathbf{e}$ is known, the decoder performance can be measured by the loss function $\mathcal{L}(\mathbf{e}, \mathcal{D}(\mathbf{f}))$. Given such a loss function $\mathcal{L}(\mathbf{e}, \mathbf{e}')$ between an automatic translation $\mathbf{e}'$ and a reference $\mathbf{e}$, and an underlying proba-

bility model $P(\mathbf{e}|\mathbf{f})$, MBR decoding has the following form (Goel and Byrne, 2000; Kumar and Byrne, 2004):

$$\hat{\mathbf{e}} = \arg\min_{\mathbf{e}' \in E} \mathcal{R}(\mathbf{e}') \quad (1)$$

$$= \arg\min_{\mathbf{e}' \in E} \sum_{\mathbf{e} \in E} P(\mathbf{e}|\mathbf{f}) \cdot \mathcal{L}(\mathbf{e}, \mathbf{e}') \ , \quad (2)$$

where $\mathcal{R}(\mathbf{e}')$ denotes the Bayes risk of candidate translation $\mathbf{e}'$ under loss function $\mathcal{L}$, and E represents the space of translations.

If the loss function between any two hypotheses can be bounded: $\mathcal{L}(\mathbf{e}, \mathbf{e}') \leq \mathcal{L}_{max}$, the MBR decoder can be rewritten in term of a similarity function $\mathcal{S}(\mathbf{e}, \mathbf{e}') = \mathcal{L}_{max} - \mathcal{L}(\mathbf{e}, \mathbf{e}')$. In this case, instead of minimizing the Bayes risk, we maximize the Bayes gain $\mathcal{G}(\mathbf{e}')$:

$$\hat{\mathbf{e}} = \arg\max_{\mathbf{e}' \in E} \mathcal{G}(\mathbf{e}') \quad (3)$$

$$= \arg\max_{\mathbf{e}' \in E} \sum_{\mathbf{e} \in E} P(\mathbf{e}|\mathbf{f}) \cdot \mathcal{S}(\mathbf{e}, \mathbf{e}') \ . \quad (4)$$

MBR decoding can use different spaces for hypothesis selection and gain computation ($\arg\max$ and summatory in Eq. (4)). Therefore, the MBR decoder can be more generally written as follows:

$$\hat{\mathbf{e}} = \arg\max_{\mathbf{e}' \in E_h} \sum_{\mathbf{e} \in E_e} P(\mathbf{e}|\mathbf{f}) \cdot \mathcal{S}(\mathbf{e}, \mathbf{e}') \ , \quad (5)$$

where E_h refers to the hypotheses space form where the translations are chosen and E_e refers to the evidences space that is used to compute the Bayes gain. We will investigate the expansion of the hypotheses space while keeping the evidences space as provided by the decoder.

4 MBR System Combination

MBR system combination is a multi-system generalization of MBR decoding. It uses the MBR decision rule on a linear combination of the probability distributions of the component systems. Unlike existing MBR decoding methods that re-rank translation outputs, MBR system combination search for the minimum risk hypotheses on the complete set of finite-length hypotheses over the output vocabulary. We assume the component systems to be statistically independent and define the Bayes gain as a linear combination of the Bayes gains of the components. Each system provides its own space of evidences $\mathcal{D}_n(\mathbf{f})$ and its posterior distribution over translations $P_n(\mathbf{e}|\mathbf{f})$. Given a sentence $\mathbf{f}$ in the source language, MBR system combination is written as follows:

$$\hat{\mathbf{e}} = \arg\max_{\mathbf{e}' \in E_h} \mathcal{G}(\mathbf{e}') \quad (6)$$

$$\approx \arg\max_{\mathbf{e}' \in E_h} \sum_{n=1}^{N} \alpha_n \cdot \mathcal{G}_n(\mathbf{e}') \quad (7)$$

$$= \arg\max_{\mathbf{e}' \in E_h} \sum_{n=1}^{N} \alpha_n \cdot \sum_{\mathbf{e} \in \mathcal{D}_n(\mathbf{f})} P_n(\mathbf{e}|\mathbf{f}) \cdot \mathcal{S}(\mathbf{e}, \mathbf{e}') \ , \quad (8)$$

where N is the total number of component systems, E_h represents the hypotheses space where the search is performed, $\mathcal{G}_n(\mathbf{e}')$ is the Bayes gain of hypothesis $\mathbf{e}'$ given by the n^{th} component system and α_n is a scaling factor introduced to take into account the differences in quality of the component models. It is worth mentioning that by using a linear combination instead of a mixture model, we avoid the problem of component systems not sharing the same search space (Duan et al., 2010).

MBR system combination parameters training and decoding in the extended hypotheses space are described below.

4.1 Model Training

We learn the scaling factors in Eq. (8) using minimum error rate training (MERT) (Och, 2003). MERT maximizes the translation quality of $\hat{\mathbf{e}}$ on a held-out set, according to an evaluation metric that compares to a reference set. We used BLEU, choosing the scaling factors to maximize BLEU score of the set of translations predicted by MBR system combination. We perform the maximization by means of the down-hill simplex algorithm (Nelder and Mead, 1965).

4.2 Model Decoding

In most MBR algorithms, the hypotheses space is equal to the evidences space. Following the underlying idea of system combination, we are interested in extend the hypotheses space by including new sentences created using fragments of the hypotheses in the evidences spaces of the component models. We perform the search ($argmax$ operation in Eq. (8))

Ensure: $\mathcal{G}(\mathbf{e}_{cur}) \geq \mathcal{G}(\mathbf{e})$

using the approximate median string (AMS) algorithm (Martínez et al., 2000). AMS algorithm perform a search on a hypotheses space equal to the free monoid Σ^* of the vocabulary of the evidences $\Sigma = Voc(E_e)$.

The AMS algorithm is shown in Algorithm 1. AMS starts with an initial hypothesis $\mathbf{e}$ that is modified using edit operations until there is no improvement in the Bayes gain (Lines 3–16). On each position j of the current solution $\mathbf{e}_{cur}$, we apply all the possible single edit operations: substitution of the j^{th} word of $\mathbf{e}_{cur}$ by each word a in the vocabulary (Lines 5–9), deletion of the j^{th} word of $\mathbf{e}_{cur}$ (Line 10) and insertion of each word a in the vocabulary in the j^{th} position of $\mathbf{e}_{cur}$ (Lines 11–15). If the Bayes gain of any of the new edited hypotheses is higher than the Bayes gain of the current hypothesis (Line 17), we repeat the loop with this new hypotheses $\hat{\mathbf{e}}$, in other case, we return the current hypothesis.

AMS algorithm takes as input an initial hypothesis $\mathbf{e}$ and the combined vocabulary of the evidences spaces Σ. Its output is a possibly new hypothesis whose Bayes gain is assured to be higher or equal than the Bayes gain of the initial hypothesis.

The complexity of the main loop (lines 2-17) is $O(|\mathbf{e}_{cur}| \cdot |\Sigma| \cdot C_{\mathcal{G}})$, where $C_{\mathcal{G}}$ is the cost of computing the gain of a hypothesis, and usually only a moderate number of iterations (< 10) is needed to converge (Martínez et al., 2000).

5 Computing BLEU-based Gain

We are interested in performing MBR system combination under BLEU. BLEU behaves as a score function: its value ranges between 0 and 1 and a larger value reflects a higher similarity. Therefore, we rewrite the gain function $\mathcal{G}(\cdot)$ using single evidence (or reference) BLEU (Papineni et al., 2002) as the similarity function:

$$\mathcal{G}_n(\mathbf{e}') = \sum_{\mathbf{e} \in \mathcal{D}_n(\mathbf{f})} P_n(\mathbf{e}|\mathbf{f}) \cdot \text{BLEU}(\mathbf{e}, \mathbf{e}') \quad (9)$$

$$\text{BLEU} = \prod_{k=1}^{4} \left(\frac{m_k}{c_k} \right)^{\frac{1}{4}} \cdot \min\left(e^{1-\frac{r}{c}}, 1.0 \right) , \quad (10)$$

where r is the length of the evidence, c the length of the hypothesis, m_k the number of n-gram matches of size k, and c_k the count of n-grams of size k in the hypothesis.

The evidences space $\mathcal{D}_n(\mathbf{f})$ may contain a huge number of hypotheses[1] which often make impractical to compute Eq. (9) directly. To avoid this problem, Tromble et al. (2008) propose *linear BLEU*, an approximation to the BLEU score to efficiently perform MBR decoding when the search space is represented with lattices. However, our hypotheses space is the full set of finite-length strings in the target vocabulary and can not be represented in a lattice.

In Eq. (9), we have one hypothesis $\mathbf{e}'$ that is to be compared to a set of evidences $\mathbf{e} \in \mathcal{D}_n(\mathbf{f})$ which follow a probability distribution $P_n(\mathbf{e}|\mathbf{f})$. Instead of computing the expected BLEU score by calculating the BLEU score with respect to each of the evidences, our approach will be to use the expected n-gram counts and sentence length of the evidences to compute a single-reference BLEU score. We replace the reference statistics (r and m_n in Eq. (10)) by the expected statistics (r' and m'_n) given the pos-

[1]For example, in a lattice the number of hypotheses may be exponential in the size of its state set.

terior distribution $P_n(\mathbf{e}|\mathbf{f})$ over the evidences:

$$\mathcal{G}_n(\mathbf{e}') = \prod_{k=1}^{4} \left(\frac{m'_k}{c_k} \right)^{\frac{1}{4}} \cdot \min\left(e^{1-\frac{r'}{c}}, 1.0 \right) \quad (11)$$

$$r' = \sum_{\mathbf{e} \in \mathcal{D}_n(\mathbf{f})} |\mathbf{e}| \cdot P_n(\mathbf{e}|\mathbf{f}) \quad (12)$$

$$m'_k = \sum_{ng \in \mathcal{N}_k(\mathbf{e}')} \min(C_{\mathbf{e}'}(ng), C'(ng)) \quad (13)$$

$$C'(ng) = \sum_{\mathbf{e} \in \mathcal{D}_n(\mathbf{f})} C_{\mathbf{e}}(ng) \cdot P_n(\mathbf{e}|\mathbf{f}) \,, \quad (14)$$

where $\mathcal{N}_k(\mathbf{e}')$ is the set of n-grams of size k in the hypothesis, $C_{\mathbf{e}'}(ng)$ is the count of the n-gram ng in the hypothesis and $C'(ng)$ is the expected count of ng in the evidences. To compute the n-gram matchings m'_k, the count of each n-gram is truncated, if necessary, to not exceed the expected count for that n-gram in the evidences.

We have replaced a summation over a possibly exponential number of items ($\mathbf{e}' \in \mathcal{D}_n(\mathbf{f})$ in Eq. (9)) with a summation over a polynomial number of n-grams that occur in the evidences[2]. Both, the expected length of the evidences r' and their expected n-gram counts m'_k can be pre-computed efficiently from N-best lists and translation lattices (Kumar et al., 2009; DeNero et al., 2010).

6 Experiments

We report results on a multi-source translation task. From the Europarl corpus released for the ACL 2006 workshop on MT (WMT2006), we select those sentence pairs from the German–English (de–en), Spanish–English (es–en) and French–English (fr–en) sub-corpora that share the same English translation. We obtain a multi-source corpus with German, Spanish and French as source languages and English as target language. All the experiments were carried out with the lowercased and tokenized version of this corpus.

We report results using BLEU (Papineni et al., 2002) and translation edit rate (Snover et al., 2006) (TER). We measure statistical significance using 95% confidence intervals computed using paired bootstrap re-sampling (Zhang and Vogel, 2004). In all table cells (except for Table 3) systems without statistically significant differences are marked with the same superscript.

Table 2: Performance from best single system max-derivation decoding (*Best MAX)*, the best single system minimum Bayes risk decoding (*Best MBR*) and minimum Bayes risk system combination (*MBR-SC*) combining three systems.

6.1 Base Systems

We combine outputs from three systems, each one translating from one source language (German, Spanish or French) into English. Each individual system is a phrase-based system trained using the Moses toolkit (Koehn et al., 2007). The parameters of the systems were tuned using MERT (Och, 2003) to optimize BLEU on the development set. Each base system yields state-of-the-art performance, summarized in Table 1. For each system, we report the performance of max-derivation decoding (MAX) and 1000-best[3] MBR decoding (Kumar and Byrne, 2004).

6.2 Experimental Results

Table 2 compares MBR system combination (MBR-SC) to the best MAX and MBR systems. Both Best

[2] If $\mathcal{D}_n(\mathbf{f})$ is represented by a lattice, the number of n-grams is polynomial in the number of edges in the lattice.

[3] Ehling et al. (2007) studied up to 10000-best and show that the use of 1000-best candidates is sufficient for MBR decoding.

Setup	BLEU	TER

MBR-SC E/C/Ex/MERT	**32.8**	**52.3**

Table 3: Results on the test set for different setups of minimum Bayes risk system combination.

MBR and MBR-SC were computed on 1000-best lists. MBR-SC uses expected BLEU as gain function using the conjoined evidences spaces of the three systems to compute expected BLEU statistics. It performs the search in the free monoid of the output vocabulary, and its model parameters were tuned using MERT on the development set. This is the standard setup for MBR system combination, and we refer to it as MBR-SC-E/C/Ex/MERT in Table 3.

MBR system combination improves single Best MAX system by $+2.0$ BLEU points in test, and always improves over MBR. This improvement could arise due to multiple reasons: the expected BLEU gain, the larger evidences space, the extended hypotheses space, or the MERT tuned scaling factor values. Table 3 teases apart these contributions.

We first apply MBR-SC to the best system (MBR-SC-Expected). Best MBR and MBR-SC-Expected differ only in the gain function: MBR uses sentence level BLEU while MBR-SC-Expected uses the expected BLEU gain described in Section 5. MBR-SC-Expected performance is comparable to MBR decoding on the 1000-best list from the single best system. The expected BLEU approximation performs as well as sentence-level BLEU and additionally requires less total computation.

We now extend the evidences space to the conjoined 1000-best lists (MBR-SC-E/Conjoin). MBR-SC-E/Conjoin is much better than the best MBR on a single system. This implies that either the expected BLEU statistics computed in the conjoined evidences space are stronger or the larger conjoined evidences spaces introduce better hypotheses.

When we restrict the BLEU statistics to be computed from only the best system's evidences space (MBR-SC-E/C/evidences-best), BLEU scores dramatically decrease relative to MBR-SC-E/Conjoin. This implies that the expected BLEU statistics computed over the conjoined 1000-best lists are stronger than the corresponding statistics from the single best system. On the other hand, if we restrict the search space to only the 1000-best list of the best system (MBR-SC-E/C/hypotheses-best), BLEU scores also decrease relative to MBR-SC-E/Conjoin. This implies that the conjoined search space also contains better hypotheses than the single best system's search space.

These results validate our approach. The linear combination of the probability distributions in the conjoined evidences spaces allows to compute much stronger statistics for the expected BLEU gain and also contains some better hypotheses than the single best system's search space does.

We next expand the conjoined evidences spaces using the decoding algorithm described in Section 4.2 (MBR-SC-E/C/Extended). In this case, the expected BLEU statistics are computed from the conjoined 1000-best lists of the three systems, but the hypotheses space where we perform the decoding is expanded to the set of all possible finite-length hypotheses over the vocabulary of the evidences. We take the output of MBR-SC-E/Conjoin as the initial hypotheses of the decoding (see Algorithm 1). MBR-SC-E/C/Extended improves BLEU score of MBR-SC-E/Conjoin but obtains a slightly worse TER score. Since these two systems are identical in their expected BLEU statistics, the improvements in BLEU imply that the extended search space has introduced better hypotheses. The degradation in TER performance can be explained by the use of a BLEU-based gain function in the decoding process.

We finally compute the optimum values for the scaling factors of the different system using MERT (MBR-SC-E/C/Ex/MERT). MBR-SC-E/C/Ex/MERT slightly improves BLEU score of MBR-SC-E/C/Extended. This implies that the optimal values of the scaling factors do not deviate much from 1.0; a similar result was reported in (Och and Ney, 2001). We hypothesize that this is because the three component systems share the same SMT model, pre-process and decoding. We expect to obtain larger improvements when combining systems implementing different MT paradigms.

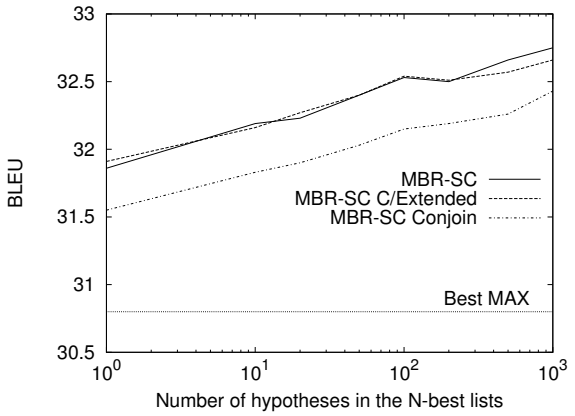

Figure 1: Performance of minimum Bayes risk system combination (MBR-SC) for different sizes of the evidences space in comparison to other MBR-SC setups.

MBR-SC-E/C/Ex/MERT is the standard setup for MBR system combination and, from now, on we will refer to it as MBR-SC.

We next evaluate performance of MBR system combination on N-best lists of increasing sizes, and compare it to MBR-SC-E/C/Extended and MBR-SC-E/Conjoin in the same N-best lists. We list the results of the Best MAX system for comparison.

Results in Figure 1 confirm the conclusions extracted from results displayed in Table 3. MBR-SC-Conjoin is consistently better than the Best MAX system, and differences in BLEU increase with the size of the evidences space. This implies that the linear combination of posterior probabilities allow to compute stronger statistics for the expected BLEU gain, and, in addition, the larger the evidences space is, the stronger the computed statistics are. MBR-SC-C/Extended is also consistently better than MBR-SC-Conjoin with an almost constant improvement of $+0.4$ BLEU points. This result show that the extended search space always contains better hypotheses than the conjoined evidences spaces; also confirms the soundness of Algorithm 1 that allows to reach them. Finally, MBR-SC also slightly improves MBR-SC-C/Extended. The optimization of the scaling factors allows only small improvements in BLEU.

Figure 2 display the MBR system combination translation and compare it to the max-derivation translations of the three component systems. Reference translation is also listed for comparison. MBR-SC adds word "*point*" to create a new translation equal to the reference. MBR-SC is able to detect that this is valuable word even though it does not appear in the max-derivation hypotheses.

6.3 Comparison to System Combination

Figure 3 compares MBR system combination (MBR-SC) with state-of-the-art system combination techniques presented to the system combination task of the ACL 2010 workshop on MT (WMT2010). All system combination techniques build a "word sausage" from the outputs of the different component systems and choose a path trough the sausage with the highest score under different models. A description of these systems can be found in (Callison-Burch et al., 2010).

In this task, the output of the component systems are single hypotheses or unweighted lists thereof. Therefore, we lack of the statistics of the components' posteriors which is one of the main advantages of MBR system combination over system combination techniques. However, we find that, even in these constrained setting, MBR system combination performance is similar to the best system combination techniques for all translation directions. These experiments validate our approach. MBR system combination yields state-of-the-art performance while avoiding the challenge of aligning translation hypotheses.

7 Conclusion

MBR system combination integrates consensus decoding and system combination into a unified multi-system MBR technique. MBR system combination uses the MBR decision rule on a linear combination of the component systems' probability distributions to search for the sentence with the minimum Bayes risk on the complete set of finite-length

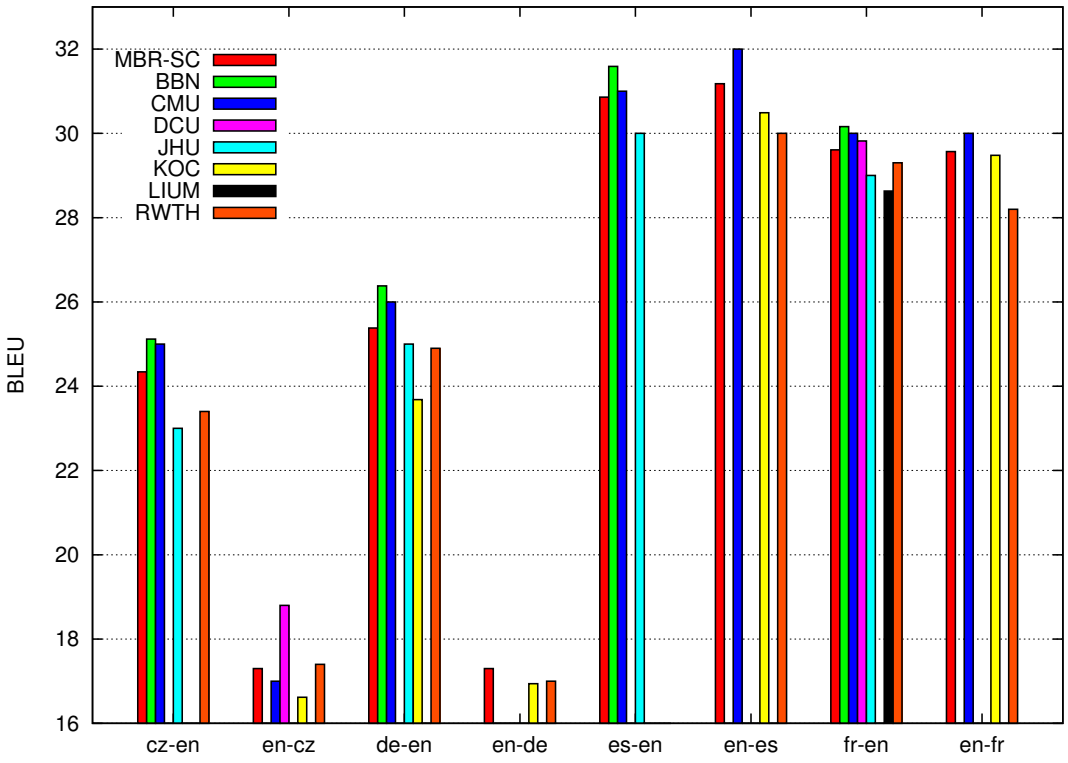

Figure 3: Performance of minimum Bayes risk system combination (MBR-SC) for different language directions in comparison to the rest of system combination techniques presented in the WMT2010 system combination task.

strings in the output vocabulary. Component systems can have varied decoding strategies; we only require that each system produce an N-best list (or a lattice) of translations. This flexibility allows the technique to be applied quite broadly. For instance, Leusch et al. (2010) generate intermediate translations in several pivot languages, translate them separately into the target language, and generate a consensus translation out of these using a system combination technique. Likewise, these pivot translations could be combined via MBR system combination.

MBR system combination has two significant advantages over current approaches to system combination. First, it does not rely on hypothesis alignment between outputs of individual systems. Aligning translation hypotheses can be challenging and has a substantial effect on combination performance (He et al., 2008). Instead of aligning the sentences, we view the sentences as vectors of n-gram counts and compute the expected statistics of the BLEU score to compute the Bayes gain. Second, we do not need to pick a backbone system for combination. Choosing a backbone system can also be challenging and also affects system combination performance (He and Toutanova, 2009). MBR system combination sidesteps this issue by working directly on the conjoined evidences space produced by the outputs of the component systems, and allows the consensus model to express system preferences via scaling factors.

Despite its simplicity, MBR system combination provides strong performance by leveraging different consensus, decoding and training techniques. It outperforms best MAX or MBR derivation on each of the component systems. In addition, it obtains state-of-the-art performance in a constrained setting better suited for dominant system combination techniques.

Abstract

We introduce synchronous tree adjoining grammars (TAG) into tree-to-string translation, which converts a source tree to a target string. Without reconstructing TAG derivations explicitly, our rule extraction algorithm directly learns tree-to-string rules from aligned Treebank-style trees. As tree-to-string translation casts decoding as a tree parsing problem rather than parsing, the decoder still runs fast when adjoining is included. Less than 2 times slower, the adjoining tree-to-string system improves translation quality by +0.7 BLEU over the baseline system only allowing for tree substitution on NIST Chinese-English test sets.

1 Introduction

Syntax-based translation models, which exploit hierarchical structures of natural languages to guide machine translation, have become increasingly popular in recent years. So far, most of them have been based on synchronous context-free grammars (CFG) (Chiang, 2007), tree substitution grammars (TSG) (Eisner, 2003; Galley et al., 2006; Liu et al., 2006; Huang et al., 2006; Zhang et al., 2008), and inversion transduction grammars (ITG) (Wu, 1997; Xiong et al., 2006). Although these formalisms present simple and precise mechanisms for describing the basic recursive structure of sentences, they are not powerful enough to model some important features of natural language syntax. For example, Chiang (2006) points out that the translation of languages that can stack an unbounded number of clauses in an "inside-out" way (Wu, 1997) provably goes beyond the expressive power of synchronous CFG and TSG. Therefore, it is necessary to find ways to take advantage of more powerful synchronous grammars to improve machine translation.

Synchronous tree adjoining grammars (TAG) (Shieber and Schabes, 1990) are a good candidate. As a formal tree rewriting system, TAG (Joshi et al., 1975; Joshi, 1985) provides a larger domain of locality than CFG to state linguistic dependencies that are far apart since the formalism treats trees as basic building blocks. As a mildly context-sensitive grammar, TAG is conjectured to be powerful enough to model natural languages. Synchronous TAG generalizes TAG by allowing the construction of a pair of trees using the TAG operations of substitution and adjoining on tree pairs. The idea of using synchronous TAG in machine translation has been pursued by several researchers (Abeille et al., 1990; Prigent, 1994; Dras, 1999), but only recently in its probabilistic form (Nesson et al., 2006; DeNeefe and Knight, 2009). Shieber (2007) argues that probabilistic synchronous TAG possesses appealing properties such as expressivity and trainability for building a machine translation system.

However, one major challenge for applying synchronous TAG to machine translation is computational complexity. While TAG requires $O(n^6)$ time for monolingual parsing, synchronous TAG requires $O(n^{12})$ for bilingual parsing. One solution is to use tree insertion grammars (TIG) introduced by Schabes and Waters (1995). As a restricted form of TAG, TIG still allows for adjoining of unbounded trees but only requires $O(n^3)$ time for monolingual parsing. Nesson et al. (2006) firstly demonstrate

Portland, Oregon, June 19-24, 2011.

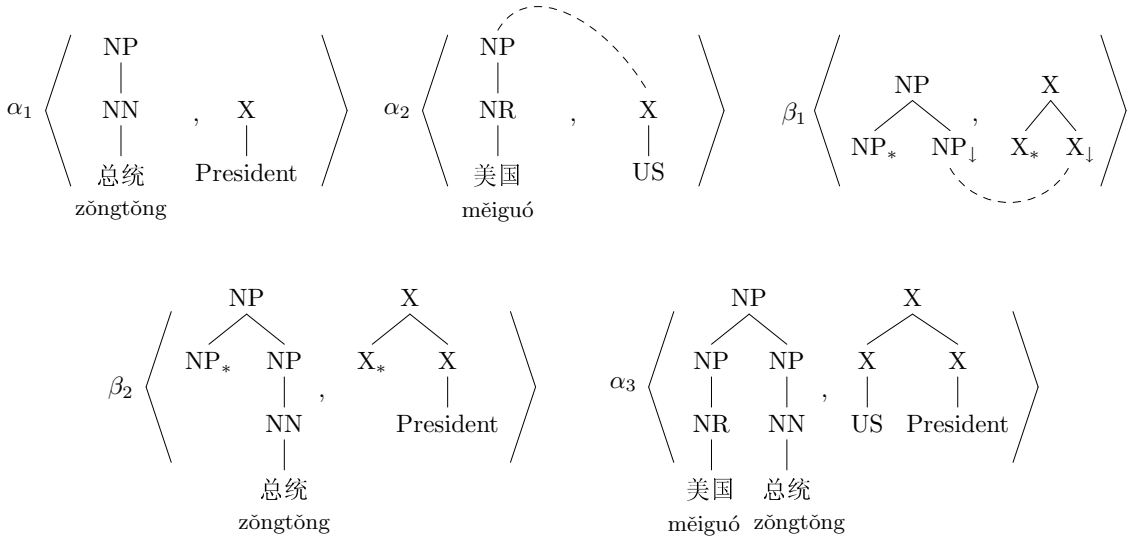

Figure 1: Initial and auxiliary tree pairs. The source side (Chinese) is a Treebank-style linguistic tree. The target side (English) is a purely structural tree using a single non-terminal (X). By convention, substitution and foot nodes are marked with a down arrow ($\downarrow$) and an asterisk ($*$), respectively. The dashed lines link substitution sites (e.g., $\text{NP}_\downarrow$ and $\text{X}_\downarrow$ in β_1) and adjoining sites (e.g., NP and X in α_2) in tree pairs. Substituting the initial tree pair α_1 at the $\text{NP}_\downarrow$-$\text{X}_\downarrow$ node pair in the auxiliary tree pair β_1 yields a derived tree pair β_2, which can be adjoined at NN-X in α_2 to generate α_3.

the use of synchronous TIG for machine translation and report promising results. DeNeefe and Knight (2009) prove that adjoining can improve translation quality significantly over a state-of-the-art string-to-tree system (Galley et al., 2006) that uses synchronous TSG with tractable computational complexity.

In this paper, we introduce synchronous TAG into tree-to-string translation (Liu et al., 2006; Huang et al., 2006), which is the simplest and fastest among syntax-based approaches (Section 2). We propose a new rule extraction algorithm based on GHKM (Galley et al., 2004) that directly induces a synchronous TAG from an aligned and parsed bilingual corpus without converting Treebank-style trees to TAG derivations explicitly (Section 3). As tree-to-string translation takes a source parse tree as input, the decoding can be cast as a tree parsing problem (Eisner, 2003): reconstructing TAG derivations from a derived tree using tree-to-string rules that allow for both substitution and adjoining. We describe how to convert TAG derivations to translation forest (Section 4). We evaluated the new tree-to-string system on NIST Chinese-English tests and obtained consistent improvements (+0.7 BLEU) over the STSG-based baseline system without significant loss in efficiency (1.6 times slower) (Section 5).

2 Model

A synchronous TAG consists of a set of linked elementary tree pairs: **initial** and **auxiliary**. An initial tree is a tree of which the interior nodes are all labeled with non-terminal symbols, and the nodes on the frontier are either words or non-terminal symbols marked with a down arrow ($\downarrow$). An auxiliary tree is defined as an initial tree, except that exactly one of its frontier nodes must be marked as foot node ($*$). The foot node must be labeled with a non-terminal symbol that is the same as the label of the root node.

Synchronous TAG defines two operations to build derived tree pairs from elementary tree pairs: **substitution** and **adjoining**. Nodes in initial and auxiliary tree pairs are linked to indicate the correspondence between substitution and adjoining sites. Figure 1 shows three initial tree pairs (i.e., α_1, α_2, and α_3) and two auxiliary tree pairs (i.e., β_1 and β_2). The dashed lines link substitution nodes (e.g., $\text{NP}_\downarrow$ and $\text{X}_\downarrow$ in β_1) and adjoining sites (e.g., NP and X in α_2) in tree pairs. Substituting the initial tree pair α_1 at

$IP_{0,8}$	[31] (IP (x_1:$NP_{\downarrow}$) (x_2:$VP_{\downarrow}$)) → x_1 has x_2	

Table 1: Minimal initial and auxiliary rules extracted from Figure 2. Note that an adjoining site has a span as subscript. For example, $NP_{0:1}$ in rule 6 indicates that the node is an adjoining site linked to a target node dominating the target string spanning from position 0 to position 1 (i.e., x_1). The target tree is hidden because tree-to-string translation only considers the target surface string.

the $\text{NP}_\downarrow$-$\text{X}_\downarrow$ node pair in the auxiliary tree pair β_1 yields a derived tree pair β_2, which can be adjoined at NN-X in α_2 to generate α_3.

For simplicity, we represent α_2 as a tree-to-string rule:

$$\text{(} \text{NP}_{0:1} \text{ (NR měiguó)) } \rightarrow \text{US}$$

where $\text{NP}_{0:1}$ indicates that the node is an adjoining site linked to a target node dominating the target string spanning from position 0 to position 1 (i.e., "US"). The target tree is hidden because tree-to-string translation only considers the target surface string. Similarly, β_1 can be written as

$$\text{(NP (} x_1\text{:NP}_* \text{) (} x_2\text{:NP}_\downarrow \text{)) } \rightarrow x_1\ x_2$$

where x denotes a non-terminal and the subscripts indicate the correspondence between source and target non-terminals.

The parameters of a probabilistic synchronous TAG are

$$\sum_\alpha P_i(\alpha) = 1 \quad (1)$$

$$\sum_\alpha P_s(\alpha|\eta) = 1 \quad (2)$$

$$\sum_\beta P_a(\beta|\eta) + P_a(\text{NONE}|\eta) = 1 \quad (3)$$

where α ranges over initial tree pairs, β over auxiliary tree pairs, and η over node pairs. $P_i(\alpha)$ is the probability of beginning a derivation with α; $P_s(\alpha|\eta)$ is the probability of substituting α at η; $P_a(\beta|\eta)$ is the probability of adjoining β at η; finally, $P_a(\text{NONE}|\eta)$ is the probability of nothing adjoining at η.

For tree-to-string translation, these parameters can be treated as feature functions of a discriminative framework (Och, 2003) combined with other conventional features such as relative frequency, lexical weight, rule count, language model, and word count (Liu et al., 2006).

3 Rule Extraction

Inducing a synchronous TAG from training data often begins with converting Treebank-style parse trees to TAG derivations (Xia, 1999; Chen and Vijay-Shanker, 2000; Chiang, 2003). DeNeefe and Knight (2009) propose an algorithm to extract synchronous TIG rules from an aligned and parsed bilingual corpus. They first classify tree nodes into heads, arguments, and adjuncts using heuristics (Collins, 2003), then transform a Treebank-style tree into a TIG derivation, and finally extract minimally-sized rules from the derivation tree and the string on the other side, constrained by the alignments. Probabilistic models can be estimated by collecting counts over the derivation trees.

However, one challenge is that there are many TAG derivations that can yield the same derived tree, even with respect to a single grammar. It is difficult to choose appropriate single derivations that enable the resulting grammar to translate unseen data well. DeNeefe and Knight (2009) indicate that the way to reconstruct TIG derivations has a direct effect on final translation quality. They suggest that one possible solution is to use derivation forest rather than a single derivation tree for rule extraction.

Alternatively, we extend the GHKM algorithm (Galley et al., 2004) to *directly* extract tree-to-string rules that allow for both substitution and adjoining from aligned and parsed data. There is no need for transforming a parse tree into a TAG derivation explicitly before rule extraction and all derivations can be easily reconstructed using extracted rules. [1] Our rule extraction algorithm involves two steps: (1) extracting minimal rules and (2) composition.

3.1 Extracting Minimal Rules

Figure 2 shows a training example, which consists of a Chinese parse tree, an English string, and the word alignment between them. By convention, shaded nodes are called **frontier** nodes from which tree-to-string rules can be extracted. Note that the source phrase dominated by a frontier node and its corresponding target phrase are consistent with the word alignment: all words in the source phrase are aligned to all words in the corresponding target phrase and vice versa.

We distinguish between three categories of tree-

[1] Note that our algorithm does not take heads, complements, and adjuncts into consideration and extracts all possible rules with respect to word alignment. Our hope is that this treatment would make our system more robust in the presence of noisy data. It is possible to use the linguistic preferences as features. We leave this for future work.

to-string rules:

1. **substitution rules**, in which the source tree is an initial tree without adjoining sites.

2. **adjoining rules**, in which the source tree is an initial tree with at least one adjoining site.

3. **auxiliary rules**, in which the source tree is an auxiliary tree.

For example, in Figure 1, α_1 is a substitution rule, α_2 is an adjoining rule, and β_1 is an auxiliary rule.

Minimal substitution rules are the same with those in STSG (Galley et al., 2004; Liu et al., 2006) and therefore can be extracted directly using GHKM. By minimal, we mean that the interior nodes are not frontier and cannot be decomposed. For example, in Table 2, rule 1 (for short r_1) is a minimal substitution rule extracted from $\text{NR}_{0,1}$.

Minimal adjoining rules are defined as minimal substitution rules, except that each root node must be an adjoining site. In Table 2, r_2 is a minimal substitution rule extracted from $\text{NP}_{0,1}$. As $\text{NP}_{0,1}$ is a descendant of $\text{NP}_{0,2}$ with the same label, $\text{NP}_{0,1}$ is a possible adjoining site. Therefore, r_6 can be derived from r_2 and licensed as a minimal adjoining rule extracted from $\text{NP}_{0,2}$. Similarly, four minimal adjoining rules are extracted from $\text{NP}_{0,3}$ because it has four frontier descendants labeled with NP.

Minimal auxiliary rules are derived from minimal substitution and adjoining rules. For example, in Table 2, r_7 and r_{10} are derived from the minimal substitution rule r_5 while r_8 and r_{11} are derived from r_{15}. Note that a minimal auxiliary rule can have adjoining sites (e.g., r_8).

Table 1 lists 17 minimal substitution rules, 7 minimal adjoining rules, and 7 minimal auxiliary rules extracted from Figure 2.

3.2 Composition

We can obtain composed rules that capture rich contexts by substituting and adjoining minimal initial and auxiliary rules. For example, the composition of r_{12}, r_{17}, r_{25}, r_{26}, r_{29}, and r_{31} yields an initial rule with two adjoining sites:

(IP ($\text{NP}_{0:1}$ (NR àobāmǎ)) ($\text{VP}_{2:3}$ (VV yǔyǐ) (NP (NN qiǎnzé)))) → Obama has condemned

Note that the source phrase "àobāmǎ . . . yǔyǐ qiǎnzé" is discontinuous. Our model allows both the source and target phrases of an initial rule with adjoining sites to be discontinuous, which goes beyond the expressive power of synchronous CFG and TSG.

Similarly, the composition of two auxiliary rules r_8 and r_{16} yields a new auxiliary rule:

(NP (NP (x_1:NP_*) (x_2:$\text{NP}_\downarrow$)) (x_3:$\text{NP}_\downarrow$)) → $x_1 x_2 x_3$

We first compose initial rules and then compose auxiliary rules, both in a bottom-up way. To maintain a reasonable grammar size, we follow Liu (2006) to restrict that the tree height of a rule is no greater than 3 and the source surface string is no longer than 7.

To learn the probability models $P_i(\alpha)$, $P_s(\alpha|\eta)$, $P_a(\beta|\eta)$, and $P_a(\text{NONE}|\eta)$, we collect and normalize counts over these extracted rules following DeNeefe and Knight (2009).

4 Decoding

Given a synchronous TAG and a derived source tree π, a tree-to-string decoder finds the English yield of the best derivation of which the Chinese yield matches π:

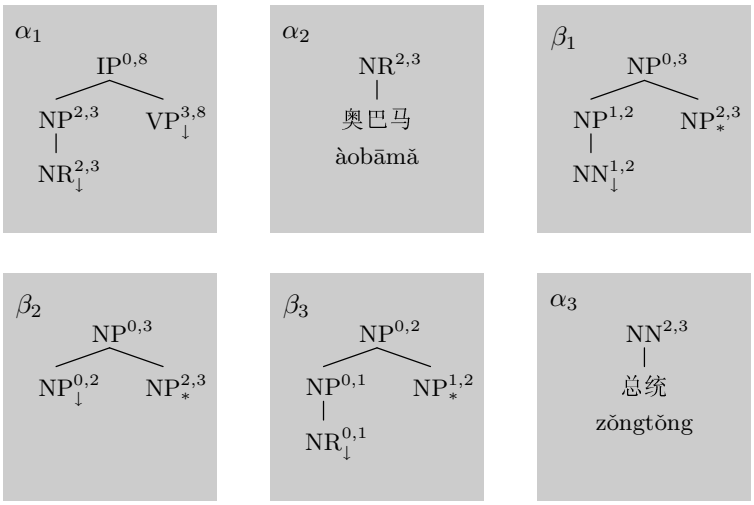
$$\hat{e} = e\left(\underset{D \text{ s.t. } f(D)=\pi}{\arg\max} P(D) \right) \quad (4)$$

This is called **tree parsing** (Eisner, 2003) as the decoder finds ways of decomposing π into elementary trees.

Tree-to-string decoding with STSG is usually treated as **forest rescoring** (Huang and Chiang, 2007) that involves two steps. The decoder first converts the input tree into a translation forest using a translation rule set by pattern matching. Huang et al. (2006) show that this step is a depth-first search with memorization in $O(n)$ time. Then, the decoder searches for the best derivation in the translation forest intersected with n-gram language models and outputs the target string. [2]

Decoding with STAG, however, poses one major challenge to forest rescoring. As translation forest only supports substitution, it is difficult to construct a translation forest for STAG derivations because of

[2] Mi et al. (2008) give a detailed description of the two-step decoding process. Huang and Mi (2010) systematically analyze the decoding complexity of tree-to-string translation.



elementary tree		translation rule
α_1	r_1	(IP ($\mathrm{NP}_{0:1}$ (x_1:$\mathrm{NR}_{\downarrow}$)) (x_2:$\mathrm{VP}_{\downarrow}$)) $\rightarrow x_1\ x_2$
α_2	r_2	(NR àobāmǎ) $\rightarrow$ Obama
β_1	r_3	(NP ($\mathrm{NP}_{0:1}$ (x_1:$\mathrm{NN}_{\downarrow}$)) (x_2:NP_{*})) $\rightarrow x_1\ x_2$
β_2	r_4	(NP (x_1:$\mathrm{NP}_{\downarrow}$) (x_2:NP_{*})) $\rightarrow x_1\ x_2$
β_3	r_5	(NP (NP (x_1:$\mathrm{NR}_{\downarrow}$)) (x_2:NP_{*})) $\rightarrow x_1\ x_2$
α_3	r_6	(NN zǒngtǒng) $\rightarrow$ President

Figure 3: Matched trees and corresponding rules. Each node in a matched tree is annotated with a span as superscript to facilitate identification. For example, $\mathrm{IP}^{0,8}$ in α_1 indicates that $\mathrm{IP}_{0,8}$ in Figure 2 is matched. Note that its left child $\mathrm{NP}^{2,3}$ is not its direct descendant in Figure 2, suggesting that adjoining is required at this site.

Figure 4: Converting a derivation forest to a translation forest. In a derivation forest, a node in a derivation forest is a matched elementary tree. A hyperedge corresponds to operations on related trees: substitution (dashed) or adjoining (solid). We use Gorn addresses as tree addresses. $\alpha_2(1.1)$ denotes that α_2 is substituted in the tree α_1 at the node $\mathrm{NR}^{2,3}_{\downarrow}$ of address 1.1 (i.e., the first child of the first child of the root node). As translation forest only supports substitution, we combine trees with adjoining sites to form an equivalent tree without adjoining sites. Rules are composed accordingly (e.g., $r_1 + r_4$).

adjoining. Therefore, we divide forest rescoring for STAG into three steps:

1. **matching**, matching STAG rules against the input tree to obtain a TAG derivation forest;

2. **conversion**, converting the TAG derivation forest into a translation forest;

3. **intersection**, intersecting the translation forest with an n-gram language model.

Given a tree-to-string rule, rule matching is to find a subtree of the input tree that is identical to the source side of the rule. While matching STSG rules against a derived tree is straightforward, it is somewhat non-trivial for STAG rules that move beyond nodes of a local tree. We follow Liu et al. (2006) to enumerate all elementary subtrees and match STAG rules against these subtrees. This can be done by first enumerating all minimal initial and auxiliary trees and then combining them to obtain composed trees, assuming that every node in the input tree is frontier (see Section 3). We impose the same restrictions on the tree height and length as in rule extraction. Figure 3 shows some matched trees and corresponding rules. Each node in a matched tree is annotated with a span as superscript to facilitate identification. For example, $\text{IP}^{0,8}$ in α_1 means that $\text{IP}_{0,8}$ in Figure 2 is matched. Note that its left child $\text{NP}^{2,3}$ is not its direct descendant in Figure 2, suggesting that adjoining is required at this site.

A **TAG derivation tree** specifies uniquely how a derived tree is constructed using elementary trees (Joshi, 1985). A node in a derivation tree is an elementary tree and an edge corresponds to operations on related elementary trees: substitution or adjoining. We introduce **TAG derivation forest**, a compact representation of multiple TAG derivation trees, to encodes all matched TAG derivation trees of the input derived tree.

Figure 4 shows part of a TAG derivation forest. The six matched elementary trees are nodes in the derivation forest. Dashed and solid lines represent substitution and adjoining, respectively. We use Gorn addresses as tree addresses: 0 is the address of the root node, p is the address of the p^{th} child of the root node, and $p \cdot q$ is the address of the q^{th} child of the node at the address p. The derivation forest should be interpreted as follows: α_2 is substituted in the tree α_1 at the node $\text{NR}^{2,3}_{\downarrow}$ of address 1.1 (i.e., the first child of the first child of the root node) and β_1 is adjoined in the tree α_1 at the node $\text{NP}^{2,3}$ of address 1.

To take advantage of existing decoding techniques, it is necessary to convert a derivation forest to a **translation forest**. A hyperedge in a translation forest corresponds to a translation rule. Mi et al. (2008) describe how to convert a derived tree to a translation forest using tree-to-string rules only allowing for substitution. Unfortunately, it is not straightforward to convert a derivation forest including adjoining to a translation forest. To alleviate this problem, we combine initial rules with adjoining sites and associated auxiliary rules to form *equivalent* initial rules without adjoining sites on the fly during decoding.

Consider α_1 in Figure 3. It has an adjoining site $\text{NP}^{2,3}$. Adjoining β_2 in α_1 at the node $\text{NP}^{2,3}$ produces an equivalent initial tree with only substitution sites:

$$(\text{IP}^{0,8} (\text{NP}^{0,3} (\text{NP}^{0,2}_{\downarrow}) (\text{NP}^{2,3} (\text{NR}^{2,3}_{\downarrow}))) (\text{VP}^{3,8}_{\downarrow}))$$

The corresponding composed rule $r_1 + r_4$ has no adjoining sites and can be added to translation forest.

We define that the elementary trees needed to be composed (e.g., α_1 and β_2) form a **composition tree** in a derivation forest. A node in a composition tree is a matched elementary tree and an edge corresponds to adjoining operations. The root node must be an initial tree with at least one adjoining site. The descendants of the root node must all be auxiliary trees. For example, (α_1 (β_2)) and (α_1 (β_1 (β_3))) are two composition trees in Figure 4. The number of children of a node in a composition tree depends on the number of adjoining sites in the node. We use **composition forest** to encode all possible composition trees.

Often, a node in a composition tree may have multiple matched rules. As a large amount of composition trees and composed rules can be identified and constructed on the fly during forest conversion, we used *cube pruning* (Chiang, 2007; Huang and Chiang, 2007) to achieve a balance between translation quality and decoding efficiency.

5 Evaluation

We evaluated our adjoining tree-to-string translation system on Chinese-English translation. The bilingual corpus consists of 1.5M sentences with 42.1M Chinese words and 48.3M English words. The Chinese sentences in the bilingual corpus were parsed by an in-house parser. To maintain a reasonable grammar size, we follow Liu et al. (2006) to restrict that the height of a rule tree is no greater than 3 and the surface string's length is no greater than 7. After running GIZA++ (Och and Ney, 2003) to obtain word alignment, our rule extraction algorithm extracted 23.0M initial rules without adjoining sites, 6.6M initial rules with adjoining sites, and 5.3M auxiliary rules. We used the SRILM toolkit (Stolcke, 2002) to train a 4-gram language model on the Xinhua portion of the GIGAWORD corpus, which contains 238M English words. We used the 2002 NIST MT Chinese-English test set as the development set and the 2003-2005 NIST test sets as the test sets. We evaluated translation quality using the BLEU metric, as calculated by mteval-v11b.pl with *case-insensitive* matching of n-grams.

Table 2 shows top-10 phrase categories of foot nodes and their average occurrences in training corpus. We find that VP (verb phrase) is most likely to be the label of a foot node in an auxiliary rule. On average, there are 12.4 nodes labeled with VP are identical to one of its ancestors per tree. NP and IP are also found to be foot node labels frequently. Figure 4 shows the average occurrences of foot node labels VP, NP, and IP over various distances. A distance is the difference of levels between a foot node and the root node. For example, in Figure 2, the distance between $\text{NP}_{0,1}$ and $\text{NP}_{0,3}$ is 2 and the distance between $\text{VP}_{6,8}$ and $\text{VP}_{3,8}$ is 1. As most foot nodes are usually very close to the root nodes, we restrict that a foot node must be the direct descendant of the root node in our experiments.

Moses	-	33.10	33.96	32.17
hierarchical	SCFG	33.40	34.65	32.88
tree-to-string	STSG	33.13	34.55	31.94
	STAG	33.64	**35.28**	**32.71**

Table 3: BLEU scores on NIST Chinese-English test sets. Scores marked in bold are significantly better that those of STSG at $pl.01$ level.

Table 3 shows the BLEU scores on the NIST Chinese-English test sets. Our baseline system is the tree-to-string system using STSG (Liu et al., 2006; Huang et al., 2006). The STAG system outperforms the STSG system significantly on the MT04 and MT05 test sets at $pl.01$ level. Table 3 also gives the results of Moses (Koehn et al., 2007) and an in-house hierarchical phrase-based system (Chiang, 2007). Our STAG system achieves comparable performance with the hierarchical system. The absolute improvement of +0.7 BLEU over STSG is close to the finding of DeNeefe and Knight (2009) on string-to-tree translation. We feel that one major obstacle for achieving further improvement is that composed rules generated on the fly during decoding (e.g., $r_1 + r_3 + r_5$ in Figure 4) usually have too many non-terminals, making cube pruning in the in-

	STSG	STAG
matching	0.086	0.109
conversion	0.000	0.562
intersection	0.946	1.064
other	0.012	0.028
total	1.044	1.763

Table 4: Comparison of average decoding time.

tersection phase suffering from severe search errors (only a tiny fraction of the search space can be explored). To produce the 1-best translations on the MT05 test set that contains 1,082 sentences, while the STSG system used 40,169 initial rules without adjoining sites, the STAG system used 28,046 initial rules without adjoining sites, 1,057 initial rules with adjoining sites, and 1,527 auxiliary rules.

Table 4 shows the average decoding time on the MT05 test set. While rule matching for STSG needs 0.086 second per sentence, the matching time for STAG only increases to 0.109 second. For STAG, the conversion of derivation forests to translation forests takes 0.562 second when we restrict that at most 200 rules can be generated on the fly for each node. As we use cube pruning, although the translation forest of STAG is bigger than that of STSG, the intersection time barely increases. In total, the STAG system runs in 1.763 seconds per sentence, only 1.6 times slower than the baseline system.

6 Conclusion

We have presented a new tree-to-string translation system based on synchronous TAG. With translation rules learned from Treebank-style trees, the adjoining tree-to-string system outperforms the baseline system using STSG without significant loss in efficiency. We plan to introduce left-to-right target generation (Huang and Mi, 2010) into the STAG tree-to-string system. Our work can also be extended to forest-based rule extraction and decoding (Mi et al., 2008; Mi and Huang, 2008). It is also interesting to introduce STAG into tree-to-tree translation (Zhang et al., 2008; Liu et al., 2009; Chiang, 2010).

Abstract

In this paper, with a belief that a language model that embraces a larger context provides better prediction ability, we present two extensions to standard n-gram language models in statistical machine translation: a backward language model that augments the conventional forward language model, and a mutual information trigger model which captures long-distance dependencies that go beyond the scope of standard n-gram language models. We integrate the two proposed models into phrase-based statistical machine translation and conduct experiments on large-scale training data to investigate their effectiveness. Our experimental results show that both models are able to significantly improve translation quality and collectively achieve up to 1 BLEU point over a competitive baseline.

1 Introduction

Language model is one of the most important knowledge sources for statistical machine translation (SMT) (Brown et al., 1993). The standard n-gram language model (Goodman, 2001) assigns probabilities to hypotheses in the target language conditioning on a context history of the preceding $n-1$ words. Along with the efforts that advance translation models from word-based paradigm to syntax-based philosophy, in recent years we have also witnessed increasing efforts dedicated to extend standard n-gram language models for SMT. We roughly categorize these efforts into two directions: data-volume-oriented and data-depth-oriented.

In the first direction, more data is better. In order to benefit from monolingual corpora (LDC news data or news data collected from web pages) that consist of billions or even trillions of English words, huge language models are built in a distributed manner (Zhang et al., 2006; Brants et al., 2007). Such language models yield better translation results but at the cost of huge storage and high computation.

The second direction digs deeply into monolingual data to build linguistically-informed language models. For example, Charniak et al. (2003) present a syntax-based language model for machine translation which is trained on syntactic parse trees. Again, Shen et al. (2008) explore a dependency language model to improve translation quality. To some extent, these syntactically-informed language models are consistent with syntax-based translation models in capturing long-distance dependencies.

In this paper, we pursue the second direction without resorting to any linguistic resources such as a syntactic parser. With a belief that a language model that embraces a larger context provides better prediction ability, we learn additional information from training data to enhance conventional n-gram language models and extend their ability to capture richer contexts and long-distance dependencies. In particular, we integrate backward n-grams and mutual information (MI) triggers into language models in SMT.

In conventional n-gram language models, we look at the preceding $n-1$ words when calculating the probability of the current word. We henceforth call the previous $n-1$ words plus the current word as **forward n-grams** and a language model built

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1288–1297,
Portland, Oregon, June 19-24, 2011.

on forward n-grams as forward n-gram language model. Similarly, **backward n-grams** refer to the succeeding $n-1$ words plus the current word. We train a backward n-gram language model on backward n-grams and integrate the forward and backward language models together into the decoder. In doing so, we attempt to capture both the preceding and succeeding contexts of the current word.

Different from the backward n-gram language model, the MI trigger model still looks at previous contexts, which however go beyond the scope of forward n-grams. If the current word is indexed as w_i, the farthest word that the forward n-gram includes is w_{i-n+1}. However, the MI triggers are capable of detecting dependencies between w_i and words from w_1 to w_{i-n}. By these triggers ($\{w_k \rightarrow w_i\}, 1 \leq k \leq i-n$), we can capture long-distance dependencies that are outside the scope of forward n-grams.

We integrate the proposed backward language model and the MI trigger model into a state-of-the-art phrase-based SMT system. We evaluate the effectiveness of both models on Chinese-to-English translation tasks with large-scale training data. Compared with the baseline which only uses the forward language model, our experimental results show that the additional backward language model is able to gain about 0.5 BLEU points, while the MI trigger model gains about 0.4 BLEU points. When both models are integrated into the decoder, they collectively improve the performance by up to 1 BLEU point.

The paper is structured as follows. In Section 2, we will briefly introduce related work and show how our models differ from previous work. Section 3 and 4 will elaborate the backward language model and the MI trigger model respectively in more detail, describe the training procedures and explain how the models are integrated into the phrase-based decoder. Section 5 will empirically evaluate the effectiveness of these two models. Section 6 will conduct an in-depth analysis. In the end, we conclude in Section 7.

2 Related Work

Previous work devoted to improving language models in SMT mostly focus on two categories as we mentioned before[1]: large language models (Zhang et al., 2006; Emami et al., 2007; Brants et al., 2007; Talbot and Osborne, 2007) and syntax-based language models (Charniak et al., 2003; Shen et al., 2008; Post and Gildea, 2008). Since our philosophy is fundamentally different from them in that we build contextually-informed language models by using backward n-grams and MI triggers, we discuss previous work that explore these two techniques (backward n-grams and MI triggers) in this section.

Since the context "history" in the backward language model (BLM) is actually the future words to be generated, BLM is normally used in a post-processing where all words have already been generated or in a scenario where sentences are proceeded from the ending to the beginning. Duchateau et al. (2002) use the BLM score as a confidence measure to detect wrongly recognized words in speech recognition. Finch and Sumita (2009) use the BLM in their reverse translation decoder where source sentences are proceeded from the ending to the beginning. Our BLM is different from theirs in that we access the BLM during decoding (rather than after decoding) where source sentences are still proceeded from the beginning to the ending.

Rosenfeld et al. (1994) introduce trigger pairs into a maximum entropy based language model as features. The trigger pairs are selected according to their mutual information. Zhou (2004) also propose an enhanced language model (MI-Ngram) which consists of a standard forward n-gram language model and an MI trigger model. The latter model measures the mutual information of distance-dependent trigger pairs. Our MI trigger model is mostly inspired by the work of these two papers, especially by Zhou's MI-Ngram model (2004). The difference is that our model is distance-independent and, of course, we are interested in an SMT problem rather than a speech recognition one.

Raybaud et al. (2009) use MI triggers in their confidence measures to assess the quality of translation results after decoding. Our method is different from theirs in the MI calculation and trigger pair selection. Mauser et al. (2009) propose bilingual triggers where two source words trigger one target word to

[1]Language model adaptation is not very related to our work so we ignore it.

improve lexical choice of target words. Our analysis (Section 6) show that our monolingual triggers can also help in the selection of target words.

3 Backward Language Model

Given a sequence of words $w_1^m = (w_1...w_m)$, a standard forward n-gram language model assigns a probability $P_f(w_1^m)$ to w_1^m as follows.

$$P_f(w_1^m) = \prod_{i=1}^{m} P(w_i|w_1^{i-1}) \approx \prod_{i=1}^{m} P(w_i|w_{i-n+1}^{i-1}) \quad (1)$$

where the approximation is based on the nth order Markov assumption. In other words, when we predict the current word w_i, we only consider the preceding $n-1$ words $w_{i-n+1}...w_{i-1}$ instead of the whole context history $w_1...w_{i-1}$.

Different from the forward n-gram language model, the backward n-gram language model assigns a probability $P_b(w_1^m)$ to w_1^m by looking at the succeeding context according to

$$P_b(w_1^m) = \prod_{i=1}^{m} P(w_i|w_{i+1}^{m}) \approx \prod_{i=1}^{m} P(w_i|w_{i+1}^{i+n-1}) \quad (2)$$

3.1 Training

For the convenience of training, we invert the order in each sentence in the training data, i.e., from the original order $(w_1...w_m)$ to the reverse order $(w_m...w_1)$. In this way, we can use the same toolkit that we use to train a forward n-gram language model to train a backward n-gram language model without any other changes. To be consistent with training, we also need to reverse the order of translation hypotheses when we access the trained backward language model[2]. Note that the Markov context history of Eq. (2) is $w_{i+n-1}...w_{i+1}$ instead of $w_{i+1}...w_{i+n-1}$ after we invert the order. The words are the same but the order is completely reversed.

3.2 Decoding

In this section, we will present two algorithms to integrate the backward n-gram language model into two kinds of phrase-based decoders respectively: 1) a CKY-style decoder that adopts bracketing transduction grammar (BTG) (Wu, 1997; Xiong et al., 2006) and 2) a standard phrase-based decoder (Koehn et al., 2003). Both decoders translate source sentences from the beginning of a sentence to the ending. Wu (1996) introduce a dynamic programming algorithm to integrate a forward bigram language model with inversion transduction grammar. His algorithm is then adapted and extended for integrating forward n-gram language models into synchronous CFGs by Chiang (2007). Our algorithms are different from theirs in two major aspects

1. The string input to the algorithms is in a reverse order.
2. We adopt a different way to calculate language model probabilities for partial hypotheses so that we can utilize incomplete n-grams.

Before we introduce the integration algorithms, we define three functions $\mathcal{P}$, $\mathcal{L}$, and $\mathcal{R}$ on strings (in a reverse order) over the English terminal alphabet T. The function $\mathcal{P}$ is defined as follows.

$$\mathcal{P}(w_k...w_1) = \underbrace{P(w_k)...P(w_{k-n+2}|w_k...w_{k-n+3})}_{a} \times \underbrace{\prod_{1\le i\le k-n+1} P(w_i|w_{i+n-1}...w_{i+1})}_{b} \quad (3)$$

This function consists of two parts:

- The first part (a) calculates incomplete n-gram language model probabilities for word w_k to w_{k-n+2}. That means, we calculate the unigram probability for w_k ($P(w_k)$), bigram probability for w_{k-1} ($P(w_{k-1}|w_k)$) and so on until we take $n-1$-gram probability for w_{k-n+2} ($P(w_{k-n+2}|w_k...w_{k-n+3})$). This resembles the way in which the forward language model probability in the future cost is computed in the standard phrase-based SMT (Koehn et al., 2003).
- The second part (b) calculates complete n-gram backward language model probabilities for word w_{k-n+1} to w_1.

The function is different from Chiang's p function in that his function p only calculates language model probabilities for the complete n-grams. Since

[2]This is different from the reverse decoding in (Finch and Sumita, 2009) where source sentences are reversed in the order.

we calculate backward language model probabilities during a beginning-to-ending (left-to-right) decoding process, the succeeding context for the current word is either yet to be generated or incomplete in terms of n-grams. The $\mathcal{P}$ function enables us to utilize incomplete succeeding contexts to approximately predict words. Once the succeeding contexts are complete, we can quickly update language model probabilities in an efficient way in our algorithms.

The other two functions $\mathcal{L}$ and $\mathcal{R}$ are defined as follows

$$\mathcal{L}(w_k...w_1) = \begin{cases} w_k...w_{k-n+2}, & \text{if } k \geq n \\ w_k...w_1, & \text{otherwise} \end{cases} \quad (4)$$

$$\mathcal{R}(w_k...w_1) = \begin{cases} w_{n-1}...w_1, & \text{if } k \geq n \\ w_k...w_1, & \text{otherwise} \end{cases} \quad (5)$$

The $\mathcal{L}$ and $\mathcal{R}$ function return the leftmost and rightmost $n-1$ words from a string in a reverse order respectively.

Following Chiang (2007), we describe our algorithms in a deductive system. We firstly show the algorithm[3] that integrates the backward language model into a BTG-style decoder (Xiong et al., 2006) in Figure 1. The item $[A, i, j; l|r]$ indicates that a BTG node A has been constructed spanning from i to j on the source side with the leftmost|rightmost $n-1$ words $l|r$ on the target side. As mentioned before, all target strings assessed by the defined functions ($\mathcal{P}$, $\mathcal{L}$, and $\mathcal{R}$) are in an inverted order (denoted by $\overline{e}$). We only display the backward language model probability for each item, ignoring all other scores such as phrase translation probabilities. The Eq. (8) in Figure 1 shows how we calculate the backward language model probability for the axiom which applies a BTG lexicon rule to translate a source phrase c into a target phrase e. The Eq. (9) and (10) show how we update the backward language model probabilities for two inference rules which combine two neighboring blocks in a straight and inverted order respectively. The fundamental theories behind this update are

$$\mathcal{P}(\overline{e_1 e_2}) = \mathcal{P}(\overline{e_1})\mathcal{P}(\overline{e_2})\frac{\mathcal{P}(\mathcal{R}(\overline{e_2})\mathcal{L}(\overline{e_1}))}{\mathcal{P}(\mathcal{R}(\overline{e_2}))\mathcal{P}(\mathcal{L}(\overline{e_1}))} \quad (6)$$

[3]It can also be easily adapted to integrate the forward n-gram language model.

Function	Value
e_1	$a_1a_2a_3$
e_2	$b_1b_2b_3$
$\mathcal{R}(\overline{e_2})$	b_2b_1
$\mathcal{L}(\overline{e_1})$	a_3a_2
$\mathcal{P}(\mathcal{R}(\overline{e_2}))$	$P(b_2)P(b_1\|b_2)$
$\mathcal{P}(\mathcal{L}(\overline{e_1}))$	$P(a_3)P(a_2\|a_3)$
$\mathcal{P}(\overline{e_1})$	$P(a_3)P(a_2\|a_3)P(a_1\|a_3a_2)$
$\mathcal{P}(\overline{e_2})$	$P(b_3)P(b_2\|b_3)P(b_1\|b_3b_2)$
$\mathcal{P}(\mathcal{R}(\overline{e_2})\mathcal{L}(\overline{e_1}))$	$P(b_2)P(b_1\|b_2)$ $P(a_3\|b_2b_1)P(a_2\|b_1a_3)$
$\mathcal{P}(\overline{e_1e_2})$	$P(b_3)P(b_2\|b_3)P(b_1\|b_3b_2)$ $P(a_3\|b_2b_1)P(a_2\|b_1a_3)P(a_1\|a_3a_2)$

Table 1: Values of $\mathcal{P}$, $\mathcal{L}$, and $\mathcal{R}$ in a 3-gram example .

$$\mathcal{P}(\overline{e_2 e_1}) = \mathcal{P}(\overline{e_1})\mathcal{P}(\overline{e_2})\frac{\mathcal{P}(\mathcal{R}(\overline{e_1})\mathcal{L}(\overline{e_2}))}{\mathcal{P}(\mathcal{R}(\overline{e_1}))\mathcal{P}(\mathcal{L}(\overline{e_2}))} \quad (7)$$

Whenever two strings e_1 and e_2 are concatenated in a straight or inverted order, we can reuse their $\mathcal{P}$ values ($\mathcal{P}(\overline{e_1})$ and $\mathcal{P}(\overline{e_2})$) in terms of dynamic programming. Only the probabilities of boundary words (e.g., $\mathcal{R}(\overline{e_2})\mathcal{L}(\overline{e_1})$ in Eq. (6)) need to be recalculated since they have complete n-grams after the concatenation. Table 1 shows values of $\mathcal{P}$, $\mathcal{L}$, and $\mathcal{R}$ in a 3-gram example which helps to verify Eq. (6). These two equations guarantee that our algorithm can correctly compute the backward language model probability of a sentence stepwise in a dynamic programming framework.[4]

The theoretical time complexity of this algorithm is $\mathcal{O}(m^3|T|^{4(n-1)})$ because in the update parts in Eq. (6) and (7) both the numerator and denominator have up to $2(n-1)$ terminal symbols. This is the same as the time complexity of Chiang's language model integration (Chiang, 2007).

Figure 2 shows the algorithm that integrates the backward language model into a standard phrase-based SMT (Koehn et al., 2003). $\mathcal{V}$ denotes a coverage vector which records source words translated so far. The Eq. (11) shows how we update the backward language model probability for a partial hypothesis when it is extended into a longer hypothesis by a target phrase translating an uncovered source

[4]The start-of-sentence symbol $\langle s \rangle$ and end-of-sentence symbol $\langle /s \rangle$ can be easily added to update the final language model probability when a translation hypothesis covering the whole source sentence is completed.

$$\frac{A \rightarrow c/e}{[A, i, j; \mathcal{L}(\overline{e})|\mathcal{R}(\overline{e})] : \mathcal{P}(\overline{e})} \tag{8}$$

$$\frac{A \rightarrow [A_1, A_2] \quad [A_1, i, k; \mathcal{L}(\overline{e_1})|\mathcal{R}(\overline{e_1})] : \mathcal{P}(\overline{e_1}) \quad [A_2, k+1, j; \mathcal{L}(\overline{e_2})|\mathcal{R}(\overline{e_2})] : \mathcal{P}(\overline{e_2})}{[A, i, j; \mathcal{L}(\overline{e_1 e_2})|\mathcal{R}(\overline{e_1 e_2})] : \mathcal{P}(\overline{e_1})\mathcal{P}(\overline{e_2})\frac{\mathcal{P}(\mathcal{R}(\overline{e_2})\mathcal{L}(\overline{e_1}))}{\mathcal{P}(\mathcal{R}(\overline{e_2}))\mathcal{P}(\mathcal{L}(\overline{e_1}))}} \tag{9}$$

$$\frac{A \rightarrow \langle A_1, A_2 \rangle \quad [A_1, i, k; \mathcal{L}(\overline{e_1})|\mathcal{R}(\overline{e_1})] : \mathcal{P}(\overline{e_1}) \quad [A_2, k+1, j; \mathcal{L}(\overline{e_2})|\mathcal{R}(\overline{e_2})] : \mathcal{P}(\overline{e_2})}{[A, i, j; \mathcal{L}(\overline{e_2 e_1})|\mathcal{R}(\overline{e_2 e_1})] : \mathcal{P}(\overline{e_1})\mathcal{P}(\overline{e_2})\frac{\mathcal{P}(\mathcal{R}(\overline{e_1})\mathcal{L}(\overline{e_2}))}{\mathcal{P}(\mathcal{R}(\overline{e_1}))\mathcal{P}(\mathcal{L}(\overline{e_2}))}} \tag{10}$$

Figure 1: Integrating the backward language model into a BTG-style decoder.

$$\frac{[\mathcal{V}; \mathcal{L}(\overline{e_1})] : \mathcal{P}(\overline{e_1}) \quad c/e_2 : \mathcal{P}(\overline{e_2})}{[\mathcal{V}'; \mathcal{L}(\overline{e_1 e_2})] : \mathcal{P}(\overline{e_1})\mathcal{P}(\overline{e_2})\frac{\mathcal{P}(\mathcal{R}(\overline{e_2})\mathcal{L}(\overline{e_1}))}{\mathcal{P}(\mathcal{R}(\overline{e_2}))\mathcal{P}(\mathcal{L}(\overline{e_1}))}} \tag{11}$$

segment. This extension on the target side is similar to the monotone combination of Eq. (9) in that a newly translated phrase is concatenated to an early translated sequence.

4 MI Trigger Model

It is well-known that long-distance dependencies between words are very important for statistical language modeling. However, n-gram language models can only capture short-distance dependencies within an n-word window. In order to model long-distance dependencies, previous work such as (Rosenfeld et al., 1994) and (Zhou, 2004) exploit trigger pairs. A trigger pair is defined as an ordered 2-tuple (x, y) where word x occurs in the preceding context of word y. It can also be denoted in a more visual manner as $x \rightarrow y$ with x being the trigger and y the triggered word[5].

We use pointwise mutual information (PMI) (Church and Hanks, 1990) to measure the strength of the association between x and y, which is defined as follows

$$PMI(x, y) = \log(\frac{P(x, y)}{P(x)P(y)}) \tag{12}$$

[5]In this paper, we require that word x and y occur in the same sentence.

Zhou (2004) proposes a new language model enhanced with MI trigger pairs. In his model, the probability of a given sentence w_1^m is approximated as

$$P(w_1^m) \approx (\prod_{i=1}^{m} P(w_i|w_{i-n+1}^{i-1})) \times \prod_{i=n+1}^{m} \prod_{k=1}^{i-n} \exp(PMI(w_k, w_i, i-k-1)) \tag{13}$$

There are two components in his model. The first component is still the standard n-gram language model. The second one is the MI trigger model which multiples all exponential PMI values for trigger pairs where the current word is the triggered word and all preceding words outside the n-gram window of the current word are triggers. Note that his MI trigger model is distance-dependent since trigger pairs (w_k, w_i) are sensitive to their distance $i-k-1$ (zero distance for adjacent words). Therefore the distance between word x and word y should be taken into account when calculating their PMI.

In this paper, for simplicity, we adopt a distance-independent MI trigger model as follows

$$MI(w_1^m) = \prod_{i=n+1}^{m} \prod_{k=1}^{i-n} \exp(PMI(w_k, w_i)) \tag{14}$$

We integrate the MI trigger model into the log-linear model of machine translation as an additional knowledge source which complements the standard n-gram language model in capturing long-distance dependencies. By MERT (Och, 2003), we are even able to tune the weight of the MI trigger model against the weight of the standard n-gram language model while Zhou (2004) sets equal weights for both models.

4.1 Training

We can use the maximum likelihood estimation method to calculate PMI for each trigger pair by taking counts from training data. Let $C(x, y)$ be the co-occurrence count of the trigger pair (x, y) in the training data. The joint probability of (x, y) is calculated as

$$P(x, y) = \frac{C(x, y)}{\sum_{x,y} C(x, y)} \tag{15}$$

The marginal probabilities of x and y can be deduced from the joint probability as follows

$$P(x) = \sum\nolimits_{y} P(x, y) \tag{16}$$

$$P(y) = \sum\nolimits_{x} P(x, y) \tag{17}$$

Since the number of distinct trigger pairs is $\mathcal{O}(|T|^2)$, the question is how to select valuable trigger pairs. We select trigger pairs according to the following three steps

1. The distance between x and y must not be less than $n - 1$. Suppose we use a 5-gram language model and $y = w_i$, then $x \in \{w_1 ... w_{i-5}\}$.

2. $C(x, y) > c$. In all our experiments we set $c = 10$.

3. Finally, we only keep trigger pairs whose PMI value is larger than 0. Trigger pairs whose PMI value is less than 0 often contain stop words, such as "the", "a". These stop words have very large marginal probabilities due to their high frequencies.

4.2 Decoding

The MI trigger model of Eq. (14) can be directly integrated into the decoder. For the standard phrase-based decoder (Koehn et al., 2003), whenever a partial hypothesis is extended by a new target phrase, we can quickly retrieve the pre-computed PMI value for each trigger pair where the triggered word locates in the newly translated target phrase and the trigger is outside the n-word window of the triggered word. It's a little more complicated to integrate the MI trigger model into the CKY-style phrase-based decoder. But we still can handle it by dynamic programming as follows

$$MI(e_1 e_2) = MI(e_1)MI(e_2)MI(e_1 \rightarrow e_2) \tag{18}$$

where $MI(e_1 \rightarrow e_2)$ represents the PMI values in which a word in e_1 triggers a word in e_2. It is defined as follows

$$MI(e_1 \rightarrow e_2) = \prod_{w_i \in e_2} \prod_{\substack{w_k \in e_1 \\ i-k \geq n}} \exp(PMI(w_k, w_i)) \tag{19}$$

5 Experiments

In this section, we conduct large-scale experiments on NIST Chinese-to-English translation tasks to evaluate the effectiveness of the proposed backward language model and MI trigger model in SMT. Our experiments focus on the following two issues:

1. How much improvements can we achieve by separately integrating the backward language model and the MI trigger model into our phrase-based SMT system?

2. Can we obtain a further improvement if we jointly apply both models?

5.1 System Overview

Without loss of generality[6], we evaluate our models in a phrase-based SMT system which adapts bracketing transduction grammars to phrasal translation (Xiong et al., 2006). The log-linear model of this system can be formulated as

$$\begin{aligned} w(\mathcal{D}) =& M_T(r^l_{1..n_l}) \cdot M_R(r^m_{1..n_m})^{\lambda_R} \\ & \cdot P_{fL}(e)^{\lambda_{fL}} \cdot exp(|e|)^{\lambda_w} \end{aligned} \tag{20}$$

where $\mathcal{D}$ denotes a derivation, $r^l_{1..n_l}$ are the BTG lexicon rules which translate source phrases to target phrases, and $r^m_{1..n_m}$ are the merging rules which combine two neighboring blocks into a larger block in a straight or inverted order. The translation model M_T consists of widely used phrase and lexical translation probabilities (Koehn et al., 2003).

[6] We have discussed how to integrate the backward language model and the MI trigger model into the standard phrase-based SMT system (Koehn et al., 2003) in Section 3.2 and 4.2 respectively.

The reordering model M_R predicts the merging order (straight or inverted) by using discriminative contextual features (Xiong et al., 2006). P_{fL} is the standard forward n-gram language model.

If we simultaneously integrate both the backward language model P_{bL} and the MI trigger model MI into the system, the new log-linear model will be formulated as

$$\begin{aligned} w(\mathcal{D}) = & M_T(r_{1..n_l}^l) \cdot M_R(r_{1..n_m}^m)^{\lambda_R} \cdot P_{fL}(e)^{\lambda_{fL}} \\ & \cdot P_{bL}(e)^{\lambda_{bL}} \cdot MI(e)^{\lambda_{MI}} \cdot exp(|e|)^{\lambda_w} \end{aligned} \quad (21)$$

5.2 Experimental Setup

Our training corpora[7] consist of 96.9M Chinese words and 109.5M English words in 3.8M sentence pairs. We used all corpora to train our translation model and smaller corpora without the United Nations corpus to build a maximum entropy based reordering model (Xiong et al., 2006).

To train our language models and MI trigger model, we used the Xinhua section of the English Gigaword corpus (306 million words). Firstly, we built a forward 5-gram language model using the SRILM toolkit (Stolcke, 2002) with modified Kneser-Ney smoothing. Then we trained a backward 5-gram language model on the same monolingual corpus in the way described in Section 3.1. Finally, we trained our MI trigger model still on this corpus according to the method in Section 4.1. The trained MI trigger model consists of 2.88M trigger pairs.

We used the NIST MT03 evaluation test data as the development set, and the NIST MT04, MT05 as the test sets. We adopted the case-insensitive BLEU-4 (Papineni et al., 2002) as the evaluation metric, which uses the shortest reference sentence length for the brevity penalty. Statistical significance in BLEU differences is tested by paired bootstrap re-sampling (Koehn, 2004).

5.3 Experimental Results

The experimental results on the two NIST test sets are shown in Table 2. When we combine the backward language model with the forward language model, we obtain 0.49 and 0.56 BLEU points over the baseline on the MT-04 and MT-05 test set respectively. Both improvements are statistically significant ($p < 0.01$). The MI trigger model also achieves statistically significant improvements of 0.33 and 0.44 BLEU points over the baseline on the MT-04 and MT-05 respectively.

Model	MT-04	MT-05
Forward (Baseline)	35.67	34.41
Forward+Backward	36.16+	34.97+
Forward+MI	36.00+	34.85+
Forward+Backward+MI	36.76+	35.12+

Table 2: BLEU-4 scores (%) on the two test sets for different language models and their combinations. +: better than the baseline ($p < 0.01$).

When we integrate both the backward language model and the MI trigger model into our system, we obtain improvements of 1.09 and 0.71 BLEU points over the single forward language model on the MT-04 and MT-05 respectively. These improvements are larger than those achieved by using only one model (the backward language model or the MI trigger model).

6 Analysis

In this section, we will study more details of the two models by looking at the differences that they make on translation hypotheses. These differences will help us gain some insights into how the presented models improve translation quality.

Table 3 shows an example from our test set. The italic words in the hypothesis generated by using the backward language model (F+B) exactly match the reference. However, the italic words in the baseline hypothesis fail to match the reference due to the incorrect position of the word "decree" (法令). We calculate the forward/backward language model score (the logarithm of language model probability) for the italic words in both the baseline and F+B hypothesis according to the trained language models. The difference in the forward language model score is only 1.58, which may be offset by differences in other features in the log-linear translation model. On the other hand, the difference in the backward language model score is 3.52. This larger difference may guarantee that the hypothesis generated by F+B

Table 4: Translation example from the MT-04 test set, comparing the baseline with the MI trigger model. Both system outputs are not detokenized so that we can see how language model scores are calculated. The underlined words highlight the difference between the enhanced models and the baseline. F+M: forward language model + MI trigger model.

is better enough to be selected as the best hypothesis by the decoder. This suggests that the backward language model is able to provide useful and discriminative information which is complementary to that given by the forward language model.

In Table 4, we present another example to show how the MI trigger model improves translation quality. The major difference in hypotheses of this example is the word choice between "is" and "was". The new system enhanced with the MI trigger model (F+M) selects the former while the baseline selects the latter. The forward language model score for the baseline hypothesis is -26.41, which is higher than the score of the F+M hypothesis -26.67. This could be the reason why the baseline selects the word "was" instead of "is". As can be seen, there is another "is" in the preceding context of the word "was" in the baseline hypothesis. Unfortunately, this word "is" is located just outside the scope of the preceding 5-gram context of "was". The forward 5-gram language model is hence not able to take it into account when calculating the probability of "was". However, this is not a problem for the MI trigger model. Since "is" and "was" rarely co-occur in the same sentence, the PMI value of the trigger pair (is, was)[8] is -1.03 while the PMI value of the trigger pair (is, is) is as high as 0.32. Therefore our MI trigger model selects "is" rather than "was".[9] This example illustrates that the MI trigger model is capable of selecting correct words by using long-distance trigger pairs.

7 Conclusion

We have presented two models to enhance the ability of standard n-gram language models in capturing richer contexts and long-distance dependencies that go beyond the scope of forward n-gram windows. The two models have been integrated into the decoder and have shown to improve a state-of-the-art phrase-based SMT system. The first model is the backward language model which uses backward n-grams to predict the current word. We introduced algorithms that directly integrate the backward language model into a CKY-style and a standard phrase-based decoder respectively. The second model is the MI trigger model that incorporates long-distance trigger pairs into language modeling.

Overall improvements are up to 1 BLEU point on the NIST Chinese-to-English translation tasks with large-scale training data. Further study of the two

[8]Since we remove all trigger pairs whose PMI value is negative, the PMI value of this pair (is, was) is set 0 in practice in the decoder.

[9]The overall MI trigger model scores (the logarithm of Eq. (14)) of the baseline hypothesis and the F+M hypothesis are 2.09 and 2.25 respectively.

models indicates that backward n-grams and long-distance triggers provide useful information to improve translation quality.

In future work, we would like to integrate the backward language model into a syntax-based system in a way that is similar to the proposed algorithm shown in Figure 1. We are also interested in exploring more morphologically- or syntactically-informed triggers. For example, a verb in the past tense triggers another verb also in the past tense rather than the present tense.

Abstract

We propose a novel approach to translating from a morphologically complex language. Unlike previous research, which has targeted word inflections and concatenations, we focus on the pairwise relationship between morphologically related words, which we treat as *potential paraphrases* and handle using paraphrasing techniques at the word, phrase, and sentence level. An important advantage of this framework is that it can cope with derivational morphology, which has so far remained largely beyond the capabilities of statistical machine translation systems. Our experiments translating from Malay, whose morphology is mostly derivational, into English show significant improvements over rivaling approaches based on five automatic evaluation measures (for 320,000 sentence pairs; 9.5 million English word tokens).

1 Introduction

Traditionally, statistical machine translation (SMT) models have assumed that the *word* should be the basic token-unit of translation, thus ignoring any word-internal morphological structure. This assumption can be traced back to the first word-based models of IBM (Brown et al., 1993), which were initially proposed for two languages with limited morphology: French and English. While several significantly improved models have been developed since then, including phrase-based (Koehn et al., 2003), hierarchical (Chiang, 2005), treelet (Quirk et al., 2005), and syntactic (Galley et al., 2004) models, they all preserved the assumption that words should be atomic.

Ignoring morphology was fine as long as the main research interest remained focused on languages with limited (e.g., English, French, Spanish) or minimal (e.g., Chinese) morphology. Since the attention shifted to languages like Arabic, however, the importance of morphology became obvious and several approaches to handle it have been proposed. Depending on the particular language of interest, researchers have paid attention to *word inflections* and *clitics*, e.g., for Arabic, Finnish, and Turkish, or to *noun compounds*, e.g., for German. However, *derivational morphology* has not been specifically targeted so far.

In this paper, we propose a paraphrase-based approach to translating from a morphologically complex language. Unlike previous research, we focus on the pairwise relationship between morphologically related wordforms, which we treat as *potential paraphrases*, and which we handle using paraphrasing techniques at various levels: word, phrase, and sentence level. An important advantage of this framework is that it can cope with various kinds of morphological wordforms, including derivational ones. We demonstrate its potential on Malay, whose morphology is mostly derivational.

The remainder of the paper is organized as follows: Section 2 gives an overview of Malay morphology, Section 3 introduces our paraphrase-based approach to translating from morphologically complex languages, Section 4 describes our dataset and our experimental setup, Section 5 presents and analyses the results, and Section 6 compares our work to previous research. Finally, Section 7 concludes the paper and suggests directions for future work.

2 Malay Morphology and SMT

Malay is an Astronesian language, spoken by about 180 million people. It is official in Malaysia, Indonesia, Singapore, and Brunei, and has two major dialects, sometimes regarded as separate languages, which are mutually intelligible, but occasionally differ in orthography/pronunciation and vocabulary: Bahasa Malaysia (*lit.* 'language of Malaysia') and Bahasa Indonesia (*lit.* 'language of Indonesia').

Malay is an agglutinative language with very rich morphology. Unlike other agglutinative languages such as Finnish, Hungarian, and Turkish, which are rich in both inflectional and derivational forms, Malay morphology is mostly derivational. Inflectionally,[1] Malay is very similar to Chinese: there is no grammatical gender, number, or tense, verbs are not marked for person, etc.

In Malay, new words can be formed by the following three morphological processes:

- **Affixation**, i.e., attaching affixes, which are not words themselves, to a word. These can be prefixes (e.g., *ajar*/'teach' → ***pel****ajar*/'student'), suffixes (e.g., *ajar* → *ajar****an***/'teachings'), circumfixes (e.g., *ajar* → ***peng****ajar****an***/'lesson'), and infixes (e.g., *gigi*/'teeth' → *ge****ri****gi*/'toothed blade'). Infixes only apply to a small number of words and are not productive.

- **Compounding**, i.e., forming a new word by putting two or more existing words together. For example, *kereta*/'car' + *api*/'fire' make *kereta api* and *keretapi* in Bahasa Indonesia and Bahasa Malaysia, respectively, both meaning 'train'. As in English, Malay compounds are written separately, but some stable ones like *kerjasama*/'collaboration' (from *kerja*/'work' and *sama*/'same') are concatenated. Concatenation is also required when a circumfix is applied to a compound, e.g., *ambil alih*/'take over' (*ambil*/'take' + *alih*/'move') is concatenated to form ***peng****ambilalih****an***/'takeover' when targeted by the circumfix *peng-. . .-an*.

- **Reduplication**, i.e., word repetition. In Malay, reduplication requires using a dash. It can be full (e.g., *pelajar-pelajar*/'students'), partial (e.g., *adik-beradik*/'siblings', from *adik*/'younger brother/sister'), and rhythmic (e.g., *gunung-ganang*/'mountains', from the word *gunung*/'mountain').

Malay has very little inflectional morphology, It also has some **clitics**[2], which are not very frequent and are typically spelled concatenated to the preceding word. For example, the politeness marker *lah* can be added to the command *duduk*/'sit down' to yield *duduk****lah***/'please, sit down', and the pronoun *nya* can attach to *kereta* to form *kereta****nya***/'his car'. Note that clitics are not affixes, and clitic attachment is not a word derivation or a word inflection process.

Taken together, affixation, compounding, reduplication, and clitic attachment yield a rich variety of wordforms, which cause data sparseness issues. Moreover, the predominantly derivational nature of Malay morphology limits the applicability of standard techniques such as (1) removing some/all of the source-language inflections, (2) segmenting affixes from the root, and (3) clustering words with the same target translation. For example, if ***pel****ajar*/'student' is an unknown word and lemmatization/stemming reduces it to *ajar*/'teach', would this enable a good translation? Similarly, would segmenting[3] ***pel****ajar* as *peN+ ajar*, i.e., as 'person doing the action' + 'teach', make it possible to generate 'student' (e.g., as opposed to 'teacher')? Finally, if affixes tend to change semantics so much, how likely are we to find morphologically related wordforms that share the same translation? Still, there are many good reasons to believe that morphological processing should help SMT for Malay.

Consider *affixation*, which can yield words with similar semantics that can use each other's translation options, e.g., ***di****ajar*/'be taught (intransitive)' and ***di****ajarkan*/'be taught (transitive)'. However, this cannot be predicted from the affix, e.g., compare *minum*/'drink (verb)' – *minum****an***/'drink (noun)' and *makan*/'eat' – *makan****an***/'food'.

[1] *Inflection* is variation in the form of a word that is obligatory in some given grammatical context. For example, *plays, playing, played* are all inflected forms of the verb *play*. It does not yield a new word and cannot change the part of speech.

[2] A *clitic* is a morpheme that has the syntactic characteristics of a word, but is phonologically bound to another word. For example, *'s* is a clitic in *The Queen of England's crown*.

[3] The prefix *peN* suffers a nasal replacement of the archiphoneme *N* to become *pel* in *pelajar*.

Looking at *compounding*, it is often the case that the semantics of a compound is a specialization of the semantics of its head, and thus the target language translations available for the head could be usable to translate the whole compound, e.g., compare *kerjasama*/'collaboration' and *kerja*/'work'. Alternatively, it might be useful to consider a segmented version of the compound, e.g., *kerja sama*.

Reduplication, among other functions, expresses plural, e.g., *pelajar-pelajar*/'students'. Note, however, that it is not used when a quantity or a number word is present, e.g., *dua pelajar*/'two students' and *banyak pelajar*/'many students'. Thus, if we do not know how to translate *pelajar-pelajar*, it would be reasonable to consider the translation options for *pelajar* since it could potentially contain among its translation options the plural 'students'.

Finally, consider *clitics*. In some cases, a clitic could express a fine-grained distinction such as politeness, which might not be expressible in the target language; thus, it might be feasible to simply remove it. In other cases, e.g., when it is a pronoun, it might be better to segment it out as a separate word.

3 Method

We propose a *paraphrase-based approach* to Malay morphology, where we use paraphrases at three different levels: word, phrase, and sentence level.

First, we transform each development/testing Malay sentence into a *word lattice*, where we add simplified *word-level paraphrasing* alternatives for each morphologically complex word. In the lattice, each alternative w' of an original word w is assigned the weight of $\Pr(w'|w)$, which is estimated using pivoting over the English side of the training bi-text. Then, we generate *sentence-level paraphrases* of the training Malay sentences, in which exactly one morphologically complex word is substituted by a simpler alternative. Finally, we extract additional Malay phrases from these sentences, which we use to augment the phrase table with additional translation options to match the alternative wordforms in the lattice. We assign each such additional phrase p' a probability $\max_p \Pr(p'|p)$, where p is a Malay phrase that is found in the original training Malay text. The probability is calculated using *phrase-level pivoting* over the English side of the training bi-text.

3.1 Morphological Analysis

Given a Malay word, we build a list of morphologically simpler words that could be derived from it; we also generate alternative word segmentations:

(a) words obtainable by affix stripping
e.g., *pelajaran* → *pelajar*, *ajaran*, *ajar*

(b) words that are part of a compound word
e.g., *kerjasama* → *kerja*

(c) words appearing on either side of a dash
e.g., *adik-beradik* → *adik*, *beradik*

(d) words without clitics
e.g., *keretanya* → *kereta*

(e) clitic-segmented word sequences
e.g., *keretanya* → *kereta nya*

(f) dash-segmented wordforms
e.g., *aceh-nias* → *aceh - nias*

(g) combinations of the above.

The list is built by reversing the basic morphological processes in Malay: (a) addresses affixation, (b) handles compounding, (c) takes care of reduplication, and (d) and (e) deal with clitics. Strictly speaking, (f) does not necessarily model a morphological process: it proposes an alternative tokenization, but this could make morphological sense too.

Note that (g) could cause potential problems when interacting with (f), e.g., *adik-beradik* would become *adik - beradik* and then by (a) it would turn into *adik - adik*, which could cause the SMT system to generate two separate translations for the two instances of *adik*. To prevent this, we forbid the application of (f) to reduplications. Taking into account that reduplications can be partial, we only allow (f) if $\frac{|LCS(l,r)|}{\min(|l|,|r|)} < 0.5$, where l and r are the strings to the left and to the right of the dash, respectively, $LCS(x, y)$ is the longest common character subsequence, not necessarily consecutive, of the strings x and y, and $|x|$ is the length of the string x. For example, LCS(*adik*,*beradik*)=*adik*, and thus, the ratio is 1 (≥ 0.5) for *adik-beradik*. Similarly, LCS(*gunung*,*ganang*)=*gnng*, and thus, the ratio is 4/6=0.67 (≥ 0.5) for *gunung-ganang*. However, for *aceh-nias*, it is 1/4=0.25, and thus (f) is applicable.

As an illustration, here are the wordforms we generate for *adik-beradiknya*/'his siblings': *adik*, *adik-beradiknya*, *adik-beradik nya*, *adik-beradik*, *beradiknya*, *beradik nya*, *adik nya*, and *beradik*. And for *berpelajaran*/'is educated', we build the list: *berpelajaran*, *pelajaran*, *pelajar*, *ajaran*, and *ajar*. Note that the lists do include the original word.

To generate the above wordforms, we used two morphological analyzers: a freely available Malay lemmatizer (Baldwin and Awab, 2006), and an in-house re-implementation of the Indonesian stemmer described in (Adriani et al., 2007). Note that these tools' objective is to return a single lemma/stem, e.g., they would return *adik* for *adik-beradiknya*, and *ajar* for *berpelajaran*. However, it was straightforward to modify them to also output the above intermediary wordforms, which the tools were generating internally anyway when looking for the final lemma/stem. Finally, since the two modified analyzers had different strengths and weaknesses, we combined their outputs to increase recall.

3.2 Word-Level Paraphrasing

We perform word-level paraphrasing of the Malay sides of the development and the testing bi-texts.

First, for each Malay word, we generate the above-described list of morphologically simpler words and alternative word segmentations; we think of the words in this list as *word-level paraphrases*. Then, for each development/testing Malay sentence, we generate a lattice encoding all possible paraphrasing options for each individual word.

We further specify a weight for each arc. We assign 1 to the original Malay word w, and $\Pr(w'|w)$ to each paraphrase w' of w, where $\Pr(w'|w)$ is the probability that w' is a *good paraphrase* of w. Note that multi-word paraphrases, e.g., resulting from clitic segmentation, are encoded using a sequence of arcs; in such cases, we assign $\Pr(w'|w)$ to the first arc, and 1 to each subsequent arc.

We calculate the probability $\Pr(w'|w)$ using the training Malay-English bi-text, which we align at the word level using IBM model 4 (Brown et al., 1993), and we observe which English words w and w' are aligned to. More precisely, we use *pivoting* to estimate the probability $\Pr(w'|w)$ as follows:

$$\Pr(w'|w) = \sum_i \Pr(w'|w, e_i)\Pr(e_i|w)$$

Then, following (Callison-Burch et al., 2006; Wu and Wang, 2007), we make the simplifying assumption that w' is conditionally independent of w given e_i, thus obtaining the following expression:

$$\Pr(w'|w) = \sum_i \Pr(w'|e_i)\Pr(e_i|w)$$

We estimate the probability $\Pr(e_i|w)$ directly from the word-aligned training bi-text as follows:

$$\Pr(e_i|w) = \frac{\#(w,e_i)}{\sum_j \#(w,e_j)}$$

where $\#(x, e)$ is the number of times the Malay word x is aligned to the English word e.

Estimating $\Pr(w'|e_i)$ cannot be done directly since w' might not be present on the Malay side of the training bi-text, e.g., because it is a multi-token sequence generated by clitic segmentation. Thus, we think of w' as a pseudoword that stands for the union of all Malay words in the training bi-text that are reducible to w' by our morphological analysis procedure. So, we estimate $\Pr(w'|e_i)$ as follows:

$$\Pr(w'|e_i) = \Pr(\{v : w' \in forms(v)\}|e_i)$$

where $forms(x)$ is the set of the word-level paraphrases[4] for the Malay word x.

Since the training bi-text occurrences of the words that are reducible to w' are distinct, we can rewrite the above as follows:

$$\Pr(w'|e_i) = \sum_{v:w' \in forms(v)} \Pr(v|e_i)$$

Finally, the probability $\Pr(v|e_i)$ can be estimated using maximum likelihood:

$$\Pr(v|e_i) = \frac{\#(v,e_i)}{\sum_u \#(u,e_i)}$$

3.3 Sentence-Level Paraphrasing

In order for the word-level paraphrases to work, there should be phrases in the phrase table that could potentially match them. For some of the words, e.g., the lemmata, there could already be such phrases, but for other transformations, e.g., clitic segmentation, this is unlikely. Thus, we need to augment the phrase table with additional translation options.

One approach would be to modify the phrase table directly, e.g., by adding additional entries, where one or more Malay words are replaced by their paraphrases. This would be problematic since the phrase translation probabilities associated with these new

[4]Note that our paraphrasing process is directed: the paraphrases are morphologically simpler than the original word.

entries would be hard to estimate. For example, the clitics, and even many of the intermediate morphological forms, would not exist as individual words in the training bi-text, which means that there would be no word alignments or lexical probabilities available for them.

Another option would be to generate separate word alignments for the original training bi-text and for a version of it where the source (Malay) side has been paraphrased. Then, the two bi-texts and their word alignments would be concatenated and used to build a phrase table (Dyer, 2007; Dyer et al., 2008; Dyer, 2009). This would solve the problems with the word alignments and the phrase pair probabilities estimations in a principled manner, but it would require choosing for each word only one of the paraphrases available to it, while we would prefer to have a way to allow all options. Moreover, the paraphrased and the original versions of the corpus would be given equal weights, which might not be desirable. Finally, since the two versions of the bi-text would be word-aligned separately, there would be no interaction between them, which might lead to missed opportunities for improved alignments in both parts of the bi-text (Nakov and Ng, 2009).

We avoid the above issues by adopting a sentence-level paraphrasing approach. Following the general framework proposed in (Nakov, 2008), we first create multiple paraphrased versions of the source-side sentences of the training bi-text. Then, each paraphrased source sentence is paired with its original translation. This augmented bi-text is word-aligned and a phrase table T' is built from it, which is merged with a phrase table T for the original bi-text. The merged table contains all phrase entries from T, and the entries for the phrase pairs from T' that are not in T. Following Nakov and Ng (2009), we add up to three additional indicator features (taking the values 0.5 and 1) to each entry in the merged phrase table, showing whether the entry came from (1) T only, (2) T' only, or (3) both T and T'. We also try using the first one or two features only. We set all feature weights using minimum error rate training (Och, 2003), and we optimize their number (one, two, or three) on the development dataset.[5]

[5]In theory, we should re-normalize the probabilities; in practice, this is not strictly required by the log-linear SMT model.

Each of our paraphrased sentences differs from its original sentence by a single word, which prevents combinatorial explosions: on average, we generate 14 paraphrased versions per input sentence. It further ensures that the paraphrased parts of the sentences will not dominate the word alignments or the phrase pairs, and that there would be sufficient interaction at word alignment time between the original sentences and their paraphrased versions.

3.4 Phrase-Level Paraphrasing

While our sentence-level paraphrasing informs the decoder about the origin of each phrase pair (original or paraphrased bi-text), it provides no indication about how good the phrase pairs from the paraphrased bi-text are likely to be.

Following Callison-Burch et al. (2006), we further augment the phrase table with one additional feature whose value is 1 for the phrase pairs coming from the original bi-text, and $\max_p \Pr(p'|p)$ for the phrase pairs extracted from the paraphrased bi-text. Here p is a Malay phrase from T, and p' is a Malay phrase from T' that does not exist in T but is obtainable from p by substituting one or more words in p with their derivationally related forms generated by morphological analysis. The probability $\Pr(p'|p)$ is calculated using phrase-level pivoting through English in the original phrase table T as follows (unlike word-level pivoting, here e_i is an English *phrase*):

$$\Pr(p'|p) = \sum_i \Pr(p'|e_i)\Pr(e_i|p)$$

We estimate the probabilities $\Pr(e_i|p)$ and $\Pr(p'|e_i)$ as we did for word-level pivoting, except that this time we use the list of the phrase pairs extracted from the original training bi-text, while before we used IBM model 4 word alignments. When calculating $\Pr(p'|e_i)$, we think of p' as the set of all possible Malay phrases q in T that are reducible to p' by morphological analysis of the words they contain. This can be rewritten as follows:

$$\Pr(p'|e_i) = \sum_{q:p' \in par(q)} \Pr(q|e_i)$$

where $par(q)$ is the set of all possible phrase-level paraphrases for the Malay phrase q.

The probability $\Pr(q|e_i)$ is estimated using maximum likelihood from the list of phrase pairs. There is no combinatorial explosion here, since the phrases are short and contain very few paraphrasable words.

4 Experiments

4.1 Data

We created our Malay-English training and development datasets from data that we downloaded from the Web and then sentence-aligned using various heuristics. Thus, we ended up with 350,003 *training* sentence pairs, including 10.4M English and 9.7M Malay word tokens. We further downloaded 49.8M word tokens of monolingual English text, which we used for *language modeling*.

For *testing*, we used 1,420 sentences with 28.8K Malay word tokens, which were translated by three human translators, yielding translations of 32.8K, 32.4K, and 32.9K English word tokens, respectively. For *development*, we used 2,000 sentence pairs of 63.4K English and 58.5K Malay word tokens.

4.2 General Experimental Setup

First, we tokenized and lowercased all datasets: training, development, and testing. We then built directed word-level alignments for the training bitext for English→Malay and for Malay→English using IBM model 4 (Brown et al., 1993), which we symmetrized using the intersect+grow heuristic (Och and Ney, 2003). Next, we extracted phrase-level translation pairs of maximum length seven, which we scored and used to build a phrase table where each phrase pair is associated with the following five standard feature functions: forward and reverse phrase translation probabilities, forward and reverse lexicalized phrase translation probabilities, and phrase penalty.

We trained a log-linear model using the following standard SMT feature functions: trigram language model probability, word penalty, distance-based distortion cost, and the five feature functions from the phrase table. We set all weights on the development dataset by optimizing BLEU (Papineni et al., 2002) using minimum error rate training (Och, 2003), and we plugged them in a beam search decoder (Koehn et al., 2007) to translate the Malay test sentences to English. Finally, we detokenized the output, and we evaluated it against the three reference translations.

4.3 Systems

Using the above general experimental setup, we implemented the following baseline systems:

- **baseline**. This is the default system, which uses no morphological processing.
- **lemmatize all**. This is the second baseline that uses lemmatized versions of the Malay side of the training, development and testing datasets.
- **'noisier' channel model**.[6] This is the model of Dyer (2007). It uses 0-1 weights in the lattice and only allows lemmata as alternative word-forms; it uses no sentence-level or phrase-level paraphrases.

[6]We also tried the word segmentation model of Dyer (2009) as implemented in the *cdec* decoder (Dyer et al., 2010), which learns word segmentation lattices from raw text in an unsupervised manner. Unfortunately, it could not learn meaningful word segmentations for Malay, and thus we do not compare against it. We believe this may be due to its focus on word segmentation, which is of limited use for Malay.

Table 3: **Results for different evaluation measures:** for *baseline* and *lattice + sent-par + word-par + phrase-par* (in % for all measures except for NIST).

Our full morphological paraphrasing system is **lattice + sent-par + word-par + phrase-par**. We also experimented with some of its components turned off. **lattice + sent-par + word-par** excludes the additional feature from phrase-level paraphrasing. **lattice + sent-par** has all the morphologically simpler derived forms in the lattice during decoding, but their weights are uniformly set to 0 rather than obtained using pivoting from word alignments. Finally, in order to compare closely to the 'noisier' channel model, we further limited the morphological variants of **lattice + sent-par** in the lattice to lemmata only in **lattice + sent-par (orig+lemma)**.

5 Results and Discussion

The experimental results are shown in Table 1.

First, we can see that *lemmatize all* has a consistently disastrous effect on BLEU, which shows that Malay morphology does indeed contain information that is important when translating to English.

Second, Dyer (2007)'s *'noisier' channel model* helps for small datasets only. It performs worse than *lattice + sent-par (orig+lemma)*, from which it differs in the phrase table only; this confirms the importance of our sentence-level paraphrasing.

Moving down to *lattice + sent-par*, we can see that using multiple morphological wordforms instead of just lemmata has a consistently positive impact on BLEU for datasets of all sizes.

Adding weights obtained using word-level pivoting in *lattice + sent-par + word-par* helps a bit more, and also using phrase-level paraphrasing weights yields even bigger further improvements for *lattice + sent-par + word-par + phrase-par*.

Overall, our morphological paraphrases yield statistically significant improvements ($p < 0.01$) in BLEU, according to Collins et al. (2005)'s sign test, for bi-texts as large as 320,000 sentence pairs.

A closer look at BLEU. Table 2 shows detailed n-gram BLEU precision scores for n=1,2,3,4. Our system outperforms the baseline on all precision scores and for all numbers of training sentences.

Other evaluation measures. Table 3 reports the results for five evaluation measures: BLEU and NIST 11b, TER 0.7.25 (Snover et al., 2006), METEOR 1.0 (Lavie and Denkowski, 2009), and TESLA (Liu et al., 2010). Our system consistently outperforms the baseline for all measures.

Example translations. Table 4 shows two translation examples. In the first example, the reduplication *bekalan-bekalan* ('supplies') is an unknown word, and was left untranslated by the baseline system. It was not a problem for our system though, which first paraphrased it as *bekalan* and then translated it as *supply*. Even though this is still wrong (we need the plural *supplies*), it is arguably preferable to passing the word untranslated; it also allowed for a better translation of the surrounding context.

src :	Mercy Relief telah menghantar 17 khemah khas bernilai $5,000 setiap satu yang boleh menampung kelas seramai 30 pelajar, selain **bekalan-bekalan lain seperti 500 khemah biasa**, barang makanan dan ubat-ubatan untuk mangsa gempa Sichuan.
ref1:	Mercy Relief has sent 17 special tents valued at $5,000 each, that can accommodate a class of 30 students, including **other aid supplies such as 500 normal tents**, food and medicine for the victims of Sichuan quake.
base:	mercy relief has sent 17 special tents worth $5,000 each class could accommodate a total of 30 students, besides ***other bekalan-bekalan 500 tents as usual***, foodstuff and medicines for sichuan quake relief.
para:	mercy relief has sent 17 special tents worth $5,000 each class could accommodate a total of 30 students, besides **other supply such as 500 tents**, food and medicines for sichuan quake relief.
src :	Walaupun hidup susah, kami tetap berusaha untuk **menjalani kehidupan** seperti biasa.
ref1:	Even though life is difficult, we are still trying to **go through life** as usual.
base:	despite the hard life, we will always strive to ***undergo training*** as usual.
para:	despite the hard life, we will always strive to **live** normal.

Table 4: **Example translations**. For each example, we show a source sentence (src), one of the three reference translations (ref1), and the outputs of *baseline* (base) and of *lattice + sent-par + word-par + phrase-par* (para).

In the second example, the baseline system translated *menjalani kehidupan* (lit. 'go through life') as *undergo training*, because of a bad phrase pair, which was extracted from wrong word alignments. Note that the words *menjalani* ('go through') and *kehidupan* ('life/existence') are derivational forms of *jalan* ('go') and *hidup* ('life/living'), respectively. Thus, in the paraphrasing system, they were involved in sentence-level paraphrasing, where the alignments were improved. While the wrong phrase pair was still available, the system chose a better one from the paraphrased training bi-text.

6 Related Work

Most research in SMT for a morphologically rich **source** language has focused on inflected *forms of the same* word. The assumption is that they would have similar semantics and thus could have the same translation. Researchers have used *stemming* (Yang and Kirchhoff, 2006), *lemmatization* (Al-Onaizan et al., 1999; Goldwater and McClosky, 2005; Dyer, 2007), or *direct clustering* (Talbot and Osborne, 2006) to identify such groups of words and use them as *equivalence classes* or as possible *alternatives* in translation. Frameworks for the simultaneous use of different word-level representations have been proposed as well (Koehn and Hoang, 2007).

A second important line of research has focused on *word segmentation*, which is useful for languages like German, which are rich in *compound words* that are spelled concatenated (Koehn and Knight, 2003; Yang and Kirchhoff, 2006), or like Arabic, Turkish, Finnish, and, to a lesser extent, Spanish and Italian, where *clitics* often attach to the preceding word (Habash and Sadat, 2006). For languages with more or less regular inflectional morphology like Arabic or Turkish, another good idea is to segment words into *morpheme sequences*, e.g., prefix(es)-stem-suffix(es), which can be used instead of the original words (Lee, 2004) or in addition to them. This can be achieved using a lattice input to the translation system (Dyer et al., 2008; Dyer, 2009).

Unfortunately, none of these general lines of research suits Malay well, whose compounds are rarely concatenated, clitics are not so frequent, and morphology is mostly derivational, and thus likely to generate words whose semantics substantially differs from the semantics of the original word. Therefore, we cannot expect the existence of equivalence classes: it is only occasionally that two derivationally related wordforms would share the same target language translation. Thus, instead of looking for equivalence classes, we have focused on the pairwise relationship between derivationally related wordforms, which we treat as *potential paraphrases*.

Our approach is an extension of the *'noisier' channel model* of Dyer (2007). He starts by generating separate word alignments for the original training bi-text and for a version of it where the source side has been lemmatized. Then, the two bi-texts and their word alignments are concatenated and used to build a phrase table. Finally, the source sides of the development and the test datasets are converted into confusion networks where additional arcs are added for word lemmata. The arc weights are set to 1 for the original wordforms and to 0 for the lemmata. In contrast, we provide *multiple* paraphrasing alternatives for each morphologically complex word, including derivational forms that occupy intermediary positions between the original wordform

and its lemma. Note that some of those paraphrasing alternatives are *multi-word*, and thus we use a *lattice* instead of a confusion network. Moreover, we give *different weights* to the different alternatives rather then assigning them all 0.

Second, our work is related to that of Dyer et al. (2008), who use a lattice to add a single alternative clitic-segmented version of the original word for Arabic. However, we provide *multiple* alternatives. We also include *derivational forms* in addition to clitic-segmented ones, and we give *different weights* to the different alternatives (instead of 0).

Third, our work is also related to that of Dyer (2009), who uses a lattice to add multiple alternative segmented versions of the original word for German, Hungarian, and Turkish. However, we focus on *derivational morphology* rather than on clitics and inflections, add *derivational forms* in addition to clitic-segmented ones, and use *cross-lingual word pivoting* to estimate paraphrase probabilities.

Finally, our work is related to that of Callison-Burch et al. (2006), who use cross-lingual pivoting to generate phrase-level paraphrases with corresponding probabilities. However, our paraphrases are derived through *morphological analysis*; thus, we do not need corpora in additional languages.

7 Conclusion and Future Work

We have presented a novel approach to translating from a morphologically complex language, which uses paraphrases and paraphrasing techniques at three different levels of translation: word-level, phrase-level, and sentence-level. Our experiments translating from Malay, whose morphology is mostly derivational, into English have shown significant improvements over rivaling approaches based on several automatic evaluation measures.

In future work, we want to improve the probability estimations for our paraphrasing models. We also want to experiment with other morphologically complex languages and other SMT models.

Abstract

We propose a principled and efficient phrase-to-phrase alignment model, useful in machine translation as well as other related natural language processing problems. In a hidden semi-Markov model, word-to-phrase and phrase-to-word translations are modeled directly by the system. Agreement between two directional models encourages the selection of parsimonious phrasal alignments, avoiding the overfitting commonly encountered in unsupervised training with multi-word units. Expanding the state space to include "gappy phrases" (such as French *ne ⋆ pas*) makes the alignment space more symmetric; thus, it allows agreement between discontinuous alignments. The resulting system shows substantial improvements in both alignment quality and translation quality over word-based Hidden Markov Models, while maintaining asymptotically equivalent runtime.

1 Introduction

Word alignment is an important part of statistical machine translation (MT) pipelines. Phrase tables containing pairs of source and target language phrases are extracted from word alignments, forming the core of phrase-based statistical machine translation systems (Koehn et al., 2003). Most syntactic machine translation systems extract synchronous context-free grammars (SCFGs) from aligned syntactic fragments (Galley et al., 2004; Zollmann et al., 2006), which in turn are derived from bilingual word alignments and syntactic parses. Alignment is also used in various other NLP problems such as entailment, paraphrasing, question answering, summarization and spelling correction.

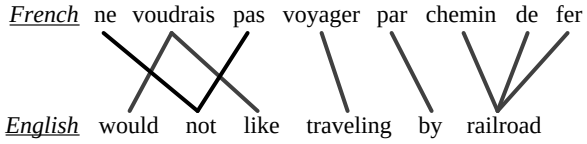

Figure 1: French-English pair with complex word alignment.

A limitation to word-based alignment is undesirable. As seen in the French-English example in Figure 1, many sentence pairs are naturally aligned with multi-word units in both languages (*chemin de fer*; *would ⋆ like*, where ⋆ indicates a gap). Much work has addressed this problem: generative models for direct phrasal alignment (Marcu and Wong, 2002), heuristic word-alignment combinations (Koehn et al., 2003; Och and Ney, 2003), models with pseudo-word collocations (Lambert and Banchs, 2006; Ma et al., 2007; Duan et al., 2010), synchronous grammar based approaches (Wu, 1997), etc. Most have a large state-space, using constraints and approximations for efficient inference.

We present a new phrasal alignment model based on the hidden Markov framework (Vogel et al., 1996). Our approach is semi-Markov: each state can generate multiple observations, representing word-to-phrase alignments. We also augment the state space to include contiguous sequences. This corresponds to phrase-to-word and phrase-to-phrase alignments. We generalize alignment by agreement (Liang et al., 2006) to this space, and find that agreement discourages EM from overfitting. Finally, we make the alignment space more symmetric by including *gappy* (or non-contiguous) phrases. This allows agreement to reinforce non-contiguous align-

Portland, Oregon, June 19-24, 2011.

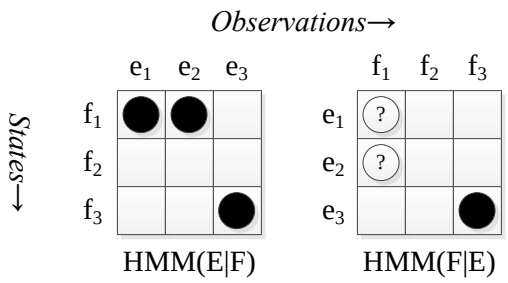

Figure 2: The model of E given F can represent the phrasal alignment $\{e_1, e_2\} \sim \{f_1\}$. However, the model of F given E cannot: the probability mass is distributed between $\{e_1\} \sim \{f_1\}$ and $\{e_2\} \sim \{f_1\}$. Agreement of the forward and backward HMM alignments tends to place less mass on phrasal links and greater mass on word-to-word links.

ments, such English *not* to French *ne ⋆ pas*. Pruning the set of allowed phrases preserves the time complexity of the word-to-word HMM alignment model.

1.1 Related Work

Our first major influence is that of *conditional phrase-based models*. An early approach by Deng and Byrne (2005) changed the parameterization of the traditional word-based HMM model, modeling subsequent words from the same state using a bigram model. However, this model changes only the parameterization and not the set of possible alignments. More closely related are the approaches of Daumé III and Marcu (2004) and DeNero et al. (2006), which allow phrase-to-phrase alignments between the source and target domain. As DeNero warns, though, an unconstrained model may overfit using unusual segmentations. Interestingly, the phrase-based hidden semi-Markov model of Andrés-Ferrer and Juan (2009) does not seem to encounter these problems. We suspect two main causes: first, the model interpolates with Model 1 (Brown et al., 1994), which may help prevent overfitting, and second, the model is monotonic, which screens out many possible alignments. Monotonicity is generally undesirable, though: almost all parallel sentences exhibit some reordering phenomena, even when languages are syntactically very similar.

The second major inspiration is *alignment by agreement* by Liang et al. (2006). Here, soft intersection between the forward (F→E) and backward (E→F) alignments during parameter estimation produces better word-to-word correspondences. This unsupervised approach produced alignments with incredibly low error rates on French-English, though only moderate gains in end-to-end machine translation results. Likely this is because the symmetric portion of the HMM space contains only single word to single word links. As shown in Figure 2, in order to retain the phrasal link $f_1 \sim e_1, e_2$ after agreement, we need the reverse phrasal link $e_1, e_2 \backsim f_1$ in the backward direction. However, this is not possible in a word-based HMM where each observation must be generated by a single state. Agreement tends to encourage 1-to-1 alignments with very high precision and but lower recall. As each word alignment acts as a constraint on phrase extraction, the phrase-pairs obtained from those alignments have high recall and low precision.

2 Gappy Phrasal Alignment

Our goal is to unify phrasal alignment and alignment by agreement. We use a phrasal hidden semi-Markov alignment model, but without the monotonicity requirement of Andrés-Ferrer and Juan (2009). Since phrases may be used in both the state and observation space of both sentences, agreement during EM training no longer penalizes phrasal links such as those in Figure 2. Moreover, the benefits of agreement are preserved: meaningful phrasal links that are likely in both directions of alignment will be reinforced, while phrasal links likely in only one direction will be discouraged. This avoids segmentation problems encountered by DeNero et al. (2006).

Non-contiguous sequences of words present an additional challenge. Even a semi-Markov model with phrases can represent the alignment between English *not* and French *ne ⋆ pas* in one direction only. To make the model more symmetric, we extend the state space to include *gappy phrases* as well.[1] The set of alignments in each model becomes symmetric, though the two directions model gappy phrases differently. Consider *not* and *ne ⋆ pas*: when predicting French given English, the alignment corresponds to generating multiple distinct ob-

[1] We only allow a single gap with one word on each end. This is sufficient for the vast majority of the gapped phenomena that we have seen in our training data.

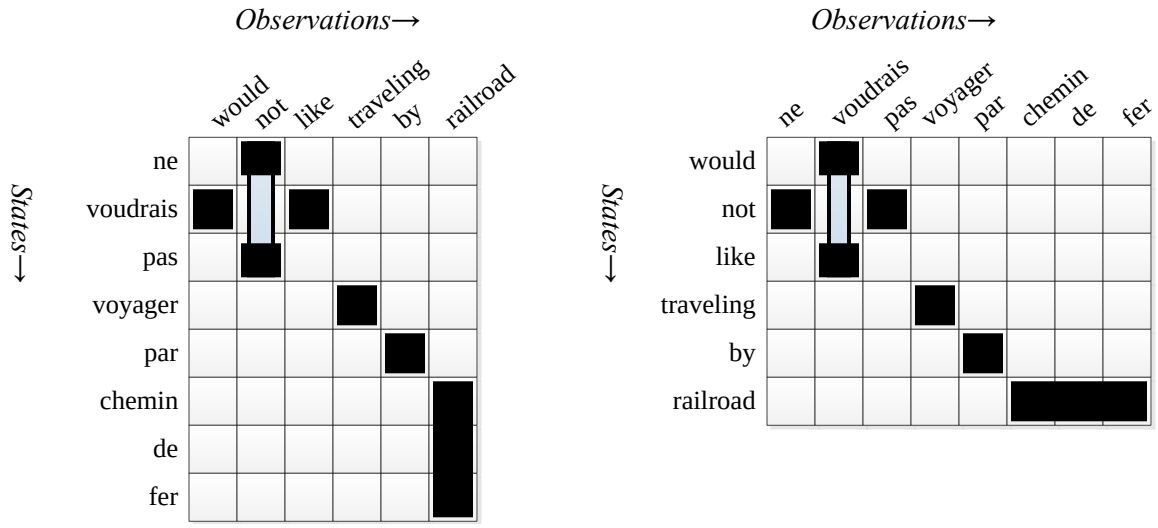

Figure 3: Example English-given-French and French-given-English alignments of the same sentence pair using the Hidden Semi-Markov Model (HSMM) for gapped-phrase-to-phrase alignment. It allows the state side phrases (denoted by vertical blocks), observation side phrases (denoted by horizontal blocks), and state-side gaps (denoted by discontinuous blocks in the same column connected by a hollow vertical "bridge"). Note both directions can capture the desired alignment for this sentence pair.

servations from the same state; in the other direction, the word *not* is generated by a single gappy phrase *ne* ⋆ *pas*. Computing posteriors for agreement is somewhat complicated, so we resort to an approximation described later. Exact inference retains a low-order polynomial runtime; we use pruning to increase speed.

2.1 Hidden Markov Alignment Models

Our model can be seen as an extension of the standard word-based Hidden Markov Model (HMM) used in alignment (Vogel et al., 1996). To ground the discussion, we first review the structure of that model. This generative model has the form $p(O|S) = \sum_A p(A, O|S)$, where $S = (s_1, \ldots, s_I) \in \Sigma^\star$ is a sequence of words from a vocabulary Σ; $O = (o_1, \ldots, o_J) \in \Pi^\star$ is a sequence from vocabulary Π; and $A = (a_1, \ldots, a_J)$ is the alignment between the two sequences. Since some words are systematically inserted during translation, the target (state) word sequence is augmented with a special NULL word. To retain the position of the last aligned word, the state space contains I copies of the NULL word, one for each position (Och and Ney, 2003). The alignment uses positive positions for words and negative positions for NULL states, so $a_j \in \{1..I\} \cup \{-1.. - I\}$, and $s_i = \text{NULL}$ if $i < 0$.

It uses the following generative procedure. First the length of the observation sequence is selected based on $p_l(J|I)$. Then for each observation position, the state is selected based on the prior state: a null state with probability p_0, or a non-null state at position a_j with probability $(1 - p_0) \cdot p_j(a_j|a_{j-1})$ where p_j is a jump distribution. Finally the observation word o_j at that position is generated with probability $p_t(o_j|s_{a_j})$, where p_t is an emission distribution:

$$p(A, O|S) = p_l(J|I) \prod_{j=1}^{J} p_j(a_j|a_{j-1}) p_t(o_j|s_{a_j})$$

$$p_j(a|a') = \begin{cases} (1 - p_0) \cdot p_d(a - |a'|) & a > 0 \\ p_0 \cdot \delta(|a|, |a'|) & a < 0 \end{cases}$$

We pick p_0 using grid search on the development set, p_l is uniform, and the p_j and p_t are optimized by EM.[2]

2.2 Gappy Semi-Markov Models

The HMM alignment model identifies a word-to-word correspondence between the observation

[2]Note that jump distances beyond -10 or 10 share a single parameter to prevent sparsity.

words and the state words. We make two changes to expand this model. First, we allow contiguous phrases on the observation side, which makes the model semi-Markov: at each time stamp, the model may emit more than one observation word. Next, we also allow contiguous and gappy phrases on the state side, leading to an alignment model that can retain phrasal links after agreement (see Section 4).

The S and O random variables are unchanged. Since a single state may generate multiple observation words, we add a new variable K representing the number of states. K should be less than J, the number of observations. The alignment variable is augmented to allow contiguous and non-contiguous ranges of words. We allow only a single gap, but of unlimited length. The null state is still present, and is again represented by negative numbers.

$$\begin{aligned} A =& (a_1, \ldots, a_K) \in \mathcal{A}(I) \\ \mathcal{A}(I) =& \{(i_1, i_2, g) | 0 < i_1 \leq i_2 \leq I, \\ & g \in \{\text{GAP}, \text{CONTIG}\}\} \cup \\ & \{(-i, -i, \text{CONTIG}) \mid 0 < i \leq I\} \end{aligned}$$

We add one more random variable to capture the total number of observations generated by each state.

$$L \in \{(l_0, l_1, \ldots, l_K) \mid 0 = l_0 < \cdots < l_K = J\}$$

The generative model takes the following form:

$$\begin{aligned} p(A, L, O|S) =& p_l(J|I) p_f(K|J) \prod_{k=1}^{K} p_j(a_k|a_{k-1}) \cdot \\ & p_t(l_k, o_{l_{k-1}+1}^{l_k} | S[a_k], l_{k-1}) \end{aligned}$$

First, the length of the observation sequence (J) is selected, based on the number of words in the state-side sentence (I). Since it does not affect the alignment, p_l is modeled as a uniform distribution. Next, we pick the total number of states to use (K), which must be less than the number of observations (J). Short state sequences receive an exponential penalty: $p_f(K|J) \propto \eta^{(J-K)}$ if $0 \leq K \leq J$, or 0 otherwise. A harsh penalty (small positive value of η) may prevent the systematic overuse of phrases.[3]

[3]We found that this penalty was crucial to prevent overfitting in independent training. Joint training with agreement made it basically unnecessary.

Next we decide the assignment of each state. We retain the first-order Markov assumption: the selection of each state is conditioned only on the prior state. The transition distribution is identical to the word-based HMM for single word states. For phrasal and gappy states, we jump into the first word of that state, and out of the last word of that state, and then pay a cost according to how many words are covered within that state. If $a = (i_1, i_2, g)$, then the beginning word of a is $F(a) = i_1$, the ending word is $L(a) = i_2$, and the length $N(a)$ is 2 for gapped states, 0 for null states, and $last(a) - first(a) + 1$ for all others. The transition probability is:

$$p_j(a|a') = \begin{cases} p_0 \cdot \delta(|F(a)|, |L(a')|) & \text{if } F(a) < 0 \\ (1 - p_0) p_d(F(a) - |L(a')|) \cdot & \\ \quad p_n(N(a)) & \text{otherwise} \end{cases}$$

where $p_n(c) \propto \kappa^c$ is an exponential distribution. As in the word HMM case, we use a mixture parameter p_0 to determine the likelihood of landing in a NULL state. The position of that NULL state remembers the last position of the prior state. For non-null words, we pick the first word of the state according to the distance from the last word of the prior state. Finally, we pick a length for that final state according to an exponential distribution: values of κ less than one will penalize the use of phrasal states.

For each set of state words, we maintain an emission distribution over observation word sequences. Let $S[a]$ be the set of state words referred to by the alignment variable a. For example, the English given French alignment of Figure 3 includes the following state word sets:

$$\begin{aligned} S[(2, 2, \text{CONTIG})] &= \textit{voudrais} \\ S[(1, 3, \text{GAP})] &= \textit{ne} \star \textit{pas} \\ S[(6, 8, \text{CONTIG})] &= \textit{chemin de fer} \end{aligned}$$

For the emission distribution we keep a multinomial over observation phrases for each set of state words:

$$p(l, o_{l'}^{l} | S[a], l') \propto c(o_{l'}^{l} | S[a])$$

In contrast to the approach of Deng and Byrne (2005), this encourages greater consistency across instances, and more closely resembles the commonly used phrasal translation models.

We note in passing that $p_f(K|J)$ may be moved inside the product: $p_f(K|J) \propto \eta^{(J-K)} = \prod_{k=1}^{K} \eta^{(l_k - l_{k-1} - 1)}$. The following form derived using the above rearrangement is helpful during EM.

$$p(A, L, O|S) \propto \prod_{k=1}^{K} p_j(a_k|a_{k-1}) \cdot p_t(l_k, o_{l_{k-1}+1}^{l_k}|S[a_k], l_{k-1}) \cdot \eta^{(l_k - l_{k-1} - 1)}$$

where $l_k - l_{k-1} - 1$ is the length of the observation phrase emitted by state $S[a_k]$.

2.3 Minimality

At alignment time we focus on finding the minimal phrase pairs, under the assumption that composed phrase pairs can be extracted in terms of these minimal pairs. We are rather strict about this, allowing only $1 \rightarrow k$ and $k \rightarrow 1$ phrasal alignment edges (or links). This should not cause undue stress, since edges of the form $2-3$ (say $e_1e_2 \sim f_1f_2f_3$) can generally be decomposed into $1-1 \cup 1-2$ (i.e., $e_1 \sim f_1 \cup e_2 \sim f_2f_3$), etc. However, the model does not require this to be true: we will describe re-estimation for unconstrained general models, but use the limited form for word alignment.

3 Parameter Estimation

We use Expectation-Maximization (EM) to estimate parameters. The forward-backward algorithm efficiently computes posteriors of transitions and emissions in the word-based HMM. In a standard HMM, emission always advances the observation position by one, and the next transition is unaffected by the emission. Neither of these assumptions hold in our model: multiple observations may be emitted at a time, and a state may cover multiple state-side words, which affects the outgoing transition. A modified dynamic program computes posteriors for this generalized model.

The following formulation of the forward-backward algorithm for word-to-word alignment is a good starting point. $\alpha[x, 0, y]$ indicates the total mass of paths that have just transitioned into state y at observation x but have not yet emitted; $\alpha[x, 1, y]$ represents the mass after emission but before subsequent transition. β is defined similarly. (We omit NULL states for brevity; the extension is straightforward.)

$$\begin{aligned}
\alpha[0, 0, y] &= p_j(y|\text{INIT}) \\
\alpha[x, 1, y] &= \alpha[x, 0, y] \cdot p_t(o_x|s_y) \\
\alpha[x, 0, y] &= \sum_{y'} \alpha[x-1, 1, y'] \cdot p_j(y|y') \\
\beta[n, 1, y] &= 1 \\
\beta[x, 0, y] &= p_t(o_x|s_y) \cdot \beta[x, 1, y] \\
\beta[x, 1, y] &= \sum_{y'} p_j(y'|y) \cdot \beta[x+1, 0, y']
\end{aligned}$$

Not only is it easy to compute posteriors of both emissions ($\alpha[x, 0, y]p_t(o_x|s_y)\beta[x, 1, y]$) and transitions ($\alpha[x, 1, y]p_j(y'|y)\beta[x+1, 0, y']$) with this formulation, it also simplifies the generalization to complex emissions. We update the emission forward probabilities to include a search over the possible starting points in the state and observation space:

$$\begin{aligned}
\alpha[0, 0, y] &= p_j(y|\text{INIT}) \\
\alpha[x, 1, y] &= \sum_{x' < x, y' \leq y} \alpha[x', 0, y'] \cdot \text{EMIT}(x' : x, y' : y) \\
\alpha[x, 0, y] &= \sum_{y'} \alpha[x-1, 1, y'] \cdot p_j(y|y')
\end{aligned}$$

$$\begin{aligned}
\beta[n, 1, y] &= 1 \\
\beta[x', 0, y'] &= \sum_{x' < x, y' \leq y} \text{EMIT}(x' : x, y' : y) \cdot \beta[x, 1, y] \\
\beta[x, 1, y] &= \sum_{y'} p_j(y'|y) \cdot \beta[x+1, 0, y']
\end{aligned}$$

Phrasal and gapped emissions are pooled into EMIT:

$$\begin{aligned}
\text{EMIT}(w : x, y : z) = &p_t(o_w^x|s_y^z) \cdot \eta^{z-y+1} \cdot \kappa^{x-w+1} + \\
&p_t(o_w^x|s_y \star s_z) \cdot \eta^2 \cdot \kappa^{x-w+1}
\end{aligned}$$

The transition posterior is the same as above. The emission is very similar: the posterior probability that o_w^x is aligned to s_y^z is proportional to $\alpha[w, 0, y] \cdot p_t(o_w^x|s_y^z) \cdot \eta^{z-y+1} \cdot \kappa^{x-w+1} \cdot \beta[x, 1, z]$. For a gapped phrase, the posterior is proportional to $\alpha[w, 0, y] \cdot p_t(o_w^x|s_y \star s_z) \cdot \eta^2 \cdot \kappa^{x-w+1} \cdot \beta[x, 1, z]$.

Given an inference procedure for computing posteriors, unsupervised training with EM follows immediately. We use a simple maximum-likelihood update of the parameters using expected counts based on the posterior distribution.

4 Alignment by Agreement

Following Liang et al. (2006), we quantify agreement between two models as the probability that the alignments produced by the two models agree on the alignment $\mathbf{z}$ of a sentence pair $\mathbf{x} = (S, O)$:

$$\sum_{\mathbf{z}} p_1(\mathbf{z}|\mathbf{x};\theta_1)p_2(\mathbf{z}|\mathbf{x};\theta_2)$$

To couple the two models, the (log) probability of agreement is added to the standard log-likelihood objective:

$$\max_{\theta_1,\theta_2} \sum_{\mathbf{x}} \Big[\log p_1(\mathbf{x};\theta_1) + \log p_2(\mathbf{x};\theta_2) + \log \sum_{\mathbf{z}} p_1(\mathbf{z}|\mathbf{x};\theta_1)p_2(\mathbf{z}|\mathbf{x};\theta_2) \Big]$$

We use the heuristic estimator from Liang et al. (2006), letting q be a product of marginals:

$$\text{E} : q(\mathbf{z};\mathbf{x}) := \prod_{z \in \mathbf{z}} p_1(z|\mathbf{x};\theta_1)p_2(z|\mathbf{x};\theta_2)$$

where each $p_k(z|\mathbf{x};\theta_k)$ is the posterior marginal of some edge z according to each model. Such a heuristic E step computes the marginals for each model separately, then multiplies the marginals corresponding to the same edge. This product of marginals acts as the approximation to the posterior used in the M step for each model. The intuition is that if the two models disagree on a certain edge z, then the marginal product is small, hence that edge is dis-preferred in each model.

Contiguous phrase agreement. It is simple to extend agreement to alignments in the absence of gaps. Multi-word (phrasal) links are assigned some posterior probability in both models, as shown in the example in Figure 3, and we multiply the posteriors of these phrasal links just as in the single word case.[4]

$$\begin{aligned}\gamma_{F\to E}(f_i, e_j) &:= \gamma_{E\to F}(e_j, f_i) \\ &:= [\gamma_{F\to E}(f_i, e_j) \times \gamma_{E\to F}(e_j, f_i)]\end{aligned}$$

[4]Phrasal correspondences can be represented in multiple ways: multiple adjacent words could be generated from the same state either using one semi-Markov emission, or using multiple single word emissions followed by self-jumps. Only the first case is reinforced through agreement, so the latter is implicitly discouraged. We explored an option to forbid same-state transitions, but found it made little difference in practice.

Gappy phrase agreement. When we introduce gappy phrasal states, agreement becomes more challenging. In the forward direction F→E, if we have a gappy state aligned to an observation, say $f_i \star f_j \sim e_k$, then its corresponding edge in the backward direction E→F would be $e_k \backsim f_i \star f_j$. However, this is represented by two distinct and unrelated emissions. Although it is possible the compute the posterior probability of two non-adjacent emissions, this requires running a separate dynamic program for each such combination to sum the mass between these emissions. For the sake of efficiency we resort to an approximate computation of posterior marginals using the two word-to-word edges $e_k \backsim f_i$ and $e_k \backsim f_j$.

The forward posterior $\gamma_{F\to E}$ for edge $f_i \star f_j \sim e_k$ is multiplied with the $\min$ of the backward posteriors of the edges $e_k \backsim f_i$ and $e_k \backsim f_j$.

$$\begin{aligned}\gamma_{F\to E}(f_i \star f_j, e_k) := \gamma_{F\to E}(f_i \star f_j, e_k) \times \\ \min\Big\{\gamma_{E\to F}(e_k, f_i), \gamma_{E\to F}(e_k, f_j)\Big\}\end{aligned}$$

Note that this $\min$ is an upper bound on the desired posterior of edge $e_k \backsim f_i \star f_j$, since every path that passes through $e_k \backsim f_i$ and $e_k \backsim f_j$ must pass through $e_k \backsim f_i$, therefore the posterior of $e_k \backsim f_i \star f_j$ is less than that of $e_k \backsim f_i$, and likewise less than that of $e_k \backsim f_j$.

The backward posteriors of the edges $e_k \backsim f_i$ and $e_k \backsim f_j$ are also mixed with the forward posteriors of the edges to which they correspond.

$$\gamma_{E\to F}(e_k, f_i) := \gamma_{E\to F}(e_k, f_i) \times \Bigg[\gamma_{F\to E}(f_i, e_k) + \sum_{h<i<j} \Big\{\gamma_{F\to E}(f_h \star f_i, e_k) + \gamma_{F\to E}(f_i \star f_j, e_k)\Big\}\Bigg]$$

5 Pruned Lists of 'Allowed' Phrases

To identify contiguous and gapped phrases that are more likely to lead to good alignments, we use word-to-word HMM alignments from the full training data in both directions (F→E and E→F). We collect observation phrases of length 2 to K aligned to a single state, i.e. $o_i^j \sim s$, to add to a list of allowed phrases. For gappy phrases, we find all non-consecutive observation pairs o_i and o_j such that: (a) both are

aligned to the same state s_k, (b) state s_k is aligned to only these two observations, and (c) at least one observation between o_i and o_j is aligned to a non-null state other than s_k. These observation phrases are collected from F→E and E→F models to build contiguous and gappy phrase lists for both languages.

Next, we order the phrases in each contiguous list using the discounted probability:

$$p_\delta(o_i^j \sim s | o_i^j) = \frac{\max(0, count(o_i^j \sim s) - \delta)}{count(o_i^j)}$$

where $count(o_i^j \sim s)$ is the count of occurrence of the observation-phrase o_i^j, all aligned to some single state s, and $count(o_i^j)$ is the count of occurrence of the observation phrase o_i^j, not all necessarily aligned to a single state. Similarly, we rank the gappy phrases using the discounted probability:

$$p_\delta(o_i \star o_j \sim s | o_i \star o_j) = \frac{\max(0, count(o_i \star o_j \sim s) - \delta)}{count(o_i \star o_j)}$$

where $count(o_i \star o_j \sim s)$ is the count of occurrence of the observations o_i and o_j aligned to a single state s with the conditions mentioned above, and $count(o_i \star o_j)$ is the count of general occurrence of the observations o_i and o_j in order. We find that 200 gappy phrases and 1000 contiguous phrases works well, based on tuning with a development set.

6 Complexity Analysis

Let m be the length of the state sentence S and n be the length of the observation sentence O. In IBM Model 1 (Brown et al., 1994), with only a translation model, we can infer posteriors or max alignments in $\mathcal{O}(mn)$. HMM-based word-to-word alignment model (Vogel et al., 1996) adds a distortion model, increasing the complexity to $\mathcal{O}(m^2 n)$.

Introducing phrases (contiguous) on the observation side, we get a HSMM (Hidden Semi-Markov Model). If we allow phrases of length no greater than K, then the number of observation types rises from n to Kn for an overall complexity of $\mathcal{O}(m^2 Kn)$. Introducing state phrases (contiguous) with length $\leq K$ grows the number of state types from m to Km. Complexity further increases to $\mathcal{O}((Km)^2 Kn) = \mathcal{O}(K^3 m^2 n)$.

Finally, when we introduce gappy state phrases of the type $s_i \star s_j$, the number of such phrases is $\mathcal{O}(m^2)$, since we may choose a start and end point independently. Thus, the total complexity rises to $\mathcal{O}((Km + m^2)^2 Kn) = \mathcal{O}(Km^4 n)$. Although this is less than the $\mathcal{O}(n^6)$ complexity of exact ITG (Inversion Transduction Grammar) model (Wu, 1997), a quintic algorithm is often quite slow.

The pruned lists of allowed phrases limit this complexity. The model is allowed to use observation (contiguous) and state (contiguous and gappy) phrases only from these lists. The number of phrases that match any given sentence pair from these pruned lists is very small ($\sim$ 2 to 5). If the number of phrases in the lists that match the observation and state side of a given sentence pair are small constants, the complexity remains $\mathcal{O}(m^2 n)$, equal to that of word-based models.

7 Results

We evaluate our models based on both word alignment and end-to-end translation with two language pairs: English-French and English-German. For French-English, we use the Hansards NAACL 2003 shared-task dataset, which contains nearly 1.1 million training sentence pairs. We also evaluated on German-English Europarl data from WMT2010, with nearly 1.6 million training sentence pairs. The model from Liang et al. (2006) is our word-based baseline.

7.1 Training Regimen

Our training regimen begins with both the forward (F→E) and backward (E→F) iterations of Model 1 run independently (i.e. without agreement). Next, we train several iterations of the forward and backward word-to-word HMMs, again with independent training. We do not use agreement during word alignment since it tends to produce sparse 1-1 alignments, which in turn leads to low phrase emission probabilities in the gappy model.

Initializing the emission probabilities of the semi-Markov model is somewhat complicated, since the word-based models do not assign any mass to the phrasal or gapped configurations. Therefore we use a heuristic method. We first retrieve the Viterbi alignments of the forward and backward

word-to-word HMM aligners. For phrasal correspondences, we combine these forward and backward Viterbi alignments using a common heuristic (Union, Intersection, Refined, or Grow-Diag-Final), and extract tight phrase-pairs (no unaligned words on the boundary) from this alignment set. We found that Grow-Diag-Final was most effective in our experiments. The counts gathered from this phrase extraction are used to initialize phrasal translation probabilities. For gappy states in a forward (F→E) model, we use alignments from the backward (E→F) model. If a state s_k is aligned to two non-consecutive observations o_i and o_j such that s_k is not aligned to any other observation, and at least one observation between o_i and o_j is aligned to a non-null state other than s_k, then we reverse this link to get $o_i \ \star \ o_j \sim s_k$ and use it as a gapped-state-phrase instance for adding fractional counts. Given these approximate fractional counts, we perform a standard MLE M-step to initialize the emission probability distributions. The distortion probabilities from the word-based model are used without changes.

7.2 Alignment Results (F1)

The validation and test sentences have been hand-aligned (see Och and Ney (2003)) and are marked with both sure and possible alignments. For French-English, following Liang et al. (2006), we lowercase all words, and use the validation set plus the first 100 test sentences as our development set and the remaining 347 test-sentences as our test-set for final F1 evaluation.[5] In German-English, we have a development set of 102 sentences, and a test set of 258 sentences, also annotated with a set of sure and possible alignments. Given a predicted alignment A, precision and recall are computed using sure alignments S and possible alignments P (where $S \subseteq P$) as in Och and Ney (2003):

$$Precision = \frac{|A \cap P|}{|A|} \times 100\%$$

$$Recall = \frac{|A \cap S|}{|S|} \times 100\%$$

[5]We report F1 rather than AER because AER appears not to correlate well with translation quality.(Fraser and Marcu, 2007)

Language pair	Word-to-word	Gappy
French-English	34.0	34.5
German-English	19.3	19.8

Table 2: BLEU results on German-English and French-English.

$$AER = \left(1 - \frac{|A \cap S| + |A \cap P|}{|A| + |S|}\right) \times 100\%$$

$$F_1 = \frac{2 \times Precision \times Recall}{Precision + Recall} \times 100\%$$

Many free parameters were tuned to optimize alignment F1 on the development set, including the number of iterations of each Model 1, HMM, and Gappy; the NULL weight p_0, the number of contiguous and gappy phrases to include, and the maximum phrase length. Five iterations of all models, $p_0 = 0.3$, using the top 1000 contiguous phrases and the top 200 gappy phrases, maximum phrase length of 5, and penalties $\eta = \kappa = 1$ produced competitive results. Note that by setting η and κ to one, we have effectively removed the penalty altogether without affecting our results. In Table 1 we see a consistent improvement with the addition of contiguous phrases, and some additional gains with gappy phrases.

7.3 Translation Results (BLEU)

We assembled a phrase-based system from the alignments (using only contiguous phrases consistent with the potentially gappy alignment), with 4 channel models, word and phrase count features, distortion penalty, lexicalized reordering model, and a 5-gram language model, weighted by MERT. The same free parameters from above were tuned to optimize development set BLEU using grid search. The improvements in Table 2 are encouraging, especially as a syntax-based or non-contiguous phrasal system (Galley and Manning, 2010) may benefit more from gappy phrases.

8 Conclusions and Future Work

We have described an algorithm for efficient unsupervised alignment of phrases. Relatively straightforward extensions to the base HMM allow for efficient inference, and agreement between the two

Data	Decoding method	Word-to-word	+Contig phrases	+Gappy phrases
FE 10K	Viterbi	89.7	90.6	90.3

GE All	Posterior ≥ 0.1	83.7	85.3	**85.7**

Table 1: F1 scores of automatic word alignments, evaluated on the test set of the hand-aligned sentence pairs.

models prevents EM from overfitting, even in the absence of harsh penalties. We also allow gappy (non-contiguous) phrases on the state side, which makes agreement more successful but agreement needs approximation of posterior marginals. Using pruned lists of good phrases, we maintain complexity equal to the baseline word-to-word model.

There are several steps forward from this point. Limiting the gap length also prevents combinatorial explosion; we hope to explore this in future work. Clearly a translation system that uses discontinuous mappings at runtime (Chiang, 2007; Galley and Manning, 2010) may make better use of discontinuous alignments. This model can also be applied at the morpheme or character level, allowing joint inference of segmentation and alignment. Furthermore the state space could be expanded and enhanced to include more possibilities: states with multiple gaps might be useful for alignment in languages with template morphology, such as Arabic or Hebrew. More exploration in the model space could be useful – a better distortion model might place a stronger distribution on the likely starting and ending points of phrases.

Abstract

While it is has often been observed that the product of translation is somehow different than non-translated text, scholars have emphasized two distinct bases for such differences. Some have noted interference from the source language spilling over into translation in a source-language-specific way, while others have noted general effects of the process of translation that are independent of source language. Using a series of text categorization experiments, we show that both these effects exist and that, moreover, there is a continuum between them. There are many effects of translation that are consistent among texts translated from a given source language, some of which are consistent even among texts translated from families of source languages. Significantly, we find that even for widely unrelated source languages and multiple genres, differences between translated texts and non-translated texts are sufficient for a learned classifier to accurately determine if a given text is translated or original.

1 Introduction

The products of translation (written or oral) are generally assumed to be ontologically different from non-translated texts. Researchers have emphasized two aspects of this difference. Some (Baker 1993) have emphasized general effects of the process of translation that are independent of source language and regard the collective product of this process in a given target language as an 'interlanguage' (Selinker, 1972), 'third code' (Frawley, 1984) or 'translationese' (Gellerstam, 1986). Others (Toury, 1995) have emphasized the effects of *interference*, the process by which a specific source language leaves distinct marks or fingerprints in the target language, so that translations from different source languages into the same target language may be regarded as distinct dialects of translationese.

We wish to use text categorization methods to set both of these claims on a firm empirical foundation. We will begin by bringing evidence for two claims:

(1) Translations from different source languages into the same target language are sufficiently different from each other for a learned classifier to accurately identify the source language of a given translated text;

(2) Translations from a mix of source languages are sufficiently distinct from texts originally written in the target language for a learned classifier to accurately determine if a given text is translated or original.

Each of these claims has been made before, but our results will strengthen them in a number of ways. Furthermore, we will show that the degree of difference between translations from two source languages reflects the degree of difference between the source languages themselves. Translations from cognate languages differ from non-translated texts in similar ways, while translations from unrelated languages differ from non-translated texts in distinct ways. The same result holds for families of languages.

The outline of the paper is as follows. In the following section, we show that translations from different source languages can be distinguished from each other and that closely related source languages manifest similar forms of interference. In section 3, we show that, in a corpus involving five European languages, we can distinguish translationese from non-translated text and we consider some salient markers of translationese. In section

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1318–1326,
Portland, Oregon, June 19-24, 2011.

4, we consider the extent to which markers of translationese cross over into non-European languages as well as into different genres. Finally, we consider possible applications and implications for future studies.

2 Interference Effects in Translationese

In this section, we perform several text categorization experiments designed to show the extent to which interference affects (both positively and negatively) our ability to classify documents.

2.1 The Europarl Corpus

The main corpus we will use throughout this paper is Europarl (Koehn, 2005), which consists of transcripts of addresses given in the European Parliament. The full corpus consists of texts translated into English from 11 different languages (and vice versa), as well as texts originally produced in English. For our purposes, it will be sufficient to use translations from five languages (Finnish, French, German, Italian and Spanish), as well as original English. We note that this corpus constitutes a *comparable corpus* (Laviosa, 1997), since it contains (1) texts written originally in a certain language (English), as well as (2) texts translated into that same language, matched for genre, domain, publication timeframe, etc. Each of the five translated components is a text file containing just under 500,000 words; the original English component is a file of the same size as the aggregate of the other five.

The five source languages we use were selected by first eliminating several source languages for which the available text was limited and then choosing from among the remaining languages, those of varying degrees of pairwise similarity. Thus, we select three cognate (Romance) languages (French, Italian and Spanish), a fourth less related language (German), and a fifth even further removed (Finnish). As will become clear, the motivation is to see whether the distance between the languages impacts the distinctiveness of the translation product.

We divide each of the translated corpora into 250 equal chunks, paying no attention to natural units within the corpus. Similarly, we divide the original English corpus into 1250 equal chunks. We set aside 50 chunks from each of the translated corpora and 250 chunks from the original English corpus for development purposes (as will be explained below). The experiments described below use the remaining 1000 translated chunks and 1000 original English chunks.

2.2 Identifying source language

Our objective in this section is to measure the extent to which translations are affected by source language. Our first experiment will be to use text categorization methods to learn a classifier that categorizes translations according to source language. We will check the accuracy of such classifiers on out-of-sample texts. High accuracy would reflect that there are exploitable differences among translations of otherwise comparable texts that differ only in terms of source language.

The details of the experiment are as follows. We use the 200 chunks from each translated corpus, as described above. We use as our feature set a list of 300 function words taken from LIWC (Pennebaker, 2001) and represent each chunk as a vector of size 300 in which each entry represents the frequency of the corresponding feature in the chunk. The restriction to function words is crucial; we wish to rely only on stylistic differences rather than content differences that might be artifacts of the corpus.

We use Bayesian logistic regression (Madigan, 2005) as our learning method in order to learn a classifier that classifies a given text into one of five classes representing the different source languages. We use 10-fold cross-validation as our testing method.

We find that 92.7% of documents are correctly classified.

In Table 1 we show the confusion matrix for the five languages. As can be seen, there are more mistakes across the three cognate languages than between those three languages and German and still fewer mistakes involving the more distant Finnish language.

	It	Fr	Es	De	Fi
It	169	19	8	4	0
Fr	18	161	12	8	1
Es	3	11	172	11	3
De	4	12	3	178	3
Fi	0	1	2	5	192

Table 1: Confusion matrix for 10-fold cross validation experiment to determine source language of texts translated into English

This result strengthens that of van Halteren (2008) in a similar experiment. Van Halteren, also using Europarl (but with Dutch as the fifth source language, rather than Finnish), obtained accuracy of 87.2%-96.7% for a two-way decision on source language, and 81.5%-87.4% for a six-way decision (including the original which has no source language). Significantly, though, van Halteren's feature set included content words and he notes that many of the most salient differences reflected differences in thematic emphasis. By restricting our feature set to function words, we neutralize such effects.

In Table 2, we show the two words most over-represented and the two words most under-represented in translations from each source language (ranked according to an unpaired T-test). For each of these, the difference between frequency of use in the indicated language and frequency of use in the other languages in aggregate is significant at $p<0.01$.

	over-represented	**under-represented**
Fr	*of, finally*	*here, also*
It	*upon, moreover*	*also, here*
Es	*with, therefore*	*too, then*
De	*here, then*	*of, moreover*
Fi	*be, example*	*me, which*

Table 2: Most salient markers of translations from each source language.

The two most underrepresented words for French and Italian, respectively, are in fact identical. Furthermore, the word *too* which is underrepresented for Spanish is a near synonym of *also* which appears in both French and Spanish. This suggests the possibility that interference effects in cognate languages such as French, Italian and Spanish might be similar. We will see presently that this is in fact the case.

When a less related language is involved we see the opposite picture. For German, both underrepresented items appear as overrepresented in the Romance languages, and, conversely, underrepresented items in the Romance languages appear as overrepresented items for German. This may cast doubt on the idea that all translations share universal properties and that at best we may claim that particular properties are shared by closely related languages but not others. In the experiments presented in the next subsection, we'll find that translationese is gradable: closely related languages share more features, yet even further removed languages share enough properties to hold the general translationese hypothesis as valid.

2.3 Identifying translationese per source language

We now wish to measure in a subtler manner the extent to which interference affects translation. In this experiment, the challenge is to learn a classifier that classifies a text as belonging to one of only two classes: original English (O) or translated-into-English (T). The catch is that all our training texts for the class T will be translations from some fixed source language, while all our test documents in T will be translations from a different source language. What accuracy can be achieved in such an experiment? The answer to this question will tell us a great deal about how much of translationese is general and how much of it is language dependent. If accuracy is close to 100%, translationese is purely general (Baker, 1993). (We already know from the previous experiment that that's not the case.). If accuracy is near 50%, there are no general effects, just language-dependent ones. Note that, whereas in our first experiment above pair-specific interference facilitated good classification, in this experiment pair-specific interference is an impediment to good classification.

The details of the experiment are as follows. We create, for example, a "French" corpus consisting of the 200 chunks of text translated from French and 200 original English texts. We similarly create a corpus for each of the other source languages, taking care that each of the 1000 original English texts appears in exactly one of the corpora. As above, we represent each chunk in terms of frequencies of function words. Now, using Bayesian logistic regression, we learn a classifier that distinguishes T from O in the French corpus. We then apply this learned classifier to the texts in, for example, the equivalent "Italian" corpus to see if we can classify them as translated or original. We repeat this for each of the 25 ⟨train_corpus, test_corpus⟩ pairs.

In Table 3, we show the accuracy obtained for each such pair. (For the case where the training corpus and testing corpus are identical – the di-

agonal of the matrix – we show results for ten-fold cross-validation.)

We note several interesting facts. First, results of cross-validation within each corpus are very strong. For any given source language, it is quite easy to distinguish translations from original English. This corroborates results obtained by Baroni and Bernardini (2006), Ilisei et al. (2010), Kurokawa et al. (2009) and van Halteren (2008), which we will discuss below.

We note further, that for the cases where we train on one source language and test on another, results are far worse. This clearly indicates that interference effects from one source language might be misleading when used to identify translations from a different language. Thus, for example, in the Finnish corpus, the word *me* is a strong indicator of original English (constituting 0.0003 of tokens in texts translated from Finnish as opposed to 0.0015 of tokens in original English texts), but in the German corpus, *me* is an indicator of translated text (constituting 0.0020 of tokens in text translated from German).

The most interesting result that can be seen in this table is that the accuracy obtained when training using language x and testing using language y depends precisely on the degree of similarity between x and y. Thus, for training and testing within the three cognate languages, results are fairly strong, ranging between 84.5% and 91.5%. For training/testing on German and testing/training on one of the other European languages, results are worse, ranging from 68.5% to 83.3%. Finally, for training/testing on Finnish and testing/training on any of the European languages, results are still worse, hovering near 60% (with the single unexplained outlier for training on German and testing on Finnish).

Finally, we note that even in the case of training or testing on Finnish, results are considerably better than random, suggesting that despite the confounding effects of interference, some general properties of translationese are being picked up in each case. We explore these in the following section.

3 General Properties of Translationese

Having established that there are source-language-dependent effects on translations, let's now consider source-language-independent effects on translation.

Train

	It	Fr	Es	De	Fi
It	98.3	91.5	86.5	71.3	61.5
Fr	91	97	86.5	68.5	60.8
Es	84.5	88.3	95.8	76.3	59.5
De	82	83.3	78.5	95	80.8
Fi	56	60.3	56	62.3	97.3

Table 3: Results of learning a T vs. O classifier using one source language and testing it using another source language

3.1 Identifying translationese

In order to identify general effects on translation, we now consider the same two-class classification problem as above, distinguishing T from O, except that now the translated texts in both our train and test data will be drawn from multiple source languages. If we succeed at this task, it must be because of features of translationese that cross source-languages.

The details of our experiment are as follows. We use as our translated corpus, the 1000 translated chunks (200 from each of five source languages) and as our original English corpus all 1000 original English chunks. As above, we represent each chunk in terms of function words frequencies. We use Bayesian logistic regression to learn a two-class classifier and test its accuracy using ten-fold cross-validation.

Remarkably, we obtain accuracy of 96.7%.

This result extends and strengthens results reported in some earlier studies. Ilisei et al. (2010), Kurokawa (2009) and van Halteren (2008) each obtained above 90% accuracy in distinguishing translation from original. However, in each case the translations were from a single source language. (Van Halteren considered multiple source languages, but each learned classifier used only one of them.) Thus, those results do not prove that translationese has distinctive source-language-independent features. To our knowledge, the only earlier work that used a learned classifier to identify translations in which both test and train sets involved multiple source languages is Baroni and Bernardini (2006), in which the target language was Italian and the source languages were known to be varied. The actual distribution of source languages was, however, not known to the researchers. They obtained accuracy of 86.7%. Their result was obtained using combinations of lexical and syntactic features.

3.2 Some distinguishing features

Let us now consider some of the most salient function words for which frequency of usage in T differs significantly from that in O. While there are many such features, we focus on two categories of words that are most prominent among those with the most significant differences.

First, we consider animate pronouns. In Table 4, we show the frequencies of animate pronouns in O and T, respectively (the possessive pronouns, *mine*, *yours* and *hers*, not shown, are extremely rare in the corpus). As can be seen, all pronouns are under-represented in T; for most (bolded), the difference is significant at $p<0.01$.

By contrast, the word *the* is significantly overrepresented in T (15.32% in T vs. 13.73% in O; significant at $p<0.01$).

word	freq O	freq T
I	**2.552%**	2.148%
we	**2.713%**	2.344%
you	0.479%	0.470%
he	**0.286%**	0.115%
she	**0.081%**	0.039%
me	0.148%	0.141%
us	**0.415%**	0.320%
him	**0.066%**	0.033%
her	**0.091%**	0.056%
my	**0.462%**	0.345%
our	**0.696%**	0.632%
your	0.119%	0.109%
his	**0.218%**	0.123%

Table 4: Frequency of pronouns in O and T in the Europarl corpus. Bold indicates significance at $p<0.01$.

In Table 5, we consider cohesive markers, tagged as adverbs (Schmid, 2004). (These are adverbs that can appear at the beginning of a sentence followed immediately by a comma.)

word	freq O	freq T
therefore	0.153%	**0.287%**
thus	0.015%	**0.041%**
consequently	0.006%	**0.014%**
hence	0.007%	**0.013%**
accordingly	0.006%	**0.011%**
however	0.216%	**0.241%**
nevertheless	0.019%	**0.045%**
also	0.460%	**0.657%**
furthermore	0.012%	**0.048%**
moreover	0.008%	**0.036%**
indeed	**0.098%**	0.053%
actually	**0.065%**	0.042%

Table 5: Frequency of cohesive adverbs in O and T in the Europarl corpus. Bold indicates significance at $p<0.01$.

We note that the preponderance of such cohesive markers are significantly more frequent in translations. In fact, we also find that a variety of phrases that serve the same purpose as cohesive adverbs, such as *in fact* and *as a result* are significantly more frequent in translationese.

The general principle underlying these phenomena is subject to speculation. Previous researchers have noted the phenomenon of *explicitation*, according to which translators tend to render implicit utterances in the source text into explicit utterances in the target text (Blum-Kulka, 1986, Laviosa-Braithwaite, 1998), for example by filling out elliptical expressions or adding connectives to increase cohesion of the text (Laviosa-Braithwaite, 1998). It is plausible that the use of cohesive adverbs is an instantiation of this phenomenon.

With regard to the under-representation of pronouns and the over-representation of *the*, there are a number of possible interpretations. It may be that this too is the result of explicitation, in which anaphora is resolved by replacing pronouns with noun phrases (e.g., *the man* instead of *he*). But it also might be that this is an example of *simplification* (Laviosa- Braithwaite 1998, Laviosa 2002), according to which the translator simplifies the message, the language, or both. Related results confirming the simplification hypothesis were found by Ilisei et al. (2010) on Spanish texts. In particular, they found that type-to-token ratio (*lexical variety*/*richness*), mean sentence length and proportion of grammatical words (*lexical density*/*readability*) are all smaller in translated texts.

We note that Van Halteren (2008) and Kurokawa et al. (2009), who considered lexical features, found cultural differences, like over-representation of *ladies* and *gentlemen* in translated speeches. Such differences, while of general interest, are orthogonal to our purposes in this paper.

3.3 Overriding language-specific effects

We found in Section 2.3 that when we trained in one language and tested in another, classification succeeded to the extent that the source languages used in training and testing, respectively, are related to each other. In effect, general differences between translationese and original English were partially overwhelmed by language-specific differences that held for the training language but not the test language. We thus now revisit that earlier experiment, but restrict ourselves to features that distinguish translationese from original English generally.

To do this, we use the small development corpus described in Section 2.1. We use Bayesian logistic regression to learn a classifier to distinguish between translationese and original English. We select the 10 highest-weighted function-word markers for T and the 10 highest-weighted function-word markers for O in the development corpus. We then rerun our train-on-source-language-x, test-on-source-language-y experiment using this restricted set as our feature set. We now find that even in the difficult case where we train on Finnish and test on another language (or vice versa), we succeed at distinguishing translationese from original English with accuracy above 80%. This considerably improves the earlier results shown in Table 3. Thus, a bit of feature engineering facilitates learning a good classifier for T vs. O even across source languages.

4 Other Genres and Language Families

We have found both general and language-specific differences between translationese and original English in one large corpus. It might be wondered whether the phenomena we have found hold in other genres and for a completely different set of source languages. To test this, we consider a second corpus.

4.1 The IHT corpus

Our second corpus includes three translated corpora, each of which is an on-line local supplement to the International Herald Tribune (IHT): *Kathimerini* (translated from Greek), *Ha'aretz* (translated from Hebrew), and the *JoongAng Daily* (translated from Korean). In addition, the corpus includes original English articles from the IHT. Each of the four components contains four different domains balanced roughly equally: news (80,000 words), arts and leisure (50,000), business and finance (50,000), and opinion (50,000) and each covers the period from April-September 2004. Each component consists of about 230,000 tokens. (Unlike for our Europarl corpus, the amount of English text available is not equal to the aggregate of the translated corpora, but rather equal to each of the individual corpora.)

It should be noted that the IHT corpus belongs to the writing modality while the Europarl corpus belongs to the speaking modality (although possibly post-edited). Furthermore, the source languages (Hebrew, Greek and Korean) in the IHT corpus are more disparate than those in the Europarl corpus.

Our first objective is to confirm that the results we obtained earlier on the Europarl corpus hold for the IHT corpus as well.

Perhaps more interestingly, our second objective is to see if the gradability phenomenon observed earlier (Table 3) generalizes to families of languages. Our first hypothesis is that a classifier for identifying translationese that is trained on Europarl will succeed only weakly to identify translationese in IHT. But our second hypothesis is that there are sufficient general properties of translationese that cross language families and genres that a learned classifier can accurately identify translationese even on a test corpus that includes both corpora, spanning eight disparate languages across two distinct genres.

4.2 Results on IHT corpus

Running essentially the same experiments as described for the Europarl corpus, we obtain the following results.

First of all, we can determine source language with accuracy of 86.5%. This is a somewhat weaker result than the 92.7% result obtained on Europarl, especially considering that there are only three classes instead of five. The difference is most likely due to the fact that the IHT corpus is about half the size of the Europarl corpus. Nevertheless, it is clear that source language strongly affects translationese in this corpus.

Second, as can be seen in Table 6, we find that the gradability phenomenon occurs in this corpus as well. Results are strongest when the train and

test corpora involve the same source language and trials involving Korean, the most distant language, are somewhat weaker than those across Greek and Hebrew.

Train	Gr	He	Ko
Gr	89.8	73.4	64.8
He	82.0	86.3	65.5
Ko	73.0	72.5	85.0

Table 6: Results of learning a T vs. O classifier using one source language and testing it using another source language

Third, we find in ten-fold cross-validation experiments that we can distinguish translationese from original English in the IHT corpus with accuracy of 86.3%. Thus, despite the great distance between the three source languages in this corpus, general differences between translationese and original English are sufficient to facilitate reasonably accurate identification of translationese.

4.3 Combining the corpora

First, we consider whether a classifier learned on the Europarl corpus can be used to identify translationese in the IHT corpus, and vice versa. It would be consistent with our findings in Section 2.3, that we would achieve better than random results but not high accuracy, since there are no doubt features common to translations from the five European languages of Europarl that are distinct from those of translations from the very different languages in IHT.

In fact, we find that training on Europarl and testing on IHT yields accuracy of 64.8%, while training on IHT and testing on Europarl yields accuracy of 58.8%. The weak results reflect both differences between the families of source languages involved in the respective corpora, as well as genre differences. Thus, for example, we find that of the pronouns shown in Table 4 above, only *he* and *his* are significantly under-represented in translationese in the IHT corpus. Thus, that effect is specific either to the genre of Europarl or to the European languages considered there.

Now, we combine the two corpora and check if we can identify translationese across two genres and eight languages. We run the same experiments as described above, using 200 texts from each of the eight source languages and 1600 non-translated English texts, 1000 from Europarl and 600 from IHT.

In 10-fold cross-validation, we find that we can distinguish translationese from non-translated English with accuracy of 90.5%.

This shows that there are features of translationese that cross genres and widely disparate languages. Thus, for one prominent example, we find that, as in Europarl, the word *the* is over-represented in translationese in IHT (15.36% in T vs. 13.31% in O; significant at $p<0.01$). In fact, the frequencies across corpora are astonishingly consistent.

To further appreciate this point, let's look at the frequencies of cohesive adverbs in the IHT corpus.

We find essentially, the same pattern in IHT as we did in Europarl. The preponderance of cohesive adverbs are over-represented in translationese, most of them with differences significant at $p<0.01$. Curiously, the word *actually* is a counter-example in both corpora.

word	freq O	freq T
therefore	0.011%	**0.031%**
thus	0.011%	**0.027%**
consequently	0.000%	**0.004%**
hence	0.003%	0.007%
accordingly	0.003%	0.003%
however	0.078%	**0.129%**
nevertheless	0.008%	**0.018%**
also	0.305%	**0.453%**
furthermore	0.003%	**0.011%**
moreover	0.009%	0.008%
indeed	0.018%	0.024%
actually	0.032%	0.018%

Table 7: Frequency of cohesive adverbs in O and T in the IHT corpus. Bold indicates significance at $p<0.01$.

5 Conclusions

We have found that we can learn classifiers that determine source language given a translated text, as well as classifiers that distinguish translated text from non-translated text in the source language. These text categorization experiments suggest that both source language and the mere fact of being

translated play a crucial role in the makeup of a translated text.

It is important to note that our learned classifiers are based solely on function words, so that, unlike earlier studies, the differences we find are unlikely to include cultural or thematic differences that might be artifacts of corpus construction.

In addition, we find that the exploitability of differences between translated texts and non-translated texts are related to the difference between source languages: translations from similar source languages are different from non-translated texts in similar ways.

Linguists use a variety of methods to quantify the extent of differences and similarities between languages. For example, Fusco (1990) studies translations between Spanish and Italian and considers the impact of structural differences between the two languages on translation quality. Studying the differences and distance between languages by comparing translations into the same language may serve as another way to deepen our typological knowledge. As we have seen, training on source language x and testing on source language y provides us with a good estimation of the distance between languages, in accordance with what we find in standard works on typology (cf. Katzner, 2002).

In addition to its intrinsic interest, the finding that the distance between languages is directly correlated with our ability to distinguish translations from a given source language from non-translated text is of great importance for several computational tasks. First, translations can be studied in order to shed new light on the differences between languages and can bear on attested techniques for using cognates to improve machine translation (Kondrak & Sherif, 2006). Additionally, given the results of our experiments, it stands to reason that using translated texts, especially from related source languages, will prove beneficial for constructing language models and will outperform results obtained from non-translated texts. This, too, bears on the quality of machine translation.

Finally, we find that there are general properties of translationese sufficiently strong that we can identify translationese even in a combined corpus that is comprised of eight very disparate languages across two distinct genres, one spoken and the other written. Prominent among these properties is the word *the*, as well as a number of cohesive adverbs, each of which is significantly over-represented in translated texts.

Rare Word Translation Extraction from Aligned Comparable Documents

Emmanuel Prochasson and Pascale Fung

Abstract

We present a first known result of high precision rare word bilingual extraction from comparable corpora, using aligned comparable documents and supervised classification. We incorporate two features, a context-vector similarity and a co-occurrence model between words in aligned documents in a machine learning approach. We test our hypothesis on different pairs of languages and corpora. We obtain very high F-Measure between 80% and 98% for recognizing and extracting correct translations for rare terms (from 1 to 5 occurrences). Moreover, we show that our system can be trained on a pair of languages and test on a different pair of languages, obtaining a F-Measure of 77% for the classification of Chinese-English translations using a training corpus of Spanish-French. Our method is therefore even potentially applicable to low resources languages without training data.

1 Introduction

Rare words have long been a challenge to translate automatically using statistical methods due to their low occurrences. However, the *Zipf's Law* claims that, for any corpus of natural language text, the frequency of a word w_n (n being its rank in the frequency table) will be roughly twice as high as the frequency of word w_{n+1}. The logical consequence is that in any corpus, there are very few frequent words and many rare words.

We propose a novel approach to extract rare word translations from comparable corpora, relying on two main features.

The first feature is the *context-vector similarity* (Fung, 2000; Chiao and Zweigenbaum, 2002; Laroche and Langlais, 2010): each word is characterized by its context in both source and target corpora, words in translation should have similar context in both languages.

The second feature follows the assumption that specific terms and their translations should appear together often in documents on the same topic, and rarely in non-related documents. This is the general assumption behind early work on bilingual lexicon extraction from parallel documents using sentence boundary as the context window size for co-occurrence computation, we suggest to extend it to aligned comparable documents using document as the context window. This document context is too large for co-occurrence computation of functional words or high frequency content words, but we show through observations and experiments that this window size is appropriate for rare words.

Both these features are unreliable when the number of occurrences of words are low. We suggest however that they are complementary and can be used together in a machine learning approach. Moreover, we suggest that the model trained for one pair of languages can be successfully applied to extract translations from another pair of languages.

This paper is organized as follows. In the next section, we discuss the challenge of rare lexicon extraction, explaining the reasons why classic approaches on comparable corpora fail at dealing with rare words. We then discuss in section 3 the concept of *aligned comparable documents* and how we exploited those documents for bilingual lexicon extraction in section 4. We present our resources and implementation in section 5 then carry out and comment several experiments in section 6.

2 The challenge of rare lexicon extraction

There are few previous works focusing on the extraction of rare word translations, especially from comparable corpora. One of the earliest works is from (Pekar et al., 2006). They emphasized the fact that the context-vector based approach, used for processing comparable corpora, *perform quite unreliably on all but the most frequent words*. In a nutshell[1], this approach proceeds by gathering the context of words in source and target languages inside *context-vectors*, then compares source and target context-vectors using similarity measures. In a monolingual context, such an approach is used to automatically get synonymy relationship between words to build thesaurus (Grefenstette, 1994). In the multilingual case, it is used to extract translations, that is, pairs of words with the same meaning in source and target corpora. It relies on the *Firthien* hypothesis that *you shall know a word by the company it keeps* (Firth, 1957).

To show that the frequency of a word influences its alignment, (Pekar et al., 2006) used six pairs of comparable corpora, ranking translations according to their frequencies. The less frequent words are ranked around 100-160 by their algorithm, while the most frequent ones typically appear at rank 20-40.

We ran a similar experiment using a French-English comparable corpus containing medical documents, all related to the topic of *breast cancer*, all manually classified as *scientific discourse*. The French part contains about 530,000 words while the English part contains about 7.4 millions words. For this experiment though, we sampled the English part to obtain a 530,000-words large corpus, matching the size of the French part.

Using an implementation of the context-vector similarity, we show in figure 1 that frequent words (above 400 occurrences in the corpus) reach a 60% precision whereas rare words (below 15 occurrences) are correctly aligned in only 5% of the time.

These results can be explained by the fact that, for the vector comparison to be efficient, the information they store has to be relevant and discriminatory. If there are not enough occurrences of a word, it is impossible to get a precise description of the *typical* context of this word, and therefore its description is likely to be very different for source and target words in translation.

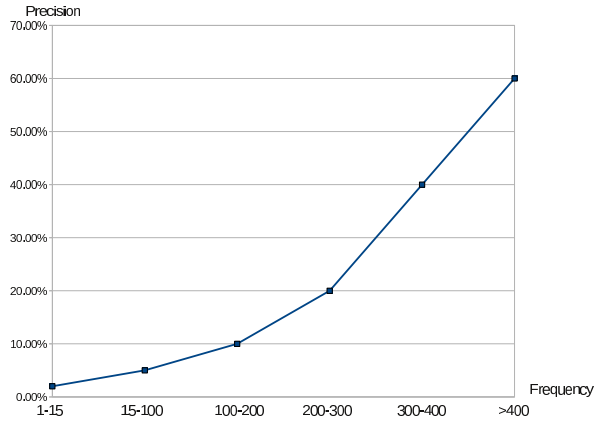

Figure 1: Results for context-vector based translations extraction with respect to word frequency. The vertical axis is the amount of correct translations found for Top_1, and the horizontal axis is the word occurrences in the corpus.

We confirmed this result with another observation on the full English part of the previous corpus, randomly split in 14 samples of the same size. The context-vectors for very frequent words, such as *cancer* (between 3,000 and 4,000 occurrences in each sample) are very similar across the subsets. Less frequent words, such as *abnormality* (between 70 and 16 occurrences in each sample) have very unstable context-vectors, hence a lower similarity across the subsets. This observation actually indicates that it will be difficult to align *abnormality* with itself.

3 Aligned comparable documents

A pair of *aligned comparable documents* is a particular case of comparable corpus: two comparable documents share the same topic and domain; they both relate the same information but are not mutual translations; although they might share parallel chunks (Munteanu and Marcu, 2005) – paragraphs, sentences or phrases – in the general case they were written independently. These comparable documents, when concatenated together in order, form an aligned comparable corpus.

[1]Detailed presentations can be found for example in (Fung, 2000; Chiao and Zweigenbaum, 2002; Laroche and Langlais, 2010).

Examples of such aligned documents can be found, for example in (Munteanu and Marcu, 2005): they aligned comparable documents with close publication dates. (Tao and Zhai, 2005) used an iterative, bootstrapping approach to align comparable documents using examples of already aligned corpora. (Smith et al., 2010) aligned documents from Wikipedia following the interlingual links provided on articles.

We take advantage of this alignment between documents: by looking at *what is common between two aligned documents* and *what is different in other documents*, we obtain more precise information about terms than when using a larger comparable corpus without alignment. This is especially interesting in the case of rare lexicon as the classic context-vector similarity is not discriminatory enough and fails at raising interesting translation for rare words.

4 Rare word translations from aligned comparable documents

4.1 Co-occurrence model

Different approaches have been proposed for bilingual lexicon extraction from parallel corpora, relying on the assumption that a word has one sense, one translation, no missing translation, and that its translation appears in aligned parallel sentences (Fung, 2000). Therefore, translations can be extracted by comparing the distribution of words across the sentences. For example, (Gale and Church, 1991) used a derivative of the χ^2 statistics to evaluate the association between words in aligned region of parallel documents. Such association scores evaluate the strength of the relation between events. In the case of parallel sentences and lexicon extraction, they measure how often two words appear in aligned sentences, and how often one appears without the other. More precisely, they will compare their number of co-occurrences against the expected number of co-occurrences under the null-hypothesis that words are randomly distributed. If they appear together more often than expected, they are considered as associated (Evert, 2008).

We focus in this work on *rare words*, more precisely on specialized terminology. We define them as the set of terms that appear from 1 (hapaxes) to 5 times. We use a strategy similar to the one applied on parallel sentences, but rely on *aligned documents*. Our hypothesis is very similar: words in translation should appear in aligned comparable documents. We used the *Jaccard similarity* (eq. 1) to evaluate the association between words among aligned comparable documents. In the general case, this measure would not give relevant scores due to frequency issue: it produces the same scores for two words that appear always together, and never one without the other, disregarding the fact that they appear 500 times or one time only. Other association scores generally rely on occurrence and co-occurrence counts to tackle this issue (such as the log-likelihood, eq. 2). In our case, the number of co-occurrences will be limited by the number of occurrences of the words, from 1 to 5. Therefore, the Jaccard similarity efficiently reflects what we want to observe.

$$J(w_i, w_j) = \frac{|A_i \cap A_j|}{|A_i \cup A_j|}; A_i = \{d : w_i \in d\} \quad (1)$$

A score of 1 indicates a perfect association (words always appear together, never one without the other), the more one word appears without the other, the lower the score.

4.2 Context-vector similarity

We implemented the context-vector similarity in a way similar to (Morin et al., 2007). In all experiments, we used the same set of parameters, as they yielded the best results on our corpora. We built the context-vectors using nouns only as seed lexicon, with a window size of 20. Source context-vectors are translated in the target language using the resources presented in the next section. We used the log-likelihood (Dunning, 1993, eq. 2) for context-vector normalization (O is the observed number of co-occurrence in the corpus, E is the expected number of co-occurrences under the null hypothesis). We used the Cosine similarity (eq. 3) for context-vector comparisons.

$$ll(w_i, w_j) = 2 \sum_{ij} O_{ij} log \frac{O_{ij}}{E_{ij}} \quad (2)$$

$$Cosine(A, B) = \frac{A \cdot B}{\|A\|^2 + \|B\|^2 - A \cdot B} \quad (3)$$

4.3 Binary classification of rare translations

We suggest to incorporate both the context-vector similarity and the co-occurrence features in a machine learning approach. This approach consists of training a classifier on positive examples of translation pairs, and negative examples of non-translations pairs. The trained model (in our case, a decision tree) is then used to tag an unknown pair of words as either ”Translation” or ”Non-Translation”.

One potential problem for building the training set, as pointed out for example by (Zhao and Ng, 2007) is this: we have a limited number of positive examples, but a very large amount of *non-translation* examples as obviously is the case for rare word translations in any training corpus. Including two many negative examples in the training set would lead the classifier to label every pairs as ”Non-Translation”.

To tackle this problem, (Zhao and Ng, 2007) tuned the imbalance of positive/negative ratio by resampling the positive examples in the training set. We chose to reduce the set of negative examples, and found that a ratio of five negative examples to one positive is optimal in our case. A lower ratio improves precision but reduces recall for the ”Translation” class.

It is also desirable that the classifier focuses on discriminating between confusing pairs of translations. As most of the negative examples have a null co-occurrence score and a null context-vector similarity, they are excluded from the training set. The negative examples are randomly chosen among those that fulfill the following constraints:

- non-null features ;
- ratio of number of occurrences between source/target words higher than 0.2 and lower than 5.

We use the J48 decision tree algorithm, in the *Weka* environment (Hall et al., 2009). Features are computed using the Jaccard similarity (section 3) for the co-occurrence model, and the implementation of the context-vector similarity presented in section 4.2.

4.4 Extension to another pair of languages

Even though the context vector similarity has been shown to achieve different accuracy depending on the pair of languages involved, the co-occurrence model is totally language independent. In the case of binary classification of translations, the two models are complementary to each other: word pairs with null co-occurrence are not considered by the context model while the context vector model gives more semantic information than the co-occurrence model.

For these reasons, we suggest that it is possible to use a decision tree trained on one pair of languages to extract translations from another pair of languages. A similar approach is proposed in (Alfonseca et al., 2008): they present a word decomposition model designed for German language that they successfully applied to other compounding languages. Our approach consists in training a decision tree on a pair of languages and applying this model to the classification of unknown pairs of words in another pair of languages. Such an approach is especially useful for prospecting new translations from less known languages, using a well known language as training.

We used the same algorithms and same features as in the previous sections, but used the data computed from one pair of languages as the training set, and the data computed from another pair of languages as the testing set.

5 Experimental setup

5.1 Corpora

We built several corpora using two different strategies. The first set was built using Wikipedia and the interlingual links available on articles (that points to another version of the same article in another language). We started from the list of all French articles[2] and randomly selected articles that provide a link to Spanish and English versions. We downloaded those, and clean them by removing the wikipedia formatting tags to obtain raw UTF8 texts. Articles were not selected based on their sizes, the vocabulary used, nor a particular topic. We obtained about 20,000 aligned documents for each language.

A second set was built using an in-house system

[2] Available on `http://download.wikimedia.org/`.

	[WP] French	[WP] English	[WP] Es	[CLIR] En	[CLIR] Zh
#documents	20,169	20,169	20,169	15,3247	15,3247
#tokens	4,008,284	5,470,661	2,741,789	1,334,071	1,228,330
#unique tokens	120,238	128,831	103,398	30,984	60,015

Table 1: Statistics for all parts of all corpora.

(unpublished) that seeks for comparable and parallel documents from the web. Starting from a list of Chinese documents (in this case, mostly news articles), we automatically selected English target documents using Cross Language Information Retrieval. About 85% of the paired documents obtained are direct translations (header/footer of web pages apart). However, they will be processed just like aligned comparable documents, that is, we will not take advantage of the structure of the parallel contents to improve accuracy, but will use the exact same approach that we applied for the Wikipedia documents. We gathered about 15,000 pairs of documents employing this method.

All corpora were processed using Tree-Tagger[3] for segmentation and Part-of-Speech tagging. We focused on nouns only and discarded all other tokens. We would record the lemmatized form of tokens when available, otherwise we would record the original form. Table 1 summarizes main statistics for each corpus; [WP] refers to the Wikipedia corpora, [CLIR] to the Chinese-English corpora extracted through cross language information retrieval.

5.2 Dictionaries

We need a bilingual seed lexicon for the context-vector similarity. We used a French-English lexicon obtained from the Web. It contains about 67,000 entries. The Spanish-English and Spanish-French dictionaries were extracted from the linguistic resources of the Apertium project[4]. We obtained approximately 22,500 Spanish-English translations and 12,000 for Spanish-French. Finally, for Chinese-English we used the LDC2002L27 resource from the Linguistic Data Consortium[5] with about 122,000 entries.

[3] http://www.ims.uni-stuttgart.de/projekte/corplex/TreeTagger/DecisionTreeTagger.html

[4] http://www.apertium.org

[5] http://www.ldc.upenn.edu

5.3 Evaluation lists

To evaluate our approach, we needed evaluation lists of terms for which translations are already known. We used the Medical Subject Headlines, from the UMLS meta-thesaurus[6] which provides a lexicon of specialized, medical terminology, notably in Spanish, English and French. We used the LDC lexicon presented in the previous section for Chinese-English.

From these resources, we selected all the source words that appears from 1 to 5 times in the corpora in order to build the evaluation lists.

5.4 Oracle translations

We looked at the corpora to evaluate how many translation pairs from the evaluation lists can be found across the aligned comparable documents. Those translations are hereafter the *oracle translations*. For French/English, French/Spanish and English/Spanish, about 60% of the translation pairs can be found. For Chinese/English, this ratio reaches 45%. The main reason for this lower result is the inaccuracy of the segmentation tool used to process Chinese. Segmentation tools usually rely on a training corpus and typically fail at handling rare words which, by definition, were unlikely to be found in the training examples. Therefore, some rare Chinese tokens found in our corpus are the results of faulty segmentation, and the translation of those faulty words can not be found in related documents. We encountered the same issue but at a much lower degree for other languages because of spelling mistakes and/or improper Part-of-Speech tagging.

6 Experiments

We ran three different experiments. Experiment I compares the accuracy of the context-vector similarity and the co-occurrence model. Experiment II uses supervised classification with both features.

[6] http://www.nlm.nih.gov/research/umls/

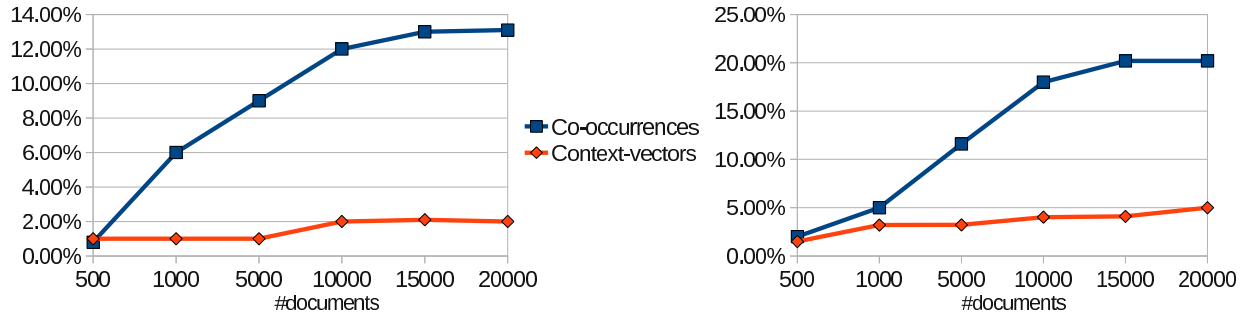

Figure 2: Experiment I: comparison of accuracy obtained for the Top_{10} with the context-vector similarity and the co-occurrence model, for hapaxes (left) and words that appear 2 to 5 times (right).

Experiment III extracts translation from a pair of languages, using a classifier trained on another pair of languages.

6.1 Experiment I: co-occurrence model vs. context-vector similarity

We split the French-English part of the Wikipedia corpus into different samples: the first sample contains 500 pairs of documents. We then aggregated more documents to this initial sample to test different sizes of corpora. We built the sample in order to ensure hapaxes in the whole corpus are hapaxes in all subsets. That is, we ensured the 431 hapaxes in the evaluation lists are represented in the 500 documents subset.

We extracted translations in two different ways:

1. using the co-occurrence model;
2. using the context-vector based approach, with the same evaluation lists.

The accuracy is computed on 1,000 pairs of translations from the set of oracle translations, and measures the amount of correct translations found for the 10 best ranks (Top_{10}) after ranking the candidates according to their score (context-vector similarity or co-occurrence model). The results are presented in figure 2.

We can draw two conclusions out of these results. First, the size of the corpus influences the quality of the bilingual lexicon extraction when using the co-occurrence model. This is especially interesting with hapaxes, for which frequency does not change with the increase of the size of the corpora. The accuracy is improved by adding more information to the corpus, even if this additional information does not cover the pairs of translations we are looking for. The added documents will weaken the association of incorrect translations, without changing the association for rare terms translations. For example, the precision for hapaxes using the co-occurrence model ranges from less than 1% when using only 500 pairs of documents, to about 13% when using all documents. The second conclusion is that the co-occurrence model outperforms the context-vector similarity.

However, both these approaches still perform poorly. In the next experiment, we propose to combine them using supervised classification.

6.2 Experiment II: binary classification of translation

For each corpus or combination of corpora – English-Spanish, English-French, Spanish-French and Chinese-English, we ran three experiments, using the following features for supervised learning of translations:

- the context-vector similarity;
- the co-occurrence model;
- both features together.

The parameters are discussed in section 4.3. We used all the oracle translations to train the positive values. Results are presented in table 2, they are computed using a 10-folds cross validation. Class T refers to "Translation", $\neg T$ to "Non-Translation". The evaluation of precision/recall/F-Measure for the class "Translation" are given in equation 4 to 6.

	Precision	Recall	F-Measure	Cl.
English-Spanish				
context-vectors	0.0%	0.0%	0.0%	T
	83.3%	99.9%	90.8%	$\neg T$
co-occ. model	66.2%	44.2%	53.0%	T
	89.5%	95.5%	92.4%	$\neg T$
both	**98.6%**	**88.6%**	**93.4%**	T
	97.8%	99.8%	98.7%	$\neg T$
French-English				
context-vectors	76.5%	10.3%	18.1%	T
	90.9%	99.6%	95.1%	$\neg T$
co-occ. model	85.7%	1.2%	2.4%	T
	90.1%	100%	94.8%	$\neg T$
both	**81.0%**	**80.2%**	**80.6%**	T
	94.9%	98.7%	96.8%	$\neg T$
French-Spanish				
context-vectors	0.0%	0.0%	0.0%	T
	81.0%	100%	89.5%	$\neg T$
co-occ. model	64.2%	46.5%	53.9%	T
	88.2%	93.9%	91.0%	$\neg T$
both	**98.7%**	**94.6%**	**96.7%**	T
	98.8%	99.7%	99.2%	$\neg T$
Chinese-English				
context-vectors	69.6%	13.3%	22.3%	T
	91.0%	93.1%	92.1%	$\neg T$
co-occ. model	73.8%	32.5%	45.1%	T
	85.2%	97.1%	90.8%	$\neg T$
both	**86.7%**	**74.7%**	**80.3%**	T
	96.3%	98.3%	97.3%	$\neg T$

Table 2: Experiment II: results of binary classification for "Translation" and "Non-Translation".

$$precision_T = \frac{|T \cap oracle|}{|T|} \quad (4)$$

$$recall_T = \frac{|T \cap oracle|}{|oracle|} \quad (5)$$

$$FMeasure = 2 \times \frac{precision \times recall}{precision + recall} \quad (6)$$

These results show first that one feature is generally not discriminatory enough to discern correct translation and non-translation pairs. For example with Spanish-English, by using context-vector similarity only, we obtained very high recall/precision for the classification of "Non-Translation", but null precision/recall for the classification of "Translation". In some other cases, we obtained high precision but poor recall with one feature only, which is not a usefully result as well since most of the correct translations are still labeled as "Non-Translation".

However, when using both features, the precision is strongly improved up to 98% (English-Spanish or French-Spanish) with a high recall of about 90% for class T. We also achieved about 86%/75% precision/recall in the case of Chinese-English, even though they are very distant languages. This last result is also very promising since it has been obtained from a fully automatically built corpus. Table 3 shows some examples of correctly labeled "Translation".

The decision trees obtained indicate that, in general, word pairs with very high co-occurrence model scores are translations, and that the context-vector similarity disambiguate candidates with lower co-occurrence model scores. Interestingly, the trained decision trees are very similar between the different pairs of languages, which inspired the next experiment.

6.3 Experiment III: extension to another pair of languages

In the last experiment, we focused on using the knowledge acquired with a given pair of languages to recognize proper translation pairs using a different pair of languages. For this experiment, we used the data from one corpus to train the classifier, and used the data from another combination of languages as the test set. Results are displayed in table 4.

These last results are of great interest because they show that translation pairs can be correctly classified even with a classifier trained on another pair of languages. This is very promising because it allows one to prospect new languages using knowledge acquired on a known pairs of languages. As an example, we reached a 77% F-Measure for Chinese-English alignment using a classifier trained on Spanish-French features. This not only confirms the precision/recall of our approach in general, but also shows that the model obtained by training tends to be very stable and accurate across different pairs of languages and different corpora.

7 Conclusion

We presented a new approach for extracting translations of rare words among aligned comparable documents. To the best of our knowledge, this is one of the first high accuracy extraction of rare lexicon from non-parallel documents. We obtained a F-Measure ranging from about 80% (French-English, Chinese-English) to 97% (French-Spanish). We also obtained good results for extracting lexicon for a pair of languages, using a decision tree trained with the data computed on another pair of languages. We yielded a 77% F-Measure for the extraction of Chinese-English lexicon, using Spanish-French for training the model.

On top of these promising results, our approach presents several other advantages. First, we showed that it works well on automatically built corpora which require minimal human intervention. Aligned comparable documents can easily be collected and are available in large volumes. Moreover, the proposed machine learning method incorporating both context-vector and co-occurrence model has shown to give good results on pairs of languages that are very different from each other, such as Chinese-English. It is also applicable across different training and testing language pairs, making it possible for us to find rare word translations even for languages without training data. The co-occurrence model is completely language independent and have been shown to give good results on various pairs of languages, including Chinese-English.

Acknowledgments

The authors would like to thank Emmanuel Morin (LINA CNRS 6241) for providing us the comparable corpus used for the experiment in section 2, Simon Shi for extracting and providing the corpus

described in section 5.1, and the anonymous reviewers for their valuable comments. This research is partly supported by ITS/189/09 AND BBNX02-20F00310/11PN.

Abstract

This paper explores the use of bilingual parallel corpora as a source of lexical knowledge for cross-lingual textual entailment. We claim that, in spite of the inherent difficulties of the task, phrase tables extracted from parallel data allow to capture both lexical relations between single words, and contextual information useful for inference. We experiment with a phrasal matching method in order to: *i)* build a system portable across languages, and *ii)* evaluate the contribution of lexical knowledge in isolation, without interaction with other inference mechanisms. Results achieved on an English-Spanish corpus obtained from the RTE3 dataset support our claim, with an overall accuracy above average scores reported by RTE participants on monolingual data. Finally, we show that using parallel corpora to extract paraphrase tables reveals their potential also in the monolingual setting, improving the results achieved with other sources of lexical knowledge.

1 Introduction

Cross-lingual Textual Entailment (CLTE) has been proposed by (Mehdad et al., 2010) as an extension of Textual Entailment (Dagan and Glickman, 2004) that consists in deciding, given two texts T and H *in different languages*, if the meaning of H can be inferred from the meaning of T. The task is inherently difficult, as it adds issues related to the multilingual dimension to the complexity of semantic inference at the textual level. For instance, the reliance of current monolingual TE systems on lexical resources (*e.g.* WordNet, VerbOcean, FrameNet) and deep processing components (*e.g.* syntactic and semantic parsers, co-reference resolution tools, temporal expressions recognizers and normalizers) has to confront, at the cross-lingual level, with the limited availability of lexical/semantic resources covering multiple languages, the limited coverage of the existing ones, and the burden of integrating language-specific components into the same cross-lingual architecture.

As a first step to overcome these problems, (Mehdad et al., 2010) proposes a "basic solution", that brings CLTE back to the monolingual scenario by translating H into the language of T. Despite the advantages in terms of modularity and portability of the architecture, and the promising experimental results, this approach suffers from one main limitation which motivates the investigation on alternative solutions. Decoupling machine translation (MT) and TE, in fact, ties CLTE performance to the availability of MT components, and to the quality of the translations. As a consequence, on one side translation errors propagate to the TE engine hampering the entailment decision process. On the other side such unpredictable errors reduce the possibility to control the behaviour of the engine, and devise *ad-hoc* solutions to specific entailment problems.

This paper investigates the idea, still unexplored, of a tighter integration of MT and TE algorithms and techniques. Our aim is to embed cross-lingual processing techniques inside the TE recognition process in order to avoid any dependency on external MT components, and eventually gain full control of the system's behaviour. Along this direction, we

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1336–1345,
Portland, Oregon, June 19-24, 2011.

start from the acquisition and use of lexical knowledge, which represents the basic building block of any TE system. Using the basic solution proposed by (Mehdad et al., 2010) as a term of comparison, we experiment with different sources of multilingual lexical knowledge to address the following questions:

(1) What is the potential of the existing multilingual lexical resources to approach CLTE? To answer this question we experiment with lexical knowledge extracted from bilingual dictionaries, and from a multilingual lexical database. Such experiments show two main limitations of these resources, namely: *i)* their limited coverage, and *ii)* the difficulty to capture contextual information when only associations between single words (or at most named entities and multiword expressions) are used to support inference.

(2) Does MT provide useful resources or techniques to overcome the limitations of existing resources? We envisage several directions in which inputs from MT research may enable or improve CLTE. As regards the resources, phrase and paraphrase tables extracted from bilingual parallel corpora can be exploited as an effective way to capture both lexical relations between single words, and contextual information useful for inference. As regards the algorithms, statistical models based on co-occurrence observations, similar to those used in MT to estimate translation probabilities, may contribute to estimate entailment probabilities in CLTE. Focusing on the resources direction, the main contribution of this paper is to show that the lexical knowledge extracted from parallel corpora allows to significantly improve the results achieved with other multilingual resources.

(3) In the cross-lingual scenario, can we achieve results comparable to those obtained in monolingual TE? Our experiments show that, although CLTE seems intrinsically more difficult, the results obtained using phrase and paraphrase tables are better than those achieved by average systems on monolingual datasets. We argue that this is due to the fact that parallel corpora are a rich source of cross-lingual paraphrases with no equivalents in monolingual TE.

(4) Can parallel corpora be useful also for monolingual TE? To answer this question, we experiment on monolingual RTE datasets using paraphrase tables extracted from bilingual parallel corpora. Our results improve those achieved with the most widely used resources in monolingual TE, namely WordNet, Verbocean, and Wikipedia.

The remainder of this paper is structured as follows. Section 2 shortly overviews the role of lexical knowledge in textual entailment, highlighting a gap between TE and CLTE in terms of available knowledge sources. Sections 3 and 4 address the first three questions, giving motivations for the use of bilingual parallel corpora in CLTE, and showing the results of our experiments. Section 5 addresses the last question, reporting on our experiments with paraphrase tables extracted from phrase tables on the monolingual RTE datasets. Section 6 concludes the paper, and outlines the directions of our future research.

2 Lexical resources for TE and CLTE

All current approaches to monolingual TE, either syntactically oriented (Rus et al., 2005), or applying logical inference (Tatu and Moldovan, 2005), or adopting transformation-based techniques (Kouleykov and Magnini, 2005; Bar-Haim et al., 2008), incorporate different types of lexical knowledge to support textual inference. Such information ranges from *i)* lexical paraphrases (textual equivalences between terms) to *ii)* lexical relations preserving entailment between words, and *iii)* word-level similarity/relatedness scores. WordNet, the most widely used resource in TE, provides all the three types of information. Synonymy relations can be used to extract lexical paraphrases indicating that words from the text and the hypothesis entail each other, thus being interchangeable. Hypernymy/hyponymy chains can provide entailment-preserving relations between concepts, indicating that a word in the hypothesis can be replaced by a word from the text. Paths between concepts and glosses can be used to calculate similarity/relatedness scores between single words, that contribute to the computation of the overall similarity between the text and the hypothesis.

Besides WordNet, the RTE literature documents the use of a variety of lexical information sources (Bentivogli et al., 2010; Dagan et al., 2009). These include, just to mention the most popular

ones, DIRT (Lin and Pantel, 2001), VerbOcean (Chklovski and Pantel, 2004), FrameNet (Baker et al., 1998), and Wikipedia (Mehdad et al., 2010; Kouylekov et al., 2009). DIRT is a collection of statistically learned inference rules, that is often integrated as a source of lexical paraphrases and entailment rules. VerbOcean is a graph of fine-grained semantic relations between verbs, which are frequently used as a source of precise entailment rules between predicates. FrameNet is a knowledge-base of frames describing prototypical situations, and the role of the participants they involve. It can be used as an alternative source of entailment rules, or to determine the semantic overlap between texts and hypotheses. Wikipedia is often used to extract probabilistic entailment rules based word similarity/relatedness scores.

Despite the consensus on the usefulness of lexical knowledge for textual inference, determining the actual impact of these resources is not straightforward, as they always represent one component in complex architectures that may use them in different ways. As emerges from the ablation tests reported in (Bentivogli et al., 2010), even the most common resources proved to have a positive impact on some systems and a negative impact on others. Some previous works (Bannard and Callison-Burch, 2005; Zhao et al., 2009; Kouylekov et al., 2009) indicate, as main limitations of the mentioned resources, their limited coverage, their low precision, and the fact that they are mostly suitable to capture relations mainly between single words.

Addressing CLTE we have to face additional and more problematic issues related to: *i)* the stronger need of lexical knowledge, and *ii)* the limited availability of multilingual lexical resources. As regards the first issue, it's worth noting that in the monolingual scenario simple "bag of words" (or "bag of n-grams") approaches are *per se* sufficient to achieve results above baseline. In contrast, their application in the cross-lingual setting is not a viable solution due to the impossibility to perform direct lexical matches between texts and hypotheses in different languages. This situation makes the availability of multilingual lexical knowledge a necessary condition to bridge the language gap. However, with the only exceptions represented by WordNet and Wikipedia, most of the aforementioned resources are available only for English. Multilingual lexical databases aligned with the English WordNet (*e.g.* MultiWordNet (Pianta et al., 2002)) have been created for several languages, with different degrees of coverage. As an example, the 57,424 synsets of the Spanish section of MultiWordNet aligned to English cover just around 50% of the WordNet's synsets, thus making the coverage issue even more problematic than for TE. As regards Wikipedia, the cross-lingual links between pages in different languages offer a possibility to extract lexical knowledge useful for CLTE. However, due to their relatively small number (especially for some languages), bilingual lexicons extracted from Wikipedia are still inadequate to provide acceptable coverage. In addition, featuring a bias towards named entities, the information acquired through cross-lingual links can at most complement the lexical knowledge extracted from more generic multilingual resources (*e.g* bilingual dictionaries).

3 Using Parallel Corpora for CLTE

Bilingual parallel corpora represent a possible solution to overcome the inadequacy of the existing resources, and to implement a portable approach for CLTE. To this aim, we exploit parallel data to: *i)* learn alignment criteria between phrasal elements in different languages, *ii)* use them to automatically extract lexical knowledge in the form of *phrase tables*, and *iii)* use the obtained phrase tables to create monolingual *paraphrase tables*.

Given a cross-lingual T/H pair (with the text in l_1 and the hypothesis in l_2), our approach leverages the vast amount of lexical knowledge provided by phrase and paraphrase tables to map H into T. We perform such mapping with two different methods. The **first method** uses a single phrase table to directly map phrases extracted from the hypothesis to phrases in the text. In order to improve our system's generalization capabilities and increase the coverage, the **second method** combines the phrase table with two monolingual paraphrase tables (one in l_1, and one in l_2). This allows to:

1. use the paraphrase table in l_2 to find paraphrases of phrases extracted from H;
2. map them to entries in the phrase table, and extract their equivalents in l_1;

3. use the paraphrase table in l_1 to find paraphrases of the extracted fragments in l_1;

4. map such paraphrases to phrases in T.

With the second method, phrasal matches between the text and the hypothesis are indirectly performed through paraphrases of the phrase table entries.

The final entailment decision for a T/H pair is assigned considering a model learned from the similarity scores based on the identified phrasal matches. In particular, "YES" and "NO" judgements are assigned considering the proportion of words in the hypothesis that are found also in the text. This way to approximate entailment reflects the intuition that, as a directional relation between the text and the hypothesis, the full content of H has to be found in T.

3.1 Extracting Phrase and Paraphrase Tables

Phrase tables (PHT) contain pairs of corresponding phrases in two languages, together with association probabilities. They are widely used in MT as a way to figure out how to translate input in one language into output in another language (Koehn et al., 2003). There are several methods to build phrase tables. The one adopted in this work consists in learning phrase alignments from a word-aligned bilingual corpus. In order to build English-Spanish phrase tables for our experiments, we used the freely available Europarl V.4, News Commentary and United Nations Spanish-English parallel corpora released for the WMT10[1]. We run TreeTagger (Schmid, 1994) for tokenization, and used the Giza++ (Och and Ney, 2003) to align the tokenized corpora at the word level. Subsequently, we extracted the bilingual phrase table from the aligned corpora using the Moses toolkit (Koehn et al., 2007). Since the resulting phrase table was very large, we eliminated all the entries with identical content in the two languages, and the ones containing phrases longer than 5 words in one of the two sides. In addition, in order to experiment with different phrase tables providing different degrees of coverage and precision, we extracted 7 phrase tables by pruning the initial one on the direct phrase translation probabilities of $0.01, 0.05, 0.1, 0.2, 0.3, 0.4$ and 0.5. The resulting phrase tables range from 76 to 48 million entries, with an average of 3.9 words per phrase.

Paraphrase tables (PPHT) contain pairs of corresponding phrases in the same language, possibly associated with probabilities. They proved to be useful in a number of NLP applications such as natural language generation (Iordanskaja et al., 1991), multidocument summarization (McKeown et al., 2002), automatic evaluation of MT (Denkowski and Lavie, 2010), and TE (Dinu and Wang, 2009).

One of the proposed methods to extract paraphrases relies on a pivot-based approach using phrase alignments in a bilingual parallel corpus (Bannard and Callison-Burch, 2005). With this method, all the different phrases in one language that are aligned with the same phrase in the other language are extracted as paraphrases. After the extraction, pruning techniques (Snover et al., 2009) can be applied to increase the precision of the extracted paraphrases.

In our work we used available[2] paraphrase databases for English and Spanish which have been extracted using the method previously outlined. Moreover, in order to experiment with different paraphrase sets providing different degrees of coverage and precision, we pruned the main paraphrase table based on the probabilities, associated to its entries, of $0.1, 0.2$ and 0.3. The number of phrase pairs extracted varies from 6 million to about 80000, with an average of 3.2 words per phrase.

3.2 Phrasal Matching Method

In order to maximize the usage of lexical knowledge, our entailment decision criterion is based on similarity scores calculated with a phrase-to-phrase matching process.

A phrase in our approach is an *n-gram* composed of up to 5 consecutive words, excluding punctuation. Entailment decisions are estimated by combining phrasal matching scores ($Score_n$) calculated for each level of *n-grams* , which is the number of *1-grams*, *2-grams*,..., *5-grams* extracted from H that match with *n-grams* in T. Phrasal matches are performed either at the level of tokens, lemmas, or stems, can be of two types:

[1] http://www.statmt.org/wmt10/

[2] http://www.cs.cmu.edu/ alavie/METEOR

1. **Exact**: in the case that two phrases are identical at one of the three levels (token, lemma, stem);

2. **Lexical**: in the case that two different phrases can be mapped through entries of the resources used to bridge T and H (*i.e.* phrase tables, paraphrases tables, dictionaries or any other source of lexical knowledge).

For each phrase in H, we first search for exact matches at the level of token with phrases in T. If no match is found at a token level, the other levels (lemma and stem) are attempted. Then, in case of failure with exact matching, lexical matching is performed at the same three levels. To reduce redundant matches, the lexical matches between pairs of phrases which have already been identified as exact matches are not considered.

Once matching for each *n-gram* level has been concluded, the number of matches (M_n) and the number of phrases in the hypothesis (Nn) are used to estimate the portion of phrases in H that are matched at each level (*n*). The phrasal matching score for each *n-gram* level is calculated as follows:

$$Score_n = \frac{M_n}{Nn}$$

To combine the phrasal matching scores obtained at each *n-gram* level, and optimize their relative weights, we trained a Support Vector Machine classifier, SVMlight (Joachims, 1999), using each score as a feature.

4 Experiments on CLTE

To address the first two questions outlined in Section 1, we experimented with the phrase matching method previously described, contrasting the effectiveness of lexical information extracted from parallel corpora with the knowledge provided by other resources used in the same way.

4.1 Dataset

The dataset used for our experiments is an English-Spanish entailment corpus obtained from the original RTE3 dataset by translating the English hypothesis into Spanish. It consists of 1600 pairs derived from the RTE3 development and test sets (800+800). Translations have been generated by the CrowdFlower[3] channel to Amazon Mechanical Turk[4] (MTurk), adopting the methodology proposed by (Negri and Mehdad, 2010). The method relies on translation-validation cycles, defined as separate jobs routed to MTurk's workforce. Translation jobs return one Spanish version for each hypothesis. Validation jobs ask multiple workers to check the correctness of each translation using the original English sentence as reference. At each cycle, the translated hypothesis accepted by the majority of trustful validators[5] are stored in the CLTE corpus, while wrong translations are sent back to workers in a new translation job. Although the quality of the results is enhanced by the possibility to automatically weed out untrusted workers using gold units, we performed a manual quality check on a subset of the acquired CLTE corpus. The validation, carried out by a Spanish native speaker on 100 randomly selected pairs after two translation-validation cycles, showed the good quality of the collected material, with only 3 minor "errors" consisting in controversial but substantially acceptable translations reflecting regional Spanish variations.

The T-H pairs in the collected English-Spanish entailment corpus were annotated using TreeTagger (Schmid, 1994) and the Snowball stemmer[6] with token, lemma, and stem information.

4.2 Knowledge sources

For comparison with the extracted phrase and paraphrase tables, we use a large bilingual dictionary and MultiWordNet as alternative sources of lexical knowledge.

Bilingual dictionaries (DIC) allow for precise mappings between words in H and T. To create a large bilingual English-Spanish dictionary we processed and combined the following dictionaries and bilingual resources:
- XDXF Dictionaries[7]: 22,486 entries.

[3] http://crowdflower.com/

[4] https://www.mturk.com/mturk/

[5] Workers' trustworthiness can be automatically determined by means of hidden gold units randomly inserted into jobs.

[6] http://snowball.tartarus.org/

[7] http://xdxf.revdanica.com/

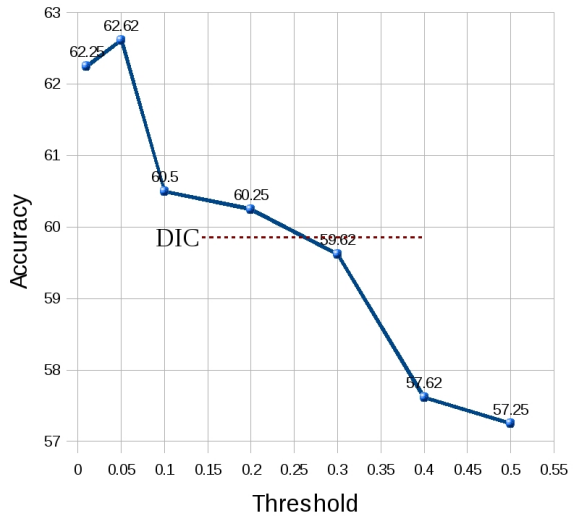

Figure 1: Accuracy on CLTE by pruning the phrase table with different thresholds.

- Universal dictionary database[8]: 9,944 entries.
- Wiktionary database[9]: 5,866 entries.
- Omegawiki database[10]: 8,237 entries.
- Wikipedia interlanguage links[11]: 7,425 entries.

The resulting dictionary features 53,958 entries, with an average length of 1.2 words.

MultiWordNet (MWN) allows to extract mappings between English and Spanish words connected by entailment-preserving semantic relations. The extraction process is dataset-dependent, as it checks for synonymy and hyponymy relations only between terms found in the dataset. The resulting collection of cross-lingual words associations contains 36,794 pairs of lemmas.

4.3 Results and Discussion

Our results are calculated over 800 test pairs of our CLTE corpus, after training the SVM classifier over 800 development pairs. This section reports the percentage of correct entailment assignments (accuracy), comparing the use of different sources of lexical knowledge.

Initially, in order to find a reasonable trade-off between precision and coverage, we used the 7 phrase tables extracted with different pruning thresholds (see Section 3.1). Figure 1 shows that with the pruning threshold set to 0.05, we obtain the highest result of 62.62% on the test set. The curve demonstrates that, although with higher pruning thresholds we retain more reliable phrase pairs, their smaller number provides limited coverage leading to lower results. In contrast, the large coverage obtained with the pruning threshold set to 0.01 leads to a slight performance decrease due to probably less precise phrase pairs.

MWN	DIC	PHT	PPHT	Acc.	δ
x				55.00	0.00
	x			59.88	+4.88
		x		**62.62**	+7.62
		x	x	**62.88**	+7.88

Table 1: Accuracy results on CLTE using different lexical resources.

Once the threshold has been set, in order to prove the effectiveness of information extracted from bilingual corpora, we conducted a series of experiments using the different resources mentioned in Section 4.2.

As it can be observed in Table 1, the highest results are achieved using the phrase table, both alone and in combination with paraphrase tables (62.62% and 62.88% respectively). These results suggest that, with appropriate pruning thresholds, the large number and the longer entries contained in the phrase and paraphrase tables represent an effective way to: *i)* obtain high coverage, and *ii)* capture cross-lingual associations between multiple lexical elements. This allows to overcome the bias towards single words featured by dictionaries and lexical databases.

As regards the other resources used for comparison, the results show that dictionaries substantially outperform MWN. This can be explained by the low coverage of MWN, whose entries also represent weaker semantic relations (preserving entailment, but with a lower probability to be applied) than the direct translations between terms contained in the dictionary.

Overall, our results suggest that the lexical knowledge extracted from parallel data can be successfully used to approach the CLTE task.

Table 2: Accuracy results on monolingual RTE using different lexical resources.

5 Using parallel corpora for TE

This section addresses the third and the fourth research questions outlined in Section 1. Building on the positive results achieved on the cross-lingual scenario, we investigate the possibility to exploit bilingual parallel corpora in the traditional monolingual scenario. Using the same approach discussed in Section 4, we compare the results achieved with English paraphrase tables with those obtained with other widely used monolingual knowledge resources over two RTE datasets.

For the sake of completeness, we report in this section also the results obtained adopting the "basic solution" proposed by (Mehdad et al., 2010). Although it was presented as an approach to CLTE, the proposed method brings the problem back to the monolingual case by translating H into the language of T. The comparison with this method aims at verifying the real potential of parallel corpora against the use of a competitive MT system (Google Translate) in the same scenario.

5.1 Dataset

We experiment with the original RTE3 and RTE5 datasets, annotated with token, lemma, and stem information using the TreeTagger and the Snowball stemmer.

In addition to confront our method with the solution proposed by (Mehdad et al., 2010) we translated the Spanish hypotheses of our CLTE dataset into English using Google Translate. The resulting dataset was annotated in the same way.

5.2 Knowledge sources

We compared the results achieved with paraphrase tables (extracted with different pruning thresholds[12]) with those obtained using the three most widely used English resources for Textual Entailment (Bentivogli et al., 2010), namely:

WordNet (WN). WordNet 3.0 has been used to extract a set of 5396 pairs of words connected by the hyponymy and synonymy relations.

VerbOcean (VO). VerbOcean has been used to extract 18232 pairs of verbs connected by the "stronger-than" relation (*e.g. "kill" stronger-than "injure"*).

Wikipedia (WIKI). We performed Latent Semantic Analysis (LSA) over Wikipedia using the jLSI tool (Giuliano, 2007) to measure the relatedness between words in the dataset. Then, we filtered all the pairs with similarity lower than 0.7 as proposed by (Kouylekov et al., 2009). In this way we obtained 13760 word pairs.

5.3 Results and Discussion

Table 2 shows the accuracy results calculated over the original RTE3 and RTE5 test sets, training our classifier over the corresponding development sets.

The first two rows of the table show that pruned paraphrase tables always outperform the other lexical resources used for comparison, with an accuracy increase up to 3%. In particular, we observe that using 0.2 as a pruning threshold provides a good trade-off between coverage and precision, leading to our best results on both datasets (63.50% for RTE3, and 62.67% for RTE5). It's worth noting that these results, compared with the average scores reported by participants in the two editions of the RTE Challenge (AVG column), represent an accuracy improvement of more than 1%. Overall, these results confirm our claim that increasing the coverage using context sensitive phrase pairs obtained from large parallel corpora, results in better performance not only in CLTE,

[12]We pruned the paraphrase table (PPHT), with probabilities set to 0.1 (PPHT 0.1), 0.2 (PPHT 0.2), and 0.3 (PPHT 0.3)

but also in the monolingual scenario.

The comparison with the results achieved on monolingual data obtained by automatically translating the Spanish hypotheses (RTE3-G row in Table 2) leads to four main observations. First, we notice that dealing with MT-derived inputs, the optimal pruning threshold changes from 0.2 to 0.1, leading to the highest accuracy of 63.50%. This suggests that the noise introduced by incorrect translations can be tackled by increasing the coverage of the paraphrase table. Second, in line with the findings of (Mehdad et al., 2010), the results obtained over the MT-derived corpus are equal to those we achieve over the original RTE3 dataset (*i.e.* 63.50%). Third, the accuracy obtained over the CLTE corpus using combined phrase and paraphrase tables (62.88%, as reported in Table 1) is comparable to the best result gained over the automatically translated dataset (63.50%). In all the other cases, the use of phrase and paraphrase tables on CLTE data outperforms the results achieved on the same data after translation. Finally, it's worth remarking that applying our phrase matching method on the translated dataset without any additional source of knowledge would result in an overall accuracy of 62.12%, which is lower than the result obtained using only phrase tables on cross-lingual data (62.62%). This demonstrates that phrase tables can successfully replace MT systems in the CLTE task.

In light of this, we suggest that extracting lexical knowledge from parallel corpora is a preferable solution to approach CLTE. One of the main reasons is that placing a black-box MT system at the front-end of the entailment process reduces the possibility to cope with wrong translations. Furthermore, the access to MT components is not easy (*e.g.* Google Translate limits the number and the size of queries, while open source MT tools cover few language pairs). Moreover, the task of developing a full-fledged MT system often requires the availability of parallel corpora, and is much more complex than extracting lexical knowledge from them.

6 Conclusion and Future Work

In this paper we approached the cross-lingual Textual Entailment task focusing on the role of lexical knowledge extracted from bilingual parallel corpora. One of the main difficulties in CLTE raises from the lack of adequate knowledge resources to bridge the lexical gap between texts and hypotheses in different languages. Our approach builds on the intuition that the vast amount of knowledge that can be extracted from parallel data (in the form of phrase and paraphrase tables) offers a possible solution to the problem. To check the validity of our assumptions we carried out several experiments on an English-Spanish corpus derived from the RTE3 dataset, using phrasal matches as a criterion to approximate entailment. Our results show that phrase and paraphrase tables allow to: *i)* outperform the results achieved with the few multilingual lexical resources available, and *ii)* reach performance levels above the average scores obtained by participants in the monolingual RTE3 challenge. These improvements can be explained by the fact that the lexical knowledge extracted from parallel data provides good coverage both at the level of single words, and at the level of phrases.

As a further contribution, we explored the application of paraphrase tables extracted from parallel data in the traditional monolingual scenario. Contrasting results with those obtained with the most widely used resources in TE, we demonstrated the effectiveness of paraphrase tables as a mean to overcome the bias towards single words featured by the existing resources.

Our future work will address both the extraction of lexical information from bilingual parallel corpora, and its use for TE and CLTE. On one side, we plan to explore alternative ways to build phrase and paraphrase tables. One possible direction is to consider linguistically motivated approaches, such as the extraction of syntactic phrase tables as proposed by (Yamada and Knight, 2001). Another interesting direction is to investigate the potential of paraphrase patterns (*i.e.* patterns including part-of-speech slots), extracted from bilingual parallel corpora with the method proposed by (Zhao et al., 2009). On the other side we will investigate more sophisticated methods to exploit the acquired lexical knowledge. As a first step, the probability scores assigned to phrasal entries will be considered to perform weighted phrase matching as an improved criterion to approximate entailment.

Abstract

Resolving coordination ambiguity is a classic hard problem. This paper looks at coordination disambiguation in complex noun phrases (NPs). Parsers trained on the Penn Treebank are reporting impressive numbers these days, but they don't do very well on this problem (79%). We explore systems trained using three types of corpora: (1) annotated (e.g. the Penn Treebank), (2) bitexts (e.g. Europarl), and (3) unannotated monolingual (e.g. Google N-grams). Size matters: (1) is a million words, (2) is potentially billions of words and (3) is potentially trillions of words. The unannotated monolingual data is helpful when the ambiguity can be resolved through associations among the lexical items. The bilingual data is helpful when the ambiguity can be resolved by the order of words in the translation. We train separate classifiers with monolingual and bilingual features and iteratively improve them via co-training. The co-trained classifier achieves close to 96% accuracy on Treebank data and makes 20% fewer errors than a supervised system trained with Treebank annotations.

1 Introduction

Determining which words are being linked by a coordinating conjunction is a classic hard problem. Consider the pair:

+**ellipsis** rocket$\backslash w_1$ and mortar$\backslash w_2$ attacks$\backslash h$
−**ellipsis** asbestos$\backslash w_1$ and polyvinyl$\backslash w_2$ chloride$\backslash h$

+ellipsis is about both *rocket attacks* and *mortar attacks*, unlike −ellipsis which is not about *asbestos chloride*. We use *h* to refer to the head of the phrase, and w_1 and w_2 to refer to the other two lexical items.

Natural Language Processing applications need to recognize NP ellipsis in order to make sense of new sentences. For example, if an Internet search engine is given the phrase *rocket attacks* as a query, it should rank documents containing *rocket and mortar attacks* highly, even though *rocket* and *attacks* are not contiguous in the document. Furthermore, NPs with ellipsis often require a distinct type of reordering when translated into a foreign language. Since coordination is both complex and productive, parsers and machine translation (MT) systems cannot simply memorize the analysis of coordinate phrases from training text. We propose an approach to recognizing ellipsis that could benefit both MT and other NLP technology that relies on shallow or deep syntactic analysis.

While the general case of coordination is quite complicated, we focus on the special case of complex NPs. Errors in NP coordination typically account for the majority of parser coordination errors (Hogan, 2007). The information needed to resolve coordinate NP ambiguity cannot be derived from hand-annotated data, and we follow previous work in looking for new information sources to apply to this problem (Resnik, 1999; Nakov and Hearst, 2005; Rus et al., 2007; Pitler et al., 2010).

We first resolve coordinate NP ambiguity in a word-aligned parallel corpus. In bitexts, both monolingual and bilingual information can indicate NP structure. We create separate classifiers using monolingual and bilingual feature views. We train the two classifiers using co-training, iteratively improving the accuracy of one classifier by learning from the predictions of the other. Starting from only two

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1346–1355,
Portland, Oregon, June 19-24, 2011.

initial labeled examples, we are able to train a highly accurate classifier using only monolingual features. The monolingual classifier can then be used both within and beyond the aligned bitext. In particular, it achieves close to 96% accuracy on both bitext data and on out-of-domain examples in the Treebank.

2 Problem Definition and Related Tasks

Our system operates over a part-of-speech tagged input corpus. We attempt to resolve the ambiguity in all tag sequences matching the expression:

[DT|PRP$] (N.*|J.*) and [DT|PRP$] (N.*|J.*) N.*
e.g. [the] rocket$\backslash w_1$ and [the] mortar$\backslash w_2$ attacks$\backslash h$

Each example ends with a noun, h. Preceding h are a pair of possibly-conjoined words, w_1 and w_2, either nouns (*rocket* and *mortar*), adjectives, or a mix of the two. We allow determiners or possessive pronouns before w_1 and/or w_2. This pattern is very common. Depending on the domain, we find it in roughly one of every 10 to 20 sentences. We merge identical matches in our corpus into a single example for labeling. Roughly 38% of w_1,w_2 pairs are both adjectives, 26% are nouns, and 36% are mixed.

The task is to determine whether w_1 and w_2 are conjoined or not. When they are not conjoined, there are two cases: 1) w_1 is actually conjoined with w_2 h as a whole (e.g. *asbestos and polyvinyl chloride*), or 2) The conjunction links something higher up in the parse tree, as in, "farmers are getting older$\backslash w_1$ and younger$\backslash w_2$ people$\backslash h$ are reluctant to take up farming." Here, *and* links two separate clauses.

Our task is both narrower and broader than previous work. It is broader than previous approaches that have focused only on conjoined nouns (Resnik, 1999; Nakov and Hearst, 2005). Although pairs of adjectives are usually conjoined (and mixed tags are usually not), this is not always true, as in *older/younger* above. For comparison, we also state accuracy on the noun-only examples (§ 8).

Our task is more narrow than the task tackled by full-sentence parsers, but most parsers do not bracket NP-internal structure at all, since such structure is absent from the primary training corpus for statistical parsers, the Penn Treebank (Marcus et al., 1993). We confirm that standard broad-coverage parsers perform poorly on our task (§ 7).

Vadas and Curran (2007a) manually annotated NP structure in the Penn Treebank, and a few custom NP parsers have recently been developed using this data (Vadas and Curran, 2007b; Pitler et al., 2010). Our task is more narrow than the task handled by these parsers since we do not handle other, less-frequent and sometimes more complex constructions (e.g. *robot arms and legs*). However, such constructions are clearly amenable to our algorithm. In addition, these parsers have only evaluated coordination resolution *within base NPs*, simplifying the task and rendering the aforementioned *older/younger* problem moot. Finally, these custom parsers have only used simple count features; for example, they have not used the paraphrases we describe below.

3 Supervised Coordination Resolution

We adopt a discriminative approach to resolving coordinate NP ambiguity. For each unique coordinate NP in our corpus, we encode relevant information in a feature vector, $\bar{x}$. A classifier scores these vectors with a set of learned weights, $\bar{w}$. We assume N labeled examples $\{(y^1, \bar{x}^1), ..., (y^N, \bar{x}^N)\}$ are available to train the classifier. We use '$y = 1$' as the class label for NPs with ellipsis and '$y = 0$' for NPs without. Since our particular task requires a binary decision, any standard learning algorithm can be used to learn the feature weights on the training data. We use (regularized) logistic regression (a.k.a. maximum entropy) since it has been shown to perform well on a range of NLP tasks, and also because its probabilistic interpretation is useful for co-training (§ 4). In binary logistic regression, the probability of a positive class takes the form of the logistic function:

$$\Pr(y = 1) = \frac{\exp(\bar{w} \cdot \bar{x})}{1 + \exp(\bar{w} \cdot \bar{x})}$$

Ellipsis is predicted if $\Pr(y = 1) > 0.5$ (equivalently, $\bar{w} \cdot \bar{x} > 0$), otherwise we predict no ellipsis.

Supervised classifiers easily incorporate a range of interdependent information into a learned decision function. The cost for this flexibility is typically the need for labeled training data. The more features we use, the more labeled data we need, since for linear classifiers, the number of examples needed to reach optimum performance is at most linear in the

Phrase	Evidence		Pattern
dairy and meat production (ellipsis)	English:	*... production of dairy and meat...*	h *of* w_1 *and* w_2
	English:	*... dairy production and meat production...*	w_1 h *and* w_2 h
	English:	*... meat and dairy production...*	w_2 *and* w_1 h
	Spanish:	*... producción láctea y cárnica...*	h w_1 ... w_2
		→ *production dairy and meat*	
	Finnish:	*... maidon- ja lihantuotantoon...*	w_1- ... w_2h
		→ *dairy- and meatproduction*	
	French:	*... production de produits laitiers et de viande...*	h ... w_1 ... w_2
		→ *production of products dairy and of meat*	
asbestos and polyvinyl chloride (no ellipsis)	English:	*... polyvinyl chloride and asbestos...*	w_2 h *and* w_1
	English:	*... asbestos , and polyvinyl chloride...*	w_1 *,* *and* w_2 h
	English:	*... asbestos and chloride...*	w_1 *and* h
	Portuguese:	*... o amianto e o cloreto de polivinilo...*	w_1 ... h ... w_2
		→ *the asbestos and the chloride of polyvinyl*	
	Italian:	*... l' asbesto e il polivinilcloruro...*	w_1 ... w_2h
		→ *the asbestos and the polyvinylchloride*	

Table 1: Monolingual and bilingual evidence for ellipsis or lack-of-ellipsis in coordination of [w_1 *and* w_2 h] phrases.

number of features (Vapnik, 1998). In § 4, we propose a way to circumvent the need for labeled data.

We now describe the particular monolingual and bilingual information we use for this problem. We refer to Table 1 for canonical examples of the two classes and also to provide intuition for the features.

3.1 Monolingual Features

Count features These real-valued features encode the frequency, in a large auxiliary corpus, of relevant word sequences. Co-occurrence frequencies have long been used to resolve linguistic ambiguities (Dagan and Itai, 1990; Hindle and Rooth, 1993; Lauer, 1995). With the massive volumes of raw text now available, we can look for very specific and indicative word sequences. Consider the phrase *dairy and meat production* (Table 1). A high count in raw text for the paraphrase "*production of dairy and meat*" implies ellipsis in the original example. In the third column of Table 1, we suggest a pattern that generalizes the particular piece of evidence. It is these patterns and other English paraphrases that we encode in our count features (Table 2). We also use (but do not list) count features for the four paraphrases proposed in Nakov and Hearst (2005, § 3.2.3). Such specific paraphrases are more common than one might think. In our experiments, at least 20% of examples have non-zero counts for a 5-gram pattern, while over 70% of examples have counts for a 4-gram pattern.

Our features also include counts for subsequences of the full phrase. High counts for "*dairy production*" alone or just "*dairy and meat*" also indicate ellipsis. On the other hand, like Pitler et al. (2010), we have a feature for the count of "*dairy and production*." Frequent conjoining of w_1 and h is evidence that there is no ellipsis, that w_1 and h are compatible and heads of two separate and conjoined NPs.

Many of our patterns are novel in that they include commas or determiners. The presence of these often indicate that there are two separate NPs. E.g. seeing *asbestos , and polyvinyl chloride* or *the asbestos and the polyvinyl chloride* suggests no ellipsis. We also propose patterns that include left-and-right context around the NP. These aim to capture salient information about the NP's distribution as an entire unit. Finally, patterns involving prepositions look for explicit paraphrasing of the nominal relations; the presence of "h PREP w_1 and w_2" in a corpus would suggest ellipsis in the original NP.

In total, we have 48 separate count features, requiring counts for 315 distinct N-grams for each example. We use **log-counts** as the feature value, and use a separate binary feature to indicate if a particular count is zero. We efficiently acquire the counts using custom tools for managing web-scale N-gram

Real-valued count features. C(p) → count of p

tag$_{12h}$=⟨tag(w_1),tag(w_1),tag(h)⟩		

Table 2: Monolingual features. For counts using the filler sets CC, DT and PREP, counts are *summed* across all filler combinations. In contrast, feature templates are denoted with $\langle\cdot\rangle$, where the feature label depends on the ⟨bracketed argument⟩. E.g., we have separate count feature for each item in the L/R context sets, where {L-CTXT} = {*with, and, as, including, on, is, are, &*}, {R-CTXT} = {*and, have, of, on, said, to, were, &*}

data (§ 5). Previous approaches have used search engine page counts as substitutes for co-occurrence information (Nakov and Hearst, 2005; Rus et al., 2007). These approaches clearly cannot scale to use the wide range of information used in our system.

Binary features Table 2 gives the binary features and feature templates. These are templates in the sense that every unique word or tag fills the template and corresponds to a unique feature. We can thus learn if particular words or tags are associated with ellipsis. We also include binary features to flag the presence of any optional determiners before w_1 or w_2. We also have binary features for the context words that precede and follow the tag sequence in the source corpus. These context features are analogous to the L/R-CTXT features that were counted in the auxiliary corpus. Our classifier learns, for example, that instances preceded by the words *its* and *in* are likely to have ellipsis: these words tend to precede single NPs as opposed to conjoined NP pairs.

Table 3: Example of actual instantiated feature vectors for *dairy and meat production* (in label:value format). Monolingual feature vector, $\bar{x}_m$, on the left (both count and binary features, see Table 2), Bilingual feature vector, $\bar{x}_b$, on the right (see Table 4).

Example Table 3 provides part of the actual instantiated monolingual feature vector for *dairy and meat production*. Note the count features have logarithmic values, while only the non-zero binary features are included.

A later stage of processing extracts a list of feature labels from the training data. This list is then used to map feature labels to integers, yielding the standard (sparse) format used by most machine learning software (e.g., 1:14.4 2:15.4 3:17.2 ... 7149:1 24208:1).

3.2 Bilingual Features

The above features represent the best of the information available to a coordinate NP classifier when operating on an arbitrary text. In some domains, however, we have additional information to inform our decisions. We consider the case where we seek to predict coordinate structure in parallel text: i.e., English text with a corresponding translation in one

or more target languages. A variety of mature NLP tools exists in this domain, allowing us to robustly align the parallel text first at the sentence and then at the word level. Given a word-aligned parallel corpus, we can see how the different types of coordinate NPs are translated in the target languages.

In Romance languages, examples with ellipsis, such as *dairy and meat production* (Table 1), tend to correspond to translations with the head in the first position, e.g. "producción láctea y cárnica" in Spanish (examples taken from Europarl (Koehn, 2005)). When there is no ellipsis, the head-first syntax leads to the "w_1 and h w_2" ordering, e.g. *amianto e o cloreto de polivinilo* in Portuguese. Another clue for ellipsis is the presence of a dangling hyphen, as in the Finnish *maidon- ja lihantuotantoon*. We find such hyphens especially common in Germanic languages like Dutch. In addition to language-specific clues, a translation may resolve an ambiguity by paraphrasing the example in the same way it may be paraphrased in English. E.g., we see *hard and soft drugs* translated into Spanish as *drogas blandas y drogas duras* with the head, *drogas*, repeated (akin to *soft drugs and hard drugs* in English).

One could imagine manually defining the relationship between English NP coordination and the patterns in each language, but this would need to be repeated for each language pair, and would likely miss many useful patterns. In contrast, by representing the translation patterns as features in a classifier, we can instead automatically learn the coordination-translation correspondences, in any language pair.

For each occurrence of a coordinate NP in a word-aligned bitext, we inspect the alignments and determine the mapping of w_1, w_2 and h. Recall that each of our examples represents all the occurrences of a unique coordinate NP in a corpus. We therefore aggregate translation information over all the occurrences. Since the alignments in automatically-aligned parallel text are noisy, the more occurrences we have, the more translations we have, and the more likely we are to make a correct decision. For some common instances in Europarl, like *Agriculture and Rural Development*, we have thousands of translations in several languages.

Table 4 provides the bilingual feature templates. The notation indicates that, for a given coordinate NP, we count the frequency of each translation pattern in each target language, and generate real-valued features for these counts. The feature counts are indexed to the particular pattern and language. We also have one language-independent feature, C$\langle$*ord*(w_1,w_2,h)$\rangle$, which gives the frequency of each ordering across all languages. The *span* is the number of tokens collectively spanned by the translations of w_1, w_2 and h. The "*detailed pattern*" represents the translation using wildcards for all other foreign words, but maintains punctuation. Letting '*' stand for the wildcard, the detailed patterns for the translations of *dairy and meat production* in Table 1 would be [h w_1 * w_2] (Spanish), [w_1- * $w_2 h$] (Finnish) and [h * * w_1 * * w_2] (French). Four or more consecutive wildcards are converted to '...'. For the "*simple pattern*," we remove the wildcards and punctuation. Note that our aligner allows the English word to map to multiple target words. The simple pattern differs from the *ordering* in that it denotes how many tokens each of w_1, w_2 and h span.

C$\langle$*detl*(w_1,w_2,h)$\rangle$,$\langle$LANG$\rangle$
C$\langle$*simp*(w_1,w_2,h)$\rangle$,$\langle$LANG$\rangle$
C$\langle$*span*(w_1,w_2,h)$\rangle$,$\langle$LANG$\rangle$
C$\langle$*ord*(w_1,w_2,h)$\rangle$,$\langle$LANG$\rangle$
C$\langle$*ord*(w_1,w_2,h)$\rangle$

Table 4: Real-valued bilingual feature templates. The shorthand is *detl*="detailed pattern," *simp*="simple pattern," *span*="span of pattern," *ord*="order of words." The notation C$\langle p \rangle$,$\langle$LANG$\rangle$ means the number of times we see the pattern (or span) $\langle p \rangle$ as the aligned translation of the coordinate NP in the target language $\langle$LANG$\rangle$.

Example Table 3 also provides part of the actual instantiated bilingual feature vector for *dairy and meat production*.

4 Bilingual Co-training

We exploit the orthogonality of the monolingual and bilingual features using semi-supervised learning. These features are orthogonal in the sense that they look at different sources of information for each example. If we had enough training data, a good classifier could be trained using either monolingual or bilingual features on their own. With classifiers trained on even a little labeled data, it's feasible that for a particular example, the monolingual classifier might be confident when the bilingual classifier is

Algorithm 1 The bilingual co-training algorithm: subscript m corresponds to monolingual, b to bilingual

Given: • a set L of labeled training examples in the bitext, $\{(\bar{x}^i, y^i)\}$
• a set U of unlabeled examples in the bitext, $\{\bar{x}^j\}$
• hyperparams: k (num. iterations), u_m and u_b (size smaller unlabeled pools), n_m and n_b (num. new labeled examples each iteration), C: regularization param. for classifier training

Create $L_m \leftarrow L$
Create $L_b \leftarrow L$
Create a pool U_m by choosing u_m examples randomly from U.
Create a pool U_b by choosing u_b examples randomly from U.
for $i = 0$ to k **do**
  Use L_m to train a classifier h_m using only $\bar{x}_m$, the monolingual features of $\bar{x}$
  Use L_b to train a classifier h_b using only $\bar{x}_b$, the bilingual features of $\bar{x}$
  Use h_m to label U_m, move the n_m most-confident examples to L_b
  Use h_b to label U_b, move the n_b most-confident examples to L_m
  Replenish U_m and U_b randomly from U with n_m and n_b new examples
end for

uncertain, and vice versa. This suggests using a co-training approach (Yarowsky, 1995; Blum and Mitchell, 1998). We train separate classifiers on the labeled data. We use the predictions of one classifier to label new examples for training the orthogonal classifier. We iterate this training and labeling.

We outline how this procedure can be applied to bitext data in **Algorithm 1** (above). We follow prior work in drawing predictions from smaller pools, U_m and U_b, rather than from U itself, to ensure the labeled examples "are more representative of the underlying distribution" (Blum and Mitchell, 1998). We use a logistic regression classifier for h_m and h_b. Like Blum and Mitchell (1998), we also create a *combined* classifier by making predictions according to $\text{argmax}_{y=1,0}\, Pr(y|x_m)Pr(y|x_b)$.

The hyperparameters of the algorithm are 1) k, the number of iterations, 2) u_m and u_b, the size of the smaller unlabeled pools, 3) n_m and n_b, the number of new labeled examples to include at each iteration, and 4) the regularization parameter of the logistic regression classifier. All such parameters can be tuned on a development set. Like Blum and Mitchell (1998), we ensure that we maintain roughly the true class balance in the labeled examples added at each iteration; we also estimate this balance using development data.

There are some differences between our approach and the co-training algorithm presented in Blum and Mitchell (1998, Table 1). One of our key goals is to produce an accurate classifier that uses only monolingual features, since only this classifier can be applied to arbitrary monolingual text. We thus break the symmetry in the original algorithm and allow h_b to label more examples for h_m than vice versa, so that h_m will improve faster. This is desirable because we don't have unlimited unlabeled examples to draw from, only those found in our parallel text.

5 Data

Web-scale text data is used for monolingual feature counts, parallel text is used for classifier co-training, and labeled data is used for training and evaluation.

Web-scale N-gram Data We extract our counts from *Google V2*: a new N-gram corpus (with N-grams of length one-to-five) created from the same one-trillion-word snapshot of the web as the Google 5-gram Corpus (Brants and Franz, 2006), but with enhanced filtering and processing of the source text (Lin et al., 2010, Section 5). We get counts using the suffix array tools described in (Lin et al., 2010). We add one to all counts for smoothing.

Parallel Data We use the Danish, German, Greek, Spanish, Finnish, French, Italian, Dutch, Portuguese, and Swedish portions of Europarl (Koehn, 2005). We also use the Czech, German, Spanish and French news commentary data from WMT

2010.[1] Word-aligned English-Foreign bitexts are created using the Berkeley aligner.[2] We run 5 iterations of joint IBM Model 1 training, followed by 3-to-5 iterations of joint HMM training, and align with the competitive-thresholding heuristic. The English portions of all bitexts are part-of-speech tagged with CRFTagger (Phan, 2006). 94K unique coordinate NPs and their translations are then extracted.

Labeled Data For experiments within the parallel text, we manually labeled 1320 of the 94K coordinate NP examples. We use 605 examples to set development parameters, 607 examples as held-out test data, and 2, 10 or 100 examples for training.

For experiments on the WSJ portion of the Penn Treebank, we merge the original Treebank annotations with the NP annotations provided by Vadas and Curran (2007a). We collect all coordinate NP sequences matching our pattern and collapse them into a single example. We label these instances by determining whether the annotations have w_1 and w_2 conjoined. In only one case did the same coordinate NP have different labels in different occurrences; this was clearly an error and resolved accordingly. We collected 1777 coordinate NPs in total, and divided them into 777 examples for training, 500 for development and 500 as a final held-out test set.

6 Evaluation and Settings

We evaluate using *accuracy*: the percentage of examples classified correctly in held-out test data. We compare our systems to a baseline referred to as the **Tag-Triple classifier**. This classifier has a single feature: the $\text{tag}(w_1), \text{tag}(w_2), \text{tag}(h)$ triple. Tag-Triple is therefore essentially a discriminative, *un*lexicalized parser for our coordinate NPs.

All classifiers use L2-regularized logistic regression training via LIBLINEAR (Fan et al., 2008). For co-training, we fix regularization at $C = 0.1$. For all other classifiers, we optimize the C parameter on the development data. At each iteration, i, classifier h_m annotates 50 new examples for training h_b, from a pool of 750 examples, while h_b annotates $50 * i$ new examples for h_m, from a pool of $750 * i$ examples. This ensures h_m gets the majority of automatically-labeled examples.

[2] nlp.cs.berkeley.edu/pages/wordaligner.html

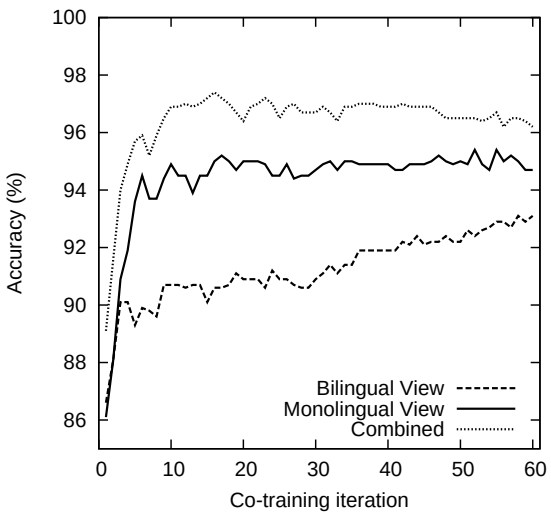

Figure 1: Accuracy on **Bitext** development data over the course of co-training (from 10 initial seed examples).

We also set k, the number of co-training iterations. The monolingual, bilingual, and combined classifiers reach their optimum levels of performance after different numbers of iterations (Figure 1). We therefore set k separately for each, stopping around 16 iterations for the combined, 51 for the monolingual, and 57 for the bilingual classifier.

7 Bitext Experiments

We evaluate our systems on our held-out bitext data. The majority class is ellipsis, in 55.8% of examples. For comparison, we ran two publicly-available broad-coverage parsers and analyzed whether they correctly predicted ellipsis. The parsers were the C&C parser (Curran et al., 2007) and Minipar (Lin, 1998). They achieved 78.6% and 77.6%.[3]

Table 5 shows that co-training results in much more accurate classifiers than supervised training alone, regardless of the features or amount of initial training data. The Tag-Triple system is the weakest system in all cases. This shows that better monolingual features are very important, but semi-supervised training can also make a big difference.

[3] We provided the parsers full sentences containing the NPs. We directly extracted the labels from the C&C bracketing, while for Minipar we checked whether w_1 was the head of w_2. Of course, the parsers performed very poorly on ellipsis involving two nouns (partly because NP structure is absent from their training corpora (see § 2 and also Vadas and Curran (2008)), but neither exceeded 88% on adjective or mixed pairs either.

System	# of Examples		
	2	10	100
Tag-Triple classifier	67.4	79.1	82.9
Monolingual classifier	69.9	90.8	91.6
Co-trained Mono. classifier	96.4	95.9	96.0
Relative error reduction via co-training	*88%*	*62%*	*52%*
Bilingual classifier	76.8	85.5	92.1
Co-trained Bili. classifier	93.2	93.2	93.9
Relative error reduction via co-training	*71%*	*53%*	*23%*
Mono.+Bili. classifier	69.9	91.4	94.9
Co-trained Combo classifier	**96.7**	**96.7**	**96.7**
Relative error reduction via co-training	*89%*	*62%*	*35%*

Table 5: Co-training improves accuracy (%) over standard supervised learning on **Bitext** test data for different feature types and number of training examples.

System	Accuracy	Δ
Monolingual alone	91.6	-
+ Bilingual	94.9	39%
+ Co-training	96.0	54%
+ Bilingual & Co-training	**96.7**	**61%**

Table 6: Net benefits of bilingual features and co-training on **Bitext** data, 100-training-example setting. Δ = relative error reduction over Monolingual alone.

Table 6 shows the net benefit of our main contributions. Bilingual features clearly help on this task, but not as much as co-training. With bilingual features and co-training together, we achieve 96.7% accuracy. This combined system could be used to very accurately resolve coordinate ambiguity in parallel data prior to training an MT system.

8 WSJ Experiments

While we can now accurately resolve coordinate NP ambiguity in parallel text, it would be even better if this accuracy carried over to new domains, where bilingual features are not available. We test the robustness of our co-trained monolingual classifier by evaluating it on our labeled WSJ data.

The Penn Treebank and the annotations added by Vadas and Curran (2007a) comprise a very special corpus; such data is clearly not available in every domain. We can take advantage of the plentiful labeled examples to also test how our co-trained system compares to supervised systems trained with in-domain labeled examples, and also other systems, like Nakov and Hearst (2005), which although unsupervised, are tuned on WSJ data.

System	Training		WSJ Acc.	
	Set	#	Nouns	All
Nakov & Hearst	-	-	79.2	84.8
Tag-Triple	WSJ	777	76.1	82.4
Pitler et al.	WSJ	777	92.3	92.8
MonoWSJ	WSJ	777	92.3	94.4
Co-trained	Bitext	2	**93.8**	**95.6**

Table 7: Coordinate resolution accuracy (%) on **WSJ**.

We reimplemented Nakov and Hearst (2005)[4] and Pitler et al. (2010)[5] and trained the latter on WSJ annotations. We compare these systems to Tag-Triple and also to a supervised system trained on the WSJ using only our monolingual features (MonoWSJ). The (out-of-domain) bitext co-trained system is the best system on the WSJ data, both on just the examples where w_1 and w_2 are nouns (Nouns), and on all examples (All) (Table 7).[6] It is statistically significantly better than the prior state-of-the-art Pitler et al. system (McNemar's test, $p<0.05$) and also exceeds the WSJ-trained system using monolingual features ($p<0.2$). This domain robustness is less surprising given its key features are derived from web-scale N-gram data; such features are known to generalize well across domains (Bergsma et al., 2010). We tried co-training without the N-gram features, and performance was worse on the WSJ (85%) than supervised training on WSJ data alone (87%).

9 Related Work

Bilingual data has been used to resolve a range of ambiguities, from PP-attachment (Schwartz et al., 2003; Fossum and Knight, 2008), to distinguishing grammatical roles (Schwarck et al., 2010), to full dependency parsing (Huang et al., 2009). Related

[4]Nakov and Hearst (2005) use an unsupervised algorithm that predicts ellipsis on the basis of a majority vote over a number of pattern counts and established heuristics.

[5]Pitler et al. (2010) uses a supervised classifier to predict bracketings; their count and binary features are a strict subset of the features used in our Monolingual classifier.

[6]For co-training, we tuned k on the WSJ dev set but left other parameters the same. We start from 2 training instances; results were the same or slightly better with 10 or 100 instances.

work has also focused on projecting syntactic annotations from one language to another (Yarowsky and Ngai, 2001; Hwa et al., 2005), and jointly parsing the two sides of a bitext by leveraging the alignments during training and testing (Smith and Smith, 2004; Burkett and Klein, 2008) or just during training (Snyder et al., 2009). None of this work has focused on coordination, nor has it combined bitexts with web-scale monolingual information.

Most prior work has focused on leveraging the alignments between a single pair of languages. Dagan et al. (1991) first articulated the need for "a multilingual corpora based system, which exploits the differences between languages to automatically acquire knowledge about word senses." Kuhn (2004) used alignments across several Europarl bitexts to devise rules for identifying parse distituents. Bannard and Callison-Burch (2005) used multiple bitexts as part of a system for extracting paraphrases.

Our co-training algorithm is well suited to using multiple bitexts because it automatically learns the value of alignment information in each language. In addition, our approach copes with noisy alignments both by aggregating information across languages (and repeated occurrences within a language), and by only selecting the most confident examples at each iteration. Burkett et al. (2010) also proposed exploiting monolingual-view and bilingual-view predictors. In their work, the bilingual view encodes the per-instance *agreement* between monolingual predictors in two languages, while our bilingual view encodes the alignment and target text together, across multiple instances and languages.

The other side of the coin is the use of syntax to perform better translation (Wu, 1997). This is a rich field of research with its own annual workshop (Syntax and Structure in Translation).

Our monolingual model is most similar to previous work using counts from web-scale text, both for resolving coordination ambiguity (Nakov and Hearst, 2005; Rus et al., 2007; Pitler et al., 2010), and for syntax and semantics in general (Lapata and Keller, 2005; Bergsma et al., 2010). We do not currently use semantic similarity (either taxonomic (Resnik, 1999) or distributional (Hogan, 2007)) which has previously been found useful for coordination. Our model can easily include such information as additional features. Adding new features without adding new training data is often problematic, but is promising in our framework, since the bitexts provide so much indirect supervision.

10 Conclusion

Resolving coordination ambiguity is hard. Parsers are reporting impressive numbers these days, but coordination remains an area with room for improvement. We focused on a specific subcase, complex NPs, and introduced a new evaluation set. We achieved a huge performance improvement from 79% for state-of-the-art parsers to 96%.[7]

Size matters. Most parsers are trained on a mere million words of the Penn Treebank. In this work, we show how to take advantage of billions of words of bitexts and trillions of words of unlabeled monolingual text. Larger corpora make it possible to use associations among lexical items (compare *dairy production* vs. *asbestos chloride*) and precise paraphrases (*production of dairy and meat*). Bitexts are helpful when the ambiguity can be resolved by some feature in another language (such as word order).

The Treebank is convenient for supervised training because it has annotations. We show that even without such annotations, high-quality supervised models can be trained using co-training and features derived from huge volumes of unlabeled data.

Abstract

We propose a novel unsupervised method for separating out distinct authorial components of a document. In particular, we show that, given a book artificially "munged" from two thematically similar biblical books, we can separate out the two constituent books almost perfectly. This allows us to automatically recapitulate many conclusions reached by Bible scholars over centuries of research. One of the key elements of our method is exploitation of differences in synonym choice by different authors.

1 Introduction

We propose a novel unsupervised method for separating out distinct authorial components of a document.

There are many instances in which one is faced with a multi-author document and wishes to delineate the contributions of each author. Perhaps the most salient example is that of documents of historical significance that appear to be composites of multiple earlier texts. The challenge for literary scholars is to tease apart the document's various components. More contemporary examples include analysis of collaborative online works in which one might wish to identify the contribution of a particular author for commercial or forensic purposes.

We treat two versions of the problem. In the first, easier, version, the document to be decomposed is given to us segmented into units, each of which is the work of a single author. The challenge is only to cluster the units according to author. In the second version, we are given an unsegmented document and the challenge includes segmenting the document as well as clustering the resulting units.

We assume here that no information about the authors of the document is available and that in particular we are not supplied with any identified samples of any author's writing. Thus, our methods must be entirely unsupervised.

There is surprisingly little literature on this problem, despite its importance. Some work in this direction has been done on intrinsic plagiarism detection (e.g., Meyer zu Eisen 2006) and document outlier detection (e.g., Guthrie et al. 2008), but this work makes the simplifying assumption that there is a single dominant author, so that outlier units can be identified as those that deviate from the document as a whole. We don't make this simplifying assumption. Some work on a problem that is more similar to ours was done by Graham et al. (2005). However, they assume that examples of pairs of paragraphs labeled as same-author/different-author are available for use as the basis of supervised learning. We make no such assumption.

The obvious approach to our unsupervised version of the problem would be to segment the text (if necessary), represent each of the resulting units of text as a bag-of-words, and then use clustering algorithms to find natural clusters. We will see, however, that this naïve method is quite inadequate. Instead, we exploit a method favored by the literary scholar, namely, the use of synonym choice. Synonym choice proves to be far more useful for authorial decomposition than ordinary lexical features. However, synonyms are relatively

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1356–1364,
Portland, Oregon, June 19-24, 2011.

sparse and hence, though reliable, they are not comprehensive; that is, they are useful for separating out some units but not all. Thus, we use a two-stage process: first find a reliable partial clustering based on synonym usage and then use these as the basis for supervised learning using a different feature set, such as bag-of-words.

We use biblical books as our testbed. We do this for two reasons. First, this testbed is well motivated, since scholars have been doing authorial analysis of biblical literature for centuries. Second, precisely because it is of great interest, the Bible has been manually tagged in a variety of ways that are extremely useful for our method.

Our main result is that given artificial books constructed by randomly "munging" together actual biblical books, we are able to separate out authorial components with extremely high accuracy, even when the components are thematically similar. Moreover, our automated methods recapitulate many of the results of extensive manual research in authorial analysis of biblical literature.

The structure of the paper is as follows. In the next section, we briefly review essential information regarding our biblical testbed. In Section 3, we introduce a naïve method for separating components and demonstrate its inadequacy. In Section 4, we introduce the synonym method, in Section 5 we extend it to the two-stage method, and in Section 6, we offer systematic empirical results to validate the method. In Section 7, we extend our method to handle documents that have not been pre-segmented and present more empirical results. In Section 8, we suggest conclusions, including some implications for Bible scholarship.

2 The Bible as Testbed

While the biblical canon differs across religions and denominations, the common denominator consists of twenty-odd books and several shorter works, ranging in length from tens to thousands of verses. These works vary significantly in genre, and include historical narrative, law, prophecy, and wisdom literature. Some of these books are regarded by scholars as largely the product of a single author's work, while others are thought to be composites in which multiple authors are well-represented – authors who in some cases lived in widely disparate periods. In this paper, we will focus exclusively on the Hebrew books of the Bible, and we will work with the original untranslated texts.

The first five books of the Bible, collectively known as the Pentateuch, are the subject of much controversy. According to the predominant Jewish and Christian traditions, the five books were written by a single author – Moses. Nevertheless, scholars have found in the Pentateuch what they believe are distinct narrative and stylistic threads corresponding to multiple authors.

Until now, the work of analyzing composite texts has been done in mostly impressionistic fashion, whereby each scholar attempts to detect the telltale signs of multiple authorship and compilation. Some work on biblical authorship problems within a computational framework has been attempted, but does not handle our problem. Much earlier work (for example, Radday 1970; Bee 1971; Holmes 1994) uses multivariate analysis to test whether the clusters in a given clustering of some biblical text are sufficiently distinct to be regarded as probably a composite text. By contrast, our aim is to find the optimal clustering of a document, given that it is composite. Crucially, unlike that earlier work, we empirically prove the efficacy of our methods by testing it against known ground truth. Other computational work on biblical authorship problems (Mealand 1995; Berryman et al. 2003) involves supervised learning problems where some disputed text is to be attributed to one of a set of known authors. The supervised authorship attribution problem has been well-researched (for surveys, see Juola (2008), Koppel et al. (2009) and Stamatatos (2009)), but it is quite distinct from the unsupervised problem we consider here.

Since our problem has been dealt with almost exclusively using heuristic methods, the subjective nature of such research has left much room for debate. We propose to set this work on a firm algorithmic basis by identifying an optimal stylistic subdivision of the text. We do not concern ourselves with how or why such distinct threads exist. Those for whom it is a matter of faith that the Pentateuch is not a composition of multiple writers can view the distinction investigated here as that of multiple styles.

3 A Naïve Algorithm

For expository purposes, we will use a canonical example to motivate and illustrate each of a

sequence of increasingly sophisticated algorithms for solving the decomposition problem. Jeremiah and Ezekiel are two roughly contemporaneous books belonging to the same biblical sub-genre (prophetic works), and each is widely thought to consist primarily of the work of a single distinct author. Jeremiah consists of 52 chapters and Ezekiel consists of 48 chapters. For our first challenge, we are given all 100 unlabeled chapters and our task is to separate them out into the two constituent books. (For simplicity, let's assume that it is known that there are exactly two natural clusters.) Note that this is a pre-segmented version of the problem since we know that each chapter belongs to only one of the books.

As a first try, the basics of which will serve as a foundation for more sophisticated attempts, we do the following:

1. Represent each chapter as a bag-of-words (using all words that appear at least k times in the corpus).
2. Compute the similarity of every pair of chapters in the corpus.
3. Use a clustering algorithm to cluster the chapters into two clusters.

We use k=2, cosine similarity and ncut clustering (Dhillon et al. 2004). Comparing the Jeremiah-Ezekiel split to the clusters thus obtained, we have the following matrix:

Book	Cluster I	Cluster II
Jer	29	23
Eze	28	20

As can be seen, the clusters are essentially orthogonal to the Jeremiah-Ezekiel split. Ideally, 100% of the chapters would lie on the majority diagonal, but in fact only 51% do. Formally, our measure of correspondence between the desired clustering and the actual one is computed by first normalizing rows and then computing the weight of the majority diagonal relative to the whole. This measure, which we call normalized majority diagonal (NMD), runs from 50% (when the clusters are completely orthogonal to the desired split) to 100% (where the clusters are identical with the desired split). NMD is equivalent to maximal macro-averaged recall where the maximum is taken over the (two) possible assignments of books to clusters. In this case, we obtain an NMD of 51.5%, barely above the theoretical minimum.

This negative result is not especially surprising since there are many ways for the chapters to split (e.g., according to thematic elements, sub-genre, etc.) and we can't expect an unsupervised method to read our minds. Thus, to guide the method in the direction of stylistic elements that might distinguish between Jeremiah and Ezekiel, we define a class of generic biblical words consisting of all 223 words that appear at least five times in each of ten different books of the Bible.

Repeating our experiment of above, though limiting our feature set to generic biblical words, we obtain the following matrix:

Book	Cluster I	Cluster II
Jer	32	20
Eze	28	20

As can be seen, using generic words yields NMD of 51.3%, which does not improve matters at all. Thus, we need to try a different approach.

4 Exploiting Synonym Usage

One of the key features used by Bible scholars to classify different components of biblical literature is synonym choice. The underlying hypothesis is that different authorial components are likely to differ in the proportions with which alternative words from a set of synonyms (synset) are used. This hypothesis played a part in the pioneering work of Astruc (1753) on the book of Genesis – using a single synset: divine names – and has been refined by many others using broader feature sets, such as that of Carpenter and Hartford-Battersby (1900). More recently, the synonym hypothesis has been used in computational work on authorship attribution of English texts in the work of Clark and Hannon (2007) and Koppel et al. (2006).

This approach presents several technical challenges. First, ideally – in the absence of a sufficiently comprehensive thesaurus – we would wish to identify synonyms in an automated fashion. Second, we need to adapt our similarity measure for reasons that will be made clear below.

4.1 (Almost) Automatic Synset Identification

One of the advantages of using biblical literature is the availability of a great deal of manual annotation. In particular, we are able to identify synsets by exploiting the availability of the standard King James translation of the Bible into Eng-

lish (KJV). Conveniently, and unlike most modern translations, KJV almost invariably translates synonyms identically. Thus, we can generally identify synonyms by considering the translated version of the text. There are two points we need to be precise about. First, it is not actually words that we regard as synonymous, but rather word roots. Second, to be even more precise, it is not quite roots that are synonymous, but rather senses of roots. Conveniently, Strong's (1890 [2010]) Concordance lists every occurrence of each sense of each root that appears in the Bible separately (where senses are distinguished in accordance with the KJV translation). Thus, we can exploit KJV and the concordance to automatically identify synsets as well as occurrences of the respective synonyms in a synset.[1] (The above notwithstanding, there is still a need for a bit of manual intervention: due to polysemy in English, false synsets are occasionally created when two non-synonymous Hebrew words are translated into two senses of the same English word. Although this could probably be handled automatically, we found it more convenient to do a manual pass over the raw synsets and eliminate the problems.)

The above procedure yields a set of 529 synsets including a total of 1595 individual synonyms. Most synsets consist of only two synonyms, but some include many more. For example, there are 7 Hebrew synonyms corresponding to "fear".

4.2 Adapting the Similarity Measure

Let's now represent a unit of text as a vector in the following way. Each entry represents a synonym in one of the synsets. If none of the synonyms in a synset appear in the unit, all their corresponding entries are 0. If j different synonyms in a synset appear in the unit, then each corresponding entry is 1/j and the rest are 0. Thus, in the typical case where exactly one of the synonyms in a synset appears, its corresponding entry in the vector is 1 and the rest are 0.

Now we wish to measure the similarity of two such vectors. The usual cosine measure doesn't capture what we want for the following reason. If the two units use different members of a synset, cosine is diminished; if they use the same members of a synset, cosine is increased. So far, so good. But suppose one unit uses a particular synonym and the other doesn't use any member of that synset. This should teach us nothing about the similarity of the two units, since it reflects only on the relevance of the synset to the content of that unit; it says nothing about which synonym is chosen when the synset is relevant. Nevertheless, in this case, cosine would be diminished.

The required adaptation is as follows: we first eliminate from the representation any synsets that do not appear in both units (where a synset is said to appear in a unit if any of its constituent synonyms appear in the unit). We then compute cosine of the truncated vectors. Formally, for a unit x represented in terms of synonyms, our new similarity measure is $\cos'(x,y) = \cos(x|_{S(x \cap y)}, y|_{S(x \cap y)})$, where $x|_{S(x \cap y)}$ is the projection of x onto the synsets that appear in both x and y.

4.3 Clustering Jeremiah-Ezekiel Using Synonyms

We now apply ncut clustering to the similarity matrix computed as described above. We obtain the following split:

Book	Cluster I	Cluster II
Jer	48	4
Eze	5	43

Clearly, this is quite a bit better than results obtained using simple lexical features as described above. Intuition for why this works can be purchased by considering concrete examples. There are two Hebrew synonyms – *pēʾâh* and *miqṣôaʿ* corresponding to the word "corner", two (*minḥâh* and *tĕrûmâh*) corresponding to the word "oblation", and two (*nāṭaʿ* and *šāṯal*) corresponding to the word "planted". We find that *pēʾâh*, *minḥâh* and *nāṭaʿ* tend to be located in the same units and, concomitantly, *miqṣôaʿ*, *tĕrûmâh* and *šāṯal* are located in the same units. Conveniently, the former are all Jeremiah and the latter are all Ezekiel.

While the above result is far better than those obtained using more naïve feature sets, it is, nevertheless, far from perfect. We have, however, one more trick at our disposal that will improve these results further.

5 Combining Partial Clustering and Supervised Learning

Analysis of the above clustering results leads to two observations. First, some of the units belong

[1] Thanks to Avi Shmidman for his assistance with this.

firmly to one cluster or the other. The rest have to be assigned to one cluster or the other because that's the nature of the clustering algorithm, but in fact are not part of what we might think of as the *core* of either cluster. Informally, we say that a unit is in the core of its cluster if it is sufficiently similar to the centroid of its cluster and it is sufficiently more similar to the centroid of its cluster than to any other centroid. Formally, let S be a set of synsets, let B be a set of units, and let C be a clustering of B where the units in B are represented in terms of the synsets in S. For a unit x in cluster C(x) with centroid c(x), we say that x is in the core of C(x) if $\cos'(x,c(x))>\theta_1$ and $\cos'(x,c(x))-\cos'(x,c)>\theta_2$ for every centroid $c \neq c(x)$. In our experiments below, we use $\theta_1=1/\sqrt{2}$ (corresponding to an angle of less than 45 degrees between x and the centroid of its cluster) and $\theta_2=0.1$.

Second, the clusters that we obtain are based on a subset of the full collection of synsets that does the heavy lifting. Formally, we say that a synonym n in synset s is *over-represented* in cluster C if $p(x \in C | n \in x) > p(x \in C | s \in x)$ and $p(x \in C | n \in x) > p(x \in C)$. That is, n is over-represented in C if knowing that n appears in a unit increases the likelihood that the unit is in C, relative to knowing only that some member of n's synset appears in the unit and relative to knowing nothing. We say that a synset s is a *separating* synset for a clustering {C1,C2} if some synonym in s is over-represented in C1 and a different synonym in s is over-represented in C2.

5.1 Defining the Core of a Cluster

We leverage these two observations to formally define the cores of the respective clusters using the following iterative algorithm.

1. Initially, let S be the collection of all synsets, let B be the set of all units in the corpus represented in terms of S, and let {C1,C2} be an initial clustering of the units in B.
2. Reduce B to the cores of C1 and C2.
3. Reduce S to the separating synsets for {C1,C2}.
4. Redefine C1 and C2 to be the clusters obtained from clustering the units in the reduced B represented in terms of the synsets in reduced S.
5. Repeat Steps 2-4 until convergence (no further changes to the retained units and synsets).

At the end of this process, we are left with two well-separated cluster cores and a set of separating synsets. When we compute cores of clusters in our Jeremiah-Ezekiel experiment, 26 of the initial 100 units are eliminated. Of the 154 synsets that appear in the Jeremiah-Ezekiel corpus, 118 are separating synsets for the resulting clustering. The resulting cluster cores split with Jeremiah and Ezekiel as follows:

Book	Cluster I	Cluster II
Jer	36	0
Eze	2	36

We find that all but two of the misplaced units are not part of the core. Thus, we have a better clustering but it is only a partial one.

5.2 Using Cores for Supervised Learning

Now that we have what we believe are strong representatives of each cluster, we can use them in a supervised way to classify the remaining unclustered units. The interesting question is which feature set we should use. Using synonyms would just get us back to where we began. Instead we use the set of generic Bible words introduced earlier. The point to recall is that while this feature set proved inadequate in an unsupervised setting, this does not mean that it is inadequate for separating Jeremiah and Ezekiel, given a few good training examples.

Thus, we use a bag-of-words representation restricted to generic Bible words for the 74 units in our cluster cores and label them according to the cluster to which they were assigned. We now apply SVM to learn a classifier for the two clusters. We assign each unit, including those in the training set, to the class assigned to it by the SVM classifier. The resulting split is as follows:

Book	Cluster I	Cluster II
Jer	51	1
Eze	0	48

Remarkably, even the two Ezekiel chapters that were in the Jeremiah cluster (and hence were essentially misleading training examples) end up on the Ezekiel side of the SVM boundary.

It should be noted that our two-stage approach to clustering is a generic method not specific to our particular application. The point is that there are some feature sets that are very well suited to a particular unsupervised problem but are sparse, so they give only a partial clustering. At the same time, there are other feature sets that are denser and, possibly for that reason, adequate for super-

vised separation of the intended classes but inadequate for unsupervised separation of the intended classes. This suggests an obvious two-stage method for clustering, which we use here to good advantage.

This method is somewhat reminiscent of semi-supervised methods sometimes used in text categorization where few training examples are available (Nigam et al. 2000). However, those methods typically begin with some information, either in the form of a small number of labeled documents or in the form of keywords, while we are not supplied with these. Furthermore, the semi-supervised work bootstraps iteratively, at each stage using features drawn from within the same feature set, while we use exactly two stages, the second of which uses a different type of feature set than the first.

For the reader's convenience, we summarize the entire two-stage method:

1. Represent units in terms of synonyms.
2. Compute similarities of pairs of units using cos'.
3. Use ncut to obtain an initial clustering.
4. Use the iterative method to find cluster cores.
5. Represent units in cluster cores in terms of generic words.
6. Use units in cluster cores as training for learning an SVM classifier.
7. Classify all units according to the learned SVM classifier.

6 Empirical Results

We now test our method on other pairs of biblical books to see if we obtain comparable results to those seen above. We need, therefore, to identify a set of biblical books such that (i) each book is sufficiently long (say, at least 20 chapters), (ii) each is written by one primary author, and (iii) the authors are distinct. Since we wish to use these books as a gold standard, it is important that there be a broad consensus regarding the latter two, potentially controversial, criteria. Our choice is thus limited to the following five books that belong to two biblical sub-genres: Isaiah, Jeremiah, Ezekiel (prophetic literature), Job and Proverbs (wisdom literature). (Due to controversies regarding authorship (Pope 1952, 1965), we include only Chapters 1-33 of Isaiah and only Chapters 3-41 of Job.)

Recall that our experiment is as follows: For each pair of books, we are given all the chapters in the union of the two books and are given no information regarding labels. The object is to sort out the chapters belonging to the respective two books. (The fact that there are precisely two constituent books is given.)

We will use the three algorithms seen above:

1. generic biblical words representation and ncut clustering;
2. synonym representation and ncut clustering;
3. our two-stage algorithm.

We display the results in two separate figures. In Figure 1, we see results for the six pairs of books that belong to different sub-genres. In Figure 2, we see results for the four pairs of books that are in the same genre. (For completeness, we include Jeremiah-Ezekiel, although it served above as a development corpus.) All results are normalized majority diagonal.

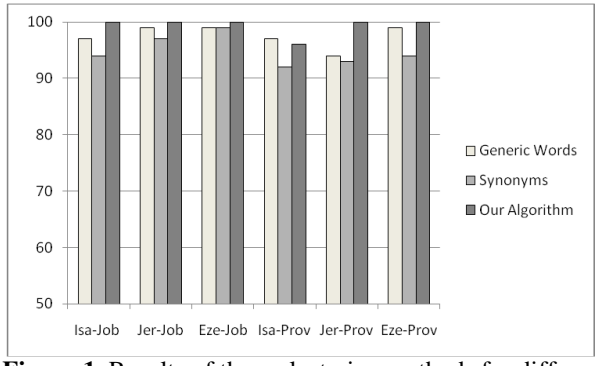

Figure 1. Results of three clustering methods for different-genre pairs

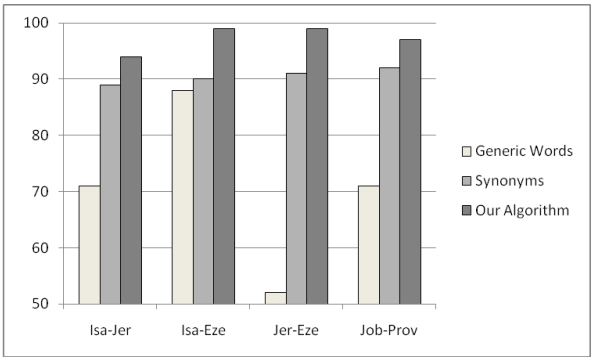

Figure 2. Results of three clustering methods for same-genre pairs

As is evident, for different-genre pairs, even the simplest method works quite well, though not as well as the two-stage method, which is perfect for five of six such pairs. The real advantage of the two-stage method is for same-genre pairs. For

these the simple method is quite erratic, while the two-stage method is near perfect. We note that the synonym method without the second stage is slightly worse than generic words for different-genre pairs (probably because these pairs share relatively few synsets) but is much more consistent for same-genre pairs, giving results in the area of 90% for each such pair. The second stage reduces the errors considerably over the synonym method for both same-genre and different-genre pairs.

7 Decomposing Unsegmented Documents

Up to now, we have considered the case where we are given text that has been pre-segmented into pure authorial units. This does not capture the kind of decomposition problems we face in real life. For example, in the Pentateuch problem, the text is divided up according to chapter, but there is no indication that the chapter breaks are correlated with crossovers between authorial units. Thus, we wish now to generalize our two-stage method to handle unsegmented text.

7.1 Generating Composite Documents

To make the problem precise, let's consider how we might create the kind of document that we wish to decompose. For concreteness, let's think about Jeremiah and Ezekiel. We create a composite document, called *Jer-iel*, as follows:

1. Choose the first k_1 available verses of Jeremiah, where k_1 is a random integer drawn from the uniform distribution over the integers 1 to m.
2. Choose the first k_2 available verses of Ezekiel, where k_2 is a new random integer drawn from the above distribution.
3. Repeat until one of the books is exhausted; then choose the remaining verses of the other book.

For the experiments discussed below, we use m=100 (though further experiments, omitted for lack of space, show that results shown are essentially unchanged for any $m \geq 60$). Furthermore, to simulate the Pentateuch problem, we break Jer-iel into initial units by beginning a new unit whenever we reach the first verse of one of the original chapters of Jeremiah or Ezekiel. (This does not leak any information since there is no inherent connection between these verses and actual crossover points.)

7.2 Applying the Two-Stage Method

Our method works as follows. First, we refine the initial units (each of which might be a mix of verses from Jeremiah and Ezekiel) by splitting them into smaller units that we hope will be pure (wholly from Jeremiah or from Ezekiel). We say that a synset is *doubly-represented* in a unit if the unit includes two different synonyms of that synset. Doubly-represented synsets are an indication that the unit might include verses from two different books. Our object is thus to split the unit in a way that minimizes doubly-represented synonyms. Formally, let M(x) represent the number of synsets for which more than one synonym appear in x. Call $\langle x_1, x_2 \rangle$ a *split* of x if $x = x_1 x_2$. A split $\langle x_1', x_2' \rangle$ is *optimal* if $\langle x_1', x_2' \rangle = \text{argmax } M(x) - \max(M(x_1), M(x_2))$ where the maximum is taken over all splits of x. If for an initial unit, there is some split for which $M(x) - \max(M(x_1), M(x_2))$ is greater than 0, we split the unit optimally; if there is more than one optimal split, we choose the one closest to the middle verse of the unit. (In principle, we could apply this procedure iteratively; in the experiments reported here, we split only the initial units but not split units.)

Next, we run the first six steps of the two-stage method on the units of Jer-iel obtained from the splitting process, as described above, until the point where the SVM classifier has been learned. Now, instead of classifying chapters as in Step 7 of the algorithm, we classify individual verses.

The problem with classifying individual verses is that verses are short and may contain few or no relevant features. In order to remedy this, and also to take advantage of the stickiness of classes across consecutive verses (if a given verse is from a certain book, there is a good chance that the next verse is from the same book), we use two smoothing tactics.

Initially, each verse is assigned a raw score by the SVM classifier, representing its signed distance from the SVM boundary. We smooth these scores by computing for each verse a refined score that is a weighted average of the verse's raw score and the raw scores of the two verses preceding and succeeding it. (In our scheme, the verse itself is given 1.5 times as much weight as its immediate neighbors and three times as much weight as secondary neighbors.)

Moreover, if the refined score is less than 1.0 (the width of the SVM margin), we do not initially

assign the verse to either class. Rather, we check the class of the last assigned verse before it and the first assigned verse after it. If these are the same, the verse is assigned to that class (an operation we call "filling the gaps"). If they are not, the verse remains unassigned.

To illustrate on the case of Jer-iel, our original "munged" book has 96 units. After pre-splitting, we have 143 units. Of these, 105 are pure units. Our two cluster cores, include 33 and 39 units, respectively; 27 of the former are pure Jeremiah and 30 of the latter are pure Ezekiel; no pure units are in the "wrong" cluster core. Applying the SVM classifier learned on the cluster cores to individual verses, 992 of the 2637 verses in Jer-iel lie outside the SVM margin and are assigned to some class. All but four of these are assigned correctly. Filling the gaps assigns a class to 1186 more verses, all but ten of them correctly. Of the remaining 459 unassigned verses, most lie along transition points (where smoothing tends to flatten scores and where preceding and succeeding assigned verses tend to belong to opposite classes).

7.3 Empirical Results

We randomly generated composite books for each of the book pairs considered above. In Figures 3 and 4, we show for each book pair the percentage of all verses in the munged document that are "correctly" classed (that is, in the majority diagonal), the percentage incorrectly classed (minority diagonal) and the percentage not assigned to either class. As is evident, in each case the vast majority of verses are correctly assigned and only a small fraction are incorrectly assigned. That is, we can tease apart the components almost perfectly.

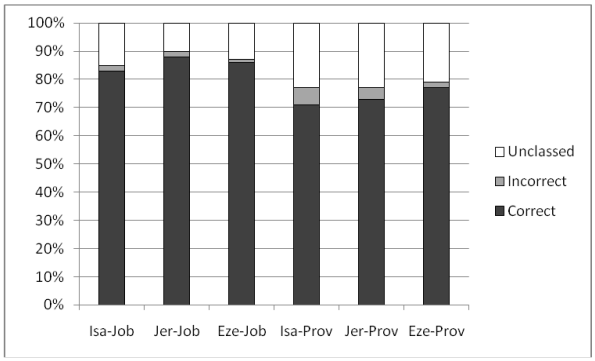

Figure 3. Percentage of verses in each munged different-genre pair of books that are correctly and incorrectly assigned or remain unassigned.

Figure 4. Percentage of verses in each munged same-genre pair of books that are correctly and incorrectly assigned or remain unassigned.

8 Conclusions and Future Work

We have shown that documents can be decomposed into authorial components with very high accuracy by using a two-stage process. First, we establish a reliable partial clustering of units by using synonym choice and then we use these partial clusters as training texts for supervised learning using generic words as features.

We have considered only decompositions into two components, although our method generalizes trivially to more than two components, for example by applying it iteratively. The real challenge is to determine the correct number of components, where this information is not given. We leave this for future work.

Despite this limitation, our success on munged biblical books suggests that our method can be fruitfully applied to the Pentateuch, since the broad consensus in the field is that the Pentateuch can be divided into two main authorial categories: Priestly (P) and non-Priestly (Driver 1909). (Both categories are often divided further, but these subdivisions are more controversial.) We find that our split corresponds to the expert consensus regarding P and non-P for over 90% of the verses in the Pentateuch for which such consensus exists. We have thus been able to largely recapitulate several centuries of painstaking manual labor with our automated method. We offer those instances in which we disagree with the consensus for the consideration of scholars in the field.

In this work, we have exploited the availability of tools for identifying synonyms in biblical literature. In future work, we intend to extend our methods to texts for which such tools are unavailable.

Discovering Sociolinguistic Associations with Structured Sparsity

Jacob Eisenstein Noah A. Smith Eric P. Xing

Carnegie Mellon University
Pittsburgh, PA 15213, USA
{jacobeis,nasmith,epxing}@cs.cmu.edu

Abstract

We present a method to discover robust and interpretable sociolinguistic associations from raw geotagged text data. Using aggregate demographic statistics about the authors' geographic communities, we solve a multi-output regression problem between demographics and lexical frequencies. By imposing a composite $\ell_{1,\infty}$ regularizer, we obtain structured sparsity, driving entire rows of coefficients to zero. We perform two regression studies. First, we use term frequencies to predict demographic attributes; our method identifies a compact set of words that are strongly associated with author demographics. Next, we conjoin demographic attributes into *features*, which we use to predict term frequencies. The composite regularizer identifies a small number of features, which correspond to communities of authors united by shared demographic and linguistic properties.

1 Introduction

How is language influenced by the speaker's sociocultural identity? Quantitative sociolinguistics usually addresses this question through carefully crafted studies that correlate individual demographic attributes and linguistic variables—for example, the interaction between income and the "dropped r" feature of the New York accent (Labov, 1966). But such studies require the knowledge to select the "dropped r" and the speaker's income, from thousands of other possibilities. In this paper, we present a method to acquire such patterns from raw data. Using multi-output regression with structured sparsity, our method identifies a small subset of lexical items that are most influenced by demographics, and discovers conjunctions of demographic attributes that are especially salient for lexical variation.

Sociolinguistic associations are difficult to model, because the space of potentially relevant interactions is large and complex. On the linguistic side there are thousands of possible variables, even if we limit ourselves to unigram lexical features. On the demographic side, the interaction between demographic attributes is often non-linear: for example, gender may negate or amplify class-based language differences (Zhang, 2005). Thus, additive models which assume that each demographic attribute makes a linear contribution are inadequate.

In this paper, we explore the large space of potential sociolinguistic associations using structured sparsity. We treat the relationship between language and demographics as a set of multi-input, multi-output regression problems. The regression coefficients are arranged in a matrix, with rows indicating predictors and columns indicating outputs. We apply a composite regularizer that drives entire rows of the coefficient matrix to zero, yielding compact, interpretable models that reuse features across different outputs. If we treat the lexical frequencies as inputs and the author's demographics as outputs, the induced sparsity pattern reveals the set of lexical items that is most closely tied to demographics. If we treat the demographic attributes as inputs and build a model to predict the text, we can incrementally construct a conjunctive feature space of demographic attributes, capturing key non-linear interactions.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1365–1374,
Portland, Oregon, June 19-24, 2011.

The primary purpose of this research is exploratory data analysis to identify both the most linguistic-salient demographic features, and the most demographically-salient words. However, this model also enables predictions about demographic features by analyzing raw text, potentially supporting applications in targeted information extraction or advertising. On the task of predicting demographics from text, we find that our sparse model yields performance that is statistically indistinguishable from the full vocabulary, even with a reduction in the model complexity an order of magnitude. On the task of predicting text from author demographics, we find that our incrementally constructed feature set obtains significantly better perplexity than a linear model of demographic attributes.

	mean	std. dev.
race & ethnicity		
% white	52.1	29.0
% African American	32.2	29.1
% Hispanic	15.7	18.3

2 Data

Our dataset is derived from prior work in which we gathered the text and geographical locations of 9,250 microbloggers on the website `twitter.com` (Eisenstein et al., 2010). Bloggers were selected from a pool of frequent posters whose messages include metadata indicating a geographical location within a bounding box around the continental United States. We limit the vocabulary to the 5,418 terms which are used by at least 40 authors; no stoplists are applied, as the use of standard or non-standard orthography for stopwords (e.g., *to* vs. *2*) may convey important information about the author. The dataset includes messages during the first week of March 2010.

O'Connor et al. (2010) obtained aggregate demographic statistics for these data by mapping geolocations to publicly-available data from the U. S. Census ZIP Code Tabulation Areas (ZCTA).[1] There are 33,178 such areas in the USA (the 9,250 microbloggers in our dataset occupy 3,458 unique ZCTAs), and they are designed to contain roughly equal numbers of inhabitants and demographically-homogeneous populations. The demographic attributes that we consider in this paper are shown in Table 1. All attributes are based on self-reports. The race and ethnicity attributes are not mutually exclusive—individuals can indicate any number of races or ethnicities. The "other language" attribute aggregates all languages besides English and Spanish. "Urban areas" refer to sets of census tracts or census blocks which contain at least 2,500 residents; our "% urban" attribute is the percentage of individuals in each ZCTA who are listed as living in an urban area. We also consider the percentage of individuals who live with their families, the percentage who live in rented housing, and the median reported income in each ZCTA.

While geographical aggregate statistics are frequently used to proxy for individual socioeconomic status in research areas such as public health (e.g., Rushton, 2008), it is clear that interpretation must proceed with caution. Consider an author from a ZIP code in which 60% of the residents are Hispanic:[2] we do not know the likelihood that the author is Hispanic, because the set of Twitter users is not a representative sample of the overall population. Polling research suggests that users of both Twitter (Smith and Rainie, 2010) and geolocation services (Zickuhr and Smith, 2010) are much more diverse with respect to age, gender, race and ethnicity than the general population of Internet users. Nonetheless, at present we can only use aggregate statistics to make inferences about the geographic communities in which our authors live, and not the authors themselves.

[1] `http://www.census.gov/support/cen2000.html`

[2] In the U.S. Census, the official ethnonym is *Hispanic or Latino*; for brevity we will use *Hispanic* in the rest of this paper.

3 Models

The selection of both words and demographic features can be framed in terms of multi-output regression with structured sparsity. To select the lexical indicators that best predict demographics, we construct a regression problem in which term frequencies are the predictors and demographic attributes are the outputs; to select the demographic features that predict word use, this arrangement is reversed. Through structured sparsity, we learn models in which entire sets of coefficients are driven to zero; this tells us which words and demographic features can safely be ignored.

This section describes the model and implementation for output-regression with structured sparsity; in Section 4 and 5 we give the details of its application to select terms and demographic features. Formally, we consider the linear equation $\mathbf{Y} = \mathbf{XB} + \epsilon$, where,

- $\mathbf{Y}$ is the dependent variable matrix, with dimensions $N \times T$, where N is the number of samples and T is the number of output dimensions (or *tasks*);
- $\mathbf{X}$ is the independent variable matrix, with dimensions $N \times P$, where P is the number of input dimensions (or *predictors*);
- $\mathbf{B}$ is the matrix of regression coefficients, with dimensions $P \times T$;
- ϵ is a $N \times T$ matrix in which each element is noise from a zero-mean Gaussian distribution.

We would like to solve the unconstrained optimization problem,

$$\text{minimize}_{\mathbf{B}} \qquad ||\mathbf{Y} - \mathbf{XB}||_F^2 + \lambda R(\mathbf{B}), \qquad (1)$$

where $||\mathbf{A}||_F^2$ indicates the squared Frobenius norm $\sum_i \sum_j a_{ij}^2$, and the function $R(\mathbf{B})$ defines a norm on the regression coefficients $\mathbf{B}$. Ridge regression applies the ℓ_2 norm $R(\mathbf{B}) = \sum_{t=1}^{T} \sqrt{\sum_p^P b_{pt}^2}$, and lasso regression applies the ℓ_1 norm $R(\mathbf{B}) = \sum_{t=1}^{T} \sum_p^P |b_{pt}|$; in both cases, it is possible to decompose the multi-output regression problem, treating each output dimension separately. However, our working hypothesis is that there will be substantial correlations across both the vocabulary and the demographic features—for example, a demographic feature such as the percentage of Spanish speakers will predict a large set of words. Our goal is to select a small set of predictors yielding good performance across all output dimensions. Thus, we desire *structured* sparsity, in which entire rows of the coefficient matrix $\mathbf{B}$ are driven to zero.

Structured sparsity is not achieved by the lasso's ℓ_1 norm. The lasso gives element-wise sparsity, in which many entries of $\mathbf{B}$ are driven to zero, but each predictor may have a non-zero value for some output dimension. To drive entire rows of $\mathbf{B}$ to zero, we require a composite regularizer. We consider the $\ell_{1,\infty}$ norm, which is the sum of ℓ_∞ norms across output dimensions: $R(\mathbf{B}) = \sum_t^T \max_p b_{pt}$ (Turlach et al., 2005). This norm, which corresponds to a *multi-output lasso* regression, has the desired property of driving entire rows of $\mathbf{B}$ to zero.

3.1 Optimization

There are several techniques for solving the $\ell_{1,\infty}$ normalized regression, including interior point methods (Turlach et al., 2005) and projected gradient (Duchi et al., 2008; Quattoni et al., 2009). We choose the blockwise coordinate descent approach of Liu et al. (2009) because it is easy to implement and efficient: the time complexity of each iteration is independent of the number of samples.[3]

Due to space limitations, we defer to Liu et al. (2009) for a complete description of the algorithm. However, we note two aspects of our implementation which are important for natural language processing applications. The algorithm's efficiency is accomplished by precomputing the matrices $\mathbf{C} = \tilde{\mathbf{X}}^\mathsf{T}\tilde{\mathbf{Y}}$ and $\mathbf{D} = \tilde{\mathbf{X}}^\mathsf{T}\tilde{\mathbf{X}}$, where $\tilde{\mathbf{X}}$ and $\tilde{\mathbf{Y}}$ are the standardized versions of $\mathbf{X}$ and $\mathbf{Y}$, obtained by subtracting the mean and scaling by the variance. Explicit mean correction would destroy the sparse term frequency data representation and render us unable to store the data in memory; however, we can achieve the same effect by computing $\mathbf{C} = \mathbf{X}^\mathsf{T}\mathbf{Y} - N\bar{\boldsymbol{x}}^\mathsf{T}\bar{\boldsymbol{y}}$, where $\bar{\boldsymbol{x}}$ and $\bar{\boldsymbol{y}}$ are row vectors indicating the means

[3] Our implementation is available at `http://sailing.cs.cmu.edu/sociolinguistic.html`.

of $\mathbf{X}$ and $\mathbf{Y}$ respectively.[4] We can similarly compute $\mathbf{D} = \mathbf{X}^\mathsf{T}\mathbf{X} - N\bar{\boldsymbol{x}}^\mathsf{T}\bar{\boldsymbol{x}}$.

If the number of predictors is too large, it may not be possible to store the dense matrix $\mathbf{D}$ in memory. We have found that approximation based on the truncated singular value decomposition provides an effective trade-off of time for space. Specifically, we compute $\mathbf{X}^\mathsf{T}\mathbf{X} \approx$

$$\mathbf{U}\mathbf{S}\mathbf{V}^\mathsf{T}\left(\mathbf{U}\mathbf{S}\mathbf{V}^\mathsf{T}\right)^\mathsf{T} = \mathbf{U}\left(\mathbf{S}\mathbf{V}^\mathsf{T}\mathbf{V}\mathbf{S}^\mathsf{T}\mathbf{U}^\mathsf{T}\right) = \mathbf{U}\mathbf{M}.$$

Lower truncation levels are less accurate, but are faster and require less space: for K singular values, the storage cost is $\mathcal{O}(KP)$, instead of $\mathcal{O}(P^2)$; the time cost increases by a factor of K. This approximation was not necessary in the experiments presented here, although we have found that it performs well as long as the regularizer is not too close to zero.

3.2 Regularization

The regularization constant λ can be computed using cross-validation. As λ increases, we reuse the previous solution of $\mathbf{B}$ for initialization; this "warm start" trick can greatly accelerate the computation of the overall regularization path (Friedman et al., 2010). At each λ_i, we solve the sparse multi-output regression; the solution $\mathbf{B}_i$ defines a sparse set of predictors for all tasks.

We then use this limited set of predictors to construct a new input matrix $\hat{\mathbf{X}}_i$, which serves as the input in a standard ridge regression, thus refitting the model. The tuning set performance of this regression is the score for λ_i. Such post hoc refitting is often used in tandem with the lasso and related sparse methods; the effectiveness of this procedure has been demonstrated in both theory (Wasserman and Roeder, 2009) and practice (Wu et al., 2010). The regularization parameter of the ridge regression is determined by internal cross-validation.

4 Predicting Demographics from Text

Sparse multi-output regression can be used to select a subset of vocabulary items that are especially indicative of demographic and geographic differences. Starting from the regression problem (1), the predictors $\mathbf{X}$ are set to the term frequencies, with one column for each word type and one row for each author in the dataset. The outputs $\mathbf{Y}$ are set to the ten demographic attributes described in Table 1 (we consider much larger demographic feature spaces in the next section) The $\ell_{1,\infty}$ regularizer will drive entire rows of the coefficient matrix $\mathbf{B}$ to zero, eliminating all demographic effects for many words.

4.1 Quantitative Evaluation

We evaluate the ability of lexical features to predict the demographic attributes of their authors (as proxied by the census data from the author's geographical area). The purpose of this evaluation is to assess the predictive ability of the compact subset of lexical items identified by the multi-output lasso, as compared with the full vocabulary. In addition, this evaluation establishes a baseline for performance on the demographic prediction task.

We perform five-fold cross-validation, using the multi-output lasso to identify a sparse feature set in the training data. We compare against several other dimensionality reduction techniques, matching the number of features obtained by the multi-output lasso at each fold. First, we compare against a truncated singular value decomposition, with the truncation level set to the number of terms selected by the multi-output lasso; this is similar in spirit to vector-based lexical semantic techniques (Schütze and Pedersen, 1993). We also compare against simply selecting the N most frequent terms, and the N terms with the greatest variance in frequency across authors. Finally, we compare against the complete set of all 5,418 terms. As before, we perform post hoc refitting on the training data using a standard ridge regression. The regularization constant for the ridge regression is identified using nested five-fold cross validation within the training set.

We evaluate on the refit models on the heldout test folds. The scoring metric is Pearson's correlation coefficient between the predicted and true demographics: $\rho(\boldsymbol{y}, \hat{\boldsymbol{y}}) = \frac{\text{cov}(\boldsymbol{y}, \hat{\boldsymbol{y}})}{\sigma_{\boldsymbol{y}}\sigma_{\hat{\boldsymbol{y}}}}$, with $\text{cov}(\boldsymbol{y}, \hat{\boldsymbol{y}})$ indicating the covariance and $\sigma_{\boldsymbol{y}}$ indicating the standard deviation. On this metric, a perfect predictor will score 1 and a random predictor will score 0. We report the average correlation across all ten demo-

[4] Assume without loss of generality that $\mathbf{X}$ and $\mathbf{Y}$ are scaled to have variance 1, because this scaling does not affect the sparsity pattern.

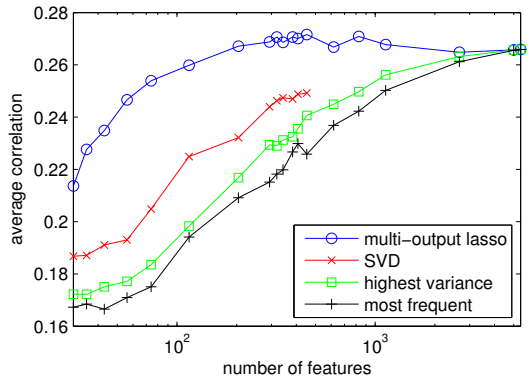

Figure 1: Average correlation plotted against the number of active features (on a logarithmic scale).

graphic attributes, as well as the individual correlations.

Results Table 2 shows the correlations obtained by regressions performed on a range of different vocabularies, averaged across all five folds. Linguistic features are best at predicting race, ethnicity, language, and the proportion of renters; the other demographic attributes are more difficult to predict. Among feature sets, the highest average correlation is obtained by the full vocabulary, but the multi-output lasso obtains nearly identical performance using a feature set that is an order of magnitude smaller. Applying the Fischer transformation, we find that all correlations are statistically significant at $p < .001$.

The Fischer transformation can also be used to estimate 95% confidence intervals around the correlations. The extent of the confidence intervals varies slightly across attributes, but all are tighter than ± 0.02. We find that the multi-output lasso and the full vocabulary regression are not significantly different on any of the attributes. Thus, the multi-output lasso achieves a 93% compression of the feature set without a significant decrease in predictive performance. The multi-output lasso yields higher correlations than the other dimensionality reduction techniques on all of the attributes; these differences are statistically significant in many—but not all—cases. The correlations for each attribute are clearly not independent, so we do not compare the average across attributes.

Recall that the regularization coefficient was chosen by nested cross-validation within the training set; the average number of features selected is 394.6. Figure 1 shows the performance of each dimensionality-reduction technique across the regularization path for the first of five cross-validation folds. Computing the truncated SVD of a sparse matrix at very large truncation levels is computationally expensive, so we cannot draw the complete performance curve for this method. The multi-output lasso dominates the alternatives, obtaining a particularly strong advantage with very small feature sets. This demonstrates its utility for identifying interpretable models which permit qualitative analysis.

4.2 Qualitative Analysis

For a qualitative analysis, we retrain the model on the full dataset, and tune the regularization to identify a compact set of 69 features. For each identified term, we apply a significance test on the relationship between the presence of each term and the demographic indicators shown in the columns of the table. Specifically, we apply the Wald test for comparing the means of independent samples, while making the Bonferroni correction for multiple comparisons (Wasserman, 2003). The use of sparse multi-output regression for variable selection increases the power of post hoc significance testing, because the Bonferroni correction bases the threshold for statistical significance on the total number of comparisons. We find 275 associations at the $p < .05$ level; at the higher threshold required by a Bonferroni correction for comparisons among all terms in the vocabulary, 69 of these associations would have been missed.

Table 3 shows the terms identified by our model which have a significant correlation with at least one of the demographic indicators. We divide words in the list into categories, which order alphabetically by the first word in each category: emoticons; standard English, defined as words with Wordnet entries; proper names; abbreviations; non-English words; non-standard words used with English. The categorization was based on the most frequent sense in an informal analysis of our data. A glossary of non-standard terms is given in Table 4.

Some patterns emerge from Table 3. Standard English words tend to appear in areas with more

Table 2: Correlations between predicted and observed demographic attributes, averaged across cross validation folds.

English speakers; predictably, Spanish words tend to appear in areas with Spanish speakers and Hispanics. Emoticons tend to be used in areas with many Hispanics and few African Americans. Abbreviations (e.g., *lmaoo*) have a nearly uniform demographic profile, displaying negative correlations with whites and English speakers, and positive correlations with African Americans, Hispanics, renters, Spanish speakers, and areas classified as urban.

Many non-standard English words (e.g., *dats*) appear in areas with high proportions of renters, African Americans, and non-English speakers, though a subset (*haha*, *hahaha*, and *yep*) display the opposite demographic pattern. Many of these non-standard words are phonetic transcriptions of standard words or phrases: *that's→dats*, *what's up→wassup*, *I'm going to→ima*. The relationship between these transcriptions and the phonological characteristics of dialects such as African-American Vernacular English is a topic for future work.

5 Conjunctive Demographic Features

Next, we demonstrate how to select conjunctions of demographic features that predict text. Again, we apply multi-output regression, but now we reverse the direction of inference: the predictors are demographic features, and the outputs are term frequencies. The sparsity-inducing $\ell_{1,\infty}$ norm will select a subset of demographic features that explain the term frequencies.

We create an initial feature set $f^{(0)}(\mathbf{X})$ by binning each demographic attribute, using five equal-frequency bins. We then constructive conjunctive features by applying a procedure inspired by related work in computational biology, called "Screen and Clean" (Wu et al., 2010). On iteration i:

- Solve the sparse multi-output regression problem $\mathbf{Y} = f^{(i)}(\mathbf{X})\mathbf{B}^{(i)} + \epsilon$.
- Select a subset of features $S^{(i)}$ such that $m \in S^{(i)}$ iff $\max_j |\boldsymbol{b}^{(i)}_{m,j}| > 0$. These are the row indices of the predictors with non-zero coefficients.
- Create a new feature set $f^{(i+1)}(\mathbf{X})$, including the conjunction of each feature (and its negation) in $S^{(i)}$ with each feature in the initial set $f^{(0)}(\mathbf{X})$.

We iterate this process to create features that conjoin as many as three attributes. In addition to the binned versions of the demographic attributes described in Table 1, we include geographical information. We built Gaussian mixture models over the locations, with 3, 5, 8, 12, 17, and 23 components. For each author we include the most likely cluster assignment in each of the six mixture models. For efficiency, the outputs $\mathbf{Y}$ are not set to the raw term frequencies; instead we compute a truncated singular value decomposition of the term frequencies $\mathbf{W} \approx \mathbf{U}\mathbf{V}\mathbf{D}^\mathsf{T}$, and use the basis $\mathbf{U}$. We set the truncation level to 100.

5.1 Quantitative Evaluation

The ability of the induced demographic features to predict text is evaluated using a traditional perplexity metric. The same test and training split is used from the vocabulary experiments. We construct a language model from the induced demographic features by training a multi-output ridge regression, which gives a matrix $\hat{\mathbf{B}}$ that maps from demographic features to term frequencies across the entire vocabulary. For each document in the test set, the "raw" predicted language model is $\hat{\boldsymbol{y}}_d = f(\boldsymbol{x}_d)\mathbf{B}$, which is then normalized. The probability mass assigned

to unseen words is determined through nested cross-validation. We compare against a baseline language model obtained from the training set, again using nested cross-validation to set the probability of unseen terms.

Results are shown in Table 5. The language models induced from demographic data yield small but statistically significant improvements over the baseline (Wilcoxon signed-rank test, $p < .001$). Moreover, the model based on conjunctive features significantly outperforms the model constructed from raw attributes ($p < .001$).

5.2 Features Discovered

Our approach discovers 37 conjunctive features, yielding the results shown in Table 5. We sort all features by frequency, and manually select a subset to display in Table 6. Alongside each feature, we show the words with the highest and lowest log-odds ratios with respect to the feature. Many of these terms are non-standard; while space does not permit a complete glossary, some are defined in Table 4 or in our earlier work (Eisenstein et al., 2010).

Table 6: Conjunctive features discovered by our method with a strong sparsity-inducing prior, ordered by frequency. We also show the words with high log-odds for each feature (postive terms) and its negation (negative terms).

In general, geography was a strong predictor, appearing in 25 of the 37 conjunctions. Features 1 and 2 (F1 and F2) are purely geographical, capturing the northeastern United States and the New York City area. The geographical area of F2 is completely contained by F1; the associated terms are thus very similar, but by having both features, the model can distinguish terms which are used in northeastern areas outside New York City, as well as terms which are especially likely in New York.[5]

Several features conjoin geography with demographic attributes. For example, F9 further refines the New York City area by focusing on communities that have relatively low numbers of Spanish speakers; F17 emphasizes New York neighborhoods that have very high numbers of African Americans and few speakers of languages other than English and Spanish. The regression model can use these features in combination to make fine-grained distinctions about the differences between such neighborhoods. Outside New York, we see that F4 combines a broad geographic area with attributes that select at least moderate levels of minorities and fewer renters (a proxy for areas that are less urban), while F15 identifies West Coast communities with large numbers of speakers of languages other than English and Spanish.

Race and ethnicity appear in 28 of the 37 conjunctions. The attribute indicating the proportion of African Americans appeared in 22 of these features, strongly suggesting that African American Vernacular English (Rickford, 1999) plays an important role in social media text. Many of these features conjoined the proportion of African Americans with geographical features, identifying local linguistic styles used predominantly in either African American or white communities. Among features which focus on minority communities, F17 emphasizes the New York area, F33 focuses on the San Francisco Bay area, and F12 selects a broad area in the Midwest and South. Conversely, F23 selects areas with very few African Americans and Spanish-speakers in the western part of the United States, and F36 selects for similar demographics in the area of Washington and Philadelphia.

Other features conjoined the proportion of African Americans with the proportion of Hispanics and/or Spanish speakers. In some cases, features selected for high proportions of both African Americans and Hispanics; for example, F7 seems to identify a general "urban minority" group, emphasizing renters, African Americans, and Spanish speakers. Other features differentiate between African Ameri-

[5] *Mangoville* and *M2* are clubs in New York; *fasho* and *coo* were previously found to be strongly associated with the West Coast (Eisenstein et al., 2010).

cans and Hispanics: F8 identifies regions with many Spanish speakers and Hispanics, but few African Americans; F20 identifies regions with both Spanish speakers and whites, but few African Americans. F8 and F20 tend to emphasize more Spanish words than features which select for both African Americans and Hispanics.

While race, geography, and language predominate, the socioeconomic attributes appear in far fewer features. The most prevalent attribute is the proportion of renters, which appears in F4 and F7, and in three other features not shown here. This attribute may be a better indicator of the urban/rural divide than the "% urban" attribute, which has a very low threshold for what counts as urban (see Table 1). It may also be a better proxy for wealth than median income, which appears in only one of the thirty-seven selected features. Overall, the selected features tend to include attributes that are easy to predict from text (compare with Table 2).

6 Related Work

Sociolinguistics has a long tradition of quantitative and computational research. Logistic regression has been used to identify relationships between demographic features and linguistic variables since the 1970s (Cedergren and Sankoff, 1974). More recent developments include the use of mixed factor models to account for idiosyncrasies of individual speakers (Johnson, 2009), as well as clustering and multidimensional scaling (Nerbonne, 2009) to enable aggregate inference across multiple linguistic variables. However, all of these approaches assume that both the linguistic indicators and demographic attributes have already been identified by the researcher. In contrast, our approach focuses on identifying these indicators automatically from data. We view our approach as an exploratory complement to more traditional analysis.

There is relatively little computational work on identifying speaker demographics. Chang et al. (2010) use U.S. Census statistics about the ethnic distribution of last names as an anchor in a latent-variable model that infers the ethnicity of Facebook users; however, their paper analyzes social behavior rather than language use. In unpublished work, David Bamman uses geotagged Twitter text and U.S. Census statistics to estimate the age, gender, and racial distributions of various lexical items.[6] Eisenstein et al. (2010) infer geographic clusters that are coherent with respect to both location and lexical distributions; follow-up work by O'Connor et al. (2010) applies a similar generative model to demographic data. The model presented here differs in two key ways: first, we use sparsity-inducing regularization to perform variable selection; second, we eschew high-dimensional mixture models in favor of a bottom-up approach of building conjunctions of demographic and geographic attributes. In a mixture model, each component must define a distribution over all demographic variables, which may be difficult to estimate in a high-dimensional setting.

Early examples of the use of sparsity in natural language processing include maximum entropy classification (Kazama and Tsujii, 2003), language modeling (Goodman, 2004), and incremental parsing (Riezler and Vasserman, 2004). These papers all apply the standard lasso, obtaining sparsity for a single output dimension. Structured sparsity has rarely been applied to language tasks, but Duh et al. (2010) reformulated the problem of reranking N-best lists as multi-task learning with structured sparsity.

7 Conclusion

This paper demonstrates how regression with structured sparsity can be applied to select words and conjunctive demographic features that reveal sociolinguistic associations. The resulting models are compact and interpretable, with little cost in accuracy. In the future we hope to consider richer linguistic models capable of identifying multi-word expressions and syntactic variation.

Acknowledgments We received helpful feedback from Moira Burke, Scott Kiesling, Seyoung Kim, André Martins, Kriti Puniyani, and the anonymous reviewers. Brendan O'Connor provided the data for this research, and Seunghak Lee shared a Matlab implementation of the multi-output lasso, which was the basis for our C implementation. Abstract

Disambiguating concepts and entities in a context sensitive way is a fundamental problem in natural language processing. The comprehensiveness of Wikipedia has made the online encyclopedia an increasingly popular target for disambiguation. Disambiguation to Wikipedia is similar to a traditional Word Sense Disambiguation task, but distinct in that the Wikipedia link structure provides additional information about which disambiguations are compatible. In this work we analyze approaches that utilize this information to arrive at coherent sets of disambiguations for a given document (which we call "global" approaches), and compare them to more traditional (local) approaches. We show that previous approaches for global disambiguation can be improved, but even then the local disambiguation provides a baseline which is very hard to beat.

1 Introduction

Wikification is the task of identifying and linking expressions in text to their referent Wikipedia pages. Recently, Wikification has been shown to form a valuable component for numerous natural language processing tasks including text classification (Gabrilovich and Markovitch, 2007b; Chang et al., 2008), measuring semantic similarity between texts (Gabrilovich and Markovitch, 2007a), cross-document co-reference resolution (Finin et al., 2009; Mayfield et al., 2009), and other tasks (Kulkarni et al., 2009).

Previous studies on Wikification differ with respect to the corpora they address and the subset of expressions they attempt to link. For example, some studies focus on linking only named entities, whereas others attempt to link all "interesting" expressions, mimicking the link structure found in Wikipedia. Regardless, all Wikification systems are faced with a key *Disambiguation to Wikipedia* (D2W) task. In the D2W task, we're given a text along with explicitly identified substrings (called *mentions*) to disambiguate, and the goal is to output the corresponding Wikipedia page, if any, for each mention. For example, given the input sentence "I am visiting friends in <Chicago>," we output *http://en.wikipedia.org/wiki/Chicago* – the Wikipedia page for the city of Chicago, Illinois, and not (for example) the page for the 2002 film of the same name.

Local D2W approaches disambiguate each mention in a document separately, utilizing clues such as the textual similarity between the document and each candidate disambiguation's Wikipedia page. Recent work on D2W has tended to focus on more sophisticated *global* approaches to the problem, in which all mentions in a document are disambiguated simultaneously to arrive at a *coherent* set of disambiguations (Cucerzan, 2007; Milne and Witten, 2008b; Han and Zhao, 2009). For example, if a mention of "Michael Jordan" refers to the computer scientist rather than the basketball player, then we would expect a mention of "Monte Carlo" in the same document to refer to the statistical technique rather than the location. Global approaches utilize the Wikipedia link graph to estimate coherence.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1375–1384,
Portland, Oregon, June 19-24, 2011.

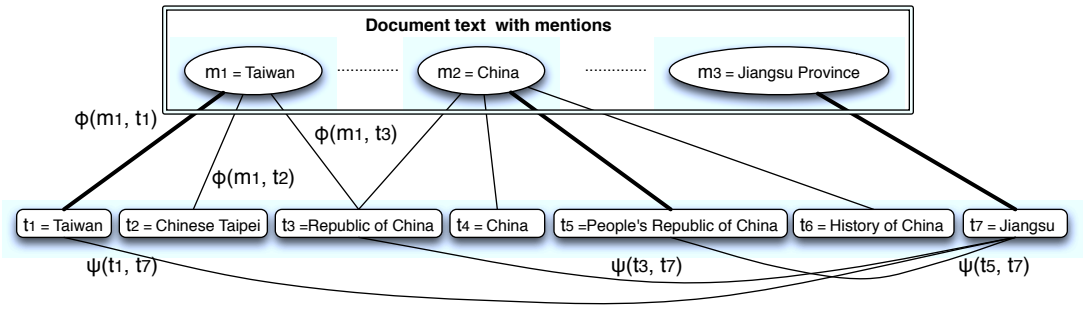

Figure 1: Sample Disambiguation to Wikipedia problem with three mentions. The mention "Jiangsu" is unambiguous. The correct mapping from mentions to titles is marked by heavy edges

In this paper, we analyze global and local approaches to the D2W task. Our contributions are as follows: (1) We present a formulation of the D2W task as an optimization problem with local and global variants, and identify the strengths and the weaknesses of each, (2) Using this formulation, we present a new global D2W system, called GLOW. In experiments on existing and novel D2W data sets,[1] GLOW is shown to outperform the previous state-of-the-art system of (Milne and Witten, 2008b), (3) We present an error analysis and identify the key remaining challenge: determining when mentions refer to concepts *not* captured in Wikipedia.

2 Problem Definition and Approach

We formalize our *Disambiguation to Wikipedia* (D2W) task as follows. We are given a document d with a set of mentions $M = \{m_1, \ldots, m_N\}$, and our goal is to produce a mapping from the set of mentions to the set of Wikipedia titles $W = \{t_1, \ldots, t_{|W|}\}$. Often, mentions correspond to a concept *without* a Wikipedia page; we treat this case by adding a special *null* title to the set W.

The D2W task can be visualized as finding a many-to-one matching on a bipartite graph, with mentions forming one partition and Wikipedia titles the other (see Figure 1). We denote the output matching as an N-tuple $\Gamma = (t_1, \ldots, t_N)$ where t_i is the output disambiguation for mention m_i.

[1]The data sets are available for download at http://cogcomp.cs.illinois.edu/Data

2.1 Local and Global Disambiguation

A *local* D2W approach disambiguates each mention m_i separately. Specifically, let $\phi(m_i, t_j)$ be a score function reflecting the likelihood that the candidate title $t_j \in W$ is the correct disambiguation for $m_i \in M$. A local approach solves the following optimization problem:

$$\Gamma^*_{\text{local}} = \arg\max_{\Gamma} \sum_{i=1}^{N} \phi(m_i, t_i) \quad (1)$$

Local D2W approaches, exemplified by (Bunescu and Pasca, 2006) and (Mihalcea and Csomai, 2007), utilize ϕ functions that assign higher scores to titles with content similar to that of the input document.

We expect, all else being equal, that the correct disambiguations will form a "coherent" set of related concepts. Global approaches define a coherence function ψ, and attempt to solve the following disambiguation problem:

$$\Gamma^* = \arg\max_{\Gamma} [\sum_{i=1}^{N} \phi(m_i, t_i) + \psi(\Gamma)] \quad (2)$$

The global optimization problem in Eq. 2 is NP-hard, and approximations are required (Cucerzan, 2007). The common approach is to utilize the Wikipedia link graph to obtain an estimate pairwise relatedness between titles $\psi(t_i, t_j)$ and to efficiently generate a *disambiguation context* Γ', a rough approximation to the optimal Γ^*. We then solve the easier problem:

$$\Gamma^* \approx \arg\max_{\Gamma} \sum_{i=1}^{N} [\phi(m_i, t_i) + \sum_{t_j \in \Gamma'} \psi(t_i, t_j)] \quad (3)$$

Eq. 3 can be solved by finding each t_i and then mapping m_i independently as in a local approach, but still enforces some degree of coherence among the disambiguations.

3 Related Work

Wikipedia was first explored as an information source for named entity disambiguation and information retrieval by Bunescu and Pasca (2006). There, disambiguation is performed using an SVM kernel that compares the lexical context around the ambiguous named entity to the content of the candidate disambiguation's Wikipedia page. However, since each ambiguous mention required a separate SVM model, the experiment was on a very limited scale. Mihalcea and Csomai applied Word Sense Disambiguation methods to the Disambiguation to Wikipedia task (2007). They experimented with two methods: (a) the lexical overlap between the Wikipedia page of the candidate disambiguations and the context of the ambiguous mention, and (b) training a Naive Bayes classiffier for each ambiguous mention, using the hyperlink information found in Wikipedia as ground truth. Both (Bunescu and Pasca, 2006) and (Mihalcea and Csomai, 2007) fall into the local framework.

Subsequent work on Wikification has stressed that assigned disambiguations for the same document should be related, introducing the global approach (Cucerzan, 2007; Milne and Witten, 2008b; Han and Zhao, 2009; Ferragina and Scaiella, 2010). The two critical components of a global approach are the semantic relatedness function ψ between two titles, and the disambiguation context Γ'. In (Milne and Witten, 2008b), the semantic context is defined to be a set of "unambiguous surface forms" in the text, and the title relatedness ψ is computed as Normalized Google Distance (NGD) (Cilibrasi and Vitanyi, 2007).[2] On the other hand, in (Cucerzan, 2007) the disambiguation context is taken to be all plausible disambiguations of the named entities in the text, and title relatedness is based on the overlap in categories and incoming links. Both approaches have limitations. The first approach relies on the presence of unambiguous mentions in the input document, and the second approach inevitably adds irrelevant titles to the disambiguation context. As we demonstrate in our experiments, by utilizing a more accurate disambiguation context, GLOW is able to achieve better performance.

[2](Milne and Witten, 2008b) also weight each mention in Γ' by its estimated disambiguation utility, which can be modeled by augmenting ψ on per-problem basis.

4 System Architecture

In this section, we present our global D2W system, which solves the optimization problem in Eq. 3. We refer to the system as GLOW, for Global Wikification. We use GLOW as a test bed for evaluating local and global approaches for D2W. GLOW combines a powerful local model ϕ with an novel method for choosing an accurate disambiguation context Γ', which as we show in our experiments allows it to outperform the previous state of the art.

We represent the functions ϕ and ψ as weighted sums of features. Specifically, we set:

$$\phi(m,t) = \sum_i w_i \phi_i(m,t) \tag{4}$$

where each feature $\phi_i(m,t)$ captures some aspect of the relatedness between the mention m and the Wikipedia title t. Feature functions $\psi_i(t,t')$ are defined analogously. We detail the specific feature functions utilized in GLOW in following sections. The coefficients w_i are learned using a Support Vector Machine over bootstrapped training data from Wikipedia, as described in Section 4.5.

At a high level, the GLOW system optimizes the objective function in Eq. 3 in a two-stage process. We first execute a *ranker* to obtain the best non-null disambiguation for each mention in the document, and then execute a *linker* that decides whether the mention should be linked to Wikipedia, or whether instead switching the top-ranked disambiguation to *null* improves the objective function. As our experiments illustrate, the linking task is the more challenging of the two by a significant margin.

Figure 2 provides detailed pseudocode for GLOW. Given a document d and a set of mentions M, we start by augmenting the set of mentions with all phrases in the document that *could* be linked to Wikipedia, but were not included in M. Introducing these additional mentions provides context that may be informative for the global coherence computation (it has no effect on local approaches). In the second

Algorithm: Disambiguate to Wikipedia
Input: document d, Mentions $M = \{m_1, \ldots, m_N\}$
Output: a disambiguation $\Gamma = (t_1, \ldots, t_N)$.
1) Let M' = $M \cup$ { Other potential mentions in d}
2) For each mention $m'_i \in M'$, construct a set of disambiguation candidates $T_i = \{t^i_1, \ldots, t^i_{k_i}\}, t^i_j \neq$ null
3) **Ranker***: Find a solution $\Gamma = (t'_1, \ldots, t'_{|M'|})$, where $t'_i \in T_i$ is the best non-null disambiguation of m'_i.*
4) **Linker***: For each m'_i, map t'_i to* null *in* Γ iff *doing so improves the objective function*
5) Return Γ entries for the original mentions M.

$I_{[t_i \leftrightarrow t_j]}$**PMI(OutLinks($t_i$),OutLinks($t_j$)) : avg/max*
$I_{[t_i \leftrightarrow t_j]}$**NGD(OutLinks($t_i$),OutLinks($t_j$)) : avg/max*

Table 1: Ranker features. $I_{[t_i - t_j]}$ is an indicator variable which is 1 iff t_i links to t_j or vise-versa. $I_{[t_i \leftrightarrow t_j]}$ is 1 iff the titles point to each other.

step, we construct for each mention m_i a limited set of candidate Wikipedia titles T_i that m_i may refer to. Considering only a small subset of Wikipedia titles as potential disambiguations is crucial for tractability (we detail which titles are selected below). In the third step, the ranker outputs the most appropriate non-null disambiguation t_i for each mention m_i.

In the final step, the linker decides whether the top-ranked disambiguation is correct. The disambiguation (m_i, t_i) may be incorrect for several reasons: (1) mention m_i does not have a corresponding Wikipedia page, (2) m_i does have a corresponding Wikipedia page, but it was not included in T_i, or (3) the ranker erroneously chose an incorrect disambiguation over the correct one.

In the below sections, we describe each step of the GLOW algorithm, and the local and global features utilized, in detail. Because we desire a system that can process documents at scale, each step requires trade-offs between accuracy and efficiency.

4.1 Disambiguation Candidates Generation

The first step in GLOW is to extract all mentions that can refer to Wikipedia titles, and to construct a set of disambiguation candidates for each mention. Following previous work, we use Wikipedia hyperlinks to perform these steps. GLOW utilizes an *anchor-title* index, computed by crawling Wikipedia, that maps each distinct hyperlink anchor text to its target Wikipedia titles. For example, the anchor text "Chicago" is used in Wikipedia to refer both to the city in Illinois and to the movie. Anchor texts in the index that appear in document d are used to supplement the mention set M in Step 1 of the GLOW algorithm in Figure 2. Because checking *all* substrings in the input text against the index is computationally inefficient, we instead prune the search space by applying a publicly available shallow parser and named entity recognition system.[3] We consider only the expressions marked as named entities by the NER tagger, the noun-phrase chunks extracted by the shallow parser, and all sub-expressions of up to 5 tokens of the noun-phrase chunks.

To retrieve the disambiguation candidates T_i for a given mention m_i in Step 2 of the algorithm, we query the anchor-title index. T_i is taken to be the set of titles most frequently linked to with anchor text m_i in Wikipedia. For computational efficiency, we utilize only the top 20 most frequent target pages for the anchor text; the accuracy impact of this optimization is analyzed in Section 6.

From the anchor-title index, we compute two local features $\phi_i(m, t)$. The first, $P(t|m)$, is the fraction of times the title t is the target page for an anchor text m. This single feature is a very reliable indicator of the correct disambiguation (Fader et al., 2009), and we use it as a baseline in our experiments. The second, $P(t)$, gives the fraction of all Wikipedia articles that link to t.

4.2 Local Features ϕ

In addition to the two baseline features mentioned in the previous section, we compute a set of text-based

[3] Available at http://cogcomp.cs.illinois.edu/page/software.

local features $\phi(t, m)$. These features capture the intuition that a given Wikipedia title t is more likely to be referred to by mention m appearing in document d if the Wikipedia page for t has high textual similarity to d, or if the context surrounding hyperlinks to t are similar to m's context in d.

For each Wikipedia title t, we construct a top-200 token TF-IDF summary of the Wikipedia page t, which we denote as $Text(t)$ and a top-200 token TF-IDF summary of the context within which t was hyperlinked to in Wikipedia, which we denote as $Context(t)$. We keep the IDF vector for all tokens in Wikipedia, and given an input mention m in a document d, we extract the TF-IDF representation of d, which we denote $Text(d)$, and a TF-IDF representation of a 100-token window around m, which we denote $Context(m)$. This allows us to define four local features described in Table 1.

We additionally compute *weighted* versions of the features described above. Error analysis has shown that in many cases the summaries of the different disambiguation candidates for the same surface form s were very similar. For example, consider the disambiguation candidates of "China' and their TF-IDF summaries in Figure 1. The majority of the terms selected in *all* summaries refer to the general issues related to China, such as *"legalism, reform, military, control, etc."*, while a minority of the terms actually allow disambiguation between the candidates. The problem stems from the fact that the TF-IDF summaries are constructed against the entire Wikipedia, and not against the confusion set of disambiguation candidates of m. Therefore, we *re-weigh* the TF-IDF vectors using the TF-IDF scheme on the disambiguation candidates as a ad-hoc document collection, similarly to an approach in (Joachims, 1997) for classifying documents. In our scenario, the TF of the a token is the original TF-IDF summary score (a real number), and the IDF term is the sum of all the TF-IDF scores for the token within the set of disambiguation candidates for m. This adds 4 more "reweighted local" features in Table 1.

4.3 Global Features ψ

Global approaches require a disambiguation context Γ' and a relatedness measure ψ in Eq. 3. In this section, we describe our method for generating a disambiguation context, and the set of global features $\psi_i(t, t')$ forming our relatedness measure.

In previous work, Cucerzan defined the disambiguation context as the union of disambiguation candidates for all the named entity mentions in the input document (2007). The disadvantage of this approach is that irrelevant titles are inevitably added to the disambiguation context, creating noise. Milne and Witten, on the other hand, use a set of unambiguous mentions (2008b). This approach utilizes only a fraction of the available mentions for context, and relies on the presence of unambiguous mentions with high disambiguation utility. In GLOW, we utilize a simple and efficient alternative approach: we first train a local disambiguation system, and then use the predictions of that system as the disambiguation context. The advantage of this approach is that unlike (Milne and Witten, 2008b) we use all the available mentions in the document, and unlike (Cucerzan, 2007) we reduce the amount of irrelevant titles in the disambiguation context by taking only the top-ranked disambiguation per mention.

Our global features are refinements of previously proposed semantic relatedness measures between Wikipedia titles. We are aware of two previous methods for estimating the relatedness between two Wikipedia concepts: (Strube and Ponzetto, 2006), which uses category overlap, and (Milne and Witten, 2008a), which uses the incoming link structure. Previous work experimented with two relatedness measures: NGD, and Specificity-weighted Cosine Similarity. Consistent with previous work, we found NGD to be the better-performing of the two. Thus we use only NGD along with a well-known Pontwise Mutual Information (PMI) relatedness measure. Given a Wikipedia title collection W, titles t_1 and t_2 with a set of incoming links L_1, and L_2 respectively, PMI and NGD are defined as follows:

$$NGD(L_1, L_2) = \frac{Log(Max(|L_1|, |L_2|)) - Log(|L_1 \cap L_2|)}{Log(|W|) - Log(Min(|L_1|, |L_2|))}$$

$$PMI(L_1, L_2) = \frac{|L_1 \cap L_2|/|W|}{|L_1|/|W||L_2|/|W|}$$

The NGD and the PMI measures can also be computed over the set of *outgoing* links, and we include these as features as well. We also included a feature indicating whether the articles each link to one

another. Lastly, rather than taking the sum of the relatedness scores as suggested by Eq. 3, we use two features: the average and the maximum relatedness to Γ'. We expect the average to be informative for many documents. The intuition for also including the maximum relatedness is that for longer documents that may cover many different subtopics, the maximum may be more informative than the average.

We have experimented with other semantic features, such as category overlap or cosine similarity between the TF-IDF summaries of the titles, but these did not improve performance in our experiments. The complete set of global features used in GLOW is given in Table 1.

4.4 Linker Features

Given the mention m and the top-ranked disambiguation t, the linker attempts to decide whether t is indeed the correct disambiguation of m. The linker includes the same features as the ranker, plus additional features we expect to be particularly relevant to the task. We include the confidence of the ranker in t with respect to second-best disambiguation t', intended to estimate whether the ranker may have made a mistake. We also include several properties of the mention m: the entropy of the distribution $P(t|m)$, the percent of Wikipedia titles in which m appears hyperlinked versus the percent of times m appears as plain text, whether m was detected by NER as a named entity, and a Good-Turing estimate of how likely m is to be out-of-Wikipedia concept based on the counts in $P(t|m)$.

4.5 Linker and Ranker Training

We train the coefficients for the ranker features using a linear Ranking Support Vector Machine, using training data gathered from Wikipedia. Wikipedia links are considered gold-standard links for the training process. The methods for compiling the Wikipedia training corpus are given in Section 5.

We train the linker as a separate linear Support Vector Machine. Training data for the linker is obtained by applying the ranker on the training set. The mentions for which the top-ranked disambiguation did not match the gold disambiguation are treated as negative examples, while the mentions the ranker got correct serve as positive examples.

Mentions/Distinct titles			
data set	Gold	Identified	Solvable
ACE	257/255	213/212	185/184
MSNBC	747/372	530/287	470/273
AQUAINT	727/727	601/601	588/588
Wikipedia	928/813	855/751	843/742

Table 2: Number of mentions and corresponding distinct titles by data set. Listed are (number of mentions)/(number of distinct titles) for each data set, for each of three mention types. *Gold* mentions include all disambiguated mentions in the data set. *Identified* mentions are gold mentions whose correct disambiguations exist in GLOW's author-title index. *Solvable* mentions are identified mentions whose correct disambiguations are among the candidates selected by GLOW (see Table 3).

5 Data sets and Evaluation Methodology

We evaluate GLOW on four data sets, of which two are from previous work. The first data set, from (Milne and Witten, 2008b), is a subset of the *AQUAINT* corpus of newswire text that is annotated to mimic the hyperlink structure in Wikipedia. That is, only the first mentions of "important" titles were hyperlinked. Titles deemed uninteresting and redundant mentions of the same title are not linked. The second data set, from (Cucerzan, 2007), is taken from *MSNBC* news and focuses on disambiguating named entities after running NER and co-reference resolution systems on newsire text. In this case, *all* mentions of all the detected named entities are linked.

We also constructed two additional data sets. The first is a subset of the *ACE* co-reference data set, which has the advantage that mentions and their types are given, and the co-reference is resolved. We asked annotators on Amazon's Mechanical Turk to link the first nominal mention of each co-reference chain to Wikipedia, if possible. Finding the accuracy of a majority vote of these annotations to be approximately 85%, we manually corrected the annotations to obtain ground truth for our experiments. The second data set we constructed, *Wiki*, is a sample of paragraphs from Wikipedia pages. Mentions in this data set correspond to existing hyperlinks in the Wikipedia text. Because Wikipedia editors explicitly link mentions to Wikipedia pages, their anchor text tends to match the title of the linked-to-page—as a result, in the overwhelming majority of

cases, the disambiguation decision is as trivial as string matching. In an attempt to generate more challenging data, we extracted 10,000 random paragraphs for which choosing the top disambiguation according to $P(t|m)$ results in at least a 10% ranker error rate. 40 paragraphs of this data was utilized for testing, while the remainder was used for training.

The data sets are summarized in Table 2. The table shows the number of annotated mentions which were hyperlinked to *non-null* Wikipedia pages, and the number of titles in the documents (without counting repetitions). For example, the AQUAINT data set contains 727 mentions,[4] all of which refer to distinct titles. The MSNBC data set contains 747 mentions mapped to non-null Wikipedia pages, but some mentions within the same document refer to the same titles. There are 372 titles in the data set, when multiple instances of the same title within one document are not counted.

To isolate the performance of the individual components of GLOW, we use multiple distinct metrics for evaluation. *Ranker accuracy*, which measures the performance of the ranker alone, is computed only over those mentions with a non-null gold disambiguation that appears in the candidate set. It is equal to the fraction of these mentions for which the ranker returns the correct disambiguation. Thus, a perfect ranker should achieve a ranker accuracy of 1.0, irrespective of limitations of the candidate generator. *Linker accuracy* is defined as the fraction of *all* mentions for which the linker outputs the correct disambiguation (note that, when the title produced by the ranker is incorrect, this penalizes linker accuracy). Lastly, we evaluate our whole system against other baselines using a previously-employed "bag of titles" (BOT) evaluation (Milne and Witten, 2008b). In BOT, we compare the set of titles output for a document with the gold set of titles for that document (ignoring duplicates), and utilize standard precision, recall, and F1 measures.

In BOT, the set of titles is collected from the mentions hyperlinked in the gold annotation. That is, if the gold annotation is { *(China, People's Republic of China), (Taiwan, Taiwan), (Jiangsu, Jiangsu)*} and the predicted anotation is: { *(China, People's Republic of China), (China, History of China), (Taiwan, null), (Jiangsu, Jiangsu), (republic, Government)*} , then the BOT for the gold annotation is: {*People's Republic of China, Taiwan, Jiangsu*} , and the BOT for the predicted annotation is: {*People's Republic of China, History of China, Jiangsu*} . The title *Government* is not included in the BOT for predicted annotation, because its associate mention *republic* did not appear as a mention in the gold annotation. Both the precision and the recall of the above prediction is 0.66. We note that in the BOT evaluation, following (Milne and Witten, 2008b) we consider all the titles within a document, even if some the titles were due to mentions we failed to identify.[5]

[4]The data set contains votes on how important the mentions are. We believe that the results in (Milne and Witten, 2008b) were reported on mentions which the majority of annotators considered important. In contrast, we used all the mentions.

Generated Candidates k	data sets			
	ACE	MSNBC	AQUAINT	Wiki
1	81.69	72.26	91.01	84.79
3	85.44	86.22	96.83	94.73
5	86.38	87.35	97.17	96.37
20	86.85	88.67	97.83	98.59

Table 3: Percent of "solvable" mentions as a function of the number of generated disambiguation candidates. Listed is the fraction of identified mentions m whose target disambiguation t is among the top k candidates ranked in descending order of $P(t|m)$.

6 Experiments and Results

In this section, we evaluate and analyze GLOW's performance on the D2W task. We begin by evaluating the mention detection component (Step 1 of the algorithm). The second column of Table 2 shows how many of the "non-null" mentions and corresponding titles we could successfully identify (e.g. out of 747 mentions in the MSNBC data set, only 530 appeared in our anchor-title index). Missing entities were primarily due to especially rare surface forms, or sometimes due to idiosyncratic capitalization in the corpus. Improving the number of identified mentions substantially is non-trivial; (Zhou et al., 2010) managed to successfully identify only 59 more entities than we do in the MSNBC data set, using a much more powerful detection method based on search engine query logs.

We generate disambiguation candidates for a

[5]We evaluate the mention identification stage in Section 6.

Table 4: Ranker Accuracy. Bold values indicate the best performance in each feature group. The global approaches marginally outperform the local approaches on *ranker accuracy* , while combing the approaches leads to further marginal performance improvement.

Data set	Local	Global	Local+Global
ACE	$80.1 \rightarrow 82.8$	$80.6 \rightarrow 80.6$	$81.5 \rightarrow 85.1$
MSNBC	$74.9 \rightarrow 76.0$	$77.9 \rightarrow 77.9$	$76.5 \rightarrow 76.9$
AQUAINT	$93.5 \rightarrow 91.5$	$93.8 \rightarrow 92.1$	$92.3 \rightarrow 91.3$
Wiki	$92.2 \rightarrow 92.0$	$88.5 \rightarrow 87.2$	$92.8 \rightarrow 92.6$

Table 5: Linker performance. The notation $X \rightarrow Y$ means that when linking all mentions, the linking accuracy is X, while when applying the trained linker, the performance is Y. The local approaches are better suited for linking than the global approaches. The linking accuracy is very sensitive to domain changes.

System	ACE	MSNBC	AQUAINT	Wiki
Baseline: $P(t\|m)$	69.52	72.83	82.67	81.77
GLOW Local	75.60	74.39	84.52	90.20
GLOW Global	74.73	74.58	84.37	86.62
GLOW	77.25	74.88	83.94	90.54
M&W	72.76	68.49	83.61	80.32

Table 6: End systems performance - BOT F1. The performance of the full system (GLOW) is similar to that of the local version. GLOW outperforms (Milne and Witten, 2008b) on all data sets.

mention m using an anchor-title index, choosing the 20 titles with maximal $P(t|m)$. Table 3 evaluates the accuracy of this generation policy. We report the percent of mentions for which the correct disambiguation is generated in the top k candidates (called "solvable" mentions). We see that the baseline prediction of choosing the disambiguation t which maximizes $P(t|m)$ is very strong (80% of the correct mentions have maximal $P(t|m)$ in all data sets except MSNBC). The fraction of solvable mentions increases until about five candidates per mention are generated, after which the increase is rather slow. Thus, we believe choosing a limit of 20 candidates per mention offers an attractive trade-off of accuracy and efficiency. The last column of Table 2 reports the number of solvable mentions and the corresponding number of titles with a cutoff of 20 disambiguation candidates, which we use in our experiments.

Next, we evaluate the accuracy of the ranker. Table 4 compares the ranker performance with baseline, local and global features. The reweighted local features outperform the unweighted ("Naive") version, and the global approach outperforms the local approach on all data sets except Wikipedia. As the table shows, our approach of defining the disambiguation context to be the predicted disambiguations of a simpler local model ("Predictions") performs better than using NER entities as in (Cucerzan, 2007), or only the unambiguous entities as in (Milne and Witten, 2008b).[6] Combining the local and the global approaches typically results in minor improvements.

While the global approaches are most effective for ranking, the linking problem has different characteristics as shown in Table 5. We can see that the global features are not helpful in general for predicting whether the top-ranked disambiguation is indeed the correct one.

Further, although the trained linker improves accuracy in some cases, the gains are marginal—and the linker decreases performance on some data sets. One explanation for the decrease is that the linker is trained on Wikipedia, but is being tested on non-Wikipedia text which has different characteristics. However, in separate experiments we found that training a linker on out-of-Wikipedia text only increased test set performance by approximately 3 percentage points. Clearly, while ranking accuracy is high overall, different strategies are needed to achieve consistently high linking performance.

A few examples from the ACE data set help il-

[6] In NER we used only the top prediction, because using all candidates as in (Cucerzan, 2007) proved prohibitively inefficient.

lustrate the tradeoffs between local and global features in GLOW. The global system mistakenly links *"<Dorothy Byrne>, a state coordinator for the Florida Green Party, said ..."* to the British journalist, because the journalist sense has high coherence with other mentions in the newswire text. However, the local approach correctly maps the mention to $null$ because of a lack of local contextual clues. On the other hand, in the sentence *"Instead of Los Angeles International, for example, consider flying into <Burbank> or John Wayne Airport in Orange County, Calif."*, the local ranker links the mention *Burbank* to *Burbank,_California*, while the global system correctly maps the entity to *Bob_Hope_Airport*, because the three airports mentioned in the sentence are highly related to one another.

Lastly, in Table 6 we compare the end system BOT F1 performance. The local approach proves a very competitive baseline which is hard to beat. Combining the global and the local approach leads to marginal improvements. The full GLOW system outperforms the existing state-of-the-art system from (Milne and Witten, 2008b), denoted as M&W, on all data sets. We also compared our system with the recent TAGME Wikification system (Ferragina and Scaiella, 2010). However, TAGME is designed for a different setting than ours: extremely short texts, like Twitter posts. The TAGME RESTful API was unable to process some of our documents at once. We attempted to input test documents one sentence at a time, disambiguating each sentence independently, which resulted in poor performance (0.07 points in F1 lower than the $P(t|m)$ baseline). This happened mainly because the same mentions were linked to different titles in different sentences, leading to low precision.

An important question is why M&W underperforms the baseline on the MSNBC and Wikipedia data sets. In an error analysis, M&W performed poorly on the MSNBC data not due to poor disambiguations, but instead because the data set contains only named entities, which were often delimited incorrectly by M&W. Wikipedia was challenging for a different reason: M&W performs less well on the short (one paragraph) texts in that set, because they contain relatively few of the unambiguous entities the system relies on for disambiguation.

7 Conclusions

We have formalized the *Disambiguation to Wikipedia* (D2W) task as an optimization problem with local and global variants, and analyzed the strengths and weaknesses of each. Our experiments revealed that previous approaches for global disambiguation can be improved, but even then the local disambiguation provides a baseline which is very hard to beat.

As our error analysis illustrates, the primary remaining challenge is determining when a mention does *not* have a corresponding Wikipedia page. Wikipedia's hyperlinks offer a wealth of disambiguated mentions that can be leveraged to train a D2W system. However, when compared with mentions from general text, Wikipedia mentions are disproportionately likely to have corresponding Wikipedia pages. Our initial experiments suggest that accounting for this bias requires more than simply training a D2W system on a moderate number of examples from non-Wikipedia text. Applying distinct semi-supervised and active learning approaches to the task is a primary area of future work.

A Stacked Sub-Word Model for Joint Chinese Word Segmentation and Part-of-Speech Tagging

Abstract

The large combined search space of joint word segmentation and Part-of-Speech (POS) tagging makes efficient decoding very hard. As a result, effective high order features representing rich contexts are inconvenient to use. In this work, we propose a novel stacked sub-word model for this task, concerning both efficiency and effectiveness. Our solution is a two step process. First, one word-based segmenter, one character-based segmenter and one local character classifier are trained to produce coarse segmentation and POS information. Second, the outputs of the three predictors are merged into sub-word sequences, which are further bracketed and labeled with POS tags by a fine-grained sub-word tagger. The coarse-to-fine search scheme is efficient, while in the sub-word tagging step rich contextual features can be approximately derived. Evaluation on the Penn Chinese Treebank shows that our model yields improvements over the best system reported in the literature.

1 Introduction

Word segmentation and part-of-speech (POS) tagging are necessary initial steps for more advanced Chinese language processing tasks, such as parsing and semantic role labeling. Joint approaches that resolve the two tasks simultaneously have received much attention in recent research. Previous work has shown that joint solutions led to accuracy improvements over pipelined systems by avoiding segmentation error propagation and exploiting POS information to help segmentation. A challenge for joint approaches is the large combined search space, which makes efficient decoding and structured learning of parameters very hard. Moreover, the representation ability of models is limited since using rich contextual word features makes the search intractable. To overcome such efficiency and effectiveness limitations, the approximate inference and reranking techniques have been explored in previous work (Zhang and Clark, 2010; Jiang et al., 2008b).

In this paper, we present an effective and efficient solution for joint Chinese word segmentation and POS tagging. Our work is motivated by several characteristics of this problem. First of all, a majority of words are easy to identify in the segmentation problem. For example, a simple maximum matching segmenter can achieve an f-score of about 90. We will show that it is possible to improve the efficiency and accuracy by using different strategies for different words. Second, segmenters designed with different views have complementary strength. We argue that the agreements and disagreements of different solvers can be used to construct an intermediate sub-word structure for joint segmentation and tagging. Since the sub-words are large enough in practice, the decoding for POS tagging over sub-words is efficient. Finally, the Chinese language is characterized by the lack of morphology that often provides important clues for POS tagging, and the POS tags contain much syntactic information, which need context information within a large window for disambiguation. For example, Huang et al. (2007) showed the effectiveness of utilizing syntactic information to rerank POS tagging results. As a result, the capability to represent rich contextual features is crucial to a POS tagger. In this work, we use a representation-efficiency tradeoff through stacked learning, a way of approximating rich *non-local* fea-

Portland, Oregon, June 19-24, 2011.

tures.

This paper describes a novel stacked sub-word model. Given multiple word segmentations of one sentence, we formally define a sub-word structure that maximizes the agreement of non-word-break positions. Based on the sub-word structure, joint word segmentation and POS tagging is addressed as a two step process. In the first step, one word-based segmenter, one character-based segmenter and one local character classifier are used to produce coarse segmentation and POS information. The results of the three predictors are then merged into sub-word sequences, which are further bracketed and labeled with POS tags by a fine-grained sub-word tagger. If a string is consistently segmented as a word by the three segmenters, it will be a correct word prediction with a very high probability. In the sub-word tagging phase, the fine-grained tagger mainly considers its POS tag prediction problem. For the words that are not consistently predicted, the fine-grained tagger will also consider their bracketing problem. The coarse-to-fine scheme significantly improves the efficiency of decoding. Furthermore, in the sub-word tagging step, word features in a large window can be approximately derived from the coarse segmentation and tagging results. To train a good sub-word tagger, we use the stacked learning technique, which can effectively correct the training/test mismatch problem.

We conduct our experiments on the Penn Chinese Treebank and compare our system with the state-of-the-art systems. We present encouraging results. Our system achieves an f-score of 98.17 for the word segmentation task and an f-score of 94.02 for the whole task, resulting in relative error reductions of 14.1% and 5.5% respectively over the best system reported in the literature.

The remaining part of the paper is organized as follows. Section 2 gives a brief introduction to the problem and reviews the relevant previous research. Section 3 describes the details of our method. Section 4 presents experimental results and empirical analyses. Section 5 concludes the paper.

2 Background

2.1 Problem Definition

Given a sequence of characters $\mathbf{c} = (c_1, ..., c_{\#\mathbf{c}})$, the task of word segmentation and POS tagging is to predict a sequence of word and POS tag pairs $\mathbf{y} = (\langle w_1, p_1 \rangle, \langle w_{\#\mathbf{y}}, p_{\#\mathbf{y}} \rangle)$, where w_i is a word, p_i is its POS tag, and a "#" symbol denotes the number of elements in each variable. In order to avoid error propagation and make use of POS information for word segmentation, the two tasks should resolved jointly. Previous research has shown that the integrated methods outperformed pipelined systems (Ng and Low, 2004; Jiang et al., 2008a; Zhang and Clark, 2008).

2.2 Character-Based and Word-Based Methods

Two kinds of approaches are popular for joint word segmentation and POS tagging. The first is the "character-based" approach, where basic processing units are characters which compose words. In this kind of approach, the task is formulated as the classification of characters into POS tags with boundary information. Both the *IOB2* representation (Ramshaw and Marcus, 1995) and the *Start/End* representation (Kudo and Matsumoto, 2001) are popular. For example, the label *B-NN* indicates that a character is located at the begging of a noun. Using this method, POS information is allowed to interact with segmentation. Note that word segmentation can also be formulated as a sequential classification problem to predict whether a character is located at the beginning of, inside or at the end of a word. This character-by-character method for segmentation was first proposed in (Xue, 2003), and was then further used in POS tagging in (Ng and Low, 2004). One main disadvantage of this model is the difficulty in incorporating the whole word information.

The second kind of solution is the "word-based" method, where the basic predicting units are words themselves. This kind of solver sequentially decides whether the local sequence of characters makes up a word as well as its possible POS tag. In particular, a word-based solver reads the input sentence from left to right, predicts whether the current piece of continuous characters is a word token and which class it belongs to. Solvers may use previously predicted words and their POS information as clues to find a new word. After one word is found and classified, solvers move on and search for the next possible word. This word-by-word method for segmentation was first proposed in (Zhang and Clark, 2007),

and was then further used in POS tagging in (Zhang and Clark, 2008).

In our previous work(Sun, 2010), we presented a theoretical and empirical comparative analysis of character-based and word-based methods for Chinese word segmentation. We showed that the two methods produced different distributions of segmentation errors in a way that could be explained by theoretical properties of the two models. A system combination method that leverages the complementary strength of word-based and character-based segmentation models was also successfully explored in their work. Different from our previous focus, the diversity of different models designed with different views is utilized to construct sub-word structures in this work. We will discuss the details in the next section.

2.3 Stacked Learning

Stacked generalization is a meta-learning algorithm that was first proposed in (Wolpert, 1992) and (Breiman, 1996). The idea is to include two "levels" of predictors. The first level includes one or more predictors $g_1, ...g_K : \mathbb{R}^d \rightarrow \mathbb{R}$; each receives input $\mathbf{x} \in \mathbb{R}^d$ and outputs a prediction $g_k(\mathbf{x})$. The second level consists of a single function $h : \mathbb{R}^{d+K} \rightarrow \mathbb{R}$ that takes as input $\langle \mathbf{x}, g_1(\mathbf{x}), ..., g_K(\mathbf{x}) \rangle$ and outputs a final prediction $\hat{y} = h(\mathbf{x}, g_1(\mathbf{x}), ..., g_K(\mathbf{x}))$.

Training is done as follows. The training data $S = \{(\mathbf{x}_t, \mathbf{y}_t) : t \in [1, T]\}$ is split into L equal-sized disjoint subsets $S_1, ..., S_L$. Then functions $\mathbf{g}_1, ..., \mathbf{g}_L$ (where $\mathbf{g}_l = \langle g_1^l, ..., g_K^l \rangle$) are seperately trained on $S - S_l$, and are used to construct the augmented dataset $\hat{S} = \{(\langle \mathbf{x}_t, \hat{\mathbf{y}}_t^1, ..., \hat{\mathbf{y}}_t^K \rangle, \mathbf{y}_t) : \hat{\mathbf{y}}_t^k = g_k^l(\mathbf{x}_t)$ and $\mathbf{x}_t \in S_l\}$. Finally, each g_k is trained on the original dataset and the second level predictor h is trained on $\hat{S}$. The intent of the *cross-validation* scheme is that $\mathbf{y}_t^k$ is similar to the prediction produced by a predictor which is learned on a sample that does not include $\mathbf{x}_t$.

Stacked learning has been applied as a system ensemble method in several NLP tasks, such as named entity recognition (Wu et al., 2003) and dependency parsing (Nivre and McDonald, 2008). This framework is also explored as a solution for learning *non-local* features in (Torres Martins et al., 2008). In the machine learning research, stacked learning has been applied to structured prediction (Cohen and Carvalho, 2005). In this work, stacked learning is used to acquire extended training data for sub-word tagging.

3 Method

3.1 Architecture

In our stacked sub-word model, joint word segmentation and POS tagging is decomposed into two steps: (1) coarse-grained word segmentation and tagging, and (2) fine-grained sub-word tagging. The workflow is shown in Figure 1. In the first phase, one word-based segmenter ($\mathrm{Seg_W}$) and one character-based segmenter ($\mathrm{Seg_C}$) are trained to produce word boundaries. Additionally, a *local* character-based joint segmentation and tagging solver ($\mathrm{SegTag_L}$) is used to provide word boundaries as well as inaccurate POS information. Here, the word *local* means the labels of nearby characters are not used as features. In other words, the local character classifier assumes that the tags of characters are independent of each other. In the second phase, our system first combines the three segmentation and tagging results to get sub-words which maximize the agreement about word boundaries. Finally, a fine-grained sub-word tagger (SubTag) is applied to bracket sub-words into words and also to obtain their POS tags.

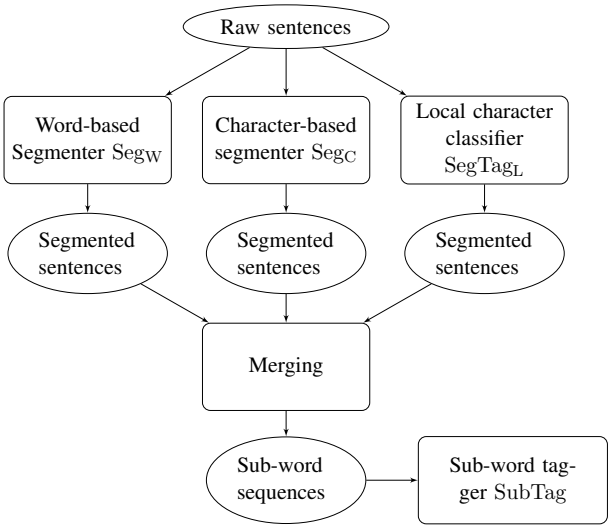

Figure 1: Workflow of the stacked sub-word model.

In our model, segmentation and POS tagging interact with each other in two processes. First, although $SegTag_L$ is locally trained, it resolves the

two sub-tasks simultaneously. Therefore, in the sub-word generating stage, segmentation and POS tagging help each other. Second, in the sub-word tagging stage, the bracketing and the classification of sub-words are jointly resolved as one sequence labeling problem.

Our experiments on the Penn Chinese Treebank will show that the word-based and character-based segmenters and the local tagger on their own produce high quality word boundaries. As a result, the oracle performance to recover words from a sub-word sequence is very high. The quality of the final tagger relies on the quality of the sub-word tagger. If a high performance sub-word tagger can be constructed, the whole task can be well resolved. The statistics will also empirically show that sub-words are significantly larger than characters and only slightly smaller than words. As a result, the search space of the sub-word tagging is significantly shrunken, and exact Viterbi decoding without approximately pruning can be efficiently processed. This property makes nearly all popular sequence labeling algorithms applicable.

Zhang et al. (2006) described a sub-word based tagging model to resolve word segmentation. To get the pieces which are larger than characters but smaller than words, they combine a character-based segmenter and a dictionary matching segmenter. Our contributions include (1) providing a formal definition of our sub-word structure that is based on multiple segmentations and (2) proposing a stacking method to acquire sub-words.

3.2 The Coarse-grained Solvers

We systematically described the implementation of two state-of-the-art Chinese word segmenters in word-based and character-based architectures, respectively (Sun, 2010). Our word-based segmenter is based on a discriminative joint model with a first order semi-Markov structure, and the other segmenter is based on a first order Markov model. Exact Viterbi-style search algorithms are used for decoding. Limited to the document length, we do not give the description of the features. We refer readers to read the above paper for details. For parameter estimation, our work adopt the *Passive-Aggressive* (PA) framework (Crammer et al., 2006), a family of margin based online learning algorithms. In this work, we introduce two simple but important refinements: (1) to shuffle the sample orders in each iteration and (2) to average the parameters in each iteration as the final parameters.

Idiom In linguistics, idioms are usually presumed to be figures of speech contradicting the principle of compositionality. As a result, it is very hard to recognize out-of-vocabulary idioms for word segmentation. However, the lexicon of idioms can be taken as a close set, which helps resolve the problem well. We collect 12992 idioms[1] from several online Chinese dictionaries. For both word-based and character-based segmentation, we first match every string of a given sentence with idioms. Every sentence is then splitted into smaller pieces which are seperated by idioms. Statistical segmentation models are then performed on these smaller character sequences.

We use a local classifier to predict the POS tag with positional information for each character. Each character can be assigned one of two possible boundary tags: "B" for a character that begins a word and "I" for a character that occurs in the middle of a word. We denote a candidate character token c_i with a fixed window $c_{i-2}c_{i-1}c_ic_{i+1}c_{i+2}$. The following features are used:

- character uni-grams: c_k $(i-2 \leq k \leq i+2)$
- character bi-grams: c_kc_{k+1} $(i-2 \leq k \leq i+1)$

To resolve the classification problem, we use the linear SVM classifier LIBLINEAR[2].

3.3 Merging Multiple Segmentation Results into Sub-Word Sequences

A majority of words are easy to identify in the segmentation problem. We favor the idea treating different words using different strategies. In this work we try to identify *simple* and *difficult* words first and to integrate them into a sub-word level. Inspired by previous work, we constructed this sub-word structure by using multiple solvers designed from different views. If a piece of continuous characters is consistently segmented by multiple segmenters, it will

Figure 2: An example phrase: 以总成绩 3 5 5 . 3 5 分居领先地位 (Being in front with a total score of 355.35 points).

not be separated in the sub-word tagging step. The intuition is that strings which are consistently segmented by the different segmenters tend to be correct predictions. In our experiment on the Penn Chinese Treebank (Xue et al., 2005), the accuracy is 98.59% on the development data which is defined in the next section. The key point for the intermediate sub-word structures is to maximize the agreement of the three coarse-grained systems. In other words, the goal is to make merged sub-words as large as possible but not overlap with any predicted word produced by the three coarse-grained solvers. In particular, if the position between two continuous characters is predicted as a word boundary by any segmenter, this position is taken as a separation position of the sub-word sequence. This strategy makes sure that it is still possible to *re*-segment the strings of which the boundaries are disagreed with by the coarse-grained segmenters in the fine-grained tagging stage.

The formal definition is as follows. Given a sequence of characters $\mathbf{c} = (c_1, ..., c_{\#\mathbf{c}})$, let $c[i:j]$ denote a string that is made up of characters between c_i and c_j (including c_i and c_j), then a partition of the sentence can be written as $c[0:e_1], c[e_1+1:e_2], ..., c[e_m:\#\mathbf{c}]$. Let $s_k = \{c[i:j]\}$ denote the set of all segments of a partition. Given multiple partitions of a character sequence $\mathcal{S} = \{s_k\}$, there is one and only one merged partition $s_{\mathcal{S}} = \{c[i:j]\}$ s.t.

1. $\forall c[i:j] \in s_{\mathcal{S}}, \forall s_k \in \mathcal{S}, \exists c[s:e] \in s_k, s \leq i \leq j \leq e$.

2. $\forall \mathcal{C}'$ satisfies the above condition, $|\mathcal{C}'| > |\mathcal{C}|$.

The first condition makes sure that all segments in the merged partition can be only embedded in but do not overlap with any segment of any partition from $\mathcal{S}$. The second condition promises that segments of the merged partition achieve maximum length.

Figure 2 is an example to illustrate the procedure of our method. The lines $\mathrm{Seg_W}$, $\mathrm{Seg_C}$ and $\mathrm{SegTag_L}$ are the predictions of the three coarse-grained solvers. For the three words at the beginning and the two words at the end, the three predictors agree with each other. And these five words are kept as sub-words. For the character sequence " 3 5 5 . 3 5 分居", the predictions are very different. Because there are no word break predictions among the first three characters " 3 5 5 ", it is as a whole taken as one sub-word. For the other five characters, either the left position or the right position is segmented as a word break by some predictor, so the merging processor seperates them and takes each one as a single sub-word. The last line shows the merged sub-word sequence. The coarse-grained POS tags with positional information are derived from the labels provided by $\mathrm{SegTag_L}$.

3.4 The Fine-grained Sub-Word Tagger

Bracketing sub-words into words is formulated as a IOB-style sequential classification problem. Each sub-word may be assigned with one POS tag as well as two possible boundary tags: "B" for the beginning position and "I" for the middle position. A tagger is trained to classify sub-word by using the features derived from its contexts.

The sub-word level allows our system to utilize features in a large context, which is very important for POS tagging of the morphologically poor language. Features are formed making use of sub-word contents, their IOB-style inaccurate POS tags. In the following description, "C" refers to the content of the sub-word, while "T" refers to the IOB-style POS tags. For convenience, we denote a sub-word with its context $...s_{i-2}s_{i-1}s_is_{i+1}s_{i+2}...$, where s_i is

C(s_{i-1})="成绩"; T(s_{i-1})="NN" C(s_i)=" 3 5 5 "; T(s_i)="B-CD" C(s_{i+1})=". "; T(s_{i+1})="I-CD"
C(s_{i-1})C(s_i)="成绩_3 5 5 " T(s_{i-1})T(s_i)="NN_B-CD" C(s_i)C(s_{i+1})=" 3 5 5 _. " T(s_i)T(s_{i+1})="B-CD_I-CD"
C(s_{i-1})C(s_{i+1})="成绩_. " T(s_{i-1})T(s_{i+1})="B-NN_I-CD"
Prefix(1)=" 3 "; Prefix(2)=" 3 5 "; Prefix(3)=" 3 5 5 " Suffix(1)=" 5 "; Suffix(2)=" 5 5 "; Suffix(3)=" 3 5 5 "

Table 1: An example of features used in the sub-word tagging.

the current token. We denote l_C, l_T as the sizes of the window.

- Uni-gram features: C(s_k) ($-l_C \leq k \leq l_C$), T(s_k) ($-l_T \leq k \leq l_T$)
- Bi-gram features: C(s_k)C(s_{k+1}) ($-l_C \leq k \leq l_C - 1$), T(s_k)T(s_{k+1}) ($-l_T \leq k \leq l_T - 1$)
- C(s_{i-1})C(s_{i+1}) (if $l_C \geq 1$), T(s_{i-1})T(s_{i+1}) (if $l_T \geq 1$)
- T(s_{i-2})T(s_{i+1}) (if $l_T \geq 2$)
- In order to better handle unknown words, we also extract morphological features: character n-gram prefixes and suffixes for n up to 3. These features have been shown useful in previous research (Huang et al., 2007).

Take the sub-word " 3 5 5 " in Figure 2 for example, when l_C and l_T are both set to 1, all features used are listed in Table 1.

In the following experiments, we will vary window sizes l_C and l_T to find out the contribution of context information for the disambiguation. A first order Max-Margin Markov Networks model is used to resolve the sequence tagging problem. We use the SVM-HMM[3] implementation for the experiments in this work. We use the basic linear model without applying any kernel function.

Algorithm 1: The stacked learning procedure for the sub-word tagger.

input : Data $S = \{(\mathbf{c}_t, \mathbf{y}_t), t = 1, 2, ..., n\}$
Split S into L partitions $\{S_1, ...S_L\}$
for $l = 1, ..., L$ **do**
  Train $\mathrm{Seg_W}^l$, $\mathrm{Seg_C}^l$ and $\mathrm{SegTag_L}^l$ using $S - S_l$.
  Predict S_l using $\mathrm{Seg_W}^l$, $\mathrm{Seg_C}^l$ and $\mathrm{SegTag_L}^l$.
  Merge the predictions to get sub-words training sample S'_l.
end
Train the sub-word tagger SubTag using S'.

3.5 Stacked Learning for the Sub-Word Tagger

The three coarse-grained solvers $\mathrm{Seg_W}$, $\mathrm{Seg_C}$ and $\mathrm{SegTag_L}$ are directly trained on the original training data. When these three predictors are used to produce the training data, the performance is perfect. However, this does not hold when these models are applied to the test data. If we directly apply $\mathrm{Seg_W}$, $\mathrm{Seg_C}$ and $\mathrm{SegTag_L}$ to extend the training data to generate sub-word samples, the extended training data for the sub-word tagger will be very different from the data in the run time, resulting in poor performance.

One way to correct the training/test mismatch is to use the stacking method, where a K-fold *cross-validation* on the original data is performed to construct the training data for sub-word tagging. Algorithm 1 illustrates the learning procedure. First, the training data $S = \{(\mathbf{c}_t, \mathbf{y}_t)\}$ is split into L equal-sized disjoint subsets $S_1, ..., S_L$. For each subset S_l, the complementary set $S - S_l$ is used to train three coarse solvers $\mathrm{Seg_W}^l$, $\mathrm{Seg_C}^l$ and $\mathrm{SegTag_L}^l$, which process the S_l and provide inaccurate predictions. Then the inaccurate predictions are merged into sub-word sequences and S_l is extended to S'_l. Finally, the sub-word tagger is trained on the whole extended data set S'.

4 Experiments

4.1 Setting

Previous studies on joint Chinese word segmentation and POS tagging have used the Penn Chinese Treebank (CTB) in experiments. We follow this set-

ting in this paper. We use CTB 5.0 as our main corpus and define the training, development and test sets according to (Jiang et al., 2008a; Jiang et al., 2008b; Kruengkrai et al., 2009; Zhang and Clark, 2010). Table 2 shows the statistics of our experimental settings.

Data set	CTB files	# of sent.	# of words
Training	1-270	18,089	493,939
	400-931		
	1001-1151		
Devel.	301-325	350	6821
Test	271-300	348	8008

Table 2: Training, development and test data on CTB 5.0

Three metrics are used for evaluation: precision (P), recall (R) and balanced f-score (F) defined by 2PR/(P+R). Precision is the relative amount of correct words in the system output. Recall is the relative amount of correct words compared to the gold standard annotations. For segmentation, a token is considered to be correct if its boundaries match the boundaries of a word in the gold standard. For the whole task, both the boundaries and the POS tag have to be correctly identified.

4.2 Performance of the Coarse-grained Solvers

Table 3 shows the performance on the development data set of the three coarse-grained solvers. In this paper, we use 20 iterations to train $\mathrm{Seg_W}$ and $\mathrm{Seg_C}$ for all experiments. Even only locally trained, the character classifier $\mathrm{SegTag_L}$ still significantly outperforms the two state-of-the-art segmenters $\mathrm{Seg_W}$ and $\mathrm{Seg_C}$. This good performance indicates that the POS information is very important for word segmentation.

Devel.	Task	P(%)	R(%)	F
$\mathrm{Seg_W}$	Seg	94.55	94.84	94.69
$\mathrm{Seg_C}$	Seg	95.10	94.38	94.73
$\mathrm{SegTag_L}$	Seg	95.67	95.98	95.83
	Seg&Tag	87.54	91.29	89.38

Table 3: Performance of the coarse-grained solvers on the development data.

4.3 Statistics of Sub-Words

Since the base predictors to generate coarse information are two word segmenters and a local character classifier, the coarse decoding is efficient. If the length of sub-words is too short, i.e. the decoding path for sub-word sequences are too long, the decoding of the fine-grained stage is still hard. Although we cannot give a theoretical average length of sub-words, we can still show the empirical one. The average length of sub-words on the development set is 1.64, while the average length of words is 1.69. The number of all IOB-style POS tags is 59 (when using 5-fold cross-validation to generate stacked training samples). The number of all POS tags is 35. Empirically, the decoding over sub-words is $\frac{1.69}{1.64} \times (\frac{59}{35})^{n+1}$ times as slow as the decoding over words, where n is the order of the markov model. When a first order markov model is used, this number is 2.93. These statistics empirically suggest that the decoding over sub-word sequence can be efficient.

On the other hand, the sub-word sequences are not perfect in the sense that they do not promise to recover all words because of the errors made in the first step. Similarly, we can only show the empirical upper bound of the sub-word tagging. The oracle performance of the final POS tagging on the development data set is shown in Table 4. The upper bound indicates that the coarse search procedure does not lose too much.

Task	P(%)	R(%)	F
Seg&Tag	99.50%	99.09%	99.29

Table 4: Upper bound of the sub-word tagging on the development data.

One main disadvantage of character-based approach is the difficulty to incorporate word features. Since the sub-words are on average close to words, sub-word features are good approximations of word features.

4.4 Rich Contextual Features Are Useful

Table 5 shows the effect that features within different window size has on the sub-word tagging task. In this table, the symbol "C" means sub-word content features while the symbol "T" means IOB-style POS tag features. The number indicates the length

Devel.		P(%)	R(%)	F
C:±0	T:±0	92.52	92.83	92.67
C:±1	T:±0	92.63	93.27	92.95
C:±1	T:±1	92.62	93.05	92.83
C:±2	T:±0	93.17	93.86	93.51
C:±2	T:±1	93.27	93.64	93.45
C:±2	T:±2	93.08	93.61	93.34
C:±3	T:±0	93.12	93.86	93.49
C:±3	T:±1	93.34	93.96	93.65
C:±3	T:±2	93.34	93.96	93.65

Table 5: Performance of the stacked sub-word model ($K = 5$) with features in different window sizes.

of the window. For example, "C:±1" means that the tagger uses one preceding sub-word and one succeeding sub-word as features. From this table, we can clearly see the impact of features derived from neighboring sub-words. There is a significant increase between "C:±2" and "C:±1" models. This confirms our motivation that longer history and future features are crucial to the Chinese POS tagging problem. It is the main advantage of our model that making rich contextual features applicable. In all previous solutions, only features within a short history can be used due to the efficiency limitation.

The performance is further slightly improved when the window size is increased to 3. Using the labeled bracketing f-score, the evaluation shows that the "C:±3 T:±1" model performs the same as the "C:±3 T:±2" model. However, the sub-word classification accuracy of the "C:±3 T:±1" model is higher, so in the following experiments and the final results reported on the test data set, we choose this setting.

This table also suggests that the IOB-style POS information of sub-words does not contribute. We think there are two main reasons: (1) The POS information provided by the local classifier is inaccurate; (2) The structured learning of the sub-word tagger can use *real predicted* sub-word labels during its decoding time, since this learning algorithm does inference during the training time. It is still an open question whether more accurate POS information in rich contexts can help this task. If the answer is *YES*, how can we efficiently incorporate these features?

4.5 Stacked Learning Is Useful

Table 6 compares the performance of "C:±3 T:±1" models trained with no stacking as well as different folds of cross-validation. We can see that although it is still possible to improve the segmentation and POS tagging performance compared to the local character classifier, the whole task just benefits only a little from the sub-word tagging procedure if the stacking technique is not applied. The stacking technique can significantly improve the system performance, both for segmentation and POS tagging. This experiment confirms the theoretical motivation of using stacked learning: simulating the test-time setting when a sub-word tagger is applied to a new instance. There is not much difference between the 5-fold and the 10-fold cross-validation.

Devel.	Task	P(%)	R(%)	F
No stacking	Seg	95.75	96.48	96.12
	Seg&Tag	91.42	92.13	91.77
$K = 5$	Seg	96.42	97.04	96.73
	Seg&Tag	93.34	93.96	93.65
$K = 10$	Seg	96.67	97.11	96.89
	Seg&Tag	93.50	94.06	93.78

Table 6: Performance on the development data. No stacking and different folds of cross-validation are separately applied.

4.6 Final Results

Table 7 summarizes the performance of our final system on the test data and other systems reported in a majority of previous work. The final results of our system are achieved by using 10-fold cross-validation "C:±3 T:±1" models. The left most column indicates the reference of previous systems that represent state-of-the-art results. The comparison of the accuracy between our stacked sub-word system and the state-of-the-art systems in the literature indicates that our method is competitive with the best systems. Our system obtains the highest f-score performance on both segmentation and the whole task, resulting in error reductions of 14.1% and 5.5% respectively.

Test	Seg	Seg&Tag
(Jiang et al., 2008a)	97.85	93.41
(Jiang et al., 2008b)	97.74	93.37
(Kruengkrai et al., 2009)	97.87	93.67
(Zhang and Clark, 2010)	97.78	93.67
Our system	**98.17**	**94.02**

Table 7: F-score performance on the test data.

5 Conclusion and Future Work

This paper has described a stacked sub-word model for joint Chinese word segmentation and POS tagging. We defined a sub-word structure which maximizes the agreement of multiple segmentations provided by different segmenters. We showed that this sub-word structure could explore the complementary strength of different systems designed with different views. Moreover, the POS tagging could be efficiently and effectively resolved over sub-word sequences. To train a good sub-word tagger, we introduced a stacked learning procedure. Experiments showed that our approach was superior to the existing approaches reported in the literature.

Machine learning and statistical approaches encounter difficulties when the input/output data have a structured and relational form. Research in empirical Natural Language Processing has been tackling these complexities since the early work in the field. Recent work in machine learning has provided several paradigms to globally represent and process such data: linear models for structured prediction, graphical models, constrained conditional models, and reranking, among others. A general expressivity-efficiency trade off is observed. Although the stacked sub-word model is an ad hoc solution for a particular problem, namely joint word segmentation and POS tagging, the idea to employ system ensemble and stacked learning in general provides an alternative for structured problems. Multiple "cheap" coarse systems are used to provide diverse outputs, which may be inaccurate. These outputs are further merged into an intermediate representation, which allows an extractive system to use rich contexts to predict the final results. A natural avenue for future work is the extension of our method to other NLP tasks.

Abstract

Translating compounds is an important problem in machine translation. Since many compounds have not been observed during training, they pose a challenge for translation systems. Previous decompounding methods have often been restricted to a small set of languages as they cannot deal with more complex compound forming processes. We present a novel and unsupervised method to learn the compound parts and morphological operations needed to split compounds into their compound parts. The method uses a bilingual corpus to learn the morphological operations required to split a compound into its parts. Furthermore, monolingual corpora are used to learn and filter the set of compound part candidates. We evaluate our method within a machine translation task and show significant improvements for various languages to show the versatility of the approach.

1 Introduction

A compound is a lexeme that consists of more than one stem. Informally, a compound is a combination of two or more words that function as a single unit of meaning. Some compounds are written as space-separated words, which are called open compounds (e.g. *hard drive*), while others are written as single words, which are called closed compounds (e.g. *wallpaper*). In this paper, we shall focus only on closed compounds because open compounds do not require further splitting.

The objective of compound splitting is to split a compound into its corresponding sequence of constituents. If we look at how compounds are created from lexemes in the first place, we find that for some languages, compounds are formed by concatenating existing words, while in other languages compounding additionally involves certain morphological operations. These morphological operations can become very complex as we illustrate in the following case studies.

1.1 Case Studies

Below, we look at splitting compounds from 3 different languages. The examples introduce in part the notation used for the decision rule outlined in Section 3.1.

1.1.1 English Compound Splitting

The word *flowerpot* can appear as a closed or open compound in English texts. To automatically split the closed form we have to try out every split point and choose the split with minimal costs according to a cost function. Let's assume that we already know that *flowerpot* must be split into two parts. Then we have to position two split points that mark the end of each part (one is always reserved for the last character position). The *number* of split points is denoted by K (i.e. $K = 2$), while the *position* of split points is denoted by n_1 and n_2. Since *flowerpot* consists of 9 characters, we have 8 possibilities to position split point n_1 within the characters $c_1, \ldots, c_8$. The final split point corresponds with the last character, that is, $n_2 = 9$. Trying out all possible single splits results in the following candidates:

$$\begin{aligned}
&\text{flowerpot} \rightarrow \text{f} + \text{lowerpot} \\
&\text{flowerpot} \rightarrow \text{fl} + \text{owerpot} \\
&\qquad\vdots \\
&\text{flowerpot} \rightarrow \textbf{flower} + \textbf{pot} \\
&\qquad\vdots \\
&\text{flowerpot} \rightarrow \text{flowerpo} + \text{t}
\end{aligned}$$

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1395–1404,
Portland, Oregon, June 19-24, 2011.

If we associate each compound part candidate with a cost that reflects how frequent this part occurs in a large collection of English texts, we expect that the correct split *flower* + *pot* will have the lowest cost.

1.1.2 German Compound Splitting

The previous example covered a case where the compound is constructed by directly concatenating the compound parts. While this works well for English, other languages require additional morphological operations. To demonstrate, we look at the German compound *Verkehrszeichen* (traffic sign) which consists of the two nouns *Verkehr* (traffic) and *Zeichen* (sign). Let's assume that we want to split this word into 3 parts, that is, $K = 3$. Then, we get the following candidates.

$$\begin{aligned}
&\text{Verkehrszeichen} \rightarrow \text{V} + \text{e} + \text{rkehrszeichen}\\
&\text{Verkehrszeichen} \rightarrow \text{V} + \text{er} + \text{kehrszeichen}\\
&\qquad\vdots\\
&\text{Verkehrszeichen} \rightarrow \textbf{Verkehr} + \textbf{s} + \textbf{zeichen}\\
&\qquad\vdots\\
&\text{Verkehrszeichen} \rightarrow \text{Verkehrszeich} + \text{e} + \text{n}
\end{aligned}$$

Using the same procedure as described before, we can lookup the compound parts in a dictionary or determine their frequency from large text collections. This yields the optimal split points $n_1 = 7, n_2 = 8, n_3 = 15$. The interesting part here is the additional s morpheme, which is called a linking morpheme, because it combines the two compound parts to form the compound *Verkehrszeichen*. If we have a list of all possible linking morphemes, we can hypothesize them between two ordinary compound parts.

1.1.3 Greek Compound Splitting

The previous example required the insertion of a linking morpheme between two compound parts. We shall now look at a more complicated morphological operation. The Greek compound χαρτόκουτο (*cardboard box*) consists of the two parts χαρτί (*paper*) and κουτί (*box*). Here, the problem is that the parts χαρτό and κουτο are not valid words in Greek. To lookup the correct words, we must substitute the suffix of the compound part candidates with some other morphemes. If we allow the compound part candidates to be transformed by some morphological operation, we can lookup the transformed compound parts in a dictionary or determine their frequencies in some large collection of Greek texts. Let's assume that we need only one split point. Then this yields the following compound part candidates:

$$\begin{aligned}
&\text{χαρτόκουτο} \rightarrow \text{χ} + \text{αρτόκουτο}\\
&\text{χαρτόκουτο} \rightarrow \text{χ} + \text{αρτίκουτο} \quad g_2 : \text{ό} \,/\, \text{ί}\\
&\text{χαρτόκουτο} \rightarrow \text{χ} + \text{αρτόκουτί} \quad g_2 : \text{ο} \,/\, \text{ί}\\
&\qquad\vdots\\
&\text{χαρτόκουτο} \rightarrow \textbf{χαρτί} + \textbf{κουτί} \quad g_1 : \text{ό} \,/\, \text{ί}\,, \quad g_2 : \text{ο} \,/\, \text{ί}\\
&\qquad\vdots\\
&\text{χαρτόκουτο} \rightarrow \text{χαρτίκουτ} + \text{ο} \quad g_1 : \text{ό} \,/\, \text{ί}\\
&\text{χαρτόκουτο} \rightarrow \text{χαρτίκουτ} + \text{ί} \quad g_2 : \text{ο} \,/\, \text{ί}
\end{aligned}$$

Here, $g_k : s/t$ denotes the kth compound part which is obtained by replacing string s with string t in the original string, resulting in the transformed part g_k.

1.2 Problems and Objectives

Our goal is to design a language-independent compound splitter that is useful for machine translation. The previous examples addressed the importance of a cost function that favors valid compound parts versus invalid ones. In addition, the examples have shown that, depending on the language, the morphological operations can become very complex. For most Germanic languages like Danish, German, or Swedish, the list of possible linking morphemes is rather small and can be provided manually. However, in general, these lists can become very large, and language experts who could provide such lists might not be at our disposal. Because it seems infeasible to list the morphological operations explicitly, we want to find and extract those operations automatically in an unsupervised way and provide them as an additional knowledge source to the decompounding algorithm.

Another problem is how to evaluate the quality of the compound splitter. One way is to compile for every language a large collection of compounds together with their valid splits and to measure the proportion of correctly split compounds. Unfortunately, such lists do not exist for many languages.

While the training algorithm for our compound splitter shall be unsupervised, the evaluation data needs to be verified by human experts. Since we are interested in improving machine translation and to circumvent the problem of explicitly annotating compounds, we evaluate the compound splitter within a machine translation task. By decompounding training and test data of a machine translation system, we expect an increase in the number of matching phrase table entries, resulting in better translation quality measured in BLEU score (Papineni et al., 2002). If BLEU score is sensitive enough to measure the quality improvements obtained from decompounding, there is no need to generate a separate gold standard for compounds.

Finally, we do not want to split non-compounds and named entities because we expect them to be translated non-compositionally. For example, the German word *Deutschland* (Germany) could be split into two parts *Deutsch* (German) + *Land* (country). Although this is a valid split, named entities should be kept as single units. An example for a non-compound is the German participle *vereinbart* (agreed) which could be wrongly split into the parts *Verein* (club) + *Bart* (beard). To avoid overly eager splitting, we will compile a list of non-compounds in an unsupervised way that serves as an exception list for the compound splitter. To summarize, we aim to solve the following problems:

- Define a cost function that favors valid compound parts and rejects invalid ones.
- Learn morphological operations, which is important for languages that have complex compound forming processes.
- Apply compound splitting to machine translation to aid in translation of compounds that have not been seen in the bilingual training data.
- Avoid splitting non-compounds and named entities as this may result in wrong translations.

2 Related work

Previous work concerning decompounding can be divided into two categories: monolingual and bilingual approaches.

Brown (2002) describes a corpus-driven approach for splitting compounds in a German-English translation task derived from a medical domain. A large proportion of the tokens in both texts are cognates with a Latin or Greek etymological origin. While the English text keeps the cognates as separate tokens, they are combined into compounds in the German text. To split these compounds, the author compares both the German and the English cognates on a character level to find reasonable split points. The algorithm described by the author consists of a sequence of *if-then-else* conditions that are applied on the two cognates to find the split points. Furthermore, since the method relies on finding similar character sequences between both the source and the target tokens, the approach is restricted to cognates and cannot be applied to split more complex compounds.

Koehn and Knight (2003) present a frequency-based approach to compound splitting for German. The compound parts and their frequencies are estimated from a monolingual corpus. As an extension to the frequency approach, the authors describe a bilingual approach where they use a dictionary extracted from parallel data to find better split options. The authors allow only two linking morphemes between compound parts and a few letters that can be dropped. In contrast to our approach, those operations are not learned automatically, but must be provided explicitly.

Garera and Yarowsky (2008) propose an approach to translate compounds without the need for bilingual training texts. The compound splitting procedure mainly follows the approach from (Brown, 2002) and (Koehn and Knight, 2003), so the emphasis is put on finding correct translations for compounds. To accomplish this, the authors use cross-language compound evidence obtained from bilingual dictionaries. In addition, the authors describe a simple way to learn glue characters by allowing the deletion of up to two middle and two end characters.[1] More complex morphological operations are not taken into account.

Alfonseca et al. (2008b) describe a state-of-the-art German compound splitter that is particularly robust with respect to noise and spelling errors. The compound splitter is trained on monolingual data. Besides applying frequency and probability-based methods, the authors also take the mutual information of compound parts into account. In addition, the

[1] However, the glue characters found by this procedure seem to be biased for at least German and Albanian. A very frequent glue morpheme like *-es-* is not listed, while glue morphemes like *-k-* and *-h-* rank very high, although they are invalid glue morphemes for German. Albanian shows similar problems.

authors look for compound parts that occur in different anchor texts pointing to the same document. All these signals are combined and the weights are trained using a support vector machine classifier. Alfonseca et al. (2008a) apply this compound splitter on various other Germanic languages.

Dyer (2009) applies a maximum entropy model of compound splitting to generate segmentation lattices that serve as input to a translation system. To train the model, reference segmentations are required. Here, we produce only single best segmentations, but otherwise do not rely on reference segmentations.

3 Compound Splitting Algorithm

In this section, we describe the underlying optimization problem and the algorithm used to split a token into its compound parts. Starting from Bayes' decision rule, we develop the Bellman equation and formulate a dynamic programming-based algorithm that takes a word as input and outputs the constituent compound parts. We discuss the procedure used to extract compound parts from monolingual texts and to learn the morphological operations using bilingual corpora.

3.1 Decision Rule for Compound Splitting

Given a token $w = c_1, \ldots, c_N = c_1^N$ consisting of a sequence of N characters c_i, the objective function is to find the optimal number $\hat{K}$ and sequence of split points $\hat{n}_0^{\hat{K}}$ such that the subwords are the constituents of the token, where[2] $n_0 := 0$ and $n_K := N$:

$$
\begin{aligned}
w = c_1^N \rightarrow (\hat{K}, \hat{n}_0^{\hat{K}}) &= \\
&= \arg\max_{K, n_0^K} \left\{ \Pr(c_1^N, K, n_0^K) \right\} \qquad (1) \\
&= \arg\max_{K, n_0^K} \left\{ \Pr(K) \cdot \Pr(c_1^N, n_0^K | K) \right\} \\
&\approx \arg\max_{K, n_0^K} \Big\{ p(K) \cdot \prod_{k=1}^{K} p(c_{n_{k-1}+1}^{n_k}, n_{k-1} | K) \cdot \\
&\qquad \cdot p(n_k | n_{k-1}, K) \Big\} \qquad (2)
\end{aligned}
$$

with $p(n_0) = p(n_K|\cdot) \equiv 1$. Equation 2 requires that token w can be fully decomposed into a sequence of lexemes, the compound parts. Thus, determining the optimal segmentation is sufficient for finding the constituents. While this may work for some languages, the subwords are not valid words in general as discussed in Section 1.1.3. Therefore, we allow the lexemes to be the result of a transformation process, where the transformed lexemes are denoted by g_1^K. This leads to the following refined decision rule:

$$
\begin{aligned}
w = c_1^N \rightarrow (\hat{K}, \hat{n}_0^{\hat{K}}, \hat{g}_1^{\hat{K}}) &= \\
&= \arg\max_{K, n_0^K, g_1^K} \left\{ \Pr(c_1^N, K, n_0^K, g_1^K) \right\} \qquad (3) \\
&= \arg\max_{K, n_0^K, g_1^K} \left\{ \Pr(K) \cdot \Pr(c_1^N, n_0^K, g_1^K | K) \right\} \qquad (4) \\
&\approx \arg\max_{K, n_0^K, g_1^K} \Big\{ p(K) \cdot \prod_{k=1}^{K} \underbrace{p(c_{n_{k-1}+1}^{n_k}, n_{k-1}, g_k | K)}_{\text{compound part probability}} \cdot \\
&\qquad \cdot p(n_k | n_{k-1}, K) \Big\} \qquad (5)
\end{aligned}
$$

The compound part probability is a zero-order model. If we penalize each split with a constant split penalty ξ, and make the probability independent of the number of splits K, we arrive at the following decision rule:

$$
\begin{aligned}
w = c_1^N \rightarrow (\hat{K}, \hat{n}_1^{\hat{K}}, \hat{g}_1^{\hat{K}}) &\\
= \arg\max_{K, n_0^K, g_1^K} \Big\{ \xi^K \cdot \prod_{k=1}^{K} p(c_{n_{k-1}+1}^{n_k}, n_{k-1}, g_k) \Big\} \qquad (6)
\end{aligned}
$$

3.2 Dynamic Programming

We use dynamic programming to find the optimal split sequence. Each split infers certain costs that are determined by a cost function. The total costs of a decomposed word can be computed from the individual costs of the component parts. For the dynamic programming approach, we define the following auxiliary function $\mathcal{Q}$ with $n_k = j$:

$$
\mathcal{Q}(c_1^j) = \max_{n_0^k, g_1^k} \Big\{ \xi^k \cdot \prod_{\kappa=1}^{k} p(c_{n_{\kappa-1}+1}^{n_\kappa}, n_{\kappa-1}, g_\kappa) \Big\}
$$

that is, $\mathcal{Q}(c_1^j)$ is equal to the minimal costs (maximum probability) that we assign to the prefix string c_1^j where we have used k split points at positions n_1^k. This yields the following recursive equation:

$$
\begin{aligned}
\mathcal{Q}(c_1^j) = \max_{n_k, g_k} \Big\{ & \xi \cdot \mathcal{Q}(c_1^{n_{k-1}}) \cdot \\
& \cdot p(c_{n_{k-1}+1}^{n_k}, n_{k-1}, g_k) \Big\} \qquad (7)
\end{aligned}
$$

[2] For algorithmic reasons, we use the start position 0 to represent a fictitious start symbol before the first character of the word.

Algorithm 1 Compound splitting

Input: input word $w = c_1^N$
Output: compound parts
  $\mathcal{Q}(0) = 0$
  $\mathcal{Q}(1) = \cdots = \mathcal{Q}(N) = \infty$
  for $i = 0, \ldots, N-1$ **do**
    for $j = i+1, \ldots, N$ **do**
      split-costs $= \mathcal{Q}(i) + \text{cost}(c_{i+1}^j, i, g_j) +$ split-penalty
      if split-costs $< \mathcal{Q}(j)$ **then**
        $\mathcal{Q}(j) =$ split-costs
        $\mathcal{B}(j) = (i, g_j)$
      end if
    end for
  end for

with backpointer

$$\mathcal{B}(j) = \arg\max_{n_k, g_k} \left\{ \xi \cdot \mathcal{Q}(c_1^{n_{k-1}}) \cdot \cdot p(c_{n_{k-1}+1}^{n_k}, n_{k-1}, g_k) \right\} \quad (8)$$

Using logarithms in Equations 7 and 8, we can interpret the quantities as additive costs rather than probabilities. This yields Algorithm 1, which is quadratic in the length of the input string. By enforcing that each compound part does not exceed a predefined constant length ℓ, we can change the second **for** loop as follows:

for $j = i+1, \ldots, \min(i+\ell, N)$ **do**

With this change, Algorithm 1 becomes linear in the length of the input word, $O(|w|)$.

4 Cost Function and Knowledge Sources

The performance of Algorithm 1 depends on the cost function cost$(\cdot)$, that is, the probability $p(c_{n_{k-1}+1}^{n_k}, n_{k-1}, g_k)$. This cost function incorporates knowledge about morpheme transformations, morpheme positions within a compound part, and the compound parts themselves.

4.1 Learning Morphological Operations using Phrase Tables

Let s and t be strings of the (source) language alphabet $\mathcal{A}$. A morphological operation s/t is a pair of strings $s, t \in \mathcal{A}^*$, where s is replaced by t. With the usual definition of the Kleene operator $*$, s and t can be empty, denoted by ε. An example for such a pair is ε/es, which models the linking morpheme *es* in the German compound *Bundesagentur* (federal agency):

$$\text{Bundesagentur} \rightarrow \text{Bund} + \text{es} + \text{Agentur} .$$

Note that by replacing either s or t with ε, we can model insertions or deletions of morphemes. The explicit dependence on position n_{k-1} in Equation 6 allows us to determine if we are at the beginning, in the middle, or at the end of a token. Thus, we can distinguish between start, middle, or end morphemes and hypothesize them during search.[3] Although not explicitly listed in Algorithm 1, we disallow sequences of linking morphemes. This can be achieved by setting the costs to infinity for those morpheme hypotheses, which directly succeed another morpheme hypothesis.

To learn the morphological operations involved in compounding, we determine the differences between a compound and its compound parts. This can be done by computing the Levenshtein distance between the compound and its compound parts, with the allowable edit operations being insertion, deletion, or substitution of one or more characters. If we store the current and previous characters, edit operation and the location (prefix, infix or suffix) at each position during calculation of the Levenshtein distance then we can obtain the morphological operations required for compounding. Applying the inverse operations, that is, replacing t with s yields the operation required for decompounding.

4.1.1 Finding Compounds and their Parts

To learn the morphological operations, we need compounds together with their compound parts. The basic idea of finding compound candidates and their compound parts in a bilingual setting are related to the ideas presented in (Garera and Yarowsky, 2008). Here, we use phrase tables rather than dictionaries. Although phrase tables might contain more noise, we believe that overall phrase tables cover more phenomena of translations than what can be found in dictionaries. The procedure is as follows. We are given a phrase table that provides translations for phrases from a source language l into English and from English into l. Under the assumption that English does not contain many closed compounds, we can search

[3] We jointly optimize over K and the split points n_k, so we know that $c_{n_{K-1}}^{n_K}$ is a suffix of w.

the phrase table for those single-token source words f in language l, which translate into multi-token English phrases $e_1, \ldots, e_n$ for $n > 1$. This results in a list of $(f; e_1, \ldots, e_n)$ pairs, which are potential compound candidates together with their English translations. If for each pair, we take each token e_i from the English (multi-token) phrase and lookup the corresponding translation for language l to get g_i, we should find entries that have at least some partial match with the original source word f, if f is a true compound. Because the translation phrase table was generated automatically during the training of a multi-language translation system, there is no guarantee that the original translations are correct. Thus, the bilingual extraction procedure is subject to introduce a certain amount of noise. To mitigate this, thresholds such as minimum edit distance between the potential compound and its parts, minimum co-occurrence frequencies for the selected bilingual phrase pairs and minimum source and target word lengths are used to reduce the noise at the expense of finding fewer compounds. Those entries that obey these constraints are output as triples of form:

$$(f; e_1, \ldots, e_n; g_1, \ldots, g_n) \tag{9}$$

where

- f is likely to be a compound,
- $e_1, \ldots, e_n$ is the English translation, and
- $g_1, \ldots, g_n$ are the compound parts of f.

The following example for German illustrates the process. Suppose that the most probable translation for *Überweisungsbetrag* is *transfer amount* using the phrase table. We then look up the translation back to German for each translated token: *transfer* translates to *Überweisung* and *amount* translates to *Betrag*. We then calculate the distance between all permutations of the parts and the original compound and choose the one with the lowest distance and highest translation probability: *Überweisung Betrag*.

4.2 Monolingual Extraction of Compound Parts

The most important knowledge source required for Algorithm 1 is a word-frequency list of compound parts that is used to compute the split costs. The procedure described in Section 4.1.1 is useful for learning morphological operations, but it is not sufficient to extract an exhaustive list of compound parts. Such lists can be extracted from monolingual data for which we use language model (LM) word frequency lists in combination with some filter steps. The extraction process is subdivided into 2 passes, one over a high-quality news LM to extract the parts and the other over a web LM to filter the parts.

4.2.1 Phase 1: Bootstrapping pass

In the first pass, we generate word frequency lists derived from news articles for multiple languages. The motivation for using news articles rather than arbitrary web texts is that news articles are in general less noisy and contain fewer spelling mistakes. The language-dependent word frequency lists are filtered according to a sequence of filter steps. These filter steps include discarding all words that contain digits or punctuations other than hyphen, minimum occurrence frequency, and a minimum length which we set to 4. The output is a table that contains preliminary compound parts together with their respective counts for each language.

4.2.2 Phase 2: Filtering pass

In the second pass, the compound part vocabulary is further reduced and filtered. We generate a LM vocabulary based on arbitrary web texts for each language and build a compound splitter based on the vocabulary list that was generated in phase 1. We now try to split every word of the web LM vocabulary based on the compound splitter model from phase 1. For the compound parts that occur in the compound splitter output, we determine how often each compound part was used and output only those compound parts whose frequency exceed a predefined threshold n.

4.3 Example

Suppose we have the following word frequencies output from pass 1:

floor	10k	poll	4k
flow	9k	pot	5k
flower	15k	potter	20k

In pass 2, we observe the word *flowerpot*. With the above list, the only compound parts used are *flower* and *pot*. If we did not split any other words and threshold at $n = 1$, our final list would consist of *flower* and *pot*. This filtering pass has the advantage of outputting only those compound part candidates

which were actually used to split words from web texts. The thresholding also further reduces the risk of introducing noise. Another advantage is that since the set of parts output in the first pass may contain a high number of compounds, the filter is able to remove a large number of these compounds by examining relative frequencies. In our experiments, we have assumed that compound part frequencies are higher than the compound frequency and so remove words from the part list that can themselves be split and have a relatively high frequency. Finally, after removing the low frequency compound parts, we obtain the final compound splitter vocabulary.

4.4 Generating Exception Lists

To avoid eager splitting of non-compounds and named entities, we use a variant of the procedure described in Section 4.1.1. By emitting all those source words that translate with high probability into single-token English words, we obtain a list of words that should not be split.[4]

4.5 Final Cost Function

The final cost function is defined by the following components which are combined log-linearly.

- The split penalty ξ penalizes each compound part to avoid eager splitting.
- The cost for each compound part g_k is computed as $-\log C(g_k)$, where $C(g_k)$ is the unigram count for g_k obtained from the news LM word frequency list. Since we use a zero-order model, we can ignore the normalization and work with unigram counts rather than unigram probabilities.
- Because Algorithm 1 iterates over the characters of the input token w, we can infer from the boundaries (i, j) if we are at the start, in the middle, or at the end of the token. Applying a morphological operation adds costs 1 to the overall costs.

Although the cost function is language dependent, we use the same split penalty weight $\xi = 20$ for all languages except for German, where the split penalty weight is set to 13.5.

5 Results

To show the language independence of the approach within a machine translation task, we translate from languages belonging to different language families into English. The publicly available Europarl corpus is not suitable for demonstrating the utility of compound splitting because there are few unseen compounds in the test section of the Europarl corpus. The WMT shared translation task has a broader domain compared to Europarl but covers only a few languages. Hence, we present results for German-English using the WMT-07 data and cover other languages using non-public corpora which contain news as well as open-domain web texts. Table 1 lists the various corpus statistics. The source languages are grouped according to their language family.

For learning the morphological operations, we allowed the substitution of at most 2 consecutive characters. Furthermore, we only allowed at most one morphological substitution to avoid introducing too much noise. The found morphological operations were sorted according to their frequencies. Those which occurred less than 100 times were discarded. Examples of extracted morphological operations are given in Table 2. Because the extraction procedure described in Section 4.1 is not purely restricted to the case of decompounding, we found that many morphological operations emitted by this procedure reflect morphological variations that are not directly linked to compounding, but caused by inflections.

To generate the language-dependent lists of compound parts, we used language model vocabulary lists[5] generated from news texts for different languages as seeds for the first pass. These lists were filtered by discarding all entries that either contained digits, punctuations other than hyphens, or sequences of the same characters. In addition, the infrequent entries were discarded as well to further reduce noise. For the second pass, we used the lists generated in the first pass together with the learned morphological operations to construct a preliminary compound splitter. We then generated vocabulary lists for monolingual web texts and applied the preliminary compound splitter onto this list. The used

[4] Because we will translate only into English, this is not an issue for the introductory example *flowerpot*.

[5] The vocabulary lists also contain the word frequencies. We use the term vocabulary list synonymously for a word frequency list.

Family	Src Language	#Tokens Train src/trg		#Tokens Dev src/trg		#Tokens Tst src/trg	
Germanic	Danish	196M	201M	43,475	44,479	72,275	74,504

Estonian	-/ε, e/ε, se/ε
Finnish	ε/n, n/ε, ε/en

Table 2: Examples of morphological operations that were extracted from bilingual corpora.

compound parts were collected and sorted according to their frequencies. Those which were used at least 2 times were kept in the final compound parts lists. Table 3 reports the number of compound parts kept after each pass. For example, the Finnish news vocabulary list initially contained 1.7M entries. After removing non-alpha and infrequent words in the first filter step, we obtained 190K entries. Using the preliminary compound splitter in the second filter step resulted in 73K compound part entries.

The finally obtained compound splitter was integrated into the preprocessing pipeline of a state-of-the-art statistical phrase-based machine translation system that works similar to the Moses decoder (Koehn et al., 2007). By applying the compound splitter during both training and decoding we ensured that source language tokens were split in the same way. Table 4 presents results for various language-pairs with and without decompounding. Both the Germanic and the Uralic languages show significant BLEU score improvements of 1.3 BLEU points on average. The confidence intervals were computed using the bootstrap resampling normal approximation method described in (Noreen, 1989). While the compounding process for Germanic languages is rather simple and requires only a few linking morphemes, compounds used in Uralic languages have a richer morphology. In contrast to the Germanic and Uralic languages, we did not observe improvements for Greek. To investigate this lack of performance, we turned off transliteration and kept unknown source words in their original script. We analyzed the number of remaining source characters in the baseline system and the system using compound splitting by counting the number of Greek characters in the translation output. The number of remaining Greek characters in the translation output was reduced from $6,715$ in the baseline system to $3,624$ in the system which used decompounding. In addition, a few other metrics like the number of source words that consisted of more than 15 characters decreased as well. Because we do not know how many compounds are actually contained in the Greek source sentences[6] and because the frequency of using compounds might vary across languages, we cannot expect the same performance gains across languages belonging to different language families. An interesting observation is, however, that if one language from a language family shows performance gains, then there are performance gains for all the languages in that family. We also investigated the effect of not using any morphological operations. Disallowing all morphological operations accounts for a loss of 0.1 - 0.2 BLEU points across translation systems and increases the compound parts vocabulary lists by up to 20%, which means that most of the gains can be achieved with simple concatenation.

The exception lists were generated according to the procedure described in Section 4.4. Since we aimed for precision rather than recall when constructing these lists, we inserted only those source

[6]Quite a few of the remaining Greek characters belong to rare named entities.

	yes	Τι είναι παλμο κωδικη διαμόρφωση;	What is pulse code modulation?
Finnish	no	Lisävuodevaatteet ja pyyheliinat ovat kaapissa.	Lisävuodevaatteet and towels are in the closet.
	yes	Lisä Vuode Vaatteet ja pyyheliinat ovat kaapissa.	Extra bed linen and towels are in the closet.

Table 5: Examples of translations into English with and without compound splitting.

words whose co-occurrence count with a unigram translation was at least $1,000$ and whose translation probability was larger than 0.1. Furthermore, we required that at least 70% of all target phrase entries for a given source word had to be unigrams. All decompounding results reported in Table 4 were generated using these exception lists, which prevented wrong splits caused by otherwise overly eager splitting.

6 Conclusion and Outlook

We have presented a language-independent method for decompounding that improves translations for compounds that otherwise rarely occur in the bilingual training data. We learned a set of morphological operations from a translation phrase table and determined suitable compound part candidates from monolingual data in a two pass process. This allowed us to learn morphemes and operations for languages where these lists are not available. In addition, we have used the bilingual information stored in the phrase table to avoid splitting non-compounds as well as frequent named entities. All knowledge sources were combined in a cost function that was applied in a compound splitter based on dynamic programming. Finally, we have shown this improves translation performance on languages from different language families.

The weights were not optimized in a systematic way but set manually to their respective values. In the future, the weights of the cost function should be learned automatically by optimizing an appropriate error function. Instead of using gold data, the development data for optimizing the error function could be collected without supervision using the methods proposed in this paper.

Parsing the Internal Structure of Words: A New Paradigm for Chinese Word Segmentation

Abstract

Lots of Chinese characters are very productive in that they can form many structured words either as prefixes or as suffixes. Previous research in Chinese word segmentation mainly focused on identifying only the word boundaries without considering the rich internal structures of many words. In this paper we argue that this is unsatisfying in many ways, both practically and theoretically. Instead, we propose that word structures should be recovered in morphological analysis. An elegant approach for doing this is given and the result is shown to be promising enough for encouraging further effort in this direction. Our probability model is trained with the Penn Chinese Treebank and actually is able to parse both word and phrase structures in a unified way.

1 Why Parse Word Structures?

Research in Chinese word segmentation has progressed tremendously in recent years, with state of the art performing at around 97% in precision and recall (Xue, 2003; Gao et al., 2005; Zhang and Clark, 2007; Li and Sun, 2009). However, virtually all these systems focus exclusively on recognizing the word boundaries, giving no consideration to the internal structures of many words. Though it has been the standard practice for many years, we argue that this paradigm is inadequate both in theory and in practice, for at least the following four reasons.

The first reason is that if we confine our definition of word segmentation to the identification of word boundaries, then people tend to have divergent opinions as to whether a linguistic unit is a word or not (Sproat et al., 1996). This has led to many different annotation standards for Chinese word segmentation. Even worse, this could cause inconsistency in the same corpus. For instance, 副主席 'vice president' is considered to be one word in the Penn Chinese Treebank (Xue et al., 2005), but is split into two words by the Peking University corpus in the SIGHAN Bakeoffs (Sproat and Emerson, 2003). Meanwhile, 副导演 'vice director' and 副经理 'deputy manager' are both segmented into two words in the same Penn Chinese Treebank. In fact, all these words are composed of the prefix 副 'vice' and a root word. Thus the structure of 副主席 'vice president' can be represented with the tree in Figure 1. Without a doubt, there is complete agreement on the correctness of this structure among native Chinese speakers. So if instead of annotating only word boundaries, we annotate the structures of every word, [1] then the annotation tends to be more

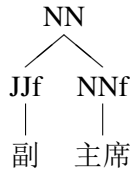

Figure 1: Example of a word with internal structure.

[1] Here it is necessary to add a note on terminology used in this paper. Since there is no universally accepted definition of the "word" concept in linguistics and especially in Chinese, whenever we use the term "word" we might mean a linguistic unit such as 副主席 'vice president' whose structure is shown as the tree in Figure 1, or we might mean a smaller unit such as 主席 'president' which is a substructure of that tree. Hopefully,

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1405–1414,
Portland, Oregon, June 19-24, 2011.

consistent and there could be less duplication of efforts in developing the expensive annotated corpus.

The second reason is applications have different requirements for granularity of words. Take the personal name 周树人 'Zhou Shuren' as an example. It's considered to be one word in the Penn Chinese Treebank, but is segmented into a surname and a given name in the Peking University corpus. For some applications such as information extraction, the former segmentation is adequate, while for others like machine translation, the later finer-grained output is more preferable. If the analyzer can produce a structure as shown in Figure 4(a), then every application can extract what it needs from this tree. A solution with tree output like this is more elegant than approaches which try to meet the needs of different applications in post-processing (Gao et al., 2004).

The third reason is that traditional word segmentation has problems in handling many phenomena in Chinese. For example, the telescopic compound 大中小学 'universities, middle schools and primary schools' is in fact composed of three coordinating elements 大学 'university', 中学 'middle school' and 小学 'primary school'. Regarding it as one flat word loses this important information. Another example is separable words like 游泳 'swim'. With a linear segmentation, the meaning of 'swimming' as in 游完泳 'after swimming' cannot be properly represented, since 游泳 'swim' will be segmented into discontinuous units. These language usages lie at the boundary between syntax and morphology, and are not uncommon in Chinese. They can be adequately represented with trees (Figure 2).

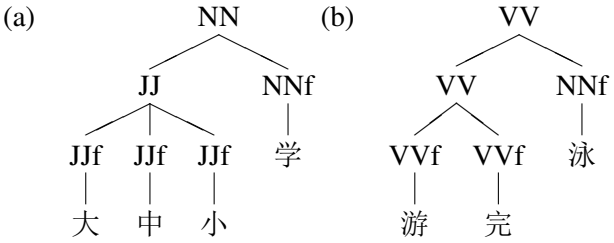

Figure 2: Example of telescopic compound (a) and separable word (b).

The last reason why we should care about word structures is related to head driven statistical parsers (Collins, 2003). To illustrate this, note that in the Penn Chinese Treebank, the word 英格兰人 'English People' does not occur at all. Hence constituents headed by such words could cause some difficulty for head driven models in which out-of-vocabulary words need to be treated specially both when they are generated and when they are conditioned upon. But this word is in turn headed by its suffix 人 'people', and there are 2,233 such words in Penn Chinese Treebank. If we annotate the structure of every compound containing this suffix (e.g. Figure 3), such data sparsity simply goes away.

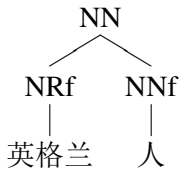

Figure 3: Structure of the out-of-vocabulary word 英格兰人 'English People'.

Had there been only a few words with internal structures, current Chinese word segmentation paradigm would be sufficient. We could simply recover word structures in post-processing. But this is far from the truth. In Chinese there is a large number of such words. We just name a few classes of these words and give one example for each class (a dot is used to separate roots from affixes):

personal name: 长尾·真 'Nagao Makoto'
location name: 纽约·州 'New York State'
noun with a suffix: 分类·器 'classifier'
noun with a prefix: 准·妈妈 'mother-to-be'
verb with a suffix: 自动·化 'automatize'
verb with a prefix: 防·水 'waterproof'
adjective with a suffix: 复合·型 'composite'
adjective with a prefix: 非·正式 'informal'
pronoun with a prefix: 各·位 'everybody'
time expression: 一九九五·年 'the year 1995'
ordinal number: 第·十一 'eleventh'
retroflex suffixation: 花朵·儿 'flower'

This list is not meant to be complete, but we can get a feel of how extensive the words with non-trivial structures can be. With so many productive suffixes and prefixes, analyzing word structures in post-processing is difficult, because a character may or may not act as an affix depending on the context.

the context will always make it clear what is being referred to with the term "word".

For example, the character 人 'people' in 植树人 'the one who plants' is a suffix, but in the personal name 周树人 'Zhou Shuren' it isn't. The structures of these two words are shown in Figure 4.

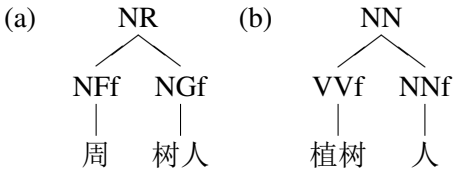

Figure 4: Two words that differ only in one character, but have different internal structures. The character 人 'people' is part of a personal name in tree (a), but is a suffix in (b).

A second reason why generally we cannot recover word structures in post-processing is that some words have very complex structures. For example, the tree of 无政府主义者 'anarchist' is shown in Figure 5. Parsing this structure correctly without a principled method is difficult and messy, if not impossible.

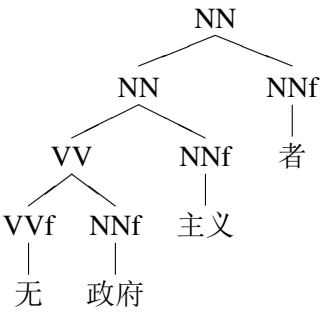

Figure 5: An example word which has very complex structures.

Finally, it must be mentioned that we cannot store all word structures in a dictionary, as the word formation process is very dynamic and productive in nature. Take 馆 'hall' as an example. Standard Chinese dictionaries usually contain 图书馆 'library', but not many other words such as 海洋馆 'aquarium' generated by this same character. This is understandable since the character 馆 'hall' is so productive that it is impossible for a dictionary to list every word with this character as a suffix. The same thing happens for natural language processing systems. Thus it is necessary to have a dynamic mechanism for parsing word structures.

In this paper, we propose a new paradigm for Chinese word segmentation in which not only word boundaries are identified but the internal structures of words are recovered (Section 3). To achieve this, we design a joint morphological and syntactic parsing model of Chinese (Section 4). Our generative story describes the complete process from sentence and word structures to the surface string of characters in a top-down fashion. With this probability model, we give an algorithm to find the parse tree of a raw sentence with the highest probability (Section 5). The output of our parser incorporates word structures naturally. Evaluation shows that the model can learn much of the regularity of word structures, and also achieves reasonable accuracy in parsing higher level constituent structures (Section 6).

2 Related Work

The necessity of parsing word structures has been noticed by Zhao (2009), who presented a character-level dependency scheme as an alternative to the linear representation of words. Although our work is based on the same notion, there are two key differences. The first one is that part-of-speech tags and constituent labels are fundamental for our parsing model, while Zhao focused on unlabeled dependencies between characters in a word, and part-of-speech information was not utilized. Secondly, we distinguish explicitly the generation of flat words such as 华盛顿 'Washington' and words with internal structures. Our parsing algorithm also has to be adapted accordingly. Such distinction was not made in Zhao's parsing model and algorithm.

Many researchers have also noticed the awkwardness and insufficiency of current boundary-only Chinese word segmentation paradigm, so they tried to customize the output to meet the requirements of various applications (Wu, 2003; Gao et al., 2004). In a related research, Jiang et al. (2009) presented a strategy to transfer annotated corpora between different segmentation standards in the hope of saving some expensive human labor. We believe the best solution to the problem of divergent standards and requirements is to annotate and analyze word structures. Then applications can make use of these structures according to their own convenience.

Since the distinction between morphology and syntax in Chinese is somewhat blurred, our model for word structure parsing is integrated with constituent parsing. There has been many efforts to integrate Chinese word segmentation, part-of-speech tagging and parsing (Wu and Zixin, 1998; Zhou and Su, 2003; Luo, 2003; Fung et al., 2004). However, in these research all words were considered to be flat, and thus word structures were not parsed. This is a crucial difference with our work. Specifically, consider the word 橄榄油 'olive oil'. Our parser output tree Figure 6(a), while Luo (2003) output tree (b), giving no hint to the structure of this word since the result is the same with a real flat word 洛杉矶 'Los Angeles'(c).

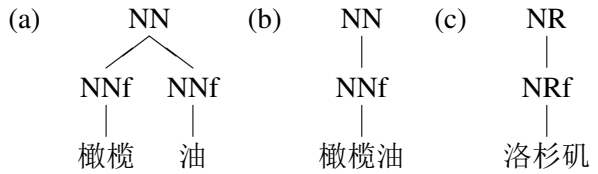

Figure 6: Difference between our output (a) of parsing the word 橄榄油 'olive oil' and the output (b) of Luo (2003). In (c) we have a true flat word, namely the location name 洛杉矶 'Los Angeles'.

The benefits of joint modeling has been noticed by many. For example, Li et al. (2010) reported that a joint syntactic and semantic model improved the accuracy of both tasks, while Ng and Low (2004) showed it's beneficial to integrate word segmentation and part-of-speech tagging into one model. The later result is confirmed by many others (Zhang and Clark, 2008; Jiang et al., 2008; Kruengkrai et al., 2009). Goldberg and Tsarfaty (2008) showed that a single model for morphological segmentation and syntactic parsing of Hebrew yielded an error reduction of 12% over the best pipelined models. This is because an integrated approach can effectively take into account more information from different levels of analysis.

Parsing of Chinese word structures can be reduced to the usual constituent parsing, for which there has been great progress in the past several years. Our generative model for unified word and phrase structure parsing is a direct adaptation of the model presented by Collins (2003). Many other approaches of constituent parsing also use this kind of head-driven generative models (Charniak, 1997; Bikel and Chiang, 2000) .

3 The New Paradigm

Given a raw Chinese sentence like 林志浩是总工程师, a traditional word segmentation system would output some result like 林志浩 是 总工程师('Lin Zhihao', 'is', 'chief engineer'). In our new paradigm, the output should at least be a linear sequence of trees representing the structures of each word as in Figure 7.

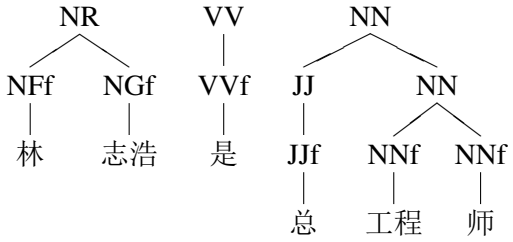

Figure 7: Proposed output for the new Chinese word segmentation paradigm.

Note that in the proposed output, all words are annotated with their part-of-speech tags. This is necessary since part-of-speech plays an important role in the generation of compound words. For example, 者 'person' usually combines with a verb to form a compound noun such as 设计者 'designer'.

In this paper, we will actually design an integrated morphological and syntactical parser trained with a treebank. Therefore, the real output of our system looks like Figure 8. It's clear that besides all the information of the proposed output for the new

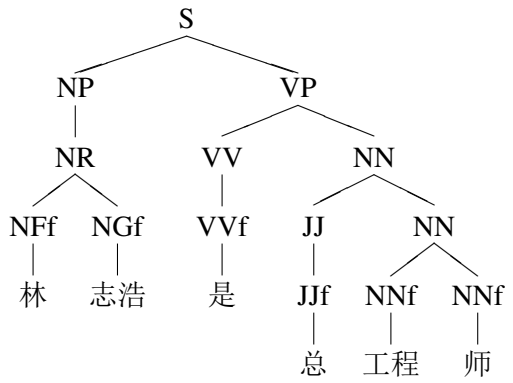

Figure 8: The actual output of our parser trained with a fully annotated treebank.

paradigm, our model's output also includes higher-level syntactic parsing results.

3.1 Training Data

We employ a statistical model to parse phrase and word structures as illustrated in Figure 8. The currently available treebank for us is the Penn Chinese Treebank (CTB) 5.0 (Xue et al., 2005). Because our model belongs to the family of head-driven statistical parsing models (Collins, 2003), we use the head-finding rules described by Sun and Jurafsky (2004).

Unfortunately, this treebank or any other treebanks for that matter, does not contain annotations of word structures. Therefore, we must annotate these structures by ourselves. The good news is that the annotation is not too complicated. First, we extract all words in the treebank and check each of them manually. Words with non-trivial structures are thus annotated. Finally, we install these small trees of words into the original treebank. Whether a word has structures or not is mostly context independent, so we only have to annotate each word once.

There are two noteworthy issues in this process. Firstly, as we'll see in Section 4, flat words and non-flat words will be modeled differently, thus it's important to adapt the part-of-speech tags to facilitate this modeling strategy. For example, the tag for nouns is NN as in 伊拉克 'Iraq' and 前总统 'former president'. After annotation, the former is flat, but the later has a structure (Figure 9). So we change the POS tag for flat nouns to NNf, then during bottom up parsing, whenever a new constituent ending with 'f' is found, we can assign it a probability in a way different from a structured word or phrase.

Secondly, we should record the head position of each word tree in accordance with the requirements of head driven parsing models. As an example, the right tree in Figure 9 has the context free rule "NN → JJf NNf", the head of which should be the rightmost NNf. Therefore, in 前总统 'former president' the head is 总统 'president'.

In passing, the readers should note the fact that in Figure 9, we have to add a parent labeled NN to the flat word 伊拉克 'Iraq' so as not to change the context-free rules contained inherently in the original treebank.

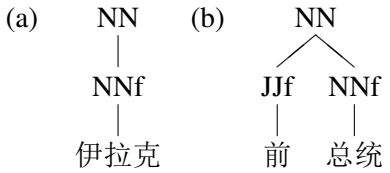

Figure 9: Example word structure annotation. We add an 'f' to the POS tags of words with no further structures.

4 The Model

Given an observed raw sentences S, our generative model tells a story about how this surface sequence of Chinese characters is generated with a linguistically plausible morphological and syntactical process, thereby defining a joint probability $\Pr(T, S)$ where T is a parse tree carrying word structures as well as phrase structures. With this model, the parsing problem is to search for the tree T^* such that

$$T^* = \arg\max_T \Pr(T, S) \tag{1}$$

The generation of S is defined in a top down fashion, which can be roughly summarized as follows. First, the lexicalized constituent structures are generated, then the lexicalized structure of each word is generated. Finally, flat words with no structures are generated. As soon as this is done, we get a tree whose leaves are Chinese characters and can be concatenated to get the surface character sequence S.

4.1 Generation of Constituent Structures

Each node in the constituent tree corresponds to a lexicalized context free rule

$$P \rightarrow L_n\, L_{n-1} \cdots L_1 H R_1\, R_2 \cdots R_m \tag{2}$$

where P, L_i, R_i and H are lexicalized nonterminals and H is the head. To generate this constituent, first P is generated, then the head child H is generated conditioned on P, and finally each L_i and R_j are generated conditioned on P and H and a distance metric. This breakdown of lexicalized PCFG rules is essentially the Model 2 defined by Collins (1999). We refer the readers to Collins' thesis for further details.

4.2 Generation of Words with Internal Structures

Words with rich internal structures can be described using a context-free grammar formalism as

$$\text{word} \rightarrow \text{root} \quad (3)$$
$$\text{word} \rightarrow \text{word suffix} \quad (4)$$
$$\text{word} \rightarrow \text{prefix word} \quad (5)$$

Here the root is any word without interesting internal structures, and the prefixes and suffixes are not limited to single characters. For example, 主义 'ism' as in 现代主义 'modernism' is a well known and very productive suffix. Also, we can see that rules (4) and (5) are recursive and hence can handle words with very complex structures.

By (3)–(5), the generation of word structures is exactly the same as that of ordinary phrase structures. Hence the probabilities of these words can be defined in the same way as higher level constituents in (2). Note that in our case, each word with structures is naturally lexicalized, since in the annotation process we have been careful to record the head position of each complex word.

As an example, consider a word $w = R(r)\,S(s)$ where R is the root part-of-speech headed by the word r, and S is the suffix part-of-speech headed by s. If the head of this word is its suffix, then we can define the probability of w by

$$\Pr(w) = \Pr(S, s) \cdot \Pr(R, r|S, s) \quad (6)$$

This is equivalent to saying that to generate w, we first generate its head $S(s)$, then conditioned on this head, other components of this word are generated. In actual parsing, because a word always occurs in some contexts, the above probability should also be conditioned on these contexts, such as its parent and the parent's head word.

4.3 Generation of Flat Words

We say a word is flat if it contains only one morpheme such as 伊拉克 'Iraq', or if it is a compound like 开发 'develop' which does not have a productive component we are currently interested in. Depending on whether a flat word is known or not, their generative probabilities are computed also differently. Generation of flat words seen in training is trivial and deterministic since every phrase and word structure rules are lexicalized.

However, the generation of unknown flat words is a different story. During training, words that occur less than 6 times are substituted with the symbol UNKNOWN. In testing, unknown words are generated after the generation of symbol UNKNOWN, and we define their probability by a first-order Markov model. That is, given a flat word $w = c_1 c_2 \cdots c_n$ not seen in training, we define its probability conditioned with the part-of-speech p as

$$\Pr(w|p) = \prod_{i=1}^{n+1} \Pr(c_i|c_{i-1}, p) \quad (7)$$

where c_0 is taken to be a START symbol indicating the left boundary of a word and c_{n+1} is the STOP symbol to indicate the right boundary. Note that the generation of w is only conditioned on its part-of-speech p, ignoring the larger constituent or word in which w occurs.

We use a back-off strategy to smooth the probabilities in (7):

$$\begin{aligned}\tilde{\Pr}(c_i|c_{i-1}, p) &= \lambda_1 \cdot \hat{\Pr}(c_i|c_{i-1}, p) \\ &\quad + \lambda_2 \cdot \hat{\Pr}(c_i|c_{i-1}) \\ &\quad + \lambda_3 \cdot \hat{\Pr}(c_i) \end{aligned} \quad (8)$$

where $\lambda_1 + \lambda_2 + \lambda_3 = 1$ to ensure the conditional probability is well formed. These λs will be estimated with held-out data. The probabilities on the right side of (8) can be estimated with simple counts:

$$\hat{\Pr}(c_i|c_{i-1}, p) = \frac{\text{COUNT}(c_{i-1}c_i, p)}{\text{COUNT}(c_{i-1}, p)} \quad (9)$$

The other probabilities can be estimated in the same way.

4.4 Summary of the Generative Story

We make a brief summary of our generative story for the integrated morphological and syntactic parsing model. For a sentence S and its parse tree T, if we denote the set of lexicalized phrase structures in T by $\mathcal{C}$, the set of lexicalized word structures by $\mathcal{W}$, and the set of unknown flat words by $\mathcal{F}$, then the joint probability $\Pr(T, S)$ according to our model is

$$\Pr(T, S) = \prod_{c \in \mathcal{C}} \Pr(c) \prod_{w \in \mathcal{W}} \Pr(w) \prod_{f \in \mathcal{F}} \Pr(f) \quad (10)$$

In practice, the logarithm of this probability can be calculated instead to avoid numerical difficulties.

5 The Parsing Algorithm

To find the parse tree with highest probability we use a chart parser adapted from Collins (1999). Two key changes must be made to the search process, though. Firstly, because we are proposing a new paradigm for Chinese word segmentation, the input to the parser must be raw sentences by definition. Hence to use the bottom-up parser, we need a lexicon of all characters together with what roles they can play in a flat word. We can get this lexicon from the treebank. For example, from the word 中央/NNf 'center', we can extract a role bNNf for character 中 'middle' and a role eNNf for character 央 'center'. The role bNNf means the beginning of the flat label NNf, while eNNf stands for the end of the label NNf. This scheme was first proposed by Luo (2003) in his character-based Chinese parser, and we find it quite adequate for our purpose here.

Secondly, in the bottom-up parser for head driven models, whenever a new edge is found, we must assign it a probability and a head word. If the newly discovered constituent is a flat word (its label ends with 'f'), then we set its head word to be the concatenation of all its child characters, i.e. the word itself. If it is an unknown word, we use (7) to assign the probability, otherwise its probability is set to be 1. On the other hand, if the new edge is a phrase or word with internal structures, the probability is set according to (2), while the head word is found with the appropriate head rules. In this bottom-up way, the probability for a complete parse tree is known as soon as it is completed. This probability includes both word generation probabilities and constituent probabilities.

6 Evaluation

For several reasons, it is a little tricky to evaluate the accuracy of our model for integrated morphological and syntactic parsing. First and foremost, we currently know of no other same effort in parsing the structures of Chinese words, and we have to annotate word structures by ourselves. Hence there is no baseline performance to compare with. Secondly, simply reporting the accuracy of labeled precision and recall is not very informative because our parser takes raw sentences as input, and its output includes a lot of easy cases like word segmentation and part-of-speech tagging results.

Despite these difficulties, we note that higher-level constituent parsing results are still somewhat comparable with previous performance in parsing Penn Chinese Treebank, because constituent parsing does not involve word structures directly. Having said that, it must be pointed out that the comparison is meaningful only in a limited sense, as in previous literatures on Chinese parsing, the input is always word segmented or even part-of-speech tagged. That is, the bracketing in our case is around characters instead of words. Another observation is we can still evaluate Chinese word segmentation and part-of-speech tagging accuracy, by reading off the corresponding result from parse trees. Again because we split the words with internal structures into their components, comparison with other systems should be viewed with that in mind.

Based on these discussions, we divide the labels of all constituents into three categories:

Phrase labels are the labels in Peen Chinese Treebank for nonterminal phrase structures, including NP, VP, PP, etc.

POS labels represent part-of-speech tags such as NN, VV, DEG, etc.

Flat labels are generated in our annotation for words with no interesting structures. Recall that they always end with an 'f' such as NNf, VVf and DEGf, etc.

With this classification, we report our parser's accuracy for phrase labels, which is approximately the accuracy of constituent parsing of Penn Chinese Treebank. We report our parser's word segmentation accuracy based on the flat labels. This accuracy is in fact the joint accuracy of segmentation and part-of-speech tagging. Most importantly, we can report our parser's accuracy in recovering word structures based on POS labels and flat labels, since word structures may contain only these two kinds of labels.

With the standard split of CTB 5.0 data into training, development and test sets (Zhang and Clark,

2009), the result are summarized in Table 1. For all label categories, the PARSEEVAL measures (Abney et al., 1991) are used in computing the labeled precision and recall.

Types	LP	LR	F_1
Phrase	79.3	80.1	79.7
Flat	93.2	93.8	93.5
Flat*	97.1	97.6	97.3
POS & Flat	92.7	93.2	92.9

Table 1: Labeled precision and recall for the three types of labels. The line labeled 'Flat*' is for unlabeled metrics of flat words, which is effectively the ordinary word segmentation accuracy.

Though not directly comparable, we can make some remarks to the accuracy of our model. For constituent parsing, the best result on CTB 5.0 is reported to be 78% F_1 measure for unlimited sentences with automatically assigned POS tags (Zhang and Clark, 2009). Our result for phrase labels is close to this accuracy. Besides, the result for flat labels compares favorably with the state of the art accuracy of about 93% F_1 for joint word segmentation and part-of-speech tagging (Jiang et al., 2008; Kruengkrai et al., 2009). For ordinary word segmentation, the best result is reported to be around 97% F_1 on CTB 5.0 (Kruengkrai et al., 2009), while our parser performs at 97.3%, though we should remember that the result concerns flat words only. Finally, we see the performance of word structure recovery is almost as good as the recognition of flat words. This means that parsing word structures accurately is possible with a generative model.

It is interesting to see how well the parser does in recognizing the structure of words that were not seen during training. For this, we sampled 100 such words including those with prefixes or suffixes and personal names. We found that for 82 of these words, our parser can correctly recognize their structures. This means our model has learnt something that generalizes well to unseen words.

In error analysis, we found that the parser tends to over generalize for prefix and suffix characters. For example, 大作家 'great writer' is a noun phrase consisting of an adjective 大 'great' and a noun 作家 'writer', as shown in Figure 10(a), but our parser incorrectly analyzed it into a root 大作 'masterpiece' and a suffix 家 'expert', as in Figure 10(b). This

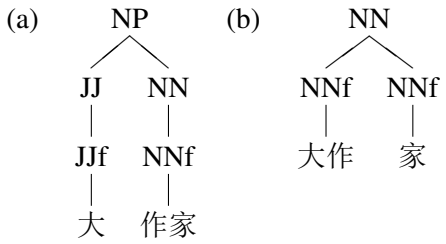

Figure 10: Example of parser error. Tree (a) is correct, and (b) is the wrong result by our parser.

is because the character 家 'expert' is a very productive suffix, as in 化学家 'chemist' and 外交家 'diplomat'. This observation is illuminating because most errors of our parser follow this pattern. Currently we don't have any non-ad hoc way of preventing such kind of over generalization.

7 Conclusion and Discussion

In this paper we proposed a new paradigm for Chinese word segmentation in which not only flat words were identified but words with structures were also parsed. We gave good reasons why this should be done, and we presented an effective method showing how this could be done. With the progress in statistical parsing technology and the development of large scale treebanks, the time has now come for this paradigm shift to happen. We believe such a new paradigm for word segmentation is linguistically justified and pragmatically beneficial to real world applications. We showed that word structures can be recovered with high precision, though there's still much room for improvement, especially for higher level constituent parsing.

Our model is generative, but discriminative models such as maximum entropy technique (Berger et al., 1996) can be used in parsing word structures too. Many parsers using these techniques have been proved to be quite successful (Luo, 2003; Fung et al., 2004; Wang et al., 2006). Another possible direction is to combine generative models with discriminative reranking to enhance the accuracy (Collins and Koo, 2005; Charniak and Johnson, 2005).

Finally, we must note that the use of flat labels such as "NNf" is less than ideal. The most impor-

tant reason these labels are used is we want to compare the performance of our parser with previous results in constituent parsing, part-of-speech tagging and word segmentation, as we did in Section 6. The problem with this approach is that word structures and phrase structures are then not treated in a truly unified way, and besides the 33 part-of-speech tags originally contained in Penn Chinese Treebank, another 33 tags ending with 'f' are introduced. We leave this problem open for now and plan to address it in future work.

Acknowledgments

I would like to thank Professor Maosong Sun for many helpful discussions on topics of Chinese morphological and syntactic analysis. The author is supported by NSFC under Grant No. 60873174. Heartfelt thanks also go to the reviewers for many pertinent comments which have greatly improved the presentation of this paper.

A Simple Measure to Assess Non-response

Abstract

There are several tasks where is preferable not responding than responding incorrectly. This idea is not new, but despite several previous attempts there isn't a commonly accepted measure to assess non-response. We study here an extension of *accuracy* measure with this feature and a very easy to understand interpretation. The measure proposed (*c@1*) has a good balance of discrimination power, stability and sensitivity properties. We show also how this measure is able to reward systems that maintain the same number of correct answers and at the same time decrease the number of incorrect ones, by leaving some questions unanswered. This measure is well suited for tasks such as Reading Comprehension tests, where multiple choices per question are given, but only one is correct.

1 Introduction

There is some tendency to consider that an incorrect result is simply the absence of a correct one. This is particularly true in the evaluation of Information Retrieval systems where, in fact, the absence of results sometimes is the worse output.

However, there are scenarios where we should consider the possibility of not responding, because this behavior has more value than responding incorrectly. For example, during the process of introducing new features in a search engine it is important to preserve users' confidence in the system. Thus, a system must decide whether it should give or not a result in the new fashion or keep on with the old kind of output. A similar example is the decision about showing or not ads related to the query. Showing wrong ads harms the business model more than showing nothing. A third example more related to Natural Language Processing is the Machine Reading evaluation through reading comprehension tests. In this case, where multiple choices for a question are offered, choosing a wrong option should be punished against leaving the question unanswered.

In the latter case, the use of utility functions is a very common option. However, utility functions give arbitrary value to not responding and ignore the system's behavior showed when it responds (see Section 2). To avoid this, we present c@1 measure (Section 2.2), as an extension of accuracy (the proportion of correctly answered questions). In Section 3 we show that no other extension produces a sensible measure. In Section 4 we evaluate c@1 in terms of stability, discrimination power and sensibility, and some real examples of its behavior are given in the context of Question Answering. Related work is discussed in Section 5.

2 Looking for the Value of Not Responding

Lets take the scenario of Reading Comprehension tests to argue about the development of the measure. Our scenario assumes the following:

- There are several questions.
- Each question has several options.
- One option is correct (and only one).

The first step is to consider the possibility of not responding. If the system responds, then the assessment will be one of two: correct or wrong. But if

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1415–1424,
Portland, Oregon, June 19-24, 2011.

the system doesn't respond there is no assessment. Since every question has a correct answer, non response is not correct but it is not incorrect either. This is represented in contingency Table 1, where:

- n_{ac}: number of questions for which the answer is correct
- n_{aw}: number of questions for which the answer is incorrect
- n_u: number of questions not answered
- n: number of questions ($n = n_{ac} + n_{aw} + n_u$)

	Correct (C)	**Incorrect (¬C)**
Answered (A)	n_{ac}	n_{aw}
Unanswered (¬A)	n_u	

Table 1: Contingency table for our scenario

Let's start studying a simple utility function able to establish the preference order we want:

- -1 if question receives an incorrect response
- 0 if question is left unanswered
- 1 if question receives a correct response

Let *U(i)* be the utility function that returns one of the above values for a given question *i*. Thus, if we want to consider *n* questions in the evaluation, the measure would be:

$$UF = \frac{1}{n}\sum_{i=1}^{n} U(i) = \frac{n_{ac} - n_{aw}}{n} \qquad (1)$$

The rationale of this utility function is intuitive: not answering adds no value and wrong answers add negative values. Positive values of *UF* indicate more correct answers than incorrect ones, while negative values indicate the opposite. However, the utility function is giving an arbitrary value to the preferences (-1, 0, 1).

Now we want to interpret in some way the value that Formula (1) assigns to unanswered questions. For this purpose, we need to transform Formula (1) into a more meaningful measure with a parameter for the number of unanswered questions (n_u). A monotonic transformation of (1) permit us to preserve the ranking produced by the measure. Let f(x)=0.5x+0.5 be the monotonic function to be used for the transformation. Applying this function to Formula (1) results in Formula (2):

$$\begin{aligned} 0.5\frac{n_{ac} - n_{aw}}{n} + 0.5 &= \frac{0.5}{n}\left[n_{ac} - n_{aw} + n\right] = \\ &= \frac{0.5}{n}\left[n_{ac} - n_{aw} + n_{ac} + n_{aw} + n_u\right] \\ &= \frac{0.5}{n}\left[2n_{ac} + n_u\right] = \frac{n_{ac}}{n} + 0.5\frac{n_u}{n} \end{aligned} \qquad (2)$$

Measure (2) provides the same ranking of systems than measure (1). The first summand of Formula (2) corresponds to *accuracy*, while the second is adding an arbitrary constant weight of 0.5 to the proportion of unanswered questions. In other words, *unanswered questions are receiving the same value as if half of them had been answered correctly*.

This does not seem correct given that not answering is being rewarded in the same proportion to all the systems, without taking into account the performance they have shown with the answered questions. We need to propose a more sensible estimation for the weight of unanswered questions.

2.1 A rationale for the Value of Unanswered Questions

According to the utility function suggested, unanswered questions would have value as if half of them had been answered correctly. Why half and not other value? Even more, Why a constant value? Let's generalize this idea and estate more clearly our hypothesis:

Unanswered questions have the same value as if a proportion of them would have been answered correctly.

We can express this idea according to contingency Table 1 in the following way:

$$\begin{aligned} P(C) &= P(C \cap A) + P(C \cap \neg A) = \\ &= P(C \cap A) + P(C/\neg A) * P(\neg A) \end{aligned} \qquad (3)$$

$P(C \cap A)$ can be estimated by n_{ac}/n, $P(\neg A)$ can be estimated by n_u/n, and we have to estimate $P(C/\neg A)$. Our hypothesis is saying that $P(C/\neg A)$

is different from 0. The utility measure (2) corresponds to P(C) in Formula (3) where $P(C/\neg A)$ receives a constant value of 0.5. It is assuming arbitrarily that $P(C/\neg A) = P(C/A)$.

Following this, our measure must consist of two parts: The overall *accuracy* and a better estimation of correctness over the unanswered questions.

2.2 The Measure Proposed: c@1

From the answered questions we have already observed the proportion of questions that received a correct answer ($P(C \cap A)$ = n_{ac}/n). We can use this observation as our estimation for $P(C/\neg A)$ instead of the arbitrary value of 0.5.

Thus, the measure we propose is c@1 (correctness at one) and is formally represented as follows:

$$c@1 = \frac{n_{ac}}{n} + \frac{n_{ac}}{n}\frac{n_u}{n} = \frac{1}{n}(n_{ac} + \frac{n_{ac}}{n}n_u) \quad (4)$$

The most important features of c@1 are:

1. A system that answers all the questions will receive a score equal to the traditional *accuracy* measure: n_u=0 and therefore *c@1*=n_{ac}/n.

2. Unanswered questions will add value to *c@1* as if they were answered with the *accuracy* already shown.

3. A system that does not return any answer would receive a score equal to 0 due to n_{ac}=0 in both summands.

According to the reasoning above, we can interpret *c@1* in terms of probability as $P(C)$ where $P(C/\neg A)$ has been estimated with $P(C \cap A)$. In the following section we will show that there is no other estimation for $P(C/\neg A)$ able to provide a reasonable evaluation measure.

3 Other Estimations for $P(C/\neg A)$

In this section we study whether other estimations of $P(C/\neg A)$ can provide a sensible measure for QA when unanswered questions are taken into account. They are:

1. $P(C/\neg A) \equiv 0$
2. $P(C/\neg A) \equiv 1$
3. $P(C/\neg A) \equiv P(\neg C/\neg A) \equiv 0.5$
4. $P(C/\neg A) \equiv P(C/A)$
5. $P(C/\neg A) \equiv P(\neg C/A)$

3.1 $P(C/\neg A) \equiv 0$

This estimation considers the absence of response as incorrect response and we have the traditional *accuracy* (n_{ac}/n).

Obviously, this is against our purposes.

3.2 $P(C/\neg A) \equiv 1$

This estimation considers all unanswered questions as correctly answered. This option is not reasonable and is given for completeness: systems giving no answer would get maximum score.

3.3 $P(C/\neg A) \equiv P(\neg C/\neg A) \equiv 0.5$

It could be argued that since we cannot have observations of correctness for unanswered questions, we should assume equiprobability between $P(C/\neg A)$ and $P(\neg C/\neg A)$. In this case, P(C) corresponds to the expression (2) already discussed. As previously explained, in this case we are giving an arbitrary constant value to unanswered questions independently of the system's performance shown with answered ones. This seems unfair. We should be aiming at rewarding those systems not responding instead of giving wrong answers, not reward the sole fact that the system is not responding.

3.4 $P(C/\neg A) \equiv P(C/A)$

An alternative is to estimate the probability of correctness for the unanswered questions as the precision observed over the answered ones: P(C/A)= n_{ac}/(n_{ac}+ n_{aw}). In this case, our measure would be like the one shown in Formula (5):

$$\begin{aligned} P(C) &= P(C \cap A) + P(C/\neg A) * P(\neg A) = \\ &= P(C/A) * P(A) + P(C/A) * P(\neg A) = \\ &= P(C/A) = \frac{n_{ac}}{n_{ac} + n_{aw}} \end{aligned} \quad (5)$$

The resulting measure is again the observed precision over the answered ones. This is not a sensible measure, as it would reward a cheating system that decides to leave all questions unanswered except one for which it is sure to have a correct answer.

Furthermore, from the idea that $P(C/\neg A)$ is equal to $P(C/A)$ the underlying assumption is that systems choose to answer or not to answer randomly, whereas we want to reward the systems that choose not responding because they are able to decide that their candidate options are wrong or because they are unable to decide which candidate is correct.

3.5 $P(C/\neg A) \equiv P(\neg C/A)$

The last option to be considered explores the idea that systems fail not responding in the same proportion that they fail when they give an answer (i.e. proportion of incorrect answers).

Estimating $P(C/\neg A)$ as n_{aw} / (n_{ac}+ n_{aw}), the measure would be:

$$\begin{aligned} P(C) &= P(C \cap A) + P(C/\neg A) * P(\neg A) = \\ &= P(C \cap A) * P(\neg C/A) * P(\neg A) = \\ &= \frac{n_{ac}}{n} + \frac{n_{aw}}{n_{ac} + n_{aw}} * \frac{n_u}{n} \end{aligned} \quad (6)$$

This measure is very easy to cheat. It is possible to obtain almost a perfect score just by answering incorrectly only one question and leaving unanswered the rest of the questions.

4 Evaluation of c@1

When a new measure is proposed, it is important to study the reliability of the results obtained using that measure. For this purpose, we have chosen the method described by Buckley and Voorhees (2000) for assessing the stability and discrimination power, as well as the method described by Voorhees and Buckley (2002) for examining the sensitivity of our measure. These methods have been used for studying IR metrics (showing similar results with the methods based on statistics (Sakai, 2006)), as well as for evaluating the reliability of other QA measures different to the ones studied here (Sakai, 2007a; Voorhees, 2002; Voorhees, 2003).

We have compared the results over c@1 with the ones obtained using both *accuracy* and the *utility function* (UF) defined in Formula (1). This comparison is useful to show how confident can a researcher be with the results obtained using each evaluation measure.

In the following subsections we will first show the data used for our study. Then, the experiments about stability and sensitivity will be described.

4.1 Data sets

We used the test collections and runs from the Question Answering track at the Cross Language Evaluation Forum 2009 (CLEF) (Peñas et al., 2010). The collection has a set of 500 questions with their answers. The 44 runs in different languages contain the human assessments for the answers given by actual participants. Systems could chose not to answer a question. In this case, they had the chance to submit their best candidate in order to assess the performance of their validation module (the one that decides whether to give or not the answer).

This data collection allows us to compare *c@1* and *accuracy* over the same runs.

4.2 Stability vs. Discrimination Power

The more stable a measure is, the lower the probability of errors associated with the conclusion *"system A is better than system B"* is. Measures with a high error must be used more carefully performing more experiments than in the case of using a measure with lower error.

In order to study the stability of c@1 and to compare it with *accuracy* we used the method described by Buckley and Voorhees (2000). This method allows also to study the number of times systems are deemed to be equivalent with respect to a certain measure, which reflects the *discrimination power* of that measure. The less discriminative the measure is, the more ties between systems there will be. This means that longer difference in scores will be needed for concluding which system is better (Buckley and Voorhees, 2000).

The method works as follows: let *S* denote a set of runs. Let *x* and *y* denote a pair of runs from *S*. Let *Q* denote the entire evaluation collection. Let *f* represents the fuzziness value, which is the percent difference between scores such that if the difference is smaller than *f* then the two scores are deemed to be equivalent. We apply the algorithm of Figure 1 to obtain the information needed for computing the error rate (Formula (7)). *Stability* is inverse to this value, the lower the error rate is, the more stable the measure is. The same algorithm gives us the

proportion of ties (Formula (8)), which we use for measuring *discrimination power*, that is the lower the proportion of ties is, the more discriminative the measure is.

```
for each pair of runs x,y ϵ S
  for each trial from 1 to 100
    Q_i = select at random subcol of size c from Q;
    margin = f * max (M(x,Q_i),M(y,Q_i));
    if(|M(x,Q_i) - M(y,Q_i)| < |margin|)
      EQ_M(x,y)++;
    else if(|M(x,Q_i) > M(y,Q_i)|)
      GT_M(x,y)++;
    else
      GT_M(y,x)++;
```

Figure 1: Algorithm for computing $EQ_M(x,y)$, $GT_M(x,y)$ and $GT_M(y,x)$ in the stability method

We assume that for each measure the correct decision about whether run x is better than run y happens when there are more cases where the value of x is better than the value of y. Then, the number of times y is better than x is considered as the number of times the test is misleading, while the number of times the values of x and y are equivalent is considered the number of ties.

On the other hand, it is clear that larger fuzziness values decrease the error rate but also decrease the discrimination power of a measure. Since a fixed fuzziness value might imply different trade-offs for different metrics, we decided to vary the fuzziness value from 0.01 to 0.10 (following the work by Sakai (2007b)) and to draw for each measure a *proportion-of-ties / error-rate* curve. Figure 2 shows these curves for the *c@1*, *accuracy* and *UF* measures. In the Figure we can see how there is a consistent decrease of the error rate of all measures when the proportion of ties increases (this corresponds to the increase in the fuzziness value). Figure 2 shows that the curves of *accuracy* and *c@1* are quite similar (slightly better behavior of c@1) , which means that they have a similar stability and discrimination power.

The results suggest that the three measures are quite stable, having *c@1* and *accuracy* a lower error rate than *UF* when the proportion of ties grows. These curves are similar to the ones obtained for other QA evaluation measures (Sakai, 2007a).

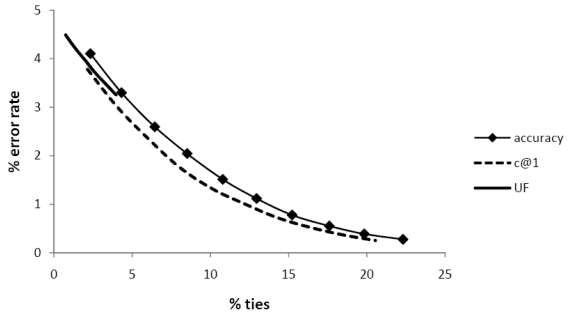

Figure 2: Error-rate / Proportion of ties curves for *accuracy*, *c@1* and *UF* with c = 250

4.3 Sensitivity

The *swap-rate* (Voorhees and Buckley, 2002) represents the chance of obtaining a discrepancy between two question sets (of the same size) as to whether a system is better than another given a certain difference bin. Looking at the swap-rates of all the difference performance bins, the performance difference required in order to conclude that a run is better than another for a given confidence value can be estimated. For example, if we want to know the required difference for concluding that system A is better than system B with a confidence of 95%, then we select the difference that represents the first bin where the swap-rate is lower or equal than 0.05.

The sensitivity of the measure is the number of times among all the comparisons in the experiment where this performance difference is obtained (Sakai, 2007b). That is, the more comparisons accomplish the estimated performance difference, the more *sensitive* is the measure. The more sensitive the measure, the more useful it is for system discrimination.

The swap method works as follows: let S denote a set of runs, let x and y denote a pair of runs from S. Let Q denote the entire evaluation collection. And let d denote a performance difference between two runs. Then, we first define 21 *performance difference bins*: the first bin represents performance differences between systems such that $0 \leq d < 0.01$; the second bin represents differences such that $0.01 \leq d < 0.02$; and the limits for the remaining bins increase by increments of 0.01, with the last bin containing all the differences equal or higher than 0.2.

$$Error\ rate_M = \frac{\sum_{x,y \epsilon S} min(GT_M(x,y), GT_M(y,x))}{\sum_{x,y \epsilon S}(GT_M(x,y) + GT_M(y,x) + EQ_M(x,y))} \quad (7)$$

$$Prop\ Ties_M = \frac{\sum_{x,y \epsilon S} EQ_M(x,y)}{\sum_{x,y \epsilon S}(GT_M(x,y) + GT_M(y,x) + EQ_M(x,y))} \quad (8)$$

Let BIN(d) denote a mapping from a difference *d* to one of the 21 bins where it belongs. Thus, algorithm in Figure 3 is applied for calculating the *swap-rate* of each bin.

```
for each pair of runs x,y ϵ S
  for each trial from 1 to 100
    select Q_i , Q_i' ⊂ Q, where
      Q_i ∩ Q_i' == φ and |Q_i| == |Q_i'| == c;
    d_M(Q_i) = M(x,Q_i) − M(y,Q_i);
    d_M(Q_i') = M(x,Q_i') − M(y,Q_i');
    counter(BIN(|d_M(Q_i)|))++;
    if(d_M(Q_i) * d_M(Q_i') < 0)
      swap_counter(BIN(|d_M(Q_i)|))++;
for each bin b
  swap_rate(b) = swap_counter(b)/counter(b);
```

Figure 3: Algorithm for computing swap-rates

	(i)	(ii)	(iii)	(iv)
UF	0.17	0.48	35.12%	59.30%
c@1	0.09	0.77	11.69%	58.40%
accuracy	0.09	0.68	13.24%	55.00%

Table 2: Results obtained applying the swap method to *accuracy*, *c@1* and *UF* at 95% of confidence, with c = 250: (i) Absolute difference required; (ii) Highest value obtained; (iii) Relative difference required ((i)/(ii)); (iv) percentage of comparisons that accomplish the required difference (sensitivity)

Given that Q_i and $Q_i^{'}$ must be disjoint, their size can only be up to half of the size of the original collection. Thus, we use the value c=250 for our experiment[1]. Table 2 shows the results obtained by applying the swap method to *accuracy*, *c@1* and *UF*, with c = 250, swap-rate ≤ 5, and sensitivity given a confidence of 95% (Column (iv)). The range of values are similar to the ones obtained for other measures according to (Sakai, 2007a).

According to Column (i), a higher absolute difference is required for concluding that a system is better than another using *UF*. However, the relative difference is similar to the one required by *c@1*. Thus, similar percentage of comparisons using *c@1* and *UF* accomplish the required difference (Column (iv)). These results show that their sensitivity values are similar, and higher than the value for *accuracy*.

4.4 Qualitative evaluation

In addition to the theoretical study, we undertook a study to interpret the results obtained by real systems in a real scenario. The aim is to compare the results of the proposed *c@1* measure with *accuracy* in order to compare their behavior. For this purpose we inspected the real systems runs in the data set.

System	c@1	accuracy	(i)	(ii)	(iii)
icia091ro	0.58	0.47	237	156	107
uaic092ro	0.47	0.47	236	264	0
loga092de	0.44	0.37	187	230	83
base092de	0.38	0.38	189	311	0

Table 3: Example of system results in QA@CLEF 2009. (i) number of questions correctly answered; (ii) number of questions incorrectly answered; (iii) number of unanswered questions.

Table 3 shows a couple of examples where two systems have answered correctly a similar number of questions. For example, this is the case of *icia091ro* and *uaic092ro* that, therefore, obtain almost the same *accuracy* value. However, *icia091ro* has returned less incorrect answers by not responding some questions. This is the kind of behavior we want to measure and reward. Table 3 shows how accuracy is sensitive only to the number of correct answers whereas *c@1* is able to distinguish when

[1]We use the same size for experiments in Section 4.2 for homogeneity reasons.

systems keep the number of correct answers but reduce the number of incorrect ones by not responding to some. The same reasoning is applicable to *loga092de* compared to *base092de* for German.

5 Related Work

The decision of leaving a query without response is related to the system ability to measure accurately its self-confidence about the correctness of their candidate answers. Although there have been one attempt to make the self-confidence score explicit and use it (Herrera et al., 2005), rankings are, usually, the implicit way to evaluate this self-confidence. Mean Reciprocal Rank (MRR) has traditionally been used to evaluate Question Answering systems when several answers per question were allowed and given in order (Fukumoto et al., 2002; Voorhees and Tice, 1999). However, as it occurs with *Accuracy* (proportion of questions correctly answered), the risk of giving a wrong answer is always preferred better than not responding.

The QA track at TREC 2001 was the first evaluation campaign in which systems were allowed to leave a question unanswered (Voorhees, 2001). The main evaluation measure was MRR, but performance was also measured by means of the percentage of answered questions and the portion of them that were correctly answered. However, no combination of these two values into a unique measure was proposed.

TREC 2002 discarded the idea of including unanswered questions in the evaluation. Only one answer by question was allowed and all answers had to be ranked according to the system's self-confidence in the correctness of the answer. Systems were evaluated by means of *Confidence Weighted Score* (*CWS*), rewarding those systems able to provide more correct answers at the top of the ranking (Voorhees, 2002). The formulation of CWS is the following:

$$CWS = \frac{1}{n}\sum_{i=1}^{n}\frac{C(i)}{i} \tag{9}$$

Where *n* is the number of questions, and *C(i)* is the number of correct answers up to the position *i* in the ranking. Formally:

$$C(i) = \sum_{j=1}^{i} I(j) \tag{10}$$

where *I(j)* is a function that returns 1 if answer *j* is correct and 0 if it is not. The formulation of *CWS* is inspired by the *Average Precision* (*AP*) over the ranking for one question:

$$AP = \frac{1}{R}\sum_{r} I(r)\frac{C(r)}{r} \tag{11}$$

where *R* is the number of known relevant results for a topic, and *r* is a position in the ranking. Since only one answer per question is requested, *R* equals to *n* (the number of questions) in *CWS*. However, in *AP* formula the summands belong to the positions of the ranking where there is a relevant result (product of I(r)), whereas in *CWS* every position of the ranking add value to the measure regardless of whether there is a relevant result or not in that position. Therefore, *CWS* gives much more value to some questions over others: questions whose answers are at the top of the ranking are giving almost the complete value to *CWS*, whereas those questions whose answers are at the bottom of the ranking are almost not counting in the evaluation.

Although *CWS* was aimed at promoting the development of better self-confidence scores, it was discussed as a measure for evaluating QA systems performance. *CWS* was discarded in the following campaigns of TREC in favor of *accuracy* (Voorhees, 2003). Subsequently, *accuracy* was adopted by the QA track at the Cross-Language Evaluation Forum from the beginning (Magnini et al., 2005).

There was an attempt to consider explicitly systems confidence self-score (Herrera et al., 2005): the use of the Pearson's correlation coefficient and the proposal of measures *K* and *K1* (see Formula 12). These measures are based in a utility function that returns -1 if the answer is incorrect and 1 if it is correct. This positive or negative value is weighted with the normalized confidence self-score given by the system to each answer. *K* is a variation of *K1* for being used in evaluations where more than an answer per question is allowed.

If the self-score is 0, then the answer is ignored and thus, this measure is permitting to leave a question unanswered. A system that always returns a

$$K1 = \frac{\sum_{i \epsilon \{correct_answers\}} self\_score(i) - \sum_{i \epsilon \{incorrect_answers\}} self\_score(i)}{n} \epsilon [-1, 1] \quad (12)$$

self-score equals to 0 (no answer) obtains a *K1* value of 0. However, the final value of *K1* is difficult to interpret: a positive value does not indicate necessarily more correct answers than incorrect ones, but that the sum of scores of correct answers is higher than the sum resulting from the scores of incorrect answers. This could explain the little success of this measure for evaluating QA systems in favor, again, of *accuracy* measure.

Accuracy is the simplest and most intuitive evaluation measure. At the same time is able to reward those systems showing good performance. However, together with MRR belongs to the set of measures that pushes in favor of giving always a response, even wrong, since there is no punishment for it. Thus, the development of better validation technologies (systems able to decide whether the candidate answers are correct or not) is not promoted, despite new QA architectures require them.

In effect, most QA systems during TREC and CLEF campaigns had an upper bound of accuracy around 60%. An explanation for this was the effect of error propagation in the most extended pipeline architecture: Passage Retrieval, Answer Extraction, Answer Ranking. Even with performances higher than 80% in each step, the overall performance drops dramatically just because of the product of partial performances. Thus, a way to break the pipeline architecture is the development of a module able to decide whether the QA system must continue or not its searching for new candidate answers: the Answer Validation module. This idea is behind the architecture of IBM's Watson (DeepQA project) that successfully participated at Jeopardy (Ferrucci et al., 2010).

In 2006, the first Answer Validation Exercise (AVE) proposed an evaluation task to advance the state of the art in Answer Validation technologies (Peñas et al., 2007). The starting point was the reformulation of Answer Validation as a Recognizing Textual Entailment problem, under the assumption that hypotheses can be automatically generated by combining the question with the candidate answer (Peñas et al., 2008a). Thus, validation was seen as a binary classification problem whose evaluation must deal with unbalanced collections (different proportion of positive and negative examples, correct and incorrect answers). For this reason, AVE 2006 used F-measure based on precision and recall for correct answers selection (Peñas et al., 2007). Other option is an evaluation based on the analysis of Receiver Operating Characteristic (ROC) space, sometimes preferred for classification tasks with unbalanced collections. A comparison of both approaches for Answer Validation evaluation is provided in (Rodrigo et al., 2011).

AVE 2007 changed its evaluation methodology with two objectives: the first one was to bring systems based on Textual Entailment to the Automatic Hypothesis Generation problem which is not part itself of the Recognising Textual Entailment (RTE) task but an Answer Validation need. The second one was an attempt to quantify the gain in QA performance when more sophisticated validation modules are introduced (Peñas et al., 2008b). With this aim, several measures were proposed to assess: the correct selection of candidate answers, the correct rejection of wrong answer and finally estimate the potential gain (in terms of accuracy) that Answer Validation modules can provide to QA (Rodrigo et al., 2008). The idea was to give value to the correctly rejected answers as if they could be correctly answered with the accuracy shown selecting the correct answers. This extension of accuracy in the Answer Validation scenario inspired the initial development of *c@1* considering non-response.

6 Conclusions

The central idea of this work is that not responding has more value than responding incorrectly. This idea is not new, but despite several attempts in TREC and CLEF there wasn't a commonly accepted mea-

sure to assess non-response. We have studied here an extension of *accuracy* measure with this feature, and with a very easy to understand rationale: Unanswered questions have the same value as if a proportion of them had been answered correctly, and the value they add is related to the performance (*accuracy*) observed over the answered questions. We have shown that no other estimation of this value produce a sensible measure.

We have shown also that the proposed measure *c@1* has a good balance of discrimination power, stability and sensitivity properties. Finally, we have shown how this measure rewards systems able to maintain the same number of correct answers and at the same time reduce the number of incorrect ones, by leaving some questions unanswered.

Among other tasks, measure *c@1* is well suited for evaluating Reading Comprehension tests, where multiple choices per question are given, but only one is correct. Non-response must be assessed if we want to measure effective reading and not just the ability to rank options. This is clearly not enough for the development of reading technologies.

Abstract

In this paper we address the problem of question recommendation from large archives of community question answering data by exploiting the users' information needs. Our experimental results indicate that questions based on the same or similar information need can provide excellent question recommendation. We show that translation model can be effectively utilized to predict the information need given only the user's query question. Experiments show that the proposed information need prediction approach can improve the performance of question recommendation.

1 Introduction

There has recently been a rapid growth in the number of community question answering (CQA) services such as Yahoo! Answers[1], Askville[2] and WikiAnswer[3] where people answer questions posted by other users. These CQA services have built up very large archives of questions and their answers. They provide a valuable resource for question answering research. Table 1 is an example from Yahoo! Answers web site. In the CQA archives, the title part is the user's query question, and the user's information need is usually expressed as natural language statements mixed with questions expressing their interests in the question body part.

In order to avoid the lag time involved with waiting for a personal response and to enable high quality answers from the archives to be retrieved, we need to search CQA archives of previous questions that are closely associated with answers. If a question is found to be interesting to the user, then a previous answer can be provided with very little delay. Question search and question recommendation are proposed to facilitate finding highly relevant or potentially interesting questions. Given a user's question as the query, *question search* tries to return the most semantically similar questions from the question archives. As the complement of question search, we define *question recommendation* as recommending questions whose information need is the same or similar to the user's original question. For example, the question "*What aspects of my computer do I need to upgrade ...*" with the information need "*... making a skate movie, my computer freezes, ...*" and the question "*What is the most cost effective way to expend memory space ...*" with information need "*... in need of more space for music and pictures ...*" are both good recommendation questions for the user in Table 1. So the recommended questions are not necessarily identical or similar to the query question.

In this paper, we discuss methods for question recommendation based on using the similarity between information need in the archive. We also propose two models to predict the information need based on the query question even if there's no information need expressed in the body of the question. We show that with the proposed models it is possible to recommend questions that have the same or similar information need.

lows. In section 2, we briefly describe the related work on question search and recommendation. Section 3 addresses in detail how we measure the similarity between short texts. Section 4 describes two models for information need prediction that we use for the experiment. Section 5 tests the performance of the proposed models for the task of question recommendation. Section 7 is the conclusion of this paper.

2 Related Work

2.1 Question Search

Burke et al. (1997) combined a lexical metric and a simple semantic knowledge-based (WordNet) similarity method to retrieve semantically similar questions from frequently asked question (FAQ) data. Jeon et al. (2005a) retrieved semantically similar questions from Korean CQA data by calculating the similarity between their answers. The assumption behind their research is that questions with very similar answers tend to be semantically similar. Jeon et al. (2005b) also discussed methods for grouping similar questions based on using the similarity between answers in the archive. These grouped question pairs were further used as training data to estimate probabilities for a translation-based question retrieval model. Wang et al. (2009) proposed a tree kernel framework to find similar questions in the CQA archive based on syntactic tree structures. Wang et al. (2010) mined lexical and syntactic features to detect question sentences in CQA data.

2.2 Question Recommendation

Wu et al. (2008) presented an incremental automatic question recommendation framework based on probabilistic latent semantic analysis. Question recommendation in their work considered both the users' interests and feedback. Duan et al. (2008) made use of a tree-cut model to represent questions as graphs of topic terms. Questions were recommended based on this topic graph. The recommended questions can provide different aspects around the topic of the query question.

The above question search and recommendation research provide different ways to retrieve questions from large archives of question answering data. However, none of them considers the similarity or diversity between questions by exploring their information needs.

3 Short Text Similarity Measures

In question retrieval systems accurate similarity measures between documents are crucial. Most traditional techniques for measuring the similarity between two documents mainly focus on comparing word co-occurrences. The methods employing this strategy for documents can usually achieve good results, because they may share more common words than short text snippets. However the state-of-the-art techniques usually fail to achieve desired results due to short questions and information need texts.

In order to measure the similarity between short texts, we make use of three kinds of text similarity measures: TFIDF based, Knowledge based and Latent Dirichlet Allocation (LDA) based similarity measures in this paper. We will compare their performance for the task of question recommendation in the experiment section.

3.1 TFIDF

Baeza-Yates and Ribeiro-Neto (1999) provides a TFIDF method to calculate the similarity between two texts. Each document is represented by a term vector using TFIDF score. The similarity between two text D_i and D_j is the cosine similarity in the vector space model:

$$cos(D_i, D_j) = \frac{D_i^T D_j}{\|D_i\|\|D_j\|}$$

This method is used in most information retrieval systems as it is both efficient and effective. However if the query text contains only one or two words this method will be biased to shorter answer texts (Jeon et al., 2005a). We also found that in CQA data short contents in the question body cannot provide any information about the users' information needs. Based on the above two reasons, in the test data sets we do not include the questions whose information need parts contain only a few noninformative words .

3.2 Knowledge-based Measure

Mihalcea et al. (2006) proposed several knowledge-based methods for measuring the semantic level similarity of texts to solve the lexical chasm problem between short texts. These knowledge-based similarity measures were derived from word semantic similarity by making use of WordNet. The evaluation on a paraphrase recognition task showed that knowledge-based measures outperform the simpler lexical level approach.

We follow the definition in (Mihalcea et al., 2006) to derive a text-to-text similarity metric mcs for two given texts D_i and D_j:

$$mcs(D_i, D_j) = \frac{\sum_{w \in D_i} maxSim(w, D_j) * idf(w)}{\sum_{w \in D_i} idf(w)} + \frac{\sum_{w \in D_j} maxSim(w, D_i) * idf(w)}{\sum_{w \in D_j} idf(w)}$$

For each word w in D_i, $maxSim(w, D_j)$ computes the maximum semantic similarity between w and any word in D_j. In this paper we choose lin (Lin, 1998) and jcn (Jiang and Conrath, 1997) to compute the word-to-word semantic similarity.

We only choose nouns and verbs for calculating mcs. Additionally, when w is a noun we restrict the words in document D_i (and D_j) to just nouns. Similarly, when w is a verb, we restrict the words in document D_i (and D_j) to just verbs.

3.3 Probabilistic Topic Model

Celikyilmaz et al. (2010) presented probabilistic topic model based methods to measure the similarity between question and candidate answers. The candidate answers were ranked based on the hidden topics discovered by Latent Dirichlet Allocation (LDA) methods.

In contrast to the TFIDF method which measures "common words", short texts are not compared to each other directly in probabilistic topic models. Instead, the texts are compared using some "third-party" topics that relate to them. A passage D in the retrieved documents (document collection) is represented as a mixture of fixed topics, with topic z getting weight $\theta_z^{(D)}$ in passage D and each topic is a distribution over a finite vocabulary of words, with word w having a probability $\phi_w^{(z)}$ in topic z. Gibbs Sampling can be used to estimate the corresponding expected posterior probabilities $P(z|D) = \hat{\theta}_z^{(D)}$ and $P(w|z) = \hat{\phi}_w^{(z)}$ (Griffiths and Steyvers, 2004).

In this paper we use two LDA based similarity measures in (Celikyilmaz et al., 2010) to measure the similarity between short information need texts. The first LDA similarity method uses KL divergence to measure the similarity between two documents under each given topic:

$$sim_{LDA1}(D_i, D_j) = \frac{1}{K} \sum_{k=1}^{K} 10^{W(D_i^{(z=k)}, D_j^{(z=k)})}$$

$$W(D_i^{(z=k)}, D_j^{(z=k)}) = - KL(D_i^{(z=k)} \| \frac{D_i^{(z=k)} + D_j^{(z=k)}}{2}) - KL(D_j^{(z=k)} \| \frac{D_i^{(z=k)} + D_j^{(z=k)}}{2})$$

$W(D_i^{(z=k)}, D_j^{(z=k)})$ calculates the similarity between two documents under topic $z = k$ using KL divergence measure. $D_i^{(z=k)}$ is the probability distribution of words in document D_i given a fixed topic z.

The second LDA similarity measure from (Griffiths and Steyvers, 2004) treats each document as a probability distribution of topics:

$$sim_{LDA2}(D_i, D_j) = 10^{W(\hat{\theta}^{(D_i)}, \hat{\theta}^{(D_j)})}$$

where $\hat{\theta}^{(D_i)}$ is document D_i's probability distribution of topics as defined earlier.

4 Information Need Prediction using Statistical Machine Translation Model

There are two reasons that we need to predict information need. It is often the case that the query question does not have a question body part. So we need a model to predict the information need part based on the query question in order to recommend questions based on the similarity of their information needs. Another reason is that information need prediction plays a crucial part not only in Question Answering but also in information retrieval (Liu et al., 2008). In this paper we propose an information need prediction method based on a statistical machine translation model.

4.1 Statistical Machine Translation Model

($\mathbf{f}^{(s)}$, $\mathbf{e}^{(s)}$), s = 1,...,S is a parallel corpus. In a sentence pair (**f**, **e**), source language String, **f** = $f_1 f_2 ... f_J$ has J words, and **e** = $e_1 e_2 ... e_I$ has I words. And alignment **a** = $a_1 a_2 ... a_J$ represents the mapping information from source language words to target words.

Statistical machine translation models estimate $Pr(\mathbf{f}|\mathbf{e})$, the translation probability from source language string **e** to target language string **f** (Och et al., 2003):

$$Pr(\mathbf{f}|\mathbf{e}) = \sum_{\mathbf{a}} Pr(\mathbf{f}, \mathbf{a}|\mathbf{e})$$

EM-algorithm is usually used to train the alignment models to estimate lexicon parameters $p(f|e)$.

In E-step, the counts for one sentence pair (**f** ,**e**) are:

$$c(f|e; \mathbf{f}, \mathbf{e}) = \sum_{\mathbf{a}} Pr(\mathbf{a}|\mathbf{f}, \mathbf{e}) \sum_{i,j} \delta(f, f_j)\delta(e, e_{a_j})$$

$$Pr(\mathbf{a}|\mathbf{f}, \mathbf{e}) = Pr(\mathbf{f}, \mathbf{a}|\mathbf{e}) / Pr(\mathbf{a}|\mathbf{e})$$

In the M-step, lexicon parameters become:

$$p(f|e) \propto \sum_{s} c(f|e; \mathbf{f}^{(s)}, \mathbf{e}^{(s)})$$

Different alignment models such as IBM-1 to IBM-5 (Brown et al., 1993) and HMM model (Och and Ney, 2000) provide different decompositions of $Pr(\mathbf{f}, \mathbf{a}|\mathbf{e})$. For different alignment models different approaches were proposed to estimate the corresponding alignments and parameters. The details can be found in (Och et al., 2003; Brown et al., 1993).

4.2 Information Need Prediction

After estimating the statistical translation probabilities, we treat the information need prediction as the process of ranking words by $p(w|Q)$, the probability of generating word w from question Q:

$$P(w|Q) = \lambda \sum_{t \in Q} P_{tr}(w|t)P(t|Q) + (1-\lambda)P(w|C)$$

The word-to-word translation probability $P_{tr}(w|t)$ is the probability of word w is translated from a word t in question Q using the translation model. The above formula uses linear interpolation smoothing of the document model with the background language model $P(t|C)$. λ is the smoothing parameter. $P(t|Q)$ and $P(t|C)$ are estimated using the maximum likelihood estimator.

One important consideration is that statistical machine translation models first estimate $Pr(\mathbf{f}|\mathbf{e})$ and then calculate $Pr(\mathbf{e}|\mathbf{f})$ using Bayes' theorem to minimize ordering errors (Brown et al., 1993):

$$Pr(\mathbf{e}|\mathbf{f}) = \frac{Pr(\mathbf{f}|\mathbf{e})Pr(\mathbf{e})}{Pr(\mathbf{f})}$$

But in this paper, we skip this step as we found out the order of words in information need part is not an important factor. In our collected CQA archive, question title and information need pairs can be considered as a type of parallel corpus, which is used for estimating word-to-word translation probabilities. More specifically, we estimated the IBM-4 model by *GIZA++*[4] with the question part as the source language and information need part as the target language.

5 Experiments and Results

5.1 Text Preprocessing

The questions posted on community QA sites often contain spelling or grammar errors. These errors in-

fluence the calculation of similarity and the performance of information retrieval (Zhao et al., 2007; Bunescu and Huang, 2010). In this paper, we use an open source software *afterthedeadline*[5] to automatically correct the spelling errors in the question and information need texts first. We also made use of Web 1T 5-gram[6] to implement an N-Gram based method (Cheng et al., 2008) to further filter out the false positive corrections and re-rank correction suggestions (Mudge, 2010). The texts are tagged by Brill's Part-of-Speech Tagger[7] as the rule-based tagger is more robust than the state-of-art statistical taggers for raw web contents. This tagging information is only used for WordNet similarity calculation. Stop word removal and lemmatization are applied to the all the raw texts before feeding into machine translation model training, the LDA model estimating and similarity calculation.

5.2 Construction of Training and Testing Sets

We made use of the questions crawled from Yahoo! Answers for the estimating models and evaluation. More specifically, we obtained 2 million questions under two categories at Yahoo! Answers: 'travel' (1 million), and 'computers&internet' (1 million). Depending on whether the best answers have been chosen by the asker, questions from Yahoo! answers can be divided into 'resolved' and 'unresolved' categories. From each of the above two categories, we randomly selected 200 resolved questions to construct two testing data sets: 'Test_t' ('travel'), and 'Test_c' ('computers&internet'). In order to measure the information need similarity in our experiment we selected only those questions whose information needs part contained at least 3 informative words after stop word removal. The rest of the questions 'Train_t' and 'Train_c' under the two categories are left for estimating the LDA topic models and the translation models. We will show how we obtain these models later.

5.3 Experimental Setup

For each question (query question) in 'Test_t' or 'Test_c', we used the words in the question title part as the main search query and the other words in the information need part as search query expansion to retrieve candidate recommended questions from Yahoo! Answers website. We obtained an average of 154 resolved questions under 'travel' or 'computers&internet' category, and three assessors were involved in the manual judgments.

Given a question returned by a recommendation

[5]http://afterthedeadline.com

[6]http://www.ldc.upenn.edu/Catalog/CatalogEntry.jsp?catalogId=LDC2006T13

[7]http://www.umiacs.umd.edu/ jimmylin/resources.html

method, two assessors are asked to label it with 'good' or 'bad'. The third assessor will judge the conflicts. The assessors are also asked to read the information need and answer parts. If a recommended question is considered to express the same or similar information need, the assessor will label it 'good'; otherwise, the assessor will label it as 'bad'.

Three measures for evaluating the recommendation performance are utilized. They are Mean Reciprocal Rank (MRR), top five prediction accuracy (precision@5) and top ten prediction accuracies (precision@10) (Voorhees and Tice, 2004; Cao et al., 2008). In MRR the reciprocal rank of a query question is the multiplicative inverse of the rank of the first 'good' recommended question. The top five prediction accuracy for a query question is the number of 'good' recommended questions out of the top five ranked questions and the top ten accuracy is calculated out of the top ten ranked questions.

5.4 Similarity Measure

The first experiment conducted question recommendation based on their information need parts. Different text similarity methods described in section 3 were used to measure the similarity between the information need texts. In TFIDF similarity measure (TFIDF), the idf values for each word were computed from frequency counts over the entire *Aquaint* corpus[8]. For calculating the word-to-word knowledge-based similarity, a WordNet::Similarity Java implementation[9] of the similarity measures lin (Knowledge2) and jcn (Knowledge1) is used in this paper. For calculating topic model based similarity, we estimated two LDA models from 'Train_t' and 'Train_c' using *GibbsLDA++*[10]. We treated each question including the question title and the information need part as a single document of a sequence of words. These documents were preprocessed before being fed into LDA model. 1800 iterations for Gibbs sampling 200 topics parameters were set for each LDA model estimation.

The results in table 2 show that TFIDF and LDA1 methods perform better for recommending questions than the others. After further analysis of the questions recommended by both methods, we discov-

Q1:	If I want a faster computer should I buy more memory or storage space?
InfoN	If I want a faster computer should I buy more memory or storage space? Whats the difference? I edit pictures and videos so I need them to work quickly. ...

ered that the ordering of the recommended questions from TFIDF and LDA1 are quite different. TFIDF similarity method prefers texts with more common words, while the LDA1 method can find the relation between the non-common words between short texts based on a series of third-party topics. The LDA1 method outperforms the TFIDF method in two ways: (1) the top recommended questions' information needs share less common words with the query question's; (2) the top recommended questions span wider topics. The questions highly recommended by LDA1 can suggest more useful topics to the user.

Knowledge-based methods are also shown to perform worse than TFIDF and LDA1. We found that some words were mis-tagged so that they were not included in the word-to-word similarity calculation. Another reason for the worse performance is that the words out of the WordNet dictionary were also not included in the similarity calculation.

The Mean Reciprocal Rank score for TFIDF and LDA1 are more than 80%. That is to say, we are able to recommend questions to the users by measuring their information needs. The first two recommended questions for Q1 and Q2 using LDA1 method are shown in table 4. InfoN is the information need part associated with each question.

In the preprocessing step, some words were successfully corrected such as "*What should I do this saturday? ... and staying in a* ***hotell*** *...*" and "*my* ***faimly*** *is traveling to* ***florda*** *...*". However, there are still a small number of texts such as "*How come my* ***Gforce*** *visualization doesn't work?*" and "*Do i need an Id to travel from new york to* ***maimi****?*" failed to be corrected. So in the future, a better method is expected to correct these failure cases.

5.5 Information Need Prediction

There are some retrieved questions whose information need parts are empty or become empty or almost empty (one or two words left) after the preprocessing step. The average number of such retrieved questions for each query question is 10 in our experiment. The similarity ranking scores of these questions are quite low or zero in the previous experiment. In this experiment, we will apply information need prediction to the questions whose information needs are missing in order to find out whether we improve the recommendation task.

The question and information need pairs in both 'Train_t' and 'Train_c' training sets were used to train two IBM-4 translation models by *GIZA++* toolkit. These pairs were also preprocessed before training. And the pairs whose information need part become empty after preprocessing were disregarded.

During the experiment, we found that some of the generated words in the information need parts are themselves. This is caused by the self translation problem in translation model: the highest translation score for a word is usually given to itself if the target and source languages are the same (Xue et al., 2008). This has always been a tough question: not using self-translated words can reduce retrieval performance as the information need parts need the terms to represent the semantic meanings; using self-translated words does not take advantage of the translation approach. To tackle this problem, we control the number of the words predicted by the translation model to be exactly twice the number of words in the corresponding preprocessed question.

The predicted information need words for the retrieved questions are shown in Table 5. In Q1, the information need behind question "*recommend website for custom built computer parts*" may imply that the users need to know some information about building computer parts such as "*ram*" and "*motherboard*" for a different purpose such as "*gaming*". While in Q2, the user may want to compare computers in different brands such as "*dell*" and "*mac*" or consider the "*price*" factor for "*purchasing a laptop for a college student*".

We also did a small scale comparison between the generated information needs against the real questions whose information need parts are not empty. Q3 and Q4 in Table 5 are two examples. The original information need for Q3 is "*looking for beautiful beaches and other things to do such as museums, zoos, shopping, and great seafood*" in CQA. The generated content for Q3 contains words in wider topics such as '*wedding*', '*surf*' and the price information ('*cheap*'). This reflects that there are some other users asking similar questions with the same or other interests.

From the results in Table 3, we can see that the performance of most similarity methods were improved by making use of information need predic-

tion. Different similarity measures received different degrees of improvement. LDA1 obtained the highest improvement followed by the TFIDF based method. These two approaches are more sensitive to the contents generated by a translation model.

However we found out that in some cases the LDA1 model failed to give higher scores to good recommendation questions. For example, Q5, Q6, and Q7 in table 5 were retrieved as recommendation candidates for the query question in Table 1. All of the three questions were good recommendation candidates, but only Q6 ranked fifth while Q5 and Q7 were out of the top 30 by LDA1 method. Moreover, in a small number of cases bad recommendation questions received higher scores and jeopardized the performance. For example, for query question "*How can you add subtitles to videos?*" with information need "*... add subtitles to a music video ... got off youtube ...download for this ...*", a retrieved question "*How would i add a music file to a video clip. ...*" was highly recommended by TFIDF approach as predicted information need contained '*youtube*', '*video*', '*music*', '*download*', ...

The MRR score received an improvement from 92.5% to 95.8% in the 'Test_c' and from 91.8% to 96.2% in 'Test_t'. This means that the top one question recommended by our methods can be quite well catering to the users' information needs. The top five precision and the top ten precision scores using TFIDF and LDA1 methods also received different degrees of improvement. Thus, we can improve the performance of question recommendation by predicting information needs.

Q1:	Please recommend A good website for Custom Built Computer parts?
InfoN	custom, site, ram, recommend, price, motherboard, gaming, ...
Q2:	What is the best laptop for a college student?

Table 5: Information need prediction examples using IBM-4 translation model

6 Conclusions

In this paper we addressed the problem of recommending questions from large archives of community question answering data based on users' information needs. We also utilized a translation model and a LDA topic model to predict the information need only given the user's query question. Different information need similarity measures were compared to prove that it is possible to satisfy user's information need by recommending questions from large archives of community QA. The Latent Dirichlet allocation based approach was proved to perform better on measuring the similarity between short

texts in the semantic level than traditional methods. Experiments showed that the proposed translation based language model for question information need prediction further enhanced the performance of question recommendation methods.

Semi-Supervised Frame-Semantic Parsing for Unknown Predicates

Dipanjan Das and **Noah A. Smith**
Language Technologies Institute
Carnegie Mellon University
Pittsburgh, PA 15213, USA
{dipanjan,nasmith}@cs.cmu.edu

Abstract

We describe a new approach to disambiguating semantic frames evoked by lexical predicates previously unseen in a lexicon or annotated data. Our approach makes use of large amounts of unlabeled data in a graph-based semi-supervised learning framework. We construct a large graph where vertices correspond to potential predicates and use label propagation to learn possible semantic frames for new ones. The label-propagated graph is used within a frame-semantic parser and, for unknown predicates, results in over 15% absolute improvement in frame identification accuracy and over 13% absolute improvement in full frame-semantic parsing F_1 score on a blind test set, over a state-of-the-art supervised baseline.

1 Introduction

Frame-semantic parsing aims to extract a shallow semantic structure from text, as shown in Figure 1. The FrameNet lexicon (Fillmore et al., 2003) is a rich linguistic resource containing expert knowledge about lexical and predicate-argument semantics. The lexicon suggests an analysis based on the theory of frame semantics (Fillmore, 1982). Recent approaches to frame-semantic parsing have broadly focused on the use of two statistical classifiers corresponding to the aforementioned subtasks: the first one to identify the most suitable semantic frame for a marked lexical predicate (*target*, henceforth) in a sentence, and the second for performing semantic role labeling (SRL) given the frame.

The FrameNet lexicon, its exemplar sentences containing instantiations of semantic frames, and full-text annotations provide supervision for learning frame-semantic parsers. Yet these annotations lack coverage, including only 9,300 annotated target types. Recent papers have tried to address the coverage problem. Johansson and Nugues (2007) used WordNet (Fellbaum, 1998) to expand the list of targets that can evoke frames and trained classifiers to identify the best-suited frame for the newly created targets. In past work, we described an approach where latent variables were used in a probabilistic model to predict frames for unseen targets (Das et al., 2010a).[1] Relatedly, for the argument identification subtask, Matsubayashi et al. (2009) proposed a technique for generalization of semantic roles to overcome data sparseness. Unseen targets continue to present a major obstacle to domain-general semantic analysis.

In this paper, we address the problem of idenfifying the semantic frames for targets unseen either in FrameNet (including the exemplar sentences) or the collection of full-text annotations released along with the lexicon. Using a standard model for the argument identification stage (Das et al., 2010a), our proposed method improves overall frame-semantic parsing, especially for unseen targets. To better handle these unseen targets, we adopt a graph-based semi-supervised learning stategy (§4). We construct a large graph over potential targets, most of which

[1] Notwithstanding state-of-the-art results, that approach was only able to identify the correct frame for 1.9% of unseen targets in the test data available at that time. That system achieves about 23% on the test set used in this paper.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1435–1444,
Portland, Oregon, June 19-24, 2011.

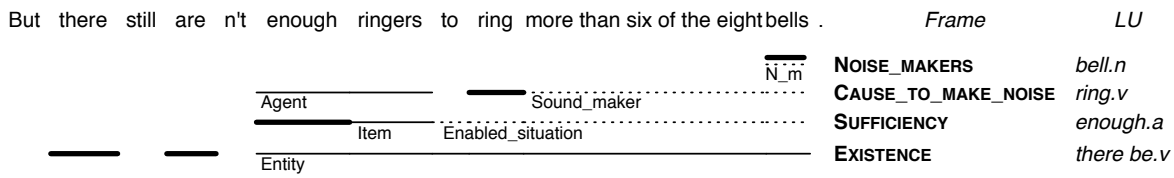

Figure 1: An example sentence from the PropBank section of the full-text annotations released as part of FrameNet 1.5. Each row under the sentence correponds to a semantic frame and its set of corresponding arguments. Thick lines indicate targets that evoke frames; thin solid/dotted lines with labels indicate arguments. N_m under "bells" is short for the Noise_maker role of the NOISE_MAKERS frame.

are drawn from unannotated data, and a fraction of which come from seen FrameNet annotations. Next, we perform label propagation on the graph, which is initialized by frame distributions over the *seen* targets. The resulting smoothed graph consists of posterior distributions over semantic frames for each target in the graph, thus increasing coverage. These distributions are then evaluated within a frame-semantic parser (§5). Considering unseen targets in test data (although few because the test data is also drawn from the training domain), significant absolute improvements of 15.7% and 13.7% are observed for frame identification and full frame-semantic parsing, respectively, indicating improved coverage for hitherto unobserved predicates (§6).

2 Background

Before going into the details of our model, we provide some background on two topics relevant to this paper: frame-semantic parsing and graph-based learning applied to natural language tasks.

2.1 Frame-semantic Parsing

Gildea and Jurafsky (2002) pioneered SRL, and since then there has been much applied research on predicate-argument semantics. Early work on frame-semantic role labeling made use of the exemplar sentences in the FrameNet corpus, each of which is annotated for a single frame and its arguments (Thompson et al., 2003; Fleischman et al., 2003; Shi and Mihalcea, 2004; Erk and Padó, 2006, *inter alia*). Most of this work was done on an older, smaller version of FrameNet. Recently, since the release of full-text annotations in SemEval'07 (Baker et al., 2007), there has been work on identifying multiple frames and their corresponding sets of arguments in a sentence. The LTH system of Johansson and Nugues (2007) performed the best in the SemEval'07 shared task on frame-semantic parsing. Our probabilistic frame-semantic parser outperforms LTH on that task and dataset (Das et al., 2010a). The current paper builds on those probabilistic models to improve coverage on unseen predicates.[2]

Expert resources have limited coverage, and FrameNet is no exception. Automatic induction of semantic resources has been a major effort in recent years (Snow et al., 2006; Ponzetto and Strube, 2007, *inter alia*). In the domain of frame semantics, previous work has sought to extend the coverage of FrameNet by exploiting resources like VerbNet, WordNet, or Wikipedia (Shi and Mihalcea, 2005; Giuglea and Moschitti, 2006; Pennacchiotti et al., 2008; Tonelli and Giuliano, 2009), and projecting entries and annotations within and across languages (Boas, 2002; Fung and Chen, 2004; Padó and Lapata, 2005). Although these approaches have increased coverage to various degrees, they rely on other lexicons and resources created by experts. Fürstenau and Lapata (2009) proposed the use of unlabeled data to improve coverage, but their work was limited to verbs. Bejan (2009) used self-training to improve frame identification and reported improvements, but did not explicitly model unknown targets. In contrast, we use statistics gathered from large volumes of unlabeled data to improve the coverage of a frame-semantic parser on several syntactic categories, in a novel framework that makes use of graph-based semi-supervised learning.

[2]SEMAFOR, the system presented by Das et al. (2010a) is publicly available at `http://www.ark.cs.cmu.edu/SEMAFOR` and has been extended in this work.

2.2 Graph-based Semi-Supervised Learning

In graph-based semi-supervised learning, one constructs a graph whose vertices are labeled and unlabeled examples. Weighted edges in the graph, connecting pairs of examples/vertices, encode the degree to which they are expected to have the same label (Zhu et al., 2003). Variants of label propagation are used to transfer labels from the labeled to the unlabeled examples. There are several instances of the use of graph-based methods for natural language tasks. Most relevant to our work an approach to word-sense disambiguation due to Niu et al. (2005). Their formulation was transductive, so that the test data was part of the constructed graph, and they did not consider predicate-argument analysis. In contrast, we make use of the smoothed graph during inference in a probabilistic setting, in turn using it for the full frame-semantic parsing task. Recently, Subramanya et al. (2010) proposed the use of a graph over substructures of an underlying sequence model, and used a smoothed graph for domain adaptation of part-of-speech taggers. Subramanya et al.'s model was extended by Das and Petrov (2011) to induce part-of-speech dictionaries for unsupervised learning of taggers. Our semi-supervised learning setting is similar to these two lines of work and, like them, we use the graph to arrive at better final structures, in an inductive setting (i.e., where a parametric model is learned and then separately applied to test data, following most NLP research).

3 Approach Overview

Our overall approach to handling unobserved targets consists of four distinct stages. Before going into the details of each stage individually, we provide their overview here:

Graph Construction: A graph consisting of vertices corresponding to targets is constructed using a combination of frame similarity (for observed targets) and distributional similarity as edge weights. This stage also determines a fixed set of nearest neighbors for each vertex in the graph.

Label Propagation: The observed targets (a small subset of the vertices) are initialized with empirical frame distributions extracted from FrameNet annotations. Label propagation results in a distribution of frames for each vertex in the graph.

Supervised Learning: Frame identification and argument identification models are trained following Das et al. (2010a). The graph is used to define the set of candidate frames for unseen targets.

Parsing: The frame identification model of Das et al. disambiguated among only those frames associated with a seen target in the annotated data. For an unseen target, all frames in the FrameNet lexicon were considered (a large number). The current work replaces that strategy, considering only the top M frames in the distribution produced by label propagation. This strategy results in large improvements in frame identification for the unseen targets and makes inference much faster. Argument identification is done exactly like Das et al. (2010a).

4 Semi-Supervised Learning

We perform semi-supervised learning by constructing a graph of vertices representing a large number of targets, and learn frame distributions for those which were not observed in FrameNet annotations.

4.1 Graph Construction

We construct a graph with targets as vertices. For us, each target corresponds to a lemmatized word or phrase appended with a coarse POS tag, and it resembles the *lexical units* in the FrameNet lexicon. For example, two targets corresponding to the same lemma would look like *boast*.N and *boast*.V. Here, the first target is a noun, while the second is a verb. An example multiword target is *chemical weapon*.N.

We use two resources for graph construction. First, we take all the words and phrases present in the dependency-based thesaurus constructed using syntactic cooccurrence statistics (Lin, 1998).[3] To construct this resource, a corpus containing 64 million words was parsed with a fast dependency parser (Lin, 1993; Lin, 1994), and syntactic contexts were used to find similar lexical items for a given word

[3]This resource is available at `http://webdocs.cs.ualberta.ca/~lindek/Downloads/sim.tgz`

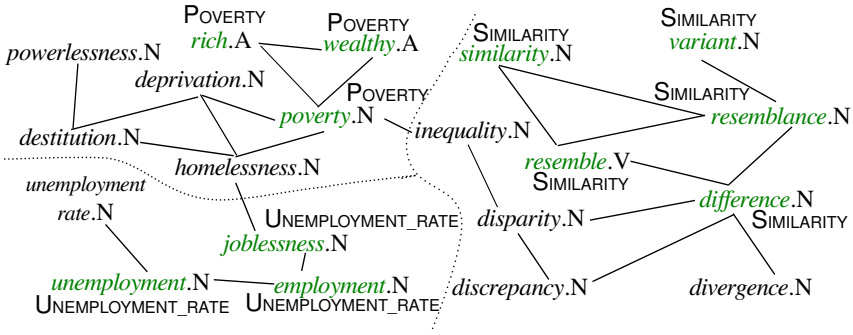

Figure 2: Excerpt from a graph over targets. Green targets are observed in the FrameNet data. Above/below them are shown the most frequently observed frame that these targets evoke. The black targets are unobserved and label propagation produces a distribution over most likely frames that they could evoke.

or phrase. Lin separately treated nouns, verbs and adjectives/adverbs and the thesaurus contains three parts for each of these categories. For each item in the thesaurus, 200 nearest neighbors are listed with a symmetric similarity score between 0 and 1. We processed this thesaurus in two ways: first, we lowercased and lemmatized each word/phrase and merged entries which shared the same lemma; second, we separated the adjectives and adverbs into two lists from Lin's original list by scanning a POS-tagged version of the Gigaword corpus (Graff, 2003) and categorizing each item into an adjective or an adverb depending on which category the item associated with more often in the data. The second step was necessary because FrameNet treats adjectives and adverbs separately. At the end of this processing step, we were left with 61,702 units—approximately six times more than the targets found in FrameNet annotations—each labeled with one of 4 coarse tags. We considered only the top 20 most similar targets for each target, and noted Lin's similarity between two targets t and u, which we call $\mathsf{sim}_{DL}(t, u)$.

The second component of graph construction comes from FrameNet itself. We scanned the exemplar sentences in FrameNet 1.5[4] and the training section of the full-text annotations that we use to train the probabilistic frame parser (see §6.1), and gathered a distribution over frames for each target. For a pair of targets t and u, we measured the Euclidean distance[5] between their frame distributions. This distance was next converted to a similarity score, namely, $\mathsf{sim}_{FN}(t, u)$ between 0 and 1 by subtracting each one from the maximum distance found in the whole data, followed by normalization. Like $\mathsf{sim}_{DL}(t, u)$, this score is symmetric. This resulted in 9,263 targets, and again for each, we considered the 20 most similar targets. Finally, the overall similarity between two given targets t and u was computed as:

$$\mathsf{sim}(t, u) = \alpha \cdot \mathsf{sim}_{FN}(t, u) + (1 - \alpha) \cdot \mathsf{sim}_{DL}(t, u)$$

Note that this score is symmetric because its two components are symmetric. The intuition behind taking a linear combination of the two types of similarity functions is as follows. We hope that distributionally similar targets would have the same semantic frames because ideally, lexical units evoking the same set of frames appear in similar syntactic contexts. We would also like to involve the annotated data in graph construction so that it can eliminate some noise in the automatically constructed thesaurus.[6] Let $\mathcal{K}(t)$ denote the K most similar targets to target t, under the score sim. We link vertices t and u in the graph with edge weight w_{tu}, defined as:

$$w_{tu} = \begin{cases} \mathsf{sim}(t, u) & \text{if } t \in \mathcal{K}(u) \text{ or } u \in \mathcal{K}(t) \\ 0 & \text{otherwise} \end{cases} \quad (1)$$

The hyperparameters α and K are tuned by cross-validation (§6.3).

4.2 Label Propagation

First, we softly label those vertices of the constructed graph for which frame distributions are available from the FrameNet data (the same distributions that are used to compute sim_{FN}). Thus, initially, a small fraction of the vertices in the graph

[4] http://framenet.icsi.berkeley.edu

[5] This could have been replaced by an entropic distance metric like KL- or JS-divergence, but we leave that exploration to future work.

[6] In future work, one might consider *learning* a similarity metric from the annotated data, so as to exactly suit the frame identification task.

have soft frame labels on them. Figure 2 shows an excerpt from a constructed graph. For simplicity, only the most probable frames under the empirical distribution for the observed targets are shown; we actually label each vertex with the full empirical distribution over frames for the corresponding observed target in the data. The dotted lines demarcate parts of the graph that associate with different frames. Label propagation helps propagate the initial soft labels throughout the graph. To this end, we use a variant of the quadratic cost criterion of Bengio et al. (2006), also used by Subramanya et al. (2010) and Das and Petrov (2011).[7]

Let V denote the set of all vertices in the graph, $V_l \subset V$ be the set of known targets and $\mathcal{F}$ denote the set of all frames. Let $\mathcal{N}(t)$ denote the set of neighbors of vertex $t \in V$. Let $\mathrm{q} = \{\mathrm{q}_1, \mathrm{q}_2, \ldots, \mathrm{q}_{|V|}\}$ be the set of frame distributions, one per vertex. For each known target $t \in V_l$, we have an initial frame distribution r_t. For every edge in the graph, weights are defined as in Eq. 1. We find q by solving:

$$\begin{aligned} \arg\min_{\mathrm{q}} \quad & \textstyle\sum_{t \in V_l} \|\mathrm{r}_t - \mathrm{q}_t\|^2 \\ & + \mu \textstyle\sum_{t \in V, u \in \mathcal{N}(t)} w_{tu} \|\mathrm{q}_t - \mathrm{q}_u\|^2 \\ & + \nu \textstyle\sum_{t \in V} \|\mathrm{q}_t - \frac{1}{|\mathcal{F}|}\|^2 \\ \text{s.t.} \quad & \forall t \in V, \ \textstyle\sum_{f \in \mathcal{F}} \mathrm{q}_t(f) = 1 \\ & \forall t \in V, f \in \mathcal{F}, \ \mathrm{q}_t(f) \geq 0 \end{aligned} \tag{2}$$

We use a squared loss to penalize various pairs of distributions over frames: $\|\mathrm{a} - \mathrm{b}\|^2 = \sum_{f \in \mathcal{F}} (\mathrm{a}(f) - \mathrm{b}(f))^2$. The first term in Eq. 2 requires that, for known targets, we stay close to the initial frame distributions. The second term is the graph smoothness regularizer, which encourages the distributions of similar nodes (large w_{tu}) to be similar. The final term is a regularizer encouraging all distributions to be uniform to the extent allowed by the first two terms. (If an unlabeled vertex does not have a path to any labeled vertex, this term ensures that its converged marginal will be uniform over all frames.) μ and ν are hyperparameters whose choice we discuss in §6.3.

Note that Eq. 2 is convex in q. While it is possible to derive a closed form solution for this objective function, it would require the inversion of a $|V| \times |V|$ matrix. Hence, like Subramanya et al. (2010), we employ an iterative method with updates defined as:

$$\begin{aligned} \gamma_t(f) \quad &\leftarrow \quad \mathrm{r}_t(f)\mathbf{1}\{t \in V_l\} \\ &\quad + \ \mu \sum_{u \in \mathcal{N}(t)} w_{tu} \mathrm{q}_u^{(m-1)}(f) + \frac{\nu}{|\mathcal{F}|} \end{aligned} \tag{3}$$

$$\kappa_t \quad \leftarrow \quad \mathbf{1}\{t \in V_l\} + \nu + \mu \sum_{u \in \mathcal{N}(t)} w_{tu} \tag{4}$$

$$\mathrm{q}_t^{(m)}(f) \quad \leftarrow \quad \gamma_t(f)/\kappa_t \tag{5}$$

Here, $\mathbf{1}\{\cdot\}$ is an indicator function. The iterative procedure starts with a uniform distribution for each $\mathrm{q}_t^{(0)}$. For all our experiments, we run 10 iterations of the updates. The final distribution of frames for a target t is denoted by q_t^*.

5 Learning and Inference for Frame-Semantic Parsing

In this section, we briefly review learning and inference techniques used in the frame-semantic parser, which are largely similar to Das et al. (2010a), except the handling of unknown targets. Note that in all our experiments, we assume that the targets are marked in a given sentence of which we want to extract a frame-semantic analysis. Therefore, unlike the systems presented in SemEval'07, we do not define a target identification module.

5.1 Frame Identification

For a given sentence $\mathbf{x}$ with frame-evoking targets $\mathbf{t}$, let t_i denote the ith target (a word sequence). We seek a list $\mathbf{f} = \langle f_1, \ldots, f_m \rangle$ of frames, one per target. Let $\mathcal{L}$ be the set of targets found in the FrameNet annotations. Let $\mathcal{L}_f \subseteq \mathcal{L}$ be the subset of these targets annotated as evoking a particular frame f.

The set of candidate frames $\mathcal{F}_i$ for t_i is defined to include every frame f such that $t_i \in \mathcal{L}_f$. If $t_i \notin \mathcal{L}$ (in other words, t_i is unseen), then Das et al. (2010a) considered all frames $\mathcal{F}$ in FrameNet as candidates. Instead, in our work, we check whether $t_i \in V$, where V are the vertices of the constructed graph, and set:

$$\mathcal{F}_i = \{f : f \in M\text{-best frames under } \mathrm{q}_{t_i}^*\} \tag{6}$$

The integer M is set using cross-validation (§6.3). If $t_i \notin V$, then all frames $\mathcal{F}$ are considered as $\mathcal{F}_i$.

[7] Instead of a quadratic cost, an entropic distance measure could have been used, e.g., KL-divergence, considered by Subramanya and Bilmes (2009). We do not explore that direction in the current paper.

The frame prediction rule uses a probabilistic model over frames for a target:

$$f_i \leftarrow \arg\max_{f \in \mathcal{F}_i} \sum_{\ell \in \mathcal{L}_f} p(f, \ell \mid t_i, \mathbf{x}) \quad (7)$$

Note that a latent variable $\ell \in \mathcal{L}_f$ is used, which is marginalized out. Broadly, lexical semantic relationships between the "prototype" variable ℓ (belonging to the set of seen targets for a frame f) and the target t_i are used as features for frame identification, but since ℓ is unobserved, it is summed out both during inference and training. A conditional log-linear model is used to model this probability: for $f \in \mathcal{F}_i$ and $\ell \in \mathcal{L}_f$, $p_{\boldsymbol{\theta}}(f, \ell \mid t_i, \mathbf{x}) =$

$$\frac{\exp \boldsymbol{\theta}^\top \mathbf{g}(f, \ell, t_i, \mathbf{x})}{\sum_{f' \in \mathcal{F}_i} \sum_{\ell' \in \mathcal{L}_{f'}} \exp \boldsymbol{\theta}^\top \mathbf{g}(f', \ell', t_i, \mathbf{x})} \quad (8)$$

where $\boldsymbol{\theta}$ are the model weights, and $\mathbf{g}$ is a vector-valued feature function. This discriminative formulation is very flexible, allowing for a variety of (possibly overlapping) features; e.g., a feature might relate a frame f to a prototype ℓ, represent a lexical-semantic relationship between ℓ and t_i, or encode part of the syntax of the sentence (Das et al., 2010b).

Given some training data, which is of the form $\left\langle \langle \mathbf{x}^{(j)}, \mathbf{t}^{(j)}, \mathbf{f}^{(j)}, \mathcal{A}^{(j)} \rangle \right\rangle_{j=1}^{N}$ (where N is the number of sentences in the data and $\mathcal{A}$ is the set of argument in a sentence), we discriminatively train the frame identification model by maximizing the following log-likelihood:[8]

$$\max_{\boldsymbol{\theta}} \sum_{j=1}^{N} \sum_{i=1}^{m_j} \log \sum_{\ell \in \mathcal{L}_{f_i^{(j)}}} p_{\boldsymbol{\theta}}(f_i^{(j)}, \ell \mid t_i^{(j)}, \mathbf{x}^{(j)}) \quad (9)$$

This non-convex objective function is locally optimized using a distributed implementation of L-BFGS (Liu and Nocedal, 1989).[9]

5.2 Argument Identification

Given a sentence $\mathbf{x} = \langle x_1, \ldots, x_n \rangle$, the set of targets $\mathbf{t} = \langle t_1, \ldots, t_m \rangle$, and a list of evoked frames $\mathbf{f} = \langle f_1, \ldots, f_m \rangle$ corresponding to each target, argument identification or SRL is the task of choosing which of each f_i's roles are filled, and by which parts of $\mathbf{x}$. We directly adopt the model of Das et al. (2010a) for the argument identification stage and briefly describe it here.

Let $\mathcal{R}_{f_i} = \{r_1, \ldots, r_{|\mathcal{R}_{f_i}|}\}$ denote frame f_i's **roles** observed in FrameNet annotations. A set $\mathcal{S}$ of spans that are candidates for filling any role $r \in \mathcal{R}_{f_i}$ are identified in the sentence. In principle, $\mathcal{S}$ could contain any subsequence of $\mathbf{x}$, but we consider only the set of contiguous spans that (a) contain a single word or (b) comprise a valid subtree of a word and all its descendants in a dependency parse. The empty span is also included in $\mathcal{S}$, since some roles are not explicitly filled. During training, if an argument is not a valid subtree of the dependency parse (this happens due to parse errors), we add its span to $\mathcal{S}$. Let $\mathcal{A}_i$ denote the mapping of roles in $\mathcal{R}_{f_i}$ to spans in $\mathcal{S}$. The model makes a prediction for each $\mathcal{A}_i(r_k)$ (for all roles $r_k \in \mathcal{R}_{f_i}$):

$$\mathcal{A}_i(r_k) \leftarrow \arg\max_{s \in \mathcal{S}} p(s \mid r_k, f_i, t_i, \mathbf{x}) \quad (10)$$

A conditional log-linear model over spans for each role of each evoked frame is defined as:

$$p_{\boldsymbol{\psi}}(\mathcal{A}_i(r_k) = s \mid f_i, t_i, \mathbf{x}) = \frac{\exp \boldsymbol{\psi}^\top \mathbf{h}(s, r_k, f_i, t_i, \mathbf{x})}{\sum_{s' \in \mathcal{S}} \exp \boldsymbol{\psi}^\top \mathbf{h}(s', r_k, f_i, t_i, \mathbf{x})} \quad (11)$$

This model is trained by optimizing:

$$\max_{\boldsymbol{\psi}} \sum_{j=1}^{N} \sum_{i=1}^{m_j} \sum_{k=1}^{|\mathcal{R}_{f_i^{(j)}}|} \log p_{\boldsymbol{\psi}}(\mathcal{A}_i^{(j)}(r_k) \mid f_i^{(j)}, t_i^{(j)}, \mathbf{x}^{(j)})$$

This objective function is convex, and we globally optimize it using the distributed implementation of L-BFGS. We regularize by including $-\frac{1}{10}\|\boldsymbol{\psi}\|_2^2$ in the objective (the strength is not tuned). Naïve prediction of roles using Equation 10 may result in overlap among arguments filling different roles of a frame, since the argument identification model fills each role independently of the others. We want to enforce the constraint that two roles of a single frame cannot be filled by overlapping spans. Hence, illegal overlap is disallowed using a 10,000-hypothesis beam search.

[8] We found no benefit from using an L_2 regularizer.

[9] While training, in the partition function of the log-linear model, all frames $\mathcal{F}$ in FrameNet are summed up for a target t_i instead of only $\mathcal{F}_i$ (as in Eq. 8), to learn interactions between the latent variables and different sentential contexts.

Model	Unknown Targets		All Targets	
	Exact Match	**Partial Match**	**Exact Match**	**Partial Match**
SEMAFOR	23.08	46.62	82.97	90.51
Self-training	18.88	42.67	82.45	90.19
LinGraph	**36.36**	**59.47**	**83.40**	**90.93**
FullGraph	**39.86**	**62.35***	**83.51**	**91.02***

Table 1: Frame identification results in percentage accuracy on 4,458 test targets. Bold scores indicate significant improvements relative to SEMAFOR and (*) denotes significant improvements over LinGraph ($p < 0.05$).

6 Experiments and Results

Before presenting our experiments and results, we will describe the datasets used in our experiments, and the various baseline models considered.

6.1 Data

We make use of the FrameNet 1.5 lexicon released in 2010. This lexicon is a superset of previous versions of FrameNet. It contains 154,607 exemplar sentences with one marked target and frame-role annotations. 78 documents with full-text annotations with multiple frames per sentence were also released (a superset of the SemEval'07 dataset). We randomly selected 55 of these documents for training and treated the 23 remaining ones as our test set. After scanning the exemplar sentences and the training data, we arrived at a set of 877 frames, 1,068 roles,[10] and 9,263 targets. Our training split of the full-text annotations contained 3,256 sentences with 19,582 frame annotatations with corresponding roles, while the test set contained 2,420 sentences with 4,458 annotations (the test set contained fewer annotated targets per sentence). We also divide the 55 training documents into 5 parts for cross-validation (see §6.3). The raw sentences in all the training and test documents were preprocessed using MXPOST (Ratnaparkhi, 1996) and the MST dependency parser (McDonald et al., 2005) following Das et al. (2010a). In this work we assume the frame-evoking targets have been correctly identified in training and test data.

[10]Note that the number of listed roles in the lexicon is nearly 9,000, but their number in actual annotations is a lot fewer.

6.2 Baselines

We compare our model with three baselines. The first baseline is the purely supervised model of Das et al. (2010a) trained on the training split of 55 documents. Note that this is the strongest baseline available for this task;[11] we refer to this model as "SEMAFOR."

The second baseline is a semi-supervised self-trained system, where we used SEMAFOR to label 70,000 sentences from the Gigaword corpus with frame-semantic parses. For finding targets in a raw sentence, we used a relaxed target identification scheme, where we marked every target seen in the lexicon and all other words which were not prepositions, particles, proper nouns, foreign words and Wh-words as potential frame evoking units. This was done so as to find unseen targets and get frame annotations with SEMAFOR on them. We appended these automatic annotations to the training data, resulting in 711,401 frame annotations, more than 36 times the supervised data. These data were next used to train a frame identification model (§5.1).[12] This setup is very similar to Bejan (2009) who used self-training to improve frame identification. We refer to this model as "Self-training."

The third baseline uses a graph constructed only with Lin's thesaurus, without using supervised data. In other words, we followed the same scheme as in §4.1 but with the hyperparameter $\alpha = 0$. Next, label propagation was run on this graph (and hyperparameters tuned using cross validation). The posterior distribution of frames over targets was next used for frame identification (Eq. 6-7), with SEMAFOR as the trained model. This model, which is very similar to our full model, is referred to as "LinGraph."

"FullGraph" refers to our full system.

6.3 Experimental Setup

We used five-fold cross-validation to tune the hyperparameters α, K, μ, and M in our model. The

[11]We do not compare our model with other systems, e.g. the ones submitted to SemEval'07 shared task, because SEMAFOR outperforms them significantly (Das et al., 2010a) on the previous version of the data. Moreover, we trained our models on the new FrameNet 1.5 data, and training code for the SemEval'07 systems was not readily available.

[12]Note that we only self-train the frame identification model and not the argument identification model, which is fixed throughout.

Model	UNKNOWN TARGETS						ALL TARGETS					
	Exact Match			Partial Match			Exact Match			Partial Match		
	P	R	F_1	P	R	F_1	P	R	F_1	P	R	F_1
SEMAFOR	19.59	16.48	17.90	33.03	27.80	30.19	66.15	61.64	63.82	70.68	65.86	68.18
Self-training	15.44	13.00	14.11	29.08	24.47	26.58	65.78	61.30	63.46	70.39	65.59	67.90
LinGraph	**29.74**	**24.88**	**27.09**	**44.08**	**36.88**	**40.16**	**66.43**	**61.89**	**64.08**	**70.97**	**66.13**	**68.46**
FullGraph	**35.27***	**28.84***	**31.74***	**48.81***	**39.91***	**43.92***	**66.59***	**62.01***	**64.22***	**71.11***	**66.22***	**68.58***

Table 2: Full frame-semantic parsing precision, recall and F_1 score on 2,420 test sentences. Bold scores indicate significant improvements relative to SEMAFOR and (*) denotes significant improvements over LinGraph ($p < 0.05$).

uniform regularization hyperparameter ν for graph construction was set to 10^{-6} and not tuned. For each cross-validation split, four folds were used to train a frame identification model, construct a graph, run label propagation and then the model was tested on the fifth fold. This was done for all hyperparameter settings, which were $\alpha \in \{0.2, 0.5, 0.8\}$, $K \in \{5, 10, 15, 20\}$, $\mu \in \{0.01, 0.1, 0.3, 0.5, 1.0\}$ and $M \in \{2, 3, 5, 10\}$. The joint setting which performed the best across five-folds was $\alpha = 0.2, K = 10, \mu = 1.0, M = 2$. Similar tuning was also done for the baseline LinGraph, where α was set to 0, and rest of the hyperparameters were tuned (the selected hyperparameters were $K = 10$, $\mu = 0.1$ and $M = 2$). With the chosen set of hyperparameters, the test set was used to measure final performance.

The standard evaluation script from the SemEval'07 task calculates precision, recall, and F_1-score for frames and arguments; it also provides a score that gives partial credit for hypothesizing a frame *related* to the correct one in the FrameNet lexicon. We present precision, recall, and F_1-measure microaveraged across the test documents, report labels-only matching scores (spans must match exactly), and do not use named entity labels. This evaluation scheme follows Das et al. (2010a). Statistical significance is measured using a reimplementation of Dan Bikel's parsing evaluation comparator.[13]

6.4 Results

Tables 1 and 2 present results for frame identification and full frame-semantic parsing respectively. They also separately tabulate the results achieved for unknown targets. Our full model, denoted by "FullGraph," outperforms all the baselines for both tasks. Note that the Self-training model even falls short of the supervised baseline SEMAFOR, unlike what was observed by Bejan (2009) for the frame identification task. The model using a graph constructed solely from the thesaurus (LinGraph) outperforms both the supervised and the self-training baselines for all tasks, but falls short of the graph constructed using the similarity metric that is a linear combination of distributional similarity and supervised frame similarity. This indicates that a graph constructed with some knowledge of the supervised data is more powerful.

For unknown targets, the gains of our approach are impressive: 15.7% absolute accuracy improvement over SEMAFOR for frame identification, and 13.7% absolute F_1 improvement over SEMAFOR for full frame-semantic parsing (both significant). When all the test targets are considered, the gains are still significant, resulting in 5.4% relative error reduction over SEMAFOR for frame identification, and 1.3% relative error reduction over SEMAFOR for full-frame semantic parsing.

Although these improvements may seem modest, this is because only 3.2% of the test set targets are unseen in training. We expect that further gains would be realized in different text domains, where FrameNet coverage is presumably weaker than in news data. A semi-supervised strategy like ours is attractive in such a setting, and future work might explore such an application.

Our approach also makes decoding much faster. For the unknown component of the test set, SEMAFOR takes a total 111 seconds to find the best set of frames, while the FullGraph model takes only 19 seconds to do so, thus bringing disambiguation time down by a factor of nearly 6. This is because our model now disambiguates between only $M = 2$ frames instead of the full set of 877 frames in FrameNet. For the full test set too, the speedup

[13] http://www.cis.upenn.edu/~dbikel/software.html#comparator

Table 3: Top 5 frames according to the graph posterior distribution $\mathrm{q}_t^*(f)$ for four targets: *discrepancy*.N, *contribution*.N, *print*.V and *mislead*.V. None of these targets were present in the supervised FrameNet data. $*$ marks the correct frame, according to the test data. EXPERIENCER_OBJ is described in FrameNet as "Some phenomenon (the Stimulus) provokes a particular emotion in an Experiencer."

is noticeable, as SEMAFOR takes 131 seconds for frame identification, while the FullGraph model only takes 39 seconds.

6.5 Discussion

The following is an example from our test set showing SEMAFOR's output (for one target):

> REASON
> Discrepancies between North Korean declarations and IAEA inspection findings Action indicate that North Korea might have reprocessed enough plutonium for one or two nuclear weapons.
> *discrepancy*.N

Note that the model identifies an incorrect frame REASON for the target *discrepancy*.N, in turn identifying the wrong semantic role Action for the underlined argument. On the other hand, the FullGraph model exactly identifies the right semantic frame, SIMILARITY, as well as the correct role, Entities. This improvement can be easily explained. The excerpt from our constructed graph in Figure 2 shows the same target *discrepancy*.N in black, conveying that it did not belong to the supervised data. However, it is connected to the target *difference*.N drawn from annotated data, which evokes the frame SIMILARITY. Thus, after label propagation, we expect the frame SIMILARITY to receive high probability for the target *discrepancy*.N.

Table 3 shows the top 5 frames that are assigned the highest posterior probabilities in the distribution q_t^* for four hand-selected test targets absent in supervised data, including *discrepancy*.N. For all of them, the FullGraph model identifies the correct frames for all four words in the test data by ranking these frames in the top $M = 2$. LinGraph also gets all four correct, Self-training only gets *print*.V/TEXT_CREATION, and SEMAFOR gets none.

Across unknown targets, on average the $M = 2$ most common frames in the posterior distribution q_t^* found by FullGraph have $\mathrm{q}_t^{(*)}(f) = \frac{7}{877}$, or seven times the average across all frames. This suggests that the graph propagation method is confident only in predicting the top few frames out of the whole possible set. Moreover, the automatically selected number of frames to extract per unknown target, $M = 2$, suggests that only a few meaningful frames were assigned to unknown predicates. This matches the nature of FrameNet data, where the average frame ambiguity for a target type is 1.20.

7 Conclusion

We have presented a semi-supervised strategy to improve the coverage of a frame-semantic parsing model. We showed that graph-based label propagation and resulting smoothed frame distributions over unseen targets significantly improved the coverage of a state-of-the-art semantic frame disambiguation model to previously unseen predicates, also improving the quality of full frame-semantic parses. The improved parser is available at `http://www.ark.cs.cmu.edu/SEMAFOR`.

Abstract

We propose a non-parametric Bayesian model for unsupervised semantic parsing. Following Poon and Domingos (2009), we consider a semantic parsing setting where the goal is to (1) decompose the syntactic dependency tree of a sentence into fragments, (2) assign each of these fragments to a cluster of semantically equivalent syntactic structures, and (3) predict predicate-argument relations between the fragments. We use hierarchical Pitman-Yor processes to model statistical dependencies between meaning representations of predicates and those of their arguments, as well as the clusters of their syntactic realizations. We develop a modification of the Metropolis-Hastings split-merge sampler, resulting in an efficient inference algorithm for the model. The method is experimentally evaluated by using the induced semantic representation for the question answering task in the biomedical domain.

1 Introduction

Statistical approaches to semantic parsing have recently received considerable attention. While some methods focus on predicting a complete formal representation of meaning (Zettlemoyer and Collins, 2005; Ge and Mooney, 2005; Mooney, 2007), others consider more shallow forms of representation (Carreras and Màrquez, 2005; Liang et al., 2009). However, most of this research has concentrated on *supervised* methods requiring large amounts of labeled data. Such annotated resources are scarce, expensive to create and even the largest of them tend to have low coverage (Palmer and Sporleder, 2010), motivating the need for unsupervised or semi-supervised techniques.

Conversely, research in the closely related task of relation extraction has focused on unsupervised or minimally supervised methods (see, for example, (Lin and Pantel, 2001; Yates and Etzioni, 2009)). These approaches cluster semantically equivalent verbalizations of relations, often relying on syntactic fragments as features for relation extraction and clustering (Lin and Pantel, 2001; Banko et al., 2007). The success of these methods suggests that semantic parsing can also be tackled as clustering of syntactic realizations of predicate-argument relations. While a similar direction has been previously explored in (Swier and Stevenson, 2004; Abend et al., 2009; Lang and Lapata, 2010), the recent work of (Poon and Domingos, 2009) takes it one step further by not only predicting predicate-argument structure of a sentence but also assigning sentence fragments to clusters of semantically similar expressions. For example, for a pair of sentences on Figure 1, in addition to inducing predicate-argument structure, they aim to assign expressions *"Steelers"* and *"the Pittsburgh team"* to the same semantic class `Steelers`, and group expressions *"defeated"* and *"secured the victory over"*. Such semantic representation can be useful for entailment or question answering tasks, as an entailment model can abstract away from specifics of syntactic and lexical realization relying instead on the induced semantic representation. For example, the two sentences in Figure 1 have identical semantic representation, and therefore can be hypothesized to be equivalent.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1445–1455,
Portland, Oregon, June 19-24, 2011.

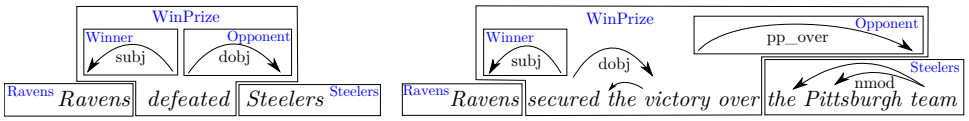

Figure 1: An example of two different syntactic trees with a common semantic representation `WinPrize(Ravens, Steelers)`.

From the statistical modeling point of view, joint learning of predicate-argument structure and discovery of semantic clusters of expressions can also be beneficial, because it results in a more compact model of selectional preference, less prone to the data-sparsity problem (Zapirain et al., 2010). In this respect our model is similar to recent LDA-based models of selectional preference (Ritter et al., 2010; Séaghdha, 2010), and can even be regarded as their recursive and non-parametric extension.

In this paper, we adopt the above definition of unsupervised semantic parsing and propose a Bayesian non-parametric approach which uses hierarchical Pitman-Yor (PY) processes (Pitman, 2002) to model statistical dependencies between predicate and argument clusters, as well as distributions over syntactic and lexical realizations of each cluster. Our non-parametric model automatically discovers granularity of clustering appropriate for the dataset, unlike the parametric method of (Poon and Domingos, 2009) which have to perform model selection and use heuristics to penalize more complex models of semantics. Additional benefits generally expected from Bayesian modeling include the ability to encode prior linguistic knowledge in the form of hyperpriors and the potential for more reliable modeling of smaller datasets. More detailed discussion of relation between the Markov Logic Network (MLN) approach of (Poon and Domingos, 2009) and our non-parametric method is presented in Section 3.

Hierarchical Pitman-Yor processes (or their special case, hierarchical Dirichlet processes) have previously been used in NLP, for example, in the context of syntactic parsing (Liang et al., 2007; Johnson et al., 2007). However, in all these cases the effective size of the state space (i.e., the number of sub-symbols in the infinite PCFG (Liang et al., 2007), or the number of adapted productions in the adaptor grammar (Johnson et al., 2007)) was not very large. In our case, the state space size equals the total number of distinct semantic clusters, and, thus, is expected to be exceedingly large even for moderate datasets: for example, the MLN model induces 18,543 distinct clusters from 18,471 sentences of the GENIA corpus (Poon and Domingos, 2009). This suggests that standard inference methods for hierarchical PY processes, such as Gibbs sampling, Metropolis-Hastings (MH) sampling with uniform proposals, or the structured mean-field algorithm, are unlikely to result in efficient inference: for example in standard Gibbs sampling all thousands of alternatives should be considered at each sampling move. Instead, we use a split-merge MH sampling algorithm, which is a standard and efficient inference tool for non-hierarchical PY processes (Jain and Neal, 2000; Dahl, 2003) but has not previously been used in hierarchical setting. We extend the sampler to include composition-decomposition of syntactic fragments in order to cluster fragments of variables size, as in the example Figure 1, and also include the argument role-syntax alignment move which attempts to improve mapping between semantic roles and syntactic paths for some fixed predicate.

Evaluating unsupervised models is a challenging task. We evaluate our model both qualitatively, examining the revealed clustering of syntactic structures, and quantitatively, on a question answering task. In both cases, we follow (Poon and Domingos, 2009) in using the corpus of biomedical abstracts. Our model achieves favorable results significantly outperforming the baselines, including state-of-the-art methods for relation extraction, and achieves scores comparable to those of the MLN model.

The rest of the paper is structured as follows. Section 2 begins with a definition of the semantic parsing task. Sections 3 and 4 give background on the MLN model and the Pitman-Yor processes, respectively. In Sections 5 and 6, we describe our model and the inference method. Section 7 provides both qualitative and quantitative evaluation. Finally, ad-

ditional related work is presented in Section 8.

2 Semantic Parsing

In this section, we briefly define the unsupervised semantic parsing task and underlying aspects and assumptions relevant to our model.

Unlike (Poon and Domingos, 2009), we do not use the lambda calculus formalism to define our task but rather treat it as an instance of frame-semantic parsing, or a specific type of semantic role labeling (Gildea and Jurafsky, 2002). The reason for this is two-fold: first, the frame semantics view is more standard in computational linguistics, sufficient to describe induced semantic representation and convenient to relate our method to the previous work. Second, lambda calculus is a considerably more powerful formalism than the predicate-argument structure used in frame semantics, normally supporting quantification and logical connectors (for example, negation and disjunction), neither of which is modeled by our model or in (Poon and Domingos, 2009).

In frame semantics, the meaning of a predicate is conveyed by a *frame*, a structure of related concepts that describes a situation, its participants and properties (Fillmore et al., 2003). Each frame is characterized by a set of semantic roles (frame elements) corresponding to the arguments of the predicate. It is evoked by a frame evoking element (a predicate). The same frame can be evoked by different but semantically similar predicates: for example, both verbs *"buy"* and *"purchase"* evoke frame `Commerce_buy` in FrameNet (Fillmore et al., 2003).

The aim of the semantic role labeling task is to identify all of the frames evoked in a sentence and label their semantic role fillers. We extend this task and treat semantic parsing as recursive prediction of predicate-argument structure and clustering of argument fillers. Thus, parsing a sentence into this representation involves (1) decomposing the sentence into lexical items (one or more words), (2) assigning a cluster label (a semantic frame or a cluster of argument fillers) to every lexical item, and (3) predicting argument-predicate relations between the lexical items. This process is illustrated in Figure 1. For the leftmost example, the sentence is decomposed into three lexical items: *"Ravens"*, *"defeated"* and *"Steelers"*, and they are assigned to clusters `Ravens`, `WinPrize` and `Steelers`, respectively. Then `Ravens` and `Steelers` are selected as a `Winner` and an `Opponent` in the `WinPrize` frame. In this work, we define a joint model for the labeling and argument identification stages. Similarly to core semantic roles in FrameNet, semantic roles are treated as frame-specific in our model, as our model does not try to discover any correspondences between roles in different frames.

As you can see from the above description, frames (which groups predicates with similar meaning such as the `WinPrize` frame in our example) and clusters of argument fillers (`Ravens` and `Steelers`) are treated in our definition in a similar way. For convenience, we will refer to both types of clusters as *semantic classes*.[1]

This definition of semantic parsing is closely related to a realistic relation extraction setting, as both clustering of syntactic forms of relations (or extraction patterns) and clustering of argument fillers for these relations is crucial for automatic construction of knowledge bases (Yates and Etzioni, 2009).

In this paper, we make three assumptions. First, we assume that each lexical item corresponds to a subtree of the syntactic dependency graph of the sentence. This assumption is similar to the adjacency assumption in (Zettlemoyer and Collins, 2005), though ours may be more appropriate for languages with free or semi-free word order, where syntactic structures are inherently non-projective. Second, we assume that the semantic arguments are local in the dependency tree; that is, one lexical item can be a semantic argument of another one only if they are connected by an arc in the dependency tree. This is a slight simplification of the semantic role labeling problem but one often made. Thus, the argument identification and labeling stages consist of labeling each syntactic arc with a semantic role label. In comparison, the MLN model does not explicitly assume contiguity of lexical items and does not make this directionality assumption but their clustering algorithm uses initialization and clusterization moves such that the resulting model also obeys both of these constraints. Third, as in (Poon and Domingos, 2009), we do not model polysemy as we assume

[1] Semantic classes correspond to lambda-form clusters in (Poon and Domingos, 2009) terminology.

that each syntactic fragment corresponds to a single semantic class. This is not a model assumption and is only used at inference as it reduces mixing time of the Markov chain. It is not likely to be restrictive for the biomedical domain studied in our experiments.

As in some of the recent work on learning semantic representations (Eisenstein et al., 2009; Poon and Domingos, 2009), we assume that dependency structures are provided for every sentence. This assumption allows us to construct models of semantics not Markovian within a sequence of words (see for an example a model described in (Liang et al., 2009)), but rather Markovian within a dependency tree. Though we include generation of the syntactic structure in our model, we would not expect that this syntactic component would result in an accurate syntactic model, even if trained in a supervised way, as the chosen independence assumptions are oversimplistic. In this way, we can use a simple generative story and build on top of the recent success in syntactic parsing.

3 Relation to the MLN Approach

The work of (Poon and Domingos, 2009) models joint probability of the dependency tree and its latent semantic representation using Markov Logic Networks (MLNs) (Richardson and Domingos, 2006), selecting parameters (weights of first-order clauses) to maximize the probability of the observed dependency structures. For each sentence, the MLN induces a Markov network, an undirected graphical model with nodes corresponding to ground atoms and cliques corresponding to ground clauses.

The MLN is a powerful formalism and allows for modeling complex interaction between features of the input (syntactic trees) and latent output (semantic representation), however, unsupervised learning of semantics with general MLNs can be prohibitively expensive. The reason for this is that MLNs are undirected models and when learned to maximize likelihood of syntactically annotated sentences, they would require marginalization over semantic representation but also over the entire space of syntactic structures and lexical units. Given the complexity of the semantic parsing task and the need to tackle large datasets, even approximate methods are likely to be infeasible. In order to overcome this problem, (Poon and Domingos, 2009) group parameters and impose local normalization constraints within each group. Given these normalization constraints, and additional structural constraints satisfied by the model, namely that the clauses should be engineered in such a way that they induce tree-structured graphs for every sentence, the parameters can be estimated by a variant of the EM algorithm.

The class of such restricted MLNs is equivalent to the class of directed graphical models over the same set of random variables corresponding to fragments of syntactic and semantic structure. Given that the above constraints do not directly fit into the MLN methodology, we believe that it is more natural to regard their model as a directed model with an underlying generative story specifying how the semantic structure is generated and how the syntactic parse is drawn for this semantic structure. This view would facilitate understanding what kind of features can easily be integrated into the model, simplify application of non-parametric Bayesian techniques and expedite the use of inference techniques designed specifically for directed models. Our approach makes one step in this direction by proposing a non-parametric version of such generative model.

4 Hierarchical Pitman-Yor Processes

The central component of our non-parametric Bayesian model are Pitman-Yor (PY) processes, which are a generalization of the Dirichlet processes (DPs) (Ferguson, 1973). We use PY processes to model distributions of semantic classes appearing as an argument of other semantic classes. We also use them to model distributions of syntactic realizations for each semantic class and distributions of syntactic dependency arcs for argument types. In this section we present relevant background on PY processes. For a more detailed consideration we refer the reader to (Teh et al., 2006).

The Pitman-Yor process over a set S, denoted $PY(\alpha, \beta, H)$, is a stochastic process whose samples G_0 constitute probability measures on partitions of S. In practice, we do not need to draw measures, as they can be analytically marginalized out. The conditional distribution of x_{j+1} given the previous j draws, with G_0 marginalized out, follows (Black-

well and MacQueen, 1973)

$$x_{j+1}|x_1,\dots x_j \sim \sum_{k=1}^{K} \frac{j_k-\beta}{j+\alpha}\delta_{\phi_k} + \frac{K\beta+\alpha}{j+\alpha}H. \quad (1)$$

where $\phi_1,\dots,\phi_K$ are K values assigned to $x_1, x_2, \dots, x_j$. The number of times ϕ_k was assigned is denoted j_k, so that $j = \sum_{k=1}^{K} j_k$. The parameter $\beta < 1$ controls how heavy the tail of the distribution is: when it approaches 1, a new value is assigned to every draw, when $\beta = 0$ the PY process reduces to DP. The expected value of K scales as $O(\alpha n^{\beta})$ with the number of draws n, while it scales only logarithmically for DP processes. PY processes are expected to be more appropriate for many NLP problems, as they model power-law type distributions common for natural language (Teh, 2006).

Hierarchical Dirichlet Processes (HDP) or hierarchical PY processes are used if the goal is to draw several related probability measures for the same set S. For example, they can be used to generate transition distributions of a Markov model, HDP-HMM (Teh et al., 2006; Beal et al., 2002). For such a HMM, the top-level state proportions are drawn from the top-level stick breaking construction $\gamma \sim GEM(\alpha,\beta)$, and then the individual transition distributions for every state $z = 1, 2, \dots$ ϕ_z are drawn from $PY(\gamma,\alpha',\beta')$. The parameters α' and β' control how similar the individual transition distributions ϕ_z are to the top-level state proportions γ, or, equivalently, how similar the transition distributions are to each other.

5 A Model for Semantic Parsing

Our model of semantics associates with each semantic class a set of distributions which govern the generation of corresponding syntactic realizations[2] and the selection of semantic classes for its arguments. Each sentence is generated starting from the root of its dependency tree, recursively drawing a semantic class, its syntactic realization, arguments and semantic classes for the arguments. Below we describe the model by first defining the set of the model parameters and then explaining the generation of individual sentences. The generative story is formally presented in Figure 2.

We associate with each semantic class c, $c = 1, 2, \dots$, a distribution of its syntactic realizations ϕ_c. For example, for the frame `WinPrize` illustrated in Figure 1 this distribution would concentrate at syntactic fragments corresponding to lexical items *"defeated"*, *"secured the victory"* and *"won"*. The distribution is drawn from $DP(w^{(C)}, H^{(C)})$, where $H^{(C)}$ is a base measure over syntactic subtrees. We use a simple generative process to define the probability of a subtree, the underlying model is similar to the base measures used in the Bayesian tree-substitution grammars (Cohn et al., 2009). We start by generating a word w uniformly from the treebank distribution, then we decide on the number of dependents of w using the geometric distribution $Geom(q^{(C)})$. For every dependent we generate a dependency relation r and a lexical form w' from $P(r|w)P(w'|r)$, where probabilities P are based on add-0.1 smoothed treebank counts. The process is continued recursively. The smaller the parameter $q^{(C)}$, the lower is the probability assigned to larger sub-trees.

Parameters $\psi_{c,t}$ and $\psi^{+}_{c,t}$, $t = 1,\dots,T$, define a distribution over vectors $(m_1, m_2, \dots, m_T)$ where m_t is the number of times an argument of type t appears for a given semantic frame occurrence[3]. For the frame `WinPrize` these parameters would enforce that there exists exactly one `Winner` and exactly one `Opponent` for each occurrence of `WinPrize`. The parameter $\psi_{c,t}$ defines the probability of having at least one argument of type t. If 0 is drawn from $\psi_{c,t}$ then $m_t = 0$, otherwise the number of additional arguments of type t $(m_t - 1)$ is drawn from the geometric distribution $Geom(\psi^{+}_{c,t})$. This generative story is flexible enough to accommodate both argument types which appear at most once per semantic class occurrence (e.g., agents), and argument types which frequently appear multiple times per semantic class occurrence (e.g., arguments corresponding to descriptors).

Parameters $\phi_{c,t}$, $t = 1,\dots,T$, define the dis-

[2]Syntactic realizations are syntactic tree fragments, and therefore they correspond both to syntactic and lexical variations.

[3]For simplicity, we assume that each semantic class has T associated argument types, note that this is not a restrictive assumption as some of the argument types can remain unused, and T can be selected to be sufficiently large to accommodate all important arguments.

Parameters:

$\gamma \sim GEM(\alpha_0, \beta_0)$ [top-level proportions of classes]
$\theta_{root} \sim PY(\alpha_{root}, \beta_{root}, \gamma)$ [distrib of sem classes at root]
for each sem class $c = 1, 2, \ldots$:
  $\phi_c \sim DP(w^{(C)}, H^{(C)})$ [distribs of synt realizations]
  for each arg type $t = 1, 2, \ldots T$:
    $\psi_{c,t} \sim Beta(\eta_0, \eta_1)$ [first argument generation]
    $\psi^+_{c,t} \sim Beta(\eta^+_0, \eta^+_1)$ [geom distr for more args]
    $\phi_{c,t} \sim DP(w^{(A)}, H^{(A)})$ [distribs of synt paths]
    $\theta_{c,t} \sim PY(\alpha, \beta, \gamma)$ [distrib of arg fillers]

Data Generation:

for each sentence:
  $c_{root} \sim \theta_{root}$ [choose sem class for root]
  GenSemClass(c_{root})

GenSemClass(c):
  $s \sim \phi_c$ [draw synt realization]
  for each arg type $t = 1, \ldots, T$:
    if $[n \sim \psi_{c,t}] = 1$: [at least one arg appears]
      GenArgument(c, t) [draw one arg]
      while $[n \sim \psi^+_{c,t}] = 1$: [continue generation]
        GenArgument(c, t) [draw more args]

GenArgument(c, t):
  $a_{c,t} \sim \phi_{c,t}$ [draw synt relation]
  $c'_{c,t} \sim \theta_{c,t}$ [draw sem class for arg]
  GenSemClass($c'_{c,t}$) [recurse]

Figure 2: The generative story for the Bayesian model for unsupervised semantic parsing.

tributions over syntactic paths for the argument type t. In our example, for argument type `Opponent`, this distribution would associate most of the probability mass with relations *pp_over*, *dobj* and *pp_against*. These distributions are drawn from $DP(w^{(A)}, H^{(A)})$. In this paper we only consider paths consisting of a single relation, therefore the base probability distribution $H^{(A)}$ is just normalized frequencies of dependency relations in the treebank.

The crucial part of the model are the selection-preference parameters $\theta_{c,t}$, the distributions of semantic classes c' for each argument type t of class c. For arguments `Winner` and `Opponent` of the frame `WinPrize` these distributions would assign most of the probability mass to semantic classes denoting teams or players. Distributions $\theta_{c,t}$ are drawn from a hierarchical PY process: first, top-level proportions of classes γ are drawn from $GEM(\alpha_0, \beta_0)$, and then the individual distributions $\theta_{c,t}$ over c' are chosen from $PY(\alpha, \beta, \gamma)$.

For each sentence, we first generate a class corresponding to the root of the dependency tree from the root-specific distribution of semantic classes θ_{root}. Then we recursively generate classes for the entire sentence. For a class c, we generate the syntactic realization s and for each of the T types, decide how many arguments of that type to generate (see **GenSemClass** in Figure 2). Then we generate each of the arguments (see **GenArgument**) by first generating a syntactic arc $a_{c,t}$, choosing a class as its filler $c'_{c,t}$ and, finally, recursing.

6 Inference

In our model, latent states, modeled with hierarchical PY processes, correspond to distinct semantic classes and, therefore, their number is expected to be very large for any reasonable model of semantics. As a result, many standard inference techniques, such as Gibbs sampling, or the structured mean-field method are unlikely to result in tractable inference. One of the standard and most efficient samplers for non-hierarchical PY processes are split-merge MH samplers (Jain and Neal, 2000; Dahl, 2003). In this section we explain how split-merge samplers can be applied to our model.

6.1 Split and Merge Moves

On each move, split-merge samplers decide either to merge two states into one (in our case, merge two semantic classes), or split one state into two. These moves can be computed efficiently for our model of semantics. Note that for any reasonable model of semantics only a small subset of the entire set of semantic classes can be used as an argument for some fixed semantic class due to selectional preferences exhibited by predicates. For instance, only teams or players can fill arguments of the frame `WinPrize` in our running example. As a result, only a small number of terms in the joint distribution has to be evaluated on every move we may consider.

When estimating the model, we start with assigning each distinct word (or, more precisely, a tuple of a word's stem and its part-of-speech tag) to an individual semantic class. Then, we would iterate by selecting a random pair of class occurrences, and decide, at random, whether we attempt to perform a split-merge move or a compose-decompose move.

6.2 Compose and Decompose Moves

The compose-decompose operations modify syntactic fragments assigned to semantic classes, composing two neighboring dependency sub-trees or decomposing a dependency sub-tree. If the two randomly-selected syntactic fragments s and s' correspond to different classes, c and c', we attempt to compose them into $\hat{s}$ and create a new semantic class $\hat{c}$. All occurrences of $\hat{s}$ are assigned to this new class $\hat{c}$. For example, if two randomly-selected occurrences have syntactic realizations *"secure"* and *"victory"* they can be composed to obtain the syntactic fragment *"secure* $\xrightarrow{dobj}$ *victory"*. This fragment will be assigned to a new semantic class which can later be merged with other classes, such as the ones containing syntactic realizations *"defeat"* or *"win"*.

Conversely, if both randomly-selected syntactic fragments are already composed in the corresponding class, we attempt to split them.

6.3 Role-Syntax Alignment Move

Merge, compose and decompose moves require recomputation of mapping between argument types (semantic roles) and syntactic fragments. Computing the best statistical mapping is infeasible and proposing a random mapping will result in many attempted moves being rejected. Instead we use a greedy randomized search method called *Gibbs scan* (Dahl, 2003). Though it is a part of the above 3 moves, this alignment move is also used on its own to induce semantic arguments for classes (frames) with a single syntactic realization.

The Gibbs scan procedure is also used during the split move to select one of the newly introduced classes for each considered syntactic fragment.

6.4 Informed Proposals

Since the number of classes is very large, selecting examples at random would result in a relatively low proportion of moves getting accepted, and, consequently, in a slow-mixing Markov chain. Instead of selecting both class occurrences uniformly, we select the first occurrence from a uniform distribution and then use a simple but effective proposal distribution for selecting the second class occurrence.

Let us denote the class corresponding to the first occurrence as c_1 and its syntactic realization as s_1 with a head word w_1. We begin by selecting uniformly randomly whether to attempt a compose-decompose or a split-merge move.

If we chose a compose-decompose move, we look for words (children) which can be attached below the syntactic fragment s_1. We use the normalized counts of these words conditioned on the parent s_1 to select the second word w_2. We then select a random occurrence of w_2; if it is a part of syntactic realization of c_1 then a decompose move is attempted. Otherwise, we try to compose the corresponding clusters together.

If we selected a split-merge move, we use a distribution based on the cosine similarity of lexical contexts of the words. The context is represented as a vector of counts of all pairs of the form (head word, dependency type) and (dependent, dependency type). So, instead of selecting a word occurrence uniformly, each occurrence of every word w_2 is weighted by its similarity to w_1, where the similarity is based on the cosine distance.

As the moves are dependent only on syntactic representations, all the proposal distributions can be computed once at the initialization stage.[4]

7 Empirical Evaluation

We induced a semantic representation over a collection of texts and evaluated it by answering questions about the knowledge contained in the corpus. We used the GENIA corpus (Kim et al., 2003), a dataset of 1999 biomedical abstracts, and a set of questions produced by (Poon and Domingos, 2009). A example question is shown in Figure 3.

All model hyperpriors were set to maximize the posterior, except for $w^{(A)}$ and $w^{(C)}$, which were set to $1.e-10$ and $1.e-35$, respectively. Inference was run for around 300,000 sampling iterations until the percentage of accepted split-merge moves became lower than 0.05%.

Let us examine some of the induced semantic classes (Table 1) before turning to the question answering task. Almost all of the clustered syntactic

[4]In order to minimize memory usage, we used frequency cut-off of 10. For split-merge moves, we select words based on the cosine distance if the distance is below 0.95 and sample the remaining words uniformly. This also reduces the required memory usage.

Class	Variations
1	motif, sequence, regulatory element, response element, element, dna sequence
2	donor, individual, subject
3	important, essential, critical
4	dose, concentration

11	antiserum, antibody, monoclonal antibody, ab, antisera, mab
12	tnfalpha, tnf-alpha, il-6, tnf

Table 1: Examples of the induced semantic classes.

realizations have a clear semantic connection. Cluster 6, for example, clusters lymphocytes with the exception of thymocyte, a type of cell which generates T cells. Cluster 8 contains verbs roughly corresponding to `Cause change of position on a scale` frame in FrameNet. Verbs in class 9 are used in the context of providing support for a finding or an action, and many of them are listed as evoking elements for the `Evidence` frame in FrameNet.

Argument types of the induced classes also show a tendency to correspond to semantic roles. For example, an argument type of class 2 is modeled as a distribution over two argument parts, *prep_of* and *prep_from*. The corresponding arguments define the origin of the cells (*transgenic mouse, smoker, volunteer, donor, . . .*).

We now turn to the QA task and compare our model (**USP-BAYES**) with the results of baselines considered in (Poon and Domingos, 2009). The first set of baselines looks for answers by attempting to match a verb and its argument in the question with the input text. The first version (**KW**) simply returns the rest of the sentence on the other side of the verb, while the second (**KW-SYN**) uses syntactic information to extract the subject or the object of the verb.

Other baselines are based on state-of-the-art relation extraction systems. When the extracted relation and one of the arguments match those in a given question, the second argument is returned as an answer. The systems include TextRunner (**TR**) (Banko et al., 2007), RESOLVER (**RS**) (Yates and Etzioni, 2009) and **DIRT** (Lin and Pantel, 2001). The **EXACT** versions of the methods return answers when they match the question argument exactly, and the **SUB** versions produce answers containing the question argument as a substring.

	Total	Correct	Accuracy
KW	150	67	45%
KW-SYN	87	67	77%
TR-EXACT	29	23	79%
TR-SUB	152	81	53%
RS-EXACT	53	24	45%
RS-SUB	196	81	41%
DIRT	159	94	59%
USP-MLN	334	295	88%
USP-BAYES	325	259	80%

Table 2: Performance on the QA task.

Similarly to the MLN system (**USP-MLN**), we generate answers as follows. We use our trained model to parse a question, i.e. recursively decompose it into lexical items and assign them to semantic classes induced at training. Using this semantic representation, we look for the type of an argument missing in the question, which, if found, is reported as an answer. It is clear that overly coarse clusters of argument fillers or clustering of semantically related but not equivalent relations can hurt precision for this evaluation method.

Each system is evaluated by counting the answers it generates, and computing the accuracy of those answers.[5] Table 2 summarizes the results. First, both USP models significantly outperform all other baselines: even though the accuracy of KW-SYN and TR-EXACT are comparable with our accuracy, the number of correct answers returned by USP-Bayes is 4 and 11 times smaller than those of KW-SYN and TR-EXACT, respectively. While we are not beating the MLN baseline, the difference is not significant. The effective number of questions is relatively small (less than 80 different questions are answered by any of the models). More than 50% of USP-BAYES mistakes were due to wrong interpretation of only 5 different questions. From another point of view, most of the mistakes are explained

[5]The true recall is not known, as computing it would require exhaustive annotation of the entire corpus.

Question: *What does cyclosporin A suppress?*
Answer: *expression of EGR-2*
Sentence: *As with EGR-3 , expression of EGR-2 was blocked by cyclosporin A .*

Question: *What inhibits tnf-alpha?*
Answer: *IL -10*
Sentence: *Our previous studies in human monocytes have demonstrated that interleukin (IL) -10 inhibits lipopolysaccharide (LPS) -stimulated production of inflammatory cytokines , IL-1 beta , IL-6 , IL-8 , and tumor necrosis factor (TNF) -alpha by blocking gene transcription .*

Figure 3: An example of questions, answers by our model and the corresponding sentences from the dataset.

by overly coarse clustering corresponding to just 3 classes, namely, 30%, 25% and 20% of errors are due to the clusters 6, 8 and 12 (Figure 1), respectively. Though all these clusters have clear semantic interpretation (white blood cells, predicates corresponding to changes and cykotines associated with cancer progression, respectively), they appear to be too coarse for the QA method we use in our experiments. Though it is likely that tuning and different heuristics may result in better scores, we chose not to perform excessive tuning, as the evaluation dataset is fairly small.

8 Related Work

There is a growing body of work on statistical learning for different versions of the semantic parsing problem (e.g., (Gildea and Jurafsky, 2002; Zettlemoyer and Collins, 2005; Ge and Mooney, 2005; Mooney, 2007)), however, most of these methods rely on human annotation, or some weaker forms of supervision (Kate and Mooney, 2007; Liang et al., 2009; Titov and Kozhevnikov, 2010; Clarke et al., 2010) and very little research has considered the unsupervised setting.

In addition to the MLN model (Poon and Domingos, 2009), another unsupervised method has been proposed in (Goldwasser et al., 2011). In that work, the task is to predict a logical formula, and the only supervision used is a lexicon providing a small number of examples for every logical symbol. A form of self-training is then used to bootstrap the model.

Unsupervised semantic role labeling with a generative model has also been considered (Grenager and Manning, 2006), however, they do not attempt to discover frames and deal only with isolated predicates. Another generative model for SRL has been proposed in (Thompson et al., 2003), but the parameters were estimated from fully annotated data.

The unsupervised setting has also been considering for the related problem of learning narrative schemas (Chambers and Jurafsky, 2009). However, their approach is quite different from our Bayesian model as it relies on similarity functions.

Though in this work we focus solely on the unsupervised setting, there has been some successful work on semi-supervised semantic-role labeling, including the Framenet version of the problem (Fürstenau and Lapata, 2009). Their method exploits graph alignments between labeled and unlabeled examples, and, therefore, crucially relies on the availability of labeled examples.

9 Conclusions and Future Work

In this work, we introduced a non-parametric Bayesian model for the semantic parsing problem based on the hierarchical Pitman-Yor process. The model defines a generative story for recursive generation of lexical items, syntactic and semantic structures. We extend the split-merge MH sampling algorithm to include composition-decomposition moves, and exploit the properties of our task to make it efficient in the hierarchical setting we consider.

We plan to explore at least two directions in our future work. First, we would like to relax some of unrealistic assumptions made in our model: for example, proper modeling of alterations requires joint generation of syntactic realizations for predicate-argument relations (Grenager and Manning, 2006; Lang and Lapata, 2010), similarly, proper modeling of nominalization implies support of arguments not immediately local in the syntactic structure. The second general direction is the use of the unsupervised methods we propose to expand the coverage of existing semantic resources, which typically require substantial human effort to produce.

Abstract

This paper presents an unsupervised method for deriving inference axioms by composing semantic relations. The method is independent of any particular relation inventory. It relies on describing semantic relations using primitives and manipulating these primitives according to an algebra. The method was tested using a set of eight semantic relations yielding 78 inference axioms which were evaluated over PropBank.

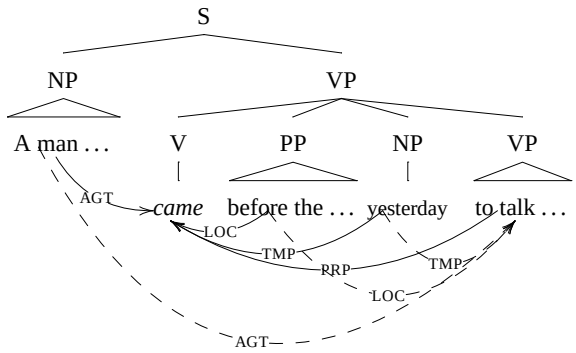

Figure 1: Semantic representation of *A man from the Bush administration came before the House Agricultural Committee yesterday to talk about* ... (wsj_0134, 0).

1 Introduction

Capturing the meaning of text is a long term goal within the NLP community. Whereas during the last decade the field has seen syntactic parsers mature and achieve high performance, the progress in semantics has been more modest. Previous research has mostly focused on relations between particular kind of arguments, e.g., semantic roles, noun compounds. Notwithstanding their significance, they target a fairly narrow text semantics compared to the broad semantics encoded in text.

Consider the sentence in Figure 1. Semantic role labelers exclusively detect the relations indicated with solid arrows, which correspond to the sentence syntactic dependencies. On top of those roles, there are at least three more relations (discontinuous arrows) that encode semantics other than the verb-argument relations.

In this paper, we venture beyond semantic relation extraction from text and investigate techniques to compose them. We explore the idea of inferring a new relation linking the ends of a chain of relations. This scheme, informally used previously for combining HYPERNYM with other relations, has not been studied for arbitrary pairs of relations.

For example, it seems adequate to state the following: if *x* is PART-OF *y* and *y* is HYPERNYM of *z*, then *x* is PART-OF *z*. An inference using this rule can be obtained instantiating *x*, *y* and *z* with *engine*, *car* and *convertible*. Going a step further, we consider nonobvious inferences involving AGENT, PURPOSE and other semantic relations.

The novelties of this paper are twofold. First, an extended definition for semantic relations is proposed, including (1) semantic restrictions for their domains and ranges, and (2) semantic primitives.

Second, an algorithm for obtaining inference axioms is described. Axioms take as their premises chains of two relations and output a new relation linking the ends of the chain. This adds an extra layer of semantics on top of previously extracted re-

lations. The conclusion of an axiom is identified using an algebra for composing semantic primitives.

We name this framework Composition of Semantic Relations (CSR). The extended definition, set of primitives, algebra to compose primitives and CSR algorithm are independent of any particular set of relations. We first presented CSR and used it over PropBank in (Blanco and Moldovan, 2011). In this paper, we extend that work using a different set of primitives and relations. Seventy eight inference axioms are obtained and an empirical evaluation shows that inferred relations have high accuracies.

2 Semantic Relations

Semantic relations are underlying relations between concepts. In general, they are defined by a textual definition accompanied by a few examples. For example, Chklovski and Pantel (2004) loosely define ENABLEMENT as a relation that holds between two verbs V_1 and V_2 when the pair can be glossed as *V_1 is accomplished by V_2* and gives two examples: *assess::review* and *accomplish::complete*.

We find this widespread kind of definition weak and prone to confusion. Following (Helbig, 2005), we propose an extended definition for semantic relations, including semantic restrictions for its arguments. For example, AGENT(*x*, *y*) holds between an animate concrete object *x* and a situation *y*.

Moreover, we propose to characterize relations by *semantic primitives*. Primitives indicate whether a property holds between the arguments of a relation, e.g., the primitive *temporal* indicates if the first argument must happen before the second.

Besides having a better understanding of each relation, this extended definition allows us to identify possible and not possible combinations of relations, as well as to automatically determine the conclusion of composing a possible combination.

Formally, for a relation R(*x*, *y*), the extended definitions specifies: (a) DOMAIN(R) and RANGE(R) (i.e., semantic restrictions for *x* and *y*); and (b) P_{R} (i.e., values for the primitives). The inverse relation R^{-1} can be obtained by switching domain and range, and defining $P_{\text{R}^{-1}}$ as depicted in Table 1.

2.1 Semantic Primitives

Semantic primitives capture deep characteristics of relations. They are independently determinable for each relation and specify a property between an element of the domain and an element of the range of the relation being described (Huhns and Stephens, 1989). Primitives are fundamental, they cannot be explained using other primitives.

For each primitive, each relation takes a value from the set $V = \{+, -, 0\}$. '+' indicates that the primitive holds, '$-$' that it does not hold, and '0' that it does not apply. Since a cause must precede its effect, we have $P^{temporal}_{\text{CAUSE}} = +$.

Primitives complement the definition of a relation and completely characterize it. Coupled with domain and range restrictions, primitives allow us to automatically manipulate and reason over relations.

Table 2: Algebra for composing semantic primitives.

The set of primitives used in this paper (Table 1) is heavily based on previous work in Knowledge Bases (Huhns and Stephens, 1989), but we considered some new primitives. The new primitives are justified by the fact that we aim at composing relations capturing the semantics from natural language. Whatever the set of relations, it will describe the characteristics of events (who / what / where / when / why / how) and connections between them (e.g., CAUSE, CORRELATION). Time, space and volition also play an important role. The third column in Table 1 indicates the value of the primitive for the inverse relation: *id.* means it takes the same; *op.* the opposite. The opposite of $-$ is $+$, the opposite of $+$ is $-$, and the opposite of 0 is 0.

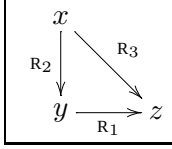
2.1.1 An Algebra for Composing Semantic Primitives

The key to automatically obtain inference axioms is the ability to know the result of composing primitives. Given $P^i_{R_1}$ and $P^i_{R_2}$, i.e., the values of the ith primitive for R_1 and R_2, we define an algebra for $P^i_{R_1} \circ P^i_{R_2}$, i.e., the result of composing them. Table 2 depicts the algebra for all primitives. An '$\times$' means that the composition is prohibited.

Consider, for example, the Intrinsic primitive: if both relations are *intrinsic* ($+$), the composition is *intrinsic* ($+$); else if *intrinsic* does not apply to either relation (0), the primitive does not apply to the composition either (0); else the composition is not *intrinsic* ($-$).

3 Inference Axioms

Semantic relations are composed using inference axioms. An axiom is defined by using the composition operator '$\circ$'; it combines two relations called *premises* and yields a *conclusion*. We denote an axiom as $R_1(x, y) \circ R_2(y, z) \rightarrow R_3(x, z)$, where R_1 and R_2 are the premises and R_3 the conclusion. In order to instantiate an axiom, the premises must form a chain by having argument *y* in common.

$R_1 \circ R_2$	${R_1}^{-1} \circ R_2$
	$R_2 \circ R_1$	$R_2 \circ {R_1}^{-1}$
	


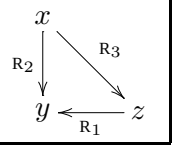


Table 3: The four unique possible axioms taking as premises R_1 and R_2. Conclusions are indicated by R_3 and are not guaranteed to be the same for the four axioms.

In general, for n relations there are $\binom{n}{2}$ pairs. For each pair, taking into account inverse relations, there are 16 possible combinations. Applying property $R_i \circ R_j = ({R_j}^{-1} \circ {R_i}^{-1})^{-1}$, only 10 are unique: (a) 4 combine R_1, R_2 and their inverses (Table 3); (b) 3 combine R_1 and ${R_1}^{-1}$; and (c) 3 combine R_2 and ${R_2}^{-1}$. The most interesting axioms fall into category (a) and there are $\binom{n}{2} \times 4 + 3n = 2 \times n(n-1) + 3n = 2n^2 + n$ potential axioms in this category.

Depending on n, the number of potential axioms to consider can be significantly large. For $n = 20$, there are 820 axioms to explore and for $n = 30$, 1,830. Manual examination of those potential ax-

Table 4: Extended definition for the set of relations.

ioms would be time-consuming and prone to errors. We avoid this by using the extended definition and the algebra for composing primitives.

3.1 Necessary Conditions for Composing Semantic Relations

There are two necessary conditions for composing R_1 and R_2:

- They have to be compatible. A pair of relations is compatible if it is possible, from a theoretical point of view, to compose them.
  Formally, R_1 and R_2 are compatible iff $\text{RANGE}(R_1) \cap \text{DOMAIN}(R_2) \neq \emptyset$.
- A third relation R_3 must match as conclusion, i.e., $\exists R_3$ such that $\text{DOMAIN}(R_3) \cap \text{DOMAIN}(R_1) \neq \emptyset$ and $\text{RANGE}(R_3) \cap \text{RANGE}(R_2) \neq \emptyset$. Furthermore, P_{R_3} must be consistent with $P_{R_1} \circ P_{R_2}$.

3.2 CSR: An Algorithm for Composing Semantic Relations

Consider any set of relations R defined using the extended definition. One can obtain inference axioms using the following algorithm:

For $(R_1, R_2) \in R \times R$:
  For $(R_i, R_j) \in [(R_1, R_2), (R_1{}^{-1}, R_2), (R_2, R_1), (R_2, R_1{}^{-1})]$:

1. **Domain and range compatibility**
   If $\text{RANGE}(R_i) \cap \text{DOMAIN}(R_j) = \emptyset$, **break**
2. **Conclusion match**
   Repeat for $R_3 \in possible\_conc(R, R_i, R_j)$:
   (a) **If** $\text{DOMAIN}(R_3) \cap \text{DOMAIN}(R_i) = \emptyset$ **or** $\text{RANGE}(R_3) \cap \text{RANGE}(R_j) = \emptyset$**, break**
   (b) **If** $consistent(P_{R_3}, P_{R_i} \circ P_{R_j})$**,**
   $axioms$ += $R_i(x, y) \circ R_j(y, z) \rightarrow R_3(x, z)$

Given R, R^{-1} can be automatically obtained (Section 2). $Possible\_conc(R, R_i, R_j)$ returns the set R unless R_i (R_j) is universal ($P^9 = +$), in which case it returns R_j (R_i). $Consistent(P_{R_1}, P_{R_2})$ is a simple procedure that compares the values assigned to each primitive; two values are consistent unless they have different opposite values or any of them is '$\times$' (i.e., the composition is prohibited).

3.3 An Example: Agent and Purpose

We present an example of applying the CSR algorithm by inspecting the potential axiom AGENT(*x*, *y*) $\circ$ PURPOSE^{-1}(*y*, *z*) $\rightarrow$ R_3(*x*, *z*), where *x* is the agent of *y*, and action *y* has as its purpose *z*. A statement instantiating the premises is *[Mary]$_x$ [came]$_y$ to [talk]$_z$ about the issue*. Knowing AGENT(*Mary*, *came*) and PURPOSE^{-1}(*came*, *talk*), our goal is to identify the links R_3(*Mary*, *talk*), if any.

We use the relations as defined in Table 4. First, we note that both AGENT and PURPOSE^{-1} are compatible (Step 1). Second, we must identify the possible conclusions R_3 that fit as conclusions (Step 2).

Given P_{AGENT} and $P_{\text{PURPOSE}^{-1}}$, we obtain $P_{\text{AGENT}} \circ P_{\text{PURPOSE}^{-1}}$ using the algebra:

$$P_{\text{AGENT}} = \{+,+,-,+,\ 0,-,-,+,-,0,\ 0\}$$
$$P_{\text{PURPOSE}^{-1}} = \{+,-,-,+,+,-,-,-,-,0,+\}$$
$$P_{\text{AGENT}} \circ P_{\text{PURPOSE}^{-1}} = \{+,+,-,+,+,-,-,+,-,0,+\}$$

Out of all relations (Section 4), AGENT and INTENT^{-1} fit the conclusion match. First, their domains and ranges are compatible with the composition (Step 2a). Second, both P_{AGENT} and $P_{\text{INTENT}^{-1}}$ are consistent with $P_{\text{AGENT}} \circ P_{\text{PURPOSE}^{-1}}$ (Step 2b). Thus, we obtain the following axioms: AGENT(*x*, *y*) $\circ$ PURPOSE^{-1}(*y*, *z*) $\rightarrow$ AGENT(*x*, *z*) and AGENT(*x*, *y*) $\circ$ PURPOSE^{-1}(*y*, *z*) $\rightarrow$ INTENT^{-1}(*x*, *z*).

Instantiating the axioms over *[Mary]$_x$ [came]$_y$ to [talk]$_z$ about the issue* yields AGENT(*Mary*, *talk*) and INTENT^{-1}(*Mary*, *talk*). Namely, the axioms

R_1 \ R_2	a	b	c	d	e	f	g	h
a	a	:	:		-	f	g	a
b				-		f	g	b
c	:	b	c	-	e	f	g	c

f						-		f
g							-	g
h	a^{-1}	b^{-1}	c^{-1}	d^{-1}	e^{-1}	f^{-1}	g^{-1}	h,h^{-1}

Table 5: Inference axioms automatically obtained using the relations from Table 4. A letter indicates an axiom $R_1 \circ R_2 \rightarrow R_3$ by indicating R_3. An empty cell indicates that R_1 and R_2 do not have compatible domains and ranges; ':' that the composition is prohibited; and '-' that a relation R_3 such that P_{R_3} is consistent with $P_{R_1} \circ P_{R_2}$ could not be found.

yield *Mary is the agent of talking*, and *she has the intention of talking*. These two relations are valid but most probably ignored by a role labeler since *Mary* is not an argument of *talk*.

4 Case Study

In this Section, we apply the CSR algorithm over a set of eight well-known relations. It is out of the scope of this paper to explain in detail the semantics of each relation or their detection. Our goal is to obtain inference axioms and, taking for granted that annotation is available, evaluate their accuracy.

The only requirement for the CSR algorithm is to define semantic relations using the extended definition (Table 4). To define domains and ranges, we use the ontology in Section 4.2. Values for the primitives are assigned manually. The meaning of each relations is as follows:

- CAU(*x*, *y*) encodes a relation between two situations, where the existence of *y* is due to the previous existence of *x*, e.g., *He [got]$_y$ a bad grade because he [didn't submit]$_x$ the project*.
- INT(*x*, *y*) links an animate concrete object and the situations he wants to become true, e.g., *[Mary]$_y$ would like to [grow]$_x$ bonsais*.
- PRP(*x*, *y*) holds between a concept *y* and its main goal *x*. Purposes can be defined for situations, e.g., *[pruning]$_y$ allows new [growth]$_x$*; concrete objects, e.g., *the [garage]$_y$ is used for [storage]$_x$*; or abstract objects, e.g., *[language]$_y$ is used to [communicate]$_x$*.
- AGT(*x*, *y*) links a situation *y* and its intentional doer *x*, e.g., *[Mary]$_x$ [went]$_y$ to Paris*. *x* is restricted to animate concrete objects.
- MNR(*x*, *y*) holds between the mode, way, style or fashion *x* in which a situation *y* happened. *x* can be a state, e.g., *[walking]$_y$ [holding]$_x$ hands*; abstract objects, e.g., *[die]$_y$ [with pain]$_x$*; or qualities, e.g. *[fast]$_x$ [delivery]$_y$*.
- AT-L(*x*, *y*) defines the spatial context *y* of an object or situation *x*, e.g., *He [went]$_x$ [to Cancun]$_y$*, *[The car]$_x$ is [in the garage]$_y$*.
- AT-T(*x*, *y*) links an object or situation *x*, with its temporal information *y*, e.g., *He [went]$_x$ [yesterday]$_y$*, *[20th century]$_y$ [sculptures]$_x$*.
- SYN(*x*, *y*) can be defined between any two entities and holds when both arguments are semantically equivalent, e.g., SYN(*dozen*, *twelve*).

4.1 Inference Axioms Automatically Obtained

After applying the CSR algorithm over the relations in Table 4, we obtain 78 unique inference axioms (Table 5). Each sub table must be indexed with the first and second premises as row and column respectively. The table on the left summarizes axioms $R_1 \circ R_2 \rightarrow R_3$ and $R_2 \circ R_1 \rightarrow R_3$, the one in the middle axiom ${R_1}^{-1} \circ R_2 \rightarrow R_3$ and the one on the right axiom $R_2 \circ {R_1}^{-1} \rightarrow R_3$.

The CSR algorithm identifies several correct axioms and accurately marks as prohibited several combinations that would lead to wrong inferences:

- For CAUSE, the inherent transitivity is detected ($a \circ a \rightarrow a$). Also, no relation is inferred between two different effects of the same cause ($a^{-1} \circ a \rightarrow :$) and between two causes of the same effect ($a \circ a^{-1} \rightarrow :$).
- The location and temporal information of concept *y* is inherited by its cause, intention, purpose, agent and manner (sub table on the left, *f* and *g* columns).

- As expected, axioms involving SYNONYMY as one of their premises yield the other premise as their conclusion (all sub tables).
- The AGENT of *y* is inherited by its causes, purposes and manners (*d* row, sub table on the right). In all examples below, AGT(*x*, *y*) holds, and we infer AGT(*x*, *z*) after composing it with R_2: (1) *[He]$_x$ [went]$_y$ after [reading]$_z$ a good review*, R_2: CAU^{-1}(*y*, *z*); (2) *[They]$_x$ [went]$_y$ to [talk]$_z$ about it*, R_2: PRP^{-1}(*y*, *z*); and (3) *[They]$_x$ [were walking]$_y$ [holding]$_z$ hands*, R_2: MNR^{-1}(*y*, *z*)
  An AGENT for a situation *y* is also inherited by its effects, and the situations that have *y* as their manner or purpose (*d* row, sub table on the left).
- A concept intends the effects of its intentions and purposes ($b^{-1} \circ a \rightarrow b^{-1}$, $c^{-1} \circ a \rightarrow b^{-1}$). For example, *[I]$_x$ printed the document to [read]$_y$ and [learn]$_z$ the contents*; INT^{-1}(*I, read*) $\circ$ CAU(*read, learn*) $\rightarrow$ INT^{-1}(*I, learn*).

It is important to note that domain and range restrictions are not sufficient to identify inference axioms; they only filter out pairs of not compatible relations. The algebra to compose primitives is used to detect prohibited combinations of relations based on semantic grounds and identify the conclusion of composing them. Without primitives, the cells in Table 5 would be either empty (marking the pair as not compatible) or would simply indicate that the pair has compatible domain and range (without identifying the conclusion).

Table 5 summarizes 136 unique pairs of premises (recall $R_i \circ R_j = ({R_j}^{-1} \circ {R_i}^{-1})^{-1}$). Domain and range restrictions mark 39 (28.7%) as not compatible. The algebra labels 12 pairs as prohibited (8.8%, [12.4% of the compatible pairs]) and is unable to find a conclusion 14 times (10.3%, [14.4%]). Finally, conclusions are found for 71 pairs (52.2%, [73.2%]). Since more than one conclusion might be detected for the same pair of premises, 78 inference axioms are ultimately identified.

4.2 Ontology

In order to define domains and ranges, we use a simplified version of the ontology presented in (Helbig, 2005). We find enough to contemplate only seven base classes: ev, st, co, aco, ao, loc and tmp. Entities (ent) refer to any concept and are divided into situations (si), objects (o) and descriptors (des).

- Situations are anything that happens at a time and place and are divided into events (ev) and states (st). Events imply a change in the status of other entities (e.g., *grow*, *conference*); states do not (e.g., *be standing*, *account for 10%*).
- Objects can be either concrete (co, palpable, tangible, e.g., *table*, *keyboard*) or abstract (ao, intangible, product of human reasoning, e.g., *disease*, *weight*). Concrete objects can be further classified as animate (aco) if they have life, vigor or spirit (e.g. *John*, *cat*).
- Descriptors state properties about the local (loc, e.g., *by the table*, *in the box*) or temporal (tmp, e.g., *yesterday*, *last month*) context of an entity.

This simplified ontology does not aim at defining domains and ranges for any relation set; it is a simplification to fit the eight relations we work with.

5 Evaluation

An evaluation was performed to estimate the validity of the 78 axioms. Because the number of axioms is large we have focused on a subset of them (Table 6). The 31 axioms having SYN as premise are intuitively correct: since synonymous concepts are interchangeable, given veracious annotation they perform valid inferences.

We use PropBank annotation (Palmer et al., 2005) to instantiate the premises of each axiom. First, all instantiations of axiom PRP $\circ$ $MNR^{-1} \rightarrow MNR^{-1}$ were manually checked. This axiom yields 237 new MANNER, 189 of which are valid (Accuracy 0.80).

Second, we evaluated axioms 1–7 (Table 6). Since PropBank is a large corpus, we restricted this phase to the first 1,000 sentences in which there is an instantiation of any axiom. These sentences contain 1,412 instantiations and are found in the first 31,450 sentences of PropBank.

Table 6 depicts the total number of instantiations for each axiom and its accuracy (columns 3 and 4). Accuracies range from 0.40 to 0.90, showing that the plausibility of an axiom depends on the axiom. The average accuracy for axioms involving CAU is 0.54 and for axioms involving PRP is 0.87.

Axiom CAU $\circ$ $AGT^{-1} \rightarrow AGT^{-1}$ adds 201 relations, which corresponds to 0.89% in relative terms. Its accuracy is low, 0.40. Other axioms are less productive but have a greater relative impact and accu-

No.	Axiom	no heuristic			with heuristic		
		No. Inst.	Acc.	Produc.	No. Inst.	Acc.	Produc.
1	CAU $\circ$ AGT^{-1} $\rightarrow$ AGT^{-1}	201	0.40	0.89%	75	0.67	0.33%
2	CAU $\circ$ AT-L $\rightarrow$ AT-L	17	0.82	0.84%	15	0.93	0.74%
3	CAU $\circ$ AT-T $\rightarrow$ AT-T	72	0.85	1.25%	69	0.87	1.20%
1–3	CAU $\circ$ R$_2$ $\rightarrow$ R$_3$	290	0.54	0.96%	159	0.78	0.52%
4	PRP $\circ$ AGT^{-1} $\rightarrow$ AGT^{-1}	375	0.89	1.66%	347	0.94	1.54%
5	PRP $\circ$ AT-L $\rightarrow$ AT-L	49	0.90	2.42%	48	0.92	2.37%
6	PRP $\circ$ AT-T $\rightarrow$ AT-T	138	0.84	2.40%	129	0.88	2.25%
7	PRP $\circ$ MNR^{-1} $\rightarrow$ MNR^{-1}	71	0.82	3.21%	70	0.83	3.16%
4–7	PRP $\circ$ R$_2$ $\rightarrow$ R$_3$	633	0.87	1.95%	594	0.91	1.83%
1–7	**All**	923	0.77	2.84%	**753**	**0.88**	**2.32%**

Table 6: Axioms used for evaluation, number of instances, accuracy and productivity (i.e., percentage of relations added on top the ones already present). Results are reported with and without the heuristic.

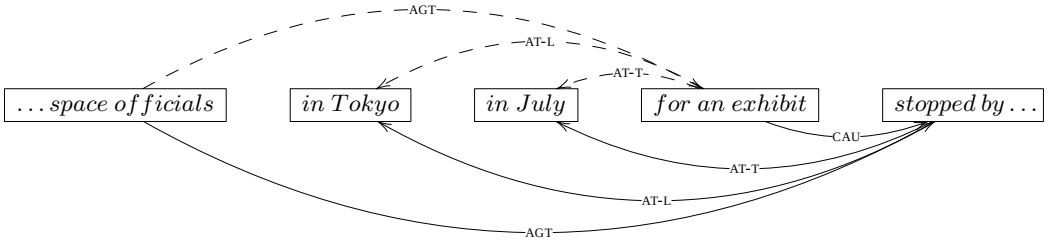

Figure 2: Basic (solid arrows) and inferred relations (discontinuous) from *A half-dozen Soviet space officials, in Tokyo in July for an exhibit, stopped by to see their counterparts at the National* ... (wsj_0405, 1).

racy. For example, axiom PRP $\circ$ MNR^{-1} $\rightarrow$ MNR^{-1}, only yields 71 new MNR, and yet it is adding 3.21% in relative terms with an accuracy of 0.82.

Overall, applying the seven axioms adds 923 relations on top of the ones already present (2.84% in relative terms) with an accuracy of 0.77. Figure 2 shows examples of inferences using axioms 1–3.

5.1 Error Analysis

Because of the low accuracy of axiom 1, an error analysis was performed. We found that unlike other axioms, this axiom often yield a relation type that is already present in the semantic representation. Specifically, it often yields R(*x, z*) when R(*x', z*) is already known. We use the following heuristic in order to improve accuracy: *do not instantiate an axiom* R$_1$*(x, y)* $\circ$ R$_2$*(y, z)* $\rightarrow$ R$_3$*(x, z) if a relation of the form* R$_3$*(x', z) is already known.*

This simple heuristic has increased the accuracy of the inferences at the cost of lowering their productivity. The last three columns in Table 6 show results when using the heuristic.

6 Comparison with Previous Work

There have been many proposals to detect semantic relations from text without composition. Researches have targeted particular relations (e.g., CAUSE (Chang and Choi, 2006; Bethard and Martin, 2008)), relations within noun phrases (Nulty, 2007), named entities (Hirano et al., 2007) or clauses (Szpakowicz et al., 1995). Competitions include (Litkowski, 2004; Carreras and Màrquez, 2005; Girju et al., 2007; Hendrickx et al., 2009).

Two recent efforts (Ruppenhofer et al., 2009; Gerber and Chai, 2010) are similar to CSR in their goal (i.e., extract meaning ignored by current semantic parsers), but completely differ in their means. Their merit relies on annotating and extracting semantic connections not originally contemplated (e.g., between concepts from two different sentences) using an already known and fixed relation set. Unlike CSR, they are dependent on the relation inventory, require annotation and do not reason or manipulate relations. In contrast to all the above references and the state of the art, the proposed framework obtains axioms that take as input semantic relations pro-

duced by others and output more relations: it adds an extra layer of semantics previously ignored.

Previous research has exploited the idea of using semantic primitives to define and classify semantic relations under the names of *relation elements*, *deep structure*, *aspects* and *primitives*. The first attempt on describing semantic relations using primitives was made by Chaffin and Herrmann (1987); they differentiate 31 relations using 30 *relation elements* clustered into five groups (intensional force, dimension, agreement, propositional and part-whole inclusion). Winston et al. (1987) introduce 3 *relation elements* (functional, homeomerous and separable) to distinguish six subtypes of PART-WHOLE. Cohen and Losielle (1988) use the notion of *deep structure* in contrast to the *surface relation* and utilizes two *aspects* (hierarchical and temporal). Huhns and Stephens (1989) consider a set of 10 *primitives*.

In theoretical linguistics, Wierzbicka (1996) introduced the notion of semantic primes to perform linguistic analysis. Dowty (2006) studies compositionality and identifies entailments associated with certain predicates and arguments (Dowty, 2001).

There has not been much work on composing relations in the field of computational linguistics. The term *compositional semantics* is used in conjunction with the principle of compositionality, i.e., the meaning of a complex expression is determined from the meanings of its parts, and the way in which those parts are combined. These approaches are usually formal and use a potentially infinite set of predicates to represent semantics. Ge and Mooney (2009) extracts semantic representations using syntactic structures while Copestake et al. (2001) develops algebras for semantic construction within grammars. Logic approaches include (Lakoff, 1970; Sánchez Valencia, 1991; MacCartney and Manning, 2009). Composition of Semantic Relations is complimentary to Compositional Semantics.

Previous research has manually extracted plausible inference axioms for WordNet relations (Harabagiu and Moldovan, 1998) and transformed chains of relations into theoretical axioms (Helbig, 2005). The CSR algorithm proposed here automatically obtains inference axioms.

Composing relations has been proposed before within knowledge bases. Cohen and Losielle (1988) combines a set of nine fairly specific relations (e.g., FOCUS-OF, PRODUCT-OF, SETTING-OF). The key to determine plausibility is the *transitivity characteristic* of the aspects: two relations shall not combine if they have contradictory values for any aspect. The first algebra to compose semantic primitives was proposed by Huhns and Stephens (1989). Their relations are not linguistically motivated and ten of them map to some sort of PART-WHOLE (e.g. PIECE-OF, SUBREGION-OF). Unlike (Cohen and Losielle, 1988; Huhns and Stephens, 1989), we use typical relations that encode the semantics of natural language, propose a method to automatically obtain the inverse of a relation and empirically test the validity of the axioms obtained.

7 Conclusions

Going beyond current research, in this paper we investigate the composition of semantic relations. The proposed CSR algorithm obtains inference axioms that take as their input semantic relations and output a relation previously ignored. Regardless of the set of relations and annotation scheme, an additional layer of semantics is created on top of the already existing relations.

An extended definition for semantic relations is proposed, including restrictions on their domains and ranges as well as values for semantic primitives. Primitives indicate if a certain property holds between the arguments of a relation. An algebra for composing semantic primitives is defined, allowing to automatically determine the primitives values for the composition of any two relations.

The CSR algorithm makes use of the extended definition and algebra to discover inference axioms in an unsupervised manner. Its usefulness is shown using a set of eight common relations, obtaining 78 axioms. Empirical evaluation shows the axioms add 2.32% of relations in relative terms with an overall accuracy of 0.88, more than what state-of-the-art semantic parsers achieve.

The framework presented is completely independent of any particular set of relations. Even though different sets may call for different ontologies and primitives, we believe the model is generally applicable; the only requirement is to use the extended definition. This is a novel way of retrieving semantic relations in the field of computational linguistics.

Abstract

Learning by Reading (LbR) aims at enabling machines to acquire knowledge from and reason about textual input. This requires knowledge about the domain structure (such as entities, classes, and actions) in order to do inference. We present a method to infer this implicit knowledge from unlabeled text. Unlike previous approaches, we use automatically extracted classes with a probability distribution over entities to allow for context-sensitive labeling. From a corpus of 1.4m sentences, we learn about 250k simple propositions about American football in the form of predicate-argument structures like "quarterbacks throw passes to receivers". Using several statistical measures, we show that our model is able to generalize and explain the data statistically significantly better than various baseline approaches. Human subjects judged up to 96.6% of the resulting propositions to be sensible. The classes and probabilistic model can be used in textual enrichment to improve the performance of LbR end-to-end systems.

1 Introduction

The goal of Learning by Reading (LbR) is to enable a computer to learn about a new domain and then to reason about it in order to perform such tasks as question answering, threat assessment, and explanation (Strassel et al., 2010). This requires joint efforts from Information Extraction, Knowledge Representation, and logical inference. All these steps depend on the system having access to basic, often unstated, foundational knowledge about the domain.

Most documents, however, do not explicitly mention this information in the text, but assume basic background knowledge about the domain, such as positions ("quarterback"), titles ("winner"), or actions ("throw") for sports game reports. Without this knowledge, the text will not make sense to the reader, despite being well-formed English. Luckily, the information is often implicitly contained in the document or can be inferred from similar texts.

Our system automatically acquires domain-specific knowledge (classes and actions) from large amounts of unlabeled data, and trains a probabilistic model to determine and apply the most informative classes (*quarterback*, etc.) at appropriate levels of generality for unseen data. E.g., from sentences such as "Steve Young threw a pass to Michael Holt", "Quarterback Steve Young finished strong", and "Michael Holt, the receiver, left early" we can learn the classes *quarterback* and *receiver*, and the proposition "*quarterbacks throw passes to receivers*".

We will thus assume that the implicit knowledge comes in two forms: actions in the form of predicate-argument structures, and classes as part of the source data. Our task is to identify and extract both. Since LbR systems must quickly adapt and scale well to new domains, we need to be able to work with large amounts of data and minimal supervision. Our approach produces simple propositions about the domain (see Figure 1 for examples of actual propositions learned by our system).

American football was the first official evaluation domain in the DARPA-sponsored Machine Reading program, and provides the background for a number

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1466–1475,
Portland, Oregon, June 19-24, 2011.

of LbR systems (Mulkar-Mehta et al., 2010). Sports is particularly amenable, since it usually follows a finite, explicit set of rules. Due to its popularity, results are easy to evaluate with lay subjects, and game reports, databases, etc. provide a large amount of data. The same need for basic knowledge appears in all domains, though. In music, *musicians* play *instruments*, in electronics, *components* constitute *circuits*, *circuits* use *electricity*, etc.

Teams beat teams
Teams play teams
Quarterbacks throw passes
Teams win games
Teams defeat teams
Receivers catch passes
Quarterbacks complete passes
Quarterbacks throw passes to receivers
Teams play games
Teams lose games

Figure 1: The ten most frequent propositions discovered by our system for the American football domain

Our approach differs from verb-argument identification or Named Entity (NE) tagging in several respects. While previous work on verb-argument selection (Pardo et al., 2006; Fan et al., 2010) uses fixed sets of classes, we cannot know a priori how many and which classes we will encounter. We therefore provide a way to derive the appropriate classes automatically and include a probability distribution for each of them. Our approach is thus less restricted and can learn context-dependent, fine-grained, domain-specific propositions. While a NE-tagged corpus could produce a general proposition like "*PERSON* throws to *PERSON*", our method enables us to distinguish the arguments and learn "*quarterback* throws to *receiver*" for American football and "*outfielder* throws to *third base*" for baseball. While in NE tagging each word has only one correct tag in a given context, we have hierarchical classes: an entity can be correctly labeled as a *player* or a *quarterback* (and possibly many more classes), depending on the context. By taking context into account, we are also able to label each sentence individually and account for unseen entities without using external resources.

Our contributions are:

- we use unsupervised learning to train a model that makes use of automatically extracted classes to uncover implicit knowledge in the form of predicate-argument propositions
- we evaluate the explanatory power, generalization capability, and sensibility of the propositions using both statistical measures and human judges, and compare them to several baselines
- we provide a model and a set of propositions that can be used to improve the performance of end-to-end LbR systems via textual enrichment.

2 Methods

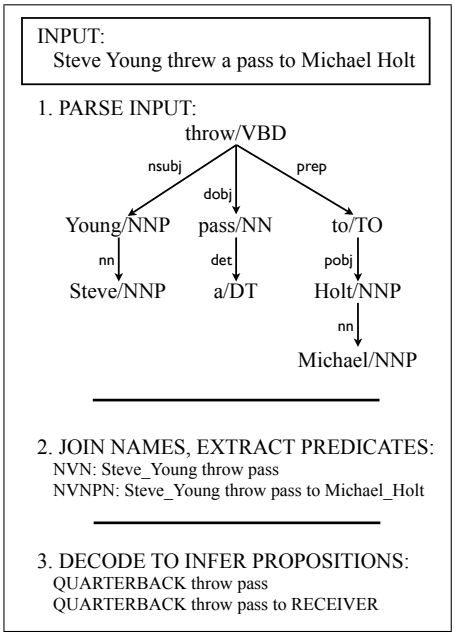

Figure 2: Illustrated example of different processing steps

Our running example will be "Steve Young threw a pass to Michael Holt". This is an instance of the underlying proposition "*quarterbacks throw passes to receivers*", which is not explicitly stated in the data. A proposition is thus a more general statement about the domain than the sentences it derives. It contains domain-specific classes (*quarterback*, *receiver*), as well as lexical items ("throw", "pass"). In order to reproduce the proposition, given the input sentences, our system has to not only identify the classes, but also learn when to

abstract away from the lexical form to the appropriate class and when to keep it (cf. Figure 2, step 3). To facilitate extraction, we focus on propositions with the following predicate-argument structures: NOUN-VERB-NOUN (e.g., "*quarterbacks throw passes*"), or NOUN-VERB-NOUN-PREPOSITION-NOUN (e.g., "*quarterbacks throw passes to receivers*". There is nothing, though, that prevents the use of other types of structures as well. We do not restrict the verbs we consider (Pardo et al., 2006; Ritter et al., 2010)), which extracts a high number of hapax structures.

Given a sentence, we want to find the most likely class for each word and thereby derive the most likely proposition. Similar to Pardo et al. (2006), we assume the observed data was produced by a process that generates the proposition and then transforms the classes into a sentence, possibly adding additional words. We model this as a Hidden Markov Model (HMM) with bigram transitions (see Section 2.3) and use the EM algorithm (Dempster et al., 1977) to train it on the observed data, with smoothing to prevent overfitting.

2.1 Data

We use a corpus of about 33k texts on American football, extracted from the New York Times (Sandhaus, 2008). To identify the articles, we rely on the provided "football" keyword classifier. The resulting corpus comprises $1,359,709$ sentences from game reports, background stories, and opinion pieces. In a first step, we parse all documents with the Stanford dependency parser (De Marneffe et al., 2006) (see Figure 2, step 1). The output is lemmatized (collapsing "*throws*", "*threw*", etc., into "*throw*"), and marked for various dependencies (*nsubj*, *amod*, etc.). This enables us to extract the predicate argument structure, like subject-verb-object, or additional prepositional phrases (see Figure 2, step 2). These structures help to simplify the model by discarding additional words like modifiers, determiners, etc., which are not essential to the proposition. The same approach is used by (Brody, 2007). We also concatenate multi-word names (identified by sequences of NNPs) with an underscore to form a single token ("Steve/NNP Young/NNP" → "Steve_Young").

2.2 Deriving Classes

To derive the classes used for entities, we do not restrict ourselves to a fixed set, but derive a domain-specific set directly from the data. This step is performed simultaneously with the corpus generation described above. We utilize three syntactic constructions to identify classes, namely *nominal modifiers*, *copula verbs*, and *appositions*, see below. This is similar in nature to Hearst's lexico-syntactic patterns (Hearst, 1992) and other approaches that derive *IS-A* relations from text. While we find it straightforward to collect classes for entities in this way, we did not find similar patterns for verbs. Given a suitable mechanism, however, these could be incorporated into our framework as well.

Nominal modifier are common nouns (labeled NN) that precede proper nouns (labeled NNP), as in "***quarterback/NN*** *Steve/NNP Young/NNP*", where "quarterback" is the nominal modifier of "Steve Young". Similar information can be gained from appositions (e.g., "*Steve Young,* ***the quarterback of his team****, said...*"), and copula verbs ("*Steve Young* ***is the quarterback*** *of the 49ers*"). We extract those co-occurrences and store the proper nouns as entities and the common nouns as their possible classes. For each pair of class and entity, we collect counts over the corpus to derive probability distributions.

Entities for which we do not find any of the above patterns in our corpus are marked "*UNK*". These entities are instantiated with the 20 most frequent classes. All other (non-entity) words (including verbs) have only their identity as class (i.e., "*pass*" remains "*pass*").

The average number of classes per entity is 6.87. The total number of distinct classes for entities is $63,942$. This is a huge number to model in our state space.[1] Instead of manually choosing a subset of the classes we extracted, we defer the task of finding the best set to the model.

We note, however, that the distribution of classes for each entity is highly skewed. Due to the unsupervised nature of the extraction process, many of the extracted classes are hapaxes and/or random noise. Most entities have only a small number of applicable classes (a football player usually has one main posi-

[1] NE taggers usually use a set of only a few dozen classes at most.

tion, and a few additional roles, such as *star*, *teammate*, etc.). We handle this by limiting the number of classes considered to 3 per entity. This constraint reduces the total number of distinct classes to $26,165$, and the average number of classes per entity to 2.53. The reduction makes for a more tractable model size without losing too much information. The class alphabet is still several magnitudes larger than that for NE or POS tagging. Alternatively, one could use external resources such as Wikipedia, Yago (Suchanek et al., 2007), or WordNet++ (Ponzetto and Navigli, 2010) to select the most appropriate classes for each entity. This is likely to have a positive effect on the quality of the applicable classes and merits further research. Here, we focus on the possibilities of a self-contained system without recurrence to outside resources.

The number of classes we consider for each entity also influences the number of possible propositions: if we consider exactly one class per entity, there will be little overlap between sentences, and thus no generalization possible—the model will produce many distinct propositions. If, on the other hand, we used only one class for all entities, there will be similarities between many sentences—the model will produce very few distinct propositions.

2.3 Probabilistic Model

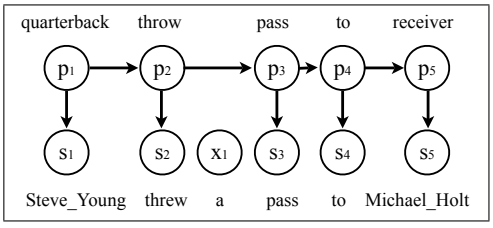

Figure 3: Graphical model for the running example

We use a generative noisy-channel model to capture the joint probability of input sentences and their underlying proposition. Our generative story of how a sentence $\mathbf{s}$ (with words $s_1, ..., s_n$) was generated assumes that a proposition $\mathbf{p}$ is generated as a sequence of classes $p_1, ..., p_n$, with transition probabilities $P(p_i|p_{i-1})$. Each class p_i generates a word s_i with probability $P(s_i|p_i)$. We allow additional words x in the sentence which do not depend on any class in the proposition and are thus generated independently with $P(x)$ (cf. model in Figure 3).

Since we observe the co-occurrence counts of classes and entities in the data, we can fix the emission parameter $P(s|p)$ in our HMM. Further, we do not want to generate sentences from propositions, so we can omit the step that adds the additional words x in our model. The removal of these words is reflected by the preprocessing step that extracts the structure (cf. Section 2.1).

Our model is thus defined as

$$P(\mathbf{s}, \mathbf{p}) = P(p_1) \cdot \prod_{i=1}^{n} \Big(P(p_i|p_{i-1}) \cdot P(s_i|p_i) \Big) \quad (1)$$

where s_i, p_i denote the i^{th} word of sentence $\mathbf{s}$ and proposition $\mathbf{p}$, respectively.

3 Evaluation

We want to evaluate how well our model predicts the data, and how sensible the resulting propositions are. We define a good model as one that generalizes well and produces semantically useful propositions.

We encounter two problems. First, since we derive the classes in a data-driven way, we have no gold standard data available for comparison. Second, there is no accepted evaluation measure for this kind of task. Ultimately, we would like to evaluate our model externally, such as measuring its impact on performance of a LbR system. In the absence thereof, we resort to several complementary measures, as well as performing an annotation task. We derive evaluation criteria as follows. A model generalizes well if it can cover ('explain') all the sentences in the corpus with a few propositions. This requires a measure of generality. However, while a proposition such as "*PERSON* does *THING*", has excellent generality, it possesses no discriminating power. We also need the propositions to partition the sentences into clusters of semantic similarity, to support effective inference. This requires a measure of distribution. Maximal distribution, achieved by assigning every sentence to a different proposition, however, is not useful either. We need to find an appropriate level of generality within which the sentences are clustered into propositions for the best overall groupings to support inference.

To assess the learned model, we apply the measures of *generalization*, *entropy*, and *perplexity* (see

Sections 3.2, 3.3, and 3.4). These measures can be used to compare different systems. We do not attempt to weight or combine the different measures, but present each in its own right.

Further, to assess label accuracy, we use Amazon's Mechanical Turk annotators to judge the sensibility of the propositions produced by each system (Section 3.5). We reason that if our system learned to infer the correct classes, then the resulting propositions should constitute true, general statements about that domain, and thus be judged as sensible.[2] This approach allows the effective annotation of sufficient amounts of data for an evaluation (first described for NLP in (Snow et al., 2008)).

3.1 Evaluation Data

With the trained model, we use Viterbi decoding to extract the best class sequence for each example in the data. This translates the original corpus sentences into propositions. See steps 2 and 3 in Figure 2.

We create two baseline systems from the same corpus, one which uses the most frequent class (MFC) for each entity, and another one which uses a class picked at random from the applicable classes of each entity.

Ultimately, we are interested in labeling unseen data from the same domain with the correct class, so we evaluate separately on the full corpus and the subset of sentences that contain unknown entities (i.e., entities for which no class information was available in the corpus, cf. Section 2.2).

For the latter case, we select all examples containing at least one unknown entity (labeled UNK), resulting in a subset of $41,897$ sentences, and repeat the evaluation steps described above. Here, we have to consider a much larger set of possible classes per entity (the 20 overall most frequent classes). The MFC baseline for these cases is the most frequent of the 20 classes for UNK tokens, while the random baseline chooses randomly from that set.

3.2 Generalization

Generalization measures how widely applicable the produced propositions are. A completely lexical approach, at one extreme, would turn each sentence into a separate proposition, thus achieving a generalization of 0%. At the other extreme, a model that produces only one proposition would generalize extremely well (but would fail to explain the data in any meaningful way). Both are of course not desirable.

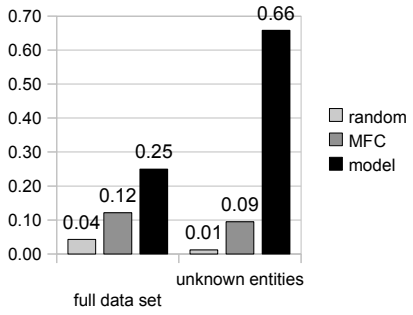

Figure 4: Generalization of models on the data sets

We define generalization as

$$g = 1 - \frac{|propositions|}{|sentences|} \quad (2)$$

The results in Figure 4 show that our model is capable of abstracting away from the lexical form, achieving a generalization rate of 25% for the full data set. The baseline approaches do significantly worse, since they are unable to detect similarities between lexically different examples, and thus create more propositions. Using a two-tailed t-test, the difference between our model and each baseline is statistically significant at $p < .001$.

Generalization on the unknown entity data set is even higher (65.84%). The difference between the model and the baselines is again statistically significant at $p < .001$. MFC always chooses the same class for UNK, regardless of context, and performs much worse. The random baseline chooses between 20 classes per entity instead of 3, and is thus even less general.

3.3 Normalized Entropy

Entropy is used in information theory to measure how predictable data is. 0 means the data is completely predictable. The higher the entropy of our propositions, the less well they explain the data. We are looking for models with low entropy. The extreme case of only one proposition has 0 entropy:

[2] Unfortunately, if judged insensible, we can not infer whether our model used the wrong class despite better options, or whether we simply have not learned the correct label.

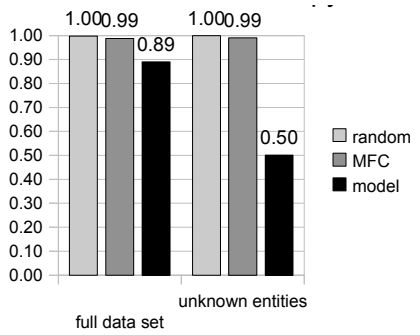

Figure 5: Entropy of models on the data sets

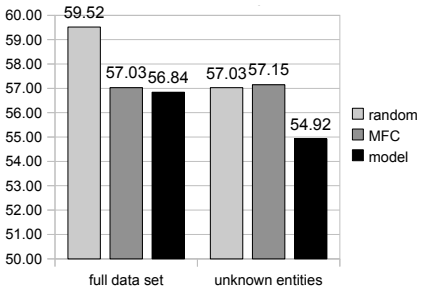

Figure 6: Perplexity of models on the data sets

we know exactly which sentences are produced by the proposition.

Entropy is directly influenced by the number of propositions used by a system.[3] In order to compare different models, we thus define normalized entropy as

$$H_N = \frac{-\sum_{i=0}^{n} P_i \cdot \log P_i}{\log n} \quad (3)$$

where P_i is the coverage of the proposition, or the percentage of sentences explained by it, and n is the number of distinct propositions.

The entropy of our model on the full data set is relatively high with 0.89, see Figure 5. The best entropy we can hope to achieve given the number of propositions and sentences is actually 0.80 (by concentrating the maximum probability mass in one proposition). The model thus does not perform as badly as the number might suggest. The entropy of our model on unseen data is better, with 0.50 (best possible: 0.41). This might be due to the fact that we considered more classes for UNK than for regular entities.

3.4 Perplexity

Since we assume that propositions are valid sentences in our domain, good propositions should have a higher probability than bad propositions in a language model. We can compute this using perplexity:[4]

$$perplexity(data) = 2^{\frac{-\log P(data)}{n}} \quad (4)$$

where $P(data)$ is the product of the proposition probabilities, and n is the number of propositions. We use the uni-, bi-, and trigram counts of the GoogleGrams corpus (Brants and Franz, 2006) with simple interpolation to compute the probability of each proposition.

The results in Figure 6 indicate that the propositions found by the model are preferable to the ones found by the baselines. As would be expected, the sensibility judgements for MFC and model[5] (Tables 1 and 2, Section 3.5) are perfectly anti-correlated (correlation coefficient -1) with the perplexity for these systems in each data set. However, due to the small sample size, this should be interpreted cautiously.

3.5 Sensibility and Label Accuracy

In unsupervised training, the model with the best data likelihood does not necessarily produce the best label accuracy. We evaluate label accuracy by presenting subjects with the propositions we obtained from the Viterbi decoding of the corpus, and ask them to rate their sensibility. We compare the different systems by computing sensibility as the percentage of propositions judged sensible for each system. Since the underlying probability distributions are quite different, we weight the sensibility judgement for each proposition by the likelihood of that proposition. We report results for both aggregate

[3] Note that how many classes we consider per entity influences how many propositions are produced (cf. Section 2.2), and thus indirectly puts a bound on entropy.

[4] Perplexity also quantifies the uncertainty of the resulting propositions, where 0 perplexity means no uncertainty.

[5] We did not collect sensibility judgements for the random baseline.

		100 most frequent		random		combined

Table 2: Percentage of propositions derived from labeling unknown entities that were judged sensible

sensibility (using the total number of individual answers), and majority sensibility, where each proposition is scored according to the majority of annotators' decisions.

The model and baseline propositions for the full data set are both judged highly sensible, achieving accuracies of 96.6% and 92.1% (cf. Table 1). While our model did slightly better, the differences are not statistically significant when using a two-tailed test. The propositions produced by the model from unknown entities are less sensible (67.8%), albeit still significantly above chance level, and the baseline propositions for the same data set ($p < 0.01$). Only 49.7% propositions of the baseline were judged sensible (cf. Table 2).

3.5.1 Annotation Task

Our model finds $250,169$ distinct propositions, the MFC baseline $293,028$. We thus have to restrict ourselves to a subset in order to judge their sensibility. For each system, we sample the 100 most frequent propositions and 100 random propositions found for both the full data set and the unknown entities[6] and have 10 annotators rate each proposition as sensible or insensible. To identify and omit bad annotators ('spammers'), we use the method described in Section 3.5.2, and measure inter-annotator agreement as described in Section 3.5.3. The details of this evaluation are given below, the results can be found in Tables 1 and 2.

The 200 propositions from each of the four systems (model and baseline on both full and unknown data set), contain 696 distinct propositions. We break these up into 70 batches (Amazon Turk annotation HIT pages) of ten propositions each. For each proposition, we request 10 annotators. Overall, 148 different annotators participated in our annotation. The annotators are asked to state whether each proposition represents a sensible statement about American Football or not. A proposition like "*Quarterbacks can throw passes to receivers*" should make sense, while "*Coaches can intercept teams*" does not. To ensure that annotators judge sensibility and not grammaticality, we format each proposition the same way, namely pluralizing the nouns and adding "can" before the verb. In addition, annotators can state whether a proposition sounds odd, seems ungrammatical, is a valid sentence, but against the rules (e.g., "*Coaches can hit players*") or whether they do not understand it.

3.5.2 Spammers

Some (albeit few) annotators on Mechanical Turk try to complete tasks as quickly as possible without paying attention to the actual requirements, introducing noise into the data. We have to identify these spammers before the evaluation. One way is to include tests. Annotators that fail these tests will be excluded. We use a repetition (first and last question are the same), and a truism (annotators answering "no" either do not know about football or just answered randomly). Alternatively, we can assume that good annotators, who are the majority, will exhibit similar behavior to one another, while spam-

[6] We omit the random baseline here due to size issues, and because it is not likely to produce any informative comparison.

mers exhibit a deviant answer pattern. To identify those outliers, we compare each annotator's agreement to the others and exclude those whose agreement falls more than one standard deviation below the average overall agreement.

We find that both methods produce similar results. The first method requires more careful planning, and the resulting set of annotators still has to be checked for outliers. The second method has the advantage that it requires no additional questions. It includes the risk, though, that one selects a set of bad annotators solely because they agree with one another.

3.5.3 Agreement

measure	100 most frequent	random	combined
agreement	0.88	0.76	0.82
κ	0.45	0.50	0.48
G-index	0.66	0.53	0.58

Table 3: Agreement measures for different samples

We use inter-annotator agreement to quantify the reliability of the judgments. Apart from the simple agreement measure, which records how often annotators choose the same value for an item, there are several statistics that qualify this measure by adjusting for other factors. One frequently used measure, Cohen's κ, has the disadvantage that if there is prevalence of one answer, κ will be low (or even negative), despite high agreement (Feinstein and Cicchetti, 1990). This phenomenon, known as the κ paradox, is a result of the formula's adjustment for chance agreement. As shown by Gwet (2008), the true level of actual chance agreement is realistically not as high as computed, resulting in the counterintuitive results. We include it for comparative reasons. Another statistic, the G-index (Holley and Guilford, 1964), avoids the paradox. It assumes that expected agreement is a function of the number of choices rather than chance. It uses the same general formula as κ,

$$\frac{(P_a - P_e)}{(1 - P_e)} \tag{5}$$

where P_a is the actual raw agreement measured, and P_e is the expected agreement. The difference with κ is that P_e for the G-index is defined as $P_e = 1/q$, where q is the number of available categories, instead of expected chance agreement. Under most conditions, G and κ are equivalent, but in the case of high raw agreement and few categories, G gives a more accurate estimation of the agreement. We thus report raw agreement, κ, and G-index.

Despite early spammer detection, there are still outliers in the final data, which have to be accounted for when calculating agreement. We take the same approach as in the statistical spammer detection and delete outliers that are more than one standard deviation below the rest of the annotators' average.

The raw agreement for both samples combined is 0.82, $G = 0.58$, and $\kappa = 0.48$. The numbers show that there is reasonably high agreement on the label accuracy.

4 Related Research

The approach we describe is similar in nature to unsupervised verb argument selection/selectional preferences and semantic role labeling, yet goes beyond it in several ways. For semantic role labeling (Gildea and Jurafsky, 2002; Fleischman et al., 2003), classes have been derived from FrameNet (Baker et al., 1998). For verb argument detection, classes are either semi-manually derived from a repository like WordNet, or from NE taggers (Pardo et al., 2006; Fan et al., 2010). This allows for domain-independent systems, but limits the approach to a fixed set of oftentimes rather inappropriate classes. In contrast, we derive the level of granularity directly from the data.

Pre-tagging the data with NE classes before training comes at a cost. It lumps entities together which can have very different classes (i.e., all people become labeled as PERSON), effectively allowing only one class per entity. Etzioni et al. (2005) resolve the problem with a web-based approach that learns hierarchies of the NE classes in an unsupervised manner. We do not enforce a taxonomy, but include statistical knowledge about the distribution of possible classes over each entity by incorporating a prior distribution $P(class, entity)$. This enables us to generalize from the lexical form without restricting ourselves to one class per entity, which helps to better fit the data. In addition, we can distinguish several classes for each entity, depending on the context

(e.g., *winner* vs. *quarterback*). Ritter et al. (2010) also use an unsupervised model to derive selectional predicates from unlabeled text. They do not assign classes altogether, but group similar predicates and arguments into unlabeled clusters using LDA. Brody (2007) uses a very similar methodology to establish relations between clauses and sentences, by clustering simplified propositions.

Peñas and Hovy (2010) employ syntactic patterns to derive classes from unlabeled data in the context of LbR. They consider a wider range of syntactic structures, but do not include a probabilistic model to label new data.

5 Conclusion

We use an unsupervised model to infer domain-specific classes from a corpus of 1.4m unlabeled sentences, and applied them to learn 250k propositions about American football. Unlike previous approaches, we use automatically extracted classes with a probability distribution over entities to allow for context-sensitive selection of appropriate classes.

We evaluate both the model qualities and sensibility of the resulting propositions. Several measures show that the model has good explanatory power and generalizes well, significantly outperforming two baseline approaches, especially where the possible classes of an entity can only be inferred from the context.

Human subjects on Amazon's Mechanical Turk judged up to 96.6% of the propositions for the full data set, and 67.8% for data containing unseen entities as sensible. Inter-annotator agreement was reasonably high ($agreement = 0.82$, $G = 0.58$, $\kappa = 0.48$).

The probabilistic model and the extracted propositions can be used to enrich texts and support post-parsing inference for question answering. We are currently applying our method to other domains.

Abstract

In this paper, we present a unified model for the automatic induction of word senses from text, and the subsequent disambiguation of particular word instances using the automatically extracted sense inventory. The induction step and the disambiguation step are based on the same principle: words and contexts are mapped to a limited number of topical dimensions in a latent semantic word space. The intuition is that a particular sense is associated with a particular topic, so that different senses can be discriminated through their association with particular topical dimensions; in a similar vein, a particular instance of a word can be disambiguated by determining its most important topical dimensions. The model is evaluated on the SEMEVAL-2010 word sense induction and disambiguation task, on which it reaches state-of-the-art results.

1 Introduction

Word sense induction (WSI) is the task of automatically identifying the senses of words in texts, without the need for handcrafted resources or manually annotated data. The manual construction of a sense inventory is a tedious and time-consuming job, and the result is highly dependent on the annotators and the domain at hand. By applying an automatic procedure, we are able to only extract the senses that are objectively present in a particular corpus, and it allows for the sense inventory to be straightforwardly adapted to a new domain.

Word sense disambiguation (WSD), on the other hand, is the closely related task of assigning a sense label to a particular instance of a word in context, using an existing sense inventory. The bulk of WSD algorithms up till now use pre-defined sense inventories (such as WordNet) that often contain fine-grained sense distinctions, which poses serious problems for computational semantic processing (Ide and Wilks, 2007). Moreover, most WSD algorithms take a supervised approach, which requires a significant amount of manually annotated training data.

The model presented here induces the senses of words in a fully unsupervised way, and subsequently uses the induced sense inventory for the unsupervised disambiguation of particular occurrences of words. The induction step and the disambiguation step are based on the same principle: words and contexts are mapped to a limited number of topical dimensions in a latent semantic word space. The key idea is that the model combines tight, synonym-like similarity (based on dependency relations) with broad, topical similarity (based on a large 'bag of words' context window). The intuition in this is that the dependency features can be disambiguated by the topical dimensions identified by the broad contextual features; in a similar vein, a particular instance of a word can be disambiguated by determining its most important topical dimensions (based on the instance's context words).

The paper is organized as follows. Section 2 presents some previous research on distributional similarity and word sense induction. Section 3 gives an overview of our method for word sense induction and disambiguation. Section 4 provides a quantitative evaluation and comparison to other algorithms in the framework of the SEMEVAL-2010 word sense

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1476–1485,
Portland, Oregon, June 19-24, 2011.

induction and disambiguation (WSI/WSD) task. The last section draws conclusions, and lays out a number of future research directions.

2 Previous Work

2.1 Distributional similarity

According to the distributional hypothesis of meaning (Harris, 1954), words that occur in similar contexts tend to be semantically similar. In the spirit of this by now well-known adage, numerous algorithms have sprouted up that try to capture the semantics of words by looking at their distribution in texts, and comparing those distributions in a vector space model.

One of the best known models in this respect is latent semantic analysis — LSA (Landauer and Dumais, 1997; Landauer et al., 1998). In LSA, a term-document matrix is created, that contains the frequency of each word in a particular document. This matrix is then decomposed into three other matrices with a mathematical factorization technique called singular value decomposition (SVD). The most important dimensions that come out of the SVD are said to represent latent semantic dimensions, according to which nouns and documents can be represented more efficiently. Our model also applies a factorization technique (albeit a different one) in order to find a reduced semantic space.

Context is a determining factor in the nature of the semantic similarity that is induced. A broad context window (e.g. a paragraph or document) yields broad, topical similarity, whereas a small context yields tight, synonym-like similarity. This has lead a number of researchers to use the dependency relations that a particular word takes part in as contextual features. One of the most important approaches is Lin (1998). An overview of dependency-based semantic space models is given in Padó and Lapata (2007).

2.2 Word sense induction

The following paragraphs provide a succinct overview of word sense induction research. A thorough survey on word sense disambiguation (including unsupervised induction algorithms) is presented in Navigli (2009).

Algorithms for word sense induction can roughly be divided into *local* and *global* ones. Local WSI algorithms extract the different senses of a word on a per-word basis, i.e. the different senses for each word are determined separately. They can be further subdivided into *context-clustering* algorithms and *graph-based* algorithms. In the context-clustering approach, context vectors are created for the different instances of a particular word, and those contexts are grouped into a number of clusters, representing the different senses of the word. The context vectors may be represented as first or second-order co-occurrences (i.e. the contexts of the target word are similar if the words they in turn co-occur with are similar). The first one to propose this idea of context-group discrimination was Schütze (1998), and many researchers followed a similar approach to sense induction (Purandare and Pedersen, 2004). In the graph-based approach, on the other hand, a co-occurrence graph is created, in which nodes represent words, and edges connect words that appear in the same context (dependency relation or context window). The senses of a word may then be discovered using graph clustering techniques (Widdows and Dorow, 2002), or algorithms such as HyperLex (Véronis, 2004) or Pagerank (Agirre et al., 2006). Finally, Bordag (2006) recently proposed an approach that uses word triplets to perform word sense induction. The underlying idea is the 'one sense per collocation' assumption, and co-occurrence triplets are clustered based on the words they have in common.

Global algorithms take an approach in which the different senses of a particular word are determined by comparing them to, and demarcating them from, the senses of other words in a full-blown word space model. The best known global approach is the one by Pantel and Lin (2002). They present a global clustering algorithm – coined clustering by committee (CBC) – that automatically discovers word senses from text. The key idea is to first discover a set of tight, unambiguous clusters, to which possibly ambiguous words can be assigned. Once a word has been assigned to a cluster, the features associated with that particular cluster are stripped off the word's vector. This way, less frequent senses of the word may be discovered.

Van de Cruys (2008) proposes a model for sense induction based on latent semantic dimensions. Using an extension of non-negative matrix factoriza-

tion, the model induces a latent semantic space according to which both dependency features and broad contextual features are classified. Using the latent space, the model is able to discriminate between different word senses. The model presented below is an extension of this approach: whereas the model described in Van de Cruys (2008) is only able to perform word sense induction, our model is capable of performing both word sense induction and disambiguation.

3 Methodology

3.1 Non-negative Matrix Factorization

Our model uses non-negative matrix factorization – NMF (Lee and Seung, 2000) in order to find latent dimensions. There are a number of reasons to prefer NMF over the better known singular value decomposition used in LSA. First of all, NMF allows us to minimize the Kullback-Leibler divergence as an objective function, whereas SVD minimizes the Euclidean distance. The Kullback-Leibler divergence is better suited for language phenomena. Minimizing the Euclidean distance requires normally distributed data, and language phenomena are typically not normally distributed. Secondly, the non-negative nature of the factorization ensures that only additive and no subtractive relations are allowed. This proves particularly useful for the extraction of semantic dimensions, so that the NMF model is able to extract much more clear-cut dimensions than an SVD model. And thirdly, the non-negative property allows the resulting model to be interpreted probabilistically, which is not straightforward with an SVD factorization.

The key idea is that a non-negative matrix $\mathbf{A}$ is factorized into two other non-negative matrices, $\mathbf{W}$ and $\mathbf{H}$

$$\mathbf{A}_{i\times j} \approx \mathbf{W}_{i\times k}\mathbf{H}_{k\times j} \tag{1}$$

where k is much smaller than i, j so that both instances and features are expressed in terms of a few components. Non-negative matrix factorization enforces the constraint that all three matrices must be non-negative, so all elements must be greater than or equal to zero.

Using the minimization of the Kullback-Leibler divergence as an objective function, we want to find the matrices $\mathbf{W}$ and $\mathbf{H}$ for which the Kullback-Leibler divergence between $\mathbf{A}$ and $\mathbf{WH}$ (the multiplication of $\mathbf{W}$ and $\mathbf{H}$) is the smallest. This factorization is carried out through the iterative application of update rules. Matrices $\mathbf{W}$ and $\mathbf{H}$ are randomly initialized, and the rules in 2 and 3 are iteratively applied – alternating between them. In each iteration, each vector is adequately normalized, so that all dimension values sum to 1.

$$\mathbf{H}_{a\mu} \leftarrow \mathbf{H}_{a\mu}\frac{\sum_i \mathbf{W}_{ia}\frac{\mathbf{A}_{i\mu}}{(\mathbf{WH})_{i\mu}}}{\sum_k \mathbf{W}_{ka}} \tag{2}$$

$$\mathbf{W}_{ia} \leftarrow \mathbf{W}_{ia}\frac{\sum_\mu \mathbf{H}_{a\mu}\frac{\mathbf{A}_{i\mu}}{(\mathbf{WH})_{i\mu}}}{\sum_v \mathbf{H}_{av}} \tag{3}$$

3.2 Word sense induction

Using an extension of non-negative matrix factorization, we are able to jointly induce latent factors for three different modes: words, their window-based ('bag of words') context words, and their dependency relations. Three matrices are constructed that capture the pairwise co-occurrence frequencies for the different modes. The first matrix contains co-occurrence frequencies of words cross-classified by dependency relations, the second matrix contains co-occurrence frequencies of words cross-classified by words that appear in the noun's context window, and the third matrix contains co-occurrence frequencies of dependency relations cross-classified by co-occurring context words. NMF is then applied to the three matrices and the separate factorizations are interleaved (i.e. the results of the former factorization are used to initialize the factorization of the next matrix). A graphical representation of the interleaved factorization algorithm is given in figure 1.

The procedure of the algorithm goes as follows. First, matrices $\mathbf{W}$, $\mathbf{H}$, $\mathbf{G}$, and $\mathbf{F}$ are randomly initialized. We then start our first iteration, and compute the update of matrix $\mathbf{W}$ (using equation 3). Matrix $\mathbf{W}$ is then copied to matrix $\mathbf{V}$, and the update of matrix $\mathbf{G}$ is computed (using equation 2). The transpose of matrix $\mathbf{G}$ is again copied to matrix $\mathbf{U}$, and the update of $\mathbf{F}$ is computed (again using equation 2). As a last step, matrix $\mathbf{F}$ is copied to matrix $\mathbf{H}$, and we restart the iteration loop until a stopping criterion (e.g. a maximum number of iterations, or no more significant change in objective function; we used the

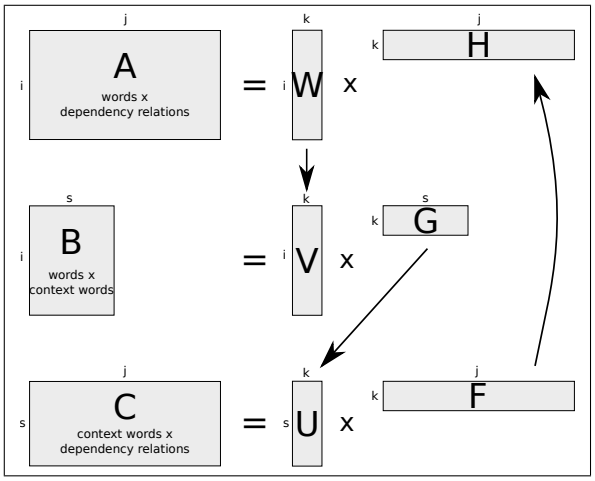

Figure 1: A graphical representation of the interleaved NMF algorithm

former one) is reached.[1] When the factorization is finished, the three different modes (words, window-based context words and dependency relations) are all represented according to a limited number of latent factors.

Next, the factorization that is thus created is used for word sense induction. The intuition is that a particular, dominant dimension of an ambiguous word is 'switched off', in order to reveal other possible senses of the word. Formally, we proceed as follows. Matrix $\mathbf{H}$ indicates the importance of each dependency relation given a topical dimension. With this knowledge, the dependency relations that are responsible for a certain dimension can be subtracted from the original noun vector. This is done by scaling down each feature of the original vector according to the load of the feature on the subtracted dimension, using equation 4.

$$\mathbf{t} = \mathbf{v}(\mathbf{u_1} - \mathbf{h_k}) \tag{4}$$

Equation 4 multiplies each dependency feature of the original noun vector $\mathbf{v}$ with a scaling factor, according to the load of the feature on the subtracted dimension ($\mathbf{h_k}$ – the vector of matrix $\mathbf{H}$ that corresponds to the dimension we want to subtract). $\mathbf{u_1}$ is a vector of ones with the same length as $\mathbf{h_k}$. The result is vector $\mathbf{t}$, in which the dependency features relevant to the particular topical dimension have been scaled down.

In order to determine which dimension(s) are responsible for a particular sense of the word, the method is embedded in a clustering approach. First, a specific word is assigned to its predominant sense (i.e. the most similar cluster). Next, the dominant semantic dimension(s) for this cluster are subtracted from the word vector, and the resulting vector is fed to the clustering algorithm again, to see if other word senses emerge. The dominant semantic dimension(s) can be identified by folding vector $\mathbf{c}$ – representing the cluster centroid – into the factorization (equation 5). This yields a probability vector $\mathbf{b}$ over latent factors for the particular centroid.

$$\mathbf{b} = \mathbf{c}\mathbf{H}^T \tag{5}$$

A simple k-means algorithm is used to compute the initial clustering, using the non-factorized dependency-based feature vectors (matrix $\mathbf{A}$). k-means yields a hard clustering, in which each noun is assigned to exactly one (dominant) cluster. In the second step, we determine for each noun whether it can be assigned to other, less dominant clusters. First, the salient dimension(s) of the centroid to which the noun is assigned are determined. The centroid of the cluster is computed by averaging the frequencies of all cluster elements except for the target word we want to reassign. After subtracting the salient dimensions from the noun vector, we check whether the vector is reassigned to another cluster centroid. If this is the case, (another instance of) the noun is assigned to the cluster, and the second step is repeated. If there is no reassignment, we continue with the next word. The target element is removed from the centroid to make sure that only the dimensions associated with the sense of the cluster are subtracted. When the algorithm is finished, each noun is assigned to a number of clusters, representing its different senses.

We use two different methods for selecting the final number of candidate senses. The first method, NMF$_{con}$, takes a conservative approach, and only selects candidate senses if – after the subtraction of salient dimensions – another sense is found that is more similar[2] to the adapted noun vector than the

[1] Note that this is not the only possibly way of interleaving the different factorizations, but in our experiments we found that different constellations lead to similar results.

[2] We use the cosine measure for our similarity calculations.

dominant sense. The second method, NMF_{lib}, is more liberal, and also selects the next best cluster centroid as candidate sense until a certain similarity threshold ϕ is reached.[3]

3.3 Word sense disambiguation

The sense inventory that results from the induction step can now be used for the disambiguation of individual instances as follows. For each instance of the target noun, we extract its context words, i.e. the words that co-occur in the same paragraph, and represent them as a probability vector $\mathbf{f}$. Using matrix $\mathbf{G}$ from our factorization model (which represents context words by semantic dimensions), this vector can be folded into the semantic space, thus representing a probability vector over latent factors for the particular instance of the target noun (equation 6).

$$\mathbf{d} = \mathbf{f}\mathbf{G}^T \tag{6}$$

Likewise, the candidate senses of the noun (represented as centroids) can be folded into our semantic space using matrix $\mathbf{H}$ (equation 5). This yields a probability distribution over the semantic dimensions for each centroid. As a last step, we compute the Kullback-Leibler divergence between the context vector and the candidate centroids, and select the candidate centroid that yields the lowest divergence as the correct sense. The disambiguation process is represented graphically in figure 2.

3.4 Example

Let us clarify the process with an example for the noun *chip*. The sense induction algorithm finds the following candidate senses:[4]

1. *cache*, *CPU*, *memory*, *microprocessor*, *processor*, *RAM*, *register*

2. *bread*, *cake*, *chocolate*, *cookie*, *recipe*, *sandwich*

3. *accessory*, *equipment*, *goods*, *item*, *machinery*, *material*, *product*, *supplies*

[3]Experimentally (examining the cluster output), we set $\phi = 0.2$

[4]Note that we do not use the word *sense* to hint at a lexicographic meaning distinction; rather, *sense* in this case should be regarded as a more coarse-grained and topic-related entity.

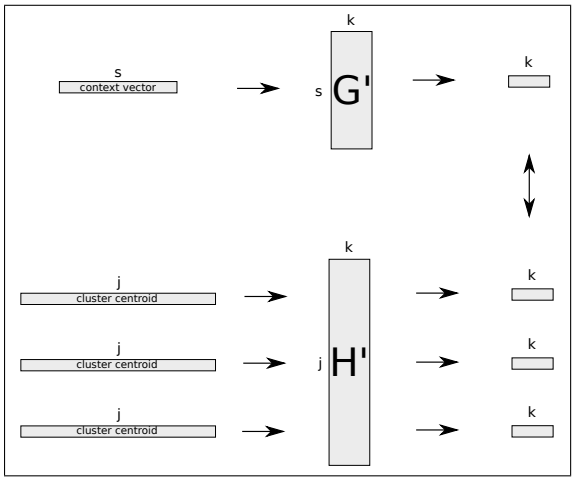

Figure 2: Graphical representation of the disambiguation process

Each candidate sense is associated with a centroid (the average frequency vector of the cluster's members), that is folded into the semantic space, which yields a 'semantic fingerprint', i.e. a distribution over the semantic dimensions. For the first sense, the 'computer' dimension will be the most important. Likewise, for the second and the third sense the 'food' dimension and the 'manufacturing' dimension will be the most important.[5]

Let us now take a particular instance of the noun *chip*, such as the one in (1).

(1) An N.V. Philips **unit** has **created** a **computer system** that **processes video images** 3,000 times faster than conventional **systems**. Using **reduced instruction** - **set computing**, or RISC, chips made by Intergraph of Huntsville, Ala., the **system** splits the **image** it '**sees**' into 20 **digital representations**, each **processed** by one *chip*.

Looking at the context of the particular instance of *chip*, a context vector is created which represents the semantic content words that appear in the same paragraph (the extracted content words are printed in boldface). This context vector is again folded into the semantic space, yielding a distribution over the semantic dimensions. By selecting the lowest

[5]In the majority of cases, the induced dimensions indeed contain such clear-cut semantics, so that the dimensions can be rightfully labeled as above.

Kullback-Leibler divergence between the semantic probability distribution of the target instance and the semantic probability distributions of the candidate senses, the algorithm is able to assign the 'computer' sense of the target noun *chip*.

4 Evaluation

4.1 Dataset

Our word sense induction and disambiguation model is trained and tested on the dataset of the SEMEVAL-2010 WSI/WSD task (Manandhar et al., 2010). The SEMEVAL-2010 WSI/WSD task is based on a dataset of 100 target words, 50 nouns and 50 verbs. For each target word, a training set is provided from which the senses of the word have to be induced without using any other resources. The training set for a target word consists of a set of target word instances in context (sentences or paragraphs). The complete training set contains 879,807 instances, viz. 716,945 noun and 162,862 verb instances.

The senses induced during training are used for disambiguation in the testing phase. In this phase, the system is provided with a test set that consists of unseen instances of the target words. The test set contains 8,915 instances in total, of which 5,285 nouns and 3,630 verbs. The instances in the test set are tagged with OntoNotes senses (Hovy et al., 2006). The system needs to disambiguate these instances using the senses acquired during training.

4.2 Implementational details

The SEMEVAL training set has been part of speech tagged and lemmatized with the Stanford Part-Of-Speech Tagger (Toutanova and Manning, 2000; Toutanova et al., 2003) and parsed with MaltParser (Nivre et al., 2006), trained on sections 2-21 of the Wall Street Journal section of the Penn Treebank extended with about 4000 questions from the QuestionBank[6] in order to extract dependency triples. The SEMEVAL test set has only been tagged and lemmatized, as our disambiguation model does not use dependency triples as features (contrary to the induction model).

[6] http://maltparser.org/mco/english_parser/engmalt.html

We constructed two different models – one for nouns and one for verbs. For each model, the matrices needed for our interleaved NMF factorization are extracted from the corpus. The noun model was built using 5K nouns, 80K dependency relations, and 2K context words (excluding stop words) with highest frequency in the training set, which yields matrices of 5K nouns $\times$ 80K dependency relations, 5K nouns $\times$ 2K context words, and 80K dependency relations $\times$ 2K context words. The model for verbs was constructed analogously, using 3K verbs, and the same number of dependency relations and context words. For our initial k-means clustering, we set $k = 600$ for nouns, and $k = 400$ for verbs. For the underlying interleaved NMF model, we used 50 iterations, and factored the model to 50 dimensions.

4.3 Evaluation measures

The results of the systems participating in the SEMEVAL-2010 WSI/WSD task are evaluated both in a supervised and in an unsupervised manner.

The supervised evaluation in the SEMEVAL-2010 WSI/WSD task follows the scheme of the SEMEVAL-2007 WSI task (Agirre and Soroa, 2007), with some modifications. One part of the test set is used as a mapping corpus, which maps the automatically induced clusters to gold standard senses; the other part acts as an evaluation corpus. The mapping between clusters and gold standard senses is used to tag the evaluation corpus with gold standard tags. The systems are then evaluated as in a standard WSD task, using recall.

In the unsupervised evaluation, the induced senses are evaluated as clusters of instances which are compared to the sets of instances tagged with the gold standard senses (corresponding to classes). Two partitions are thus created over the test set of a target word: a set of automatically generated clusters and a set of gold standard classes. A number of these instances will be members of both one gold standard class and one cluster. Consequently, the quality of the proposed clustering solution is evaluated by comparing the two groupings and measuring their similarity.

Two evaluation metrics are used during the unsupervised evaluation in order to estimate the quality of the clustering solutions, the *V-Measure* (Rosenberg and Hirschberg, 2007) and the *paired F-*

Score (Artiles et al., 2009). *V-Measure* assesses the quality of a clustering by measuring its *homogeneity* (h) and its *completeness* (c). Homogeneity refers to the degree that each cluster consists of data points primarily belonging to a single gold standard class, while completeness refers to the degree that each gold standard class consists of data points primarily assigned to a single cluster. V-Measure is the harmonic mean of h and c.

$$VM = \frac{2 \cdot h \cdot c}{h + c} \tag{7}$$

In the *paired F-Score* (Artiles et al., 2009) evaluation, the clustering problem is transformed into a classification problem (Manandhar et al., 2010). A set of instance pairs is generated from the automatically induced clusters, which comprises pairs of the instances found in each cluster. Similarly, a set of instance pairs is created from the gold standard classes, containing pairs of the instances found in each class. *Precision* is then defined as the number of common instance pairs between the two sets to the total number of pairs in the clustering solution (cf. formula 8). *Recall* is defined as the number of common instance pairs between the two sets to the total number of pairs in the gold standard (cf. formula 9). Precision and recall are finally combined to produce the harmonic mean (cf. formula 10).

$$P = \frac{|F(K) \cap F(S)|}{|F(K)|} \tag{8}$$

$$R = \frac{|F(K) \cap F(S)|}{|F(S)|} \tag{9}$$

$$FS = \frac{2 \cdot P \cdot R}{P + R} \tag{10}$$

The obtained results are also compared to two baselines. The most frequent sense (MFS) baseline groups all testing instances of a target word into one cluster. The *Random* baseline randomly assigns an instance to one of the clusters.[7] This baseline is executed five times and the results are averaged.

[7]The number of clusters in *Random* was chosen to be roughly equal to the average number of senses in the gold standard.

4.4 Results

4.4.1 Unsupervised evaluation

In table 1, we present the performance of a number of algorithms on the V-measure. We compare our V-measure scores with the scores of the best-ranked systems in the SEMEVAL 2010 WSI/WSD task, both for the complete data set and for nouns and verbs separately. The fourth column shows the average number of clusters induced in the test set by each algorithm. The MFS baseline has a V-Measure equal to 0, since by definition its completeness is 1 and its homogeneity is 0.

NMF$_{con}$ – our model that takes a conservative approach in the induction of candidate senses – does not beat the random baseline. NMF$_{lib}$ – our model that is more liberal in inducing senses – reaches better results. With 11.8%, it scores similar to other algorithms that induce a similar average number of clusters, such as Duluth-WSI (Pedersen, 2010).

Pedersen (2010) has shown that the V-Measure tends to favour systems producing a higher number of clusters than the number of gold standard senses. This is reflected in the scores of our models as well.

VM (%)	**all**	**noun**	**verb**	**#cl**
Hermit	16.2	16.7	15.6	10.78
UoY	15.7	20.6	8.5	11.54
KSU KDD	15.7	18.0	12.4	17.50
NMF$_{lib}$	11.8	13.5	9.4	4.80
Duluth-WSI	9.0	11.4	5.7	4.15
Random	4.4	4.2	4.6	4.00
NMF$_{con}$	3.9	3.9	3.9	1.58
MFS	0.0	0.0	0.0	1.00

Table 1: Unsupervised V-measure evaluation on SEMEVAL test set

Motivated by the large divergences in the system rankings on the different metrics used in the SEMEVAL-2010 WSI/WSD task, Pedersen evaluated the metrics themselves. His evaluation relied on the assumption that a good measure should assign low scores to random baselines. Pedersen showed that the V-Measure continued to improve as randomness increased. We agree with Pedersen's conclusion that the V-Measure results should be interpreted with caution, but we still report the results in order

to perform a global comparison, on all metrics, of our system's performance to the systems that participated to the SEMEVAL task.

Contrary to V-Measure, paired F-score is a fairly reliable measure and the only one that managed to identify and expose random baselines in the above mentioned metric evaluation. This means that the random systems used for testing were ranked low when a high number of random senses was used.

In table 2, the paired F-Score of a number of algorithms is given. The paired F-Score penalizes systems when they produce a higher number of clusters (low recall) or a lower number of clusters (low precision) than the gold standard number of senses. We again compare our results with the scores of the best-ranked systems in the SEMEVAL-2010 WSI/WSD TASK.

FS (%)	all	noun	verb	#cl
MFS	63.5	57.0	72.7	1.00
Duluth-WSI-SVD-Gap	63.3	57.0	72.4	1.02
NMF$_{con}$	60.2	54.6	68.4	1.58
NMF$_{lib}$	45.3	42.2	49.8	5.42
Duluth-WSI	41.1	37.1	46.7	4.15
Random	31.9	30.4	34.1	4.00

Table 2: Unsupervised paired F-score evaluation on SEMEVAL testset

NMF$_{con}$ reaches a score of 60.2%, which is again similar to other algorithms that induce the same average number of clusters. NMF$_{lib}$ scores 45.3%, indicating that the algorithm is able to retain a reasonable F-Score while at the same time inducing a significant number of clusters. This especially becomes clear when comparing its score to the other algorithms.

4.4.2 Supervised evaluation

In the supervised evaluation, the automatically induced clusters are mapped to gold standard senses, using the mapping corpus (i.e. one part of the test set). The obtained mapping is used to tag the evaluation corpus (i.e. the other part of the test set) with gold standard tags, which means that the methods are evaluated in a standard WSD task.

Table 3 shows the recall of our algorithms in the supervised evaluation, again compared to other algorithms evaluated in the SEMEVAL-2010 WSI/WSD task.

SR (%)	all	noun	verb	#S
NMF$_{lib}$	62.6	57.3	70.2	1.82
UoY	62.4	59.4	66.8	1.51
Duluth-WSI	60.5	54.7	68.9	1.66
NMF$_{con}$	60.3	54.5	68.8	1.21
MFS	58.7	53.2	66.6	1.00
Random	57.3	51.5	65.7	1.53

Table 3: Supervised recall for SEMEVAL testset, 80% mapping, 20% evaluation

NMF$_{lib}$ gets 62.6%, which makes it the best scoring algorithm on the supervised evaluation. NMF$_{con}$ reaches 60.3%, which again indicates that it is in the same ballpark as other algorithms that induce a similar average number of senses.

Some doubts have been cast on the representativeness of the supervised recall results as well. According to Pedersen (2010), the supervised learning algorithm that underlies this evaluation method tends to converge to the Most Frequent Sense (MFS) baseline, because the number of senses that the classifier assigns to the test instances is rather low. We think these shortcomings indicate the need for the development of new evaluation metrics, capable of providing a more accurate evaluation of the performance of WSI systems. Nevertheless, these metrics still constitute a useful testbed for comparing the performance of different systems.

5 Conclusion and future work

In this paper, we presented a model based on latent semantics that is able to perform word sense induction as well as disambiguation. Using latent topical dimensions, the model is able to discriminate between different senses of a word, and subsequently disambiguate particular instances of a word. The evaluation results indicate that our model reaches state-of-the-art performance compared to other systems that participated in the SEMEVAL-2010 word sense induction and disambiguation task. Moreover, our global approach is able to reach similar performance on an evaluation set that is tuned to fit the needs of local approaches. The evaluation set con-

tains an enormous amount of contexts for only a small number of target words, favouring methods that induce senses on a per-word basis. A global approach like ours is likely to induce a more balanced sense inventory using an unbiased corpus, and is likely to outperform local methods when such an unbiased corpus is used as input. We therefore think that the global, unified approach to word sense induction and disambiguation presented here provides a genuine and powerful solution to the problem at hand.

We conclude with some issues for future work. First of all, we would like to evaluate the approach presented here using a more balanced and unbiased corpus, and compare its performance on such a corpus to local approaches. Secondly, we would also like to include grammatical dependency information in the disambiguation step of the algorithm. For now, the disambiguation step only uses a word's context words; enriching the feature set with dependency information is likely to improve the performance of the disambiguation.

Abstract

Current approaches for semantic parsing take a supervised approach requiring a considerable amount of training data which is expensive and difficult to obtain. This supervision bottleneck is one of the major difficulties in scaling up semantic parsing.

We argue that a semantic parser can be trained effectively without annotated data, and introduce an unsupervised learning algorithm. The algorithm takes a self training approach driven by confidence estimation. Evaluated over Geoquery, a standard dataset for this task, our system achieved 66% accuracy, compared to 80% of its fully supervised counterpart, demonstrating the promise of unsupervised approaches for this task.

1 Introduction

Semantic parsing, the ability to transform Natural Language (NL) input into a formal Meaning Representation (MR), is one of the longest standing goals of natural language processing. The importance of the problem stems from both theoretical and practical reasons, as the ability to convert NL into a formal MR has countless applications.

The term *semantic parsing* has been used ambiguously to refer to several semantic tasks (e.g., semantic role labeling). We follow the most common definition of this task: finding a mapping between NL input and its interpretation expressed in a well-defined formal MR language. Unlike shallow semantic analysis tasks, the output of a semantic parser is complete and unambiguous to the extent it can be understood or even executed by a computer system.

Current approaches for this task take a data driven approach (Zettlemoyer and Collins, 2007; Wong and Mooney, 2007), in which the learning algorithm is given a set of NL sentences as input and their corresponding MR, and learns a statistical semantic parser — a set of parameterized rules mapping lexical items and syntactic patterns to their MR. Given a sentence, these rules are applied recursively to derive the most probable interpretation.

Since semantic interpretation is limited to the syntactic patterns observed in the training data, in order to work well these approaches require considerable amounts of annotated data. Unfortunately annotating sentences with their MR is a time consuming task which requires specialized domain knowledge and therefore minimizing the supervision effort is one of the key challenges in scaling semantic parsers.

In this work we present the first unsupervised approach for this task. Our model compensates for the lack of training data by employing a self training protocol based on identifying high confidence self labeled examples and using them to retrain the model. We base our approach on a simple observation: semantic parsing is a difficult structured prediction task, which requires learning a complex model, however identifying good predictions can be done with a far simpler model capturing repeating patterns in the predicted data. We present several simple, yet highly effective confidence measures capturing such patterns, and show how to use them to train a semantic parser without manually annotated sentences.

Our basic premise, that predictions with high confidence score are of high quality, is further used to improve the performance of the unsupervised train-

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1486–1495,
Portland, Oregon, June 19-24, 2011.

ing procedure. Our learning algorithm takes an EM-like iterative approach, in which the predictions of the previous stage are used to bias the model. While this basic scheme was successfully applied to many unsupervised tasks, it is known to converge to a sub optimal point. We show that by using confidence estimation as a proxy for the model's prediction quality, the learning algorithm can identify a better model compared to the default convergence criterion.

We evaluate our learning approach and model on the well studied Geoquery domain (Zelle and Mooney, 1996; Tang and Mooney, 2001), consisting of natural language questions and their prolog interpretations used to query a database consisting of U.S. geographical information. Our experimental results show that using our approach we are able to train a good semantic parser without annotated data, and that using a confidence score to identify good models results in a significant performance improvement.

2 Semantic Parsing

We formulate semantic parsing as a structured prediction problem, mapping a NL input sentence (denoted $\mathbf{x}$), to its highest ranking MR (denoted $\mathbf{z}$). In order to correctly parametrize and weight the possible outputs, the decision relies on an intermediate representation: an alignment between textual fragments and their meaning representation (denoted $\mathbf{y}$). Fig. 1 describes a concrete example of this terminology. In our experiments the input sentences $\mathbf{x}$ are natural language queries about U.S. geography taken from the Geoquery dataset. The meaning representation $\mathbf{z}$ is a formal language database query, this output representation language is described in Sec. 2.1.

The prediction function, mapping a sentence to its corresponding MR, is formalized as follows:

$$\hat{\mathbf{z}} = F_{\mathbf{w}}(\mathbf{x}) = \arg\max_{\mathbf{y}\in\mathcal{Y},\mathbf{z}\in\mathcal{Z}} \mathbf{w}^T \Phi(\mathbf{x}, \mathbf{y}, \mathbf{z}) \qquad (1)$$

Where Φ is a feature function defined over an input sentence $\mathbf{x}$, alignment $\mathbf{y}$ and output $\mathbf{z}$. The weight vector $\mathbf{w}$ contains the model's parameters, whose values are determined by the learning process.

We refer to the $\arg\max$ above as the inference problem. Given an input sentence, solving this inference problem based on Φ and $\mathbf{w}$ is what compromises our semantic parser. In practice the parsing decision is decomposed into smaller decisions (Sec. 2.2). Sec. 4 provides more details about the feature representation and inference procedure used.

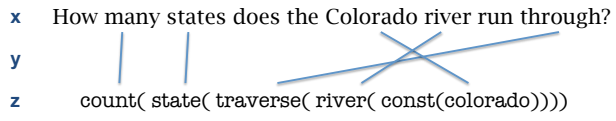

Figure 1: Example of an input sentence ($\mathbf{x}$), meaning representation ($\mathbf{z}$) and the alignment between the two ($\mathbf{y}$) for the Geoquery domain

Current approaches obtain $\mathbf{w}$ using annotated data, typically consisting of ($\mathbf{x}$, $\mathbf{z}$) pairs. In Sec. 3 we describe our unsupervised learning procedure, that is how to obtain $\mathbf{w}$ without annotated data.

2.1 Target Meaning Representation

The output of the semantic parser is a logical formula, grounding the semantics of the input sentence in the domain language (i.e., the Geoquery domain). We use a subset of first order logic consisting of typed constants (corresponding to specific states, etc.) and functions, which capture relations between domains entities and properties of entities (e.g., `population` : $E \rightarrow N$). The semantics of the input sentence is constructed via functional composition, done by the substitution operator. For example, given the function `next_to(x)` and the expression `const(texas)`, substitution replaces the occurrence of the free variable `x` with the expression, resulting in a new formula: `next_to(const(texas))`. For further details we refer the reader to (Zelle and Mooney, 1996).

2.2 Semantic Parsing Decisions

The inference problem described in Eq. 1 selects the top ranking output formula. In practice this decision is decomposed into smaller decisions, capturing local mapping of input tokens to logical fragments and their composition into larger fragments. These decisions are further decomposed into a feature representation, described in Sec. 4.

The first type of decisions are encoded directly by the alignment ($\mathbf{y}$) between the input tokens and their corresponding predicates. We refer to these as **first**

order decisions. The pairs connected by the alignment ($\mathbf{y}$) in Fig. 1 are examples of such decisions.

The final output structure $\mathbf{z}$ is constructed by composing individual predicates into a complete formula. For example, consider the formula presented in Fig. 1: `river( const(colorado))` is a composition of two predicates `river` and `const(colorado)`. We refer to the composition of two predicates, associated with their respective input tokens, as **second order decisions**.

In order to formulate these decisions, we introduce the following notation. c is a constituent in the input sentence $\mathbf{x}$ and $\mathcal{D}$ is the set of all function and constant symbols in the domain. The alignment $\mathbf{y}$ is a set of mappings between constituents and symbols in the domain $\mathbf{y} = \{(c, s)\}$ where $s \in \mathcal{D}$.

We denote by s_i the i-th output predicate composition in $\mathbf{z}$, by $s_{i-1}(s_i)$ the composition of the $(i-1)$-th predicate on the i-th predicate and by $y(s_i)$ the input word corresponding to that predicate according to the alignment $\mathbf{y}$.

3 Unsupervised Semantic Parsing

Our learning framework takes a self training approach in which the learner is iteratively trained over its own predictions. Successful application of this approach depends heavily on two important factors - how to select high quality examples to train the model on, and how to define the learning objective so that learning can halt once a good model is found.

Both of these questions are trivially answered when working in a supervised setting: by using the labeled data for training the model, and defining the learning objective with respect to the annotated data (for example, loss-minimization in the supervised version of our system).

In this work we suggest to address both of the above concerns by approximating the quality of the model's predictions using a confidence measure computed over the statistics of the self generated predictions. Output structures which fall close to the center of mass of these statistics will receive a high confidence score.

The first issue is addressed by using examples assigned a high confidence score to train the model, acting as labeled examples.

We also note that since the confidence score provides a good indication for the model's prediction performance, it can be used to approximate the overall *model* performance, by observing the model's total confidence score over all its predictions. This allows us to set a performance driven goal for our learning process - return the model maximizing the confidence score over all predictions. We describe the details of integrating the confidence score into the learning framework in Sec. 3.1.

Although using the model's prediction score (i.e., $\mathbf{w}^T\Phi(\mathbf{x}, \mathbf{y}, \mathbf{z})$) as an indication of correctness is a natural choice, we argue and show empirically, that unsupervised learning driven by confidence estimation results in a better performing model. This empirical behavior also has theoretical justification: training the model using examples selected according to the model's parameters (i.e., the top ranking structures) may not generalize much further beyond the existing model, as the training examples will simply reinforce the existing model. The statistics used for confidence estimation are different than those used by the model to create the output structures, and can therefore capture additional information unobserved by the prediction model. This assumption is based on the well established idea of multi-view learning, applied successfully to many NL applications (Blum and Mitchell, 1998; Collins and Singer, 1999). According to this idea if two models use different views of the data, each of them can enhance the learning process of the other.

The success of our learning procedure hinges on finding good confidence measures, whose confidence prediction correlates well with the true quality of the prediction. The ability of unsupervised confidence estimation to provide high quality confidence predictions can be explained by the observation that prominent prediction patterns are more likely to be correct. If a non-random model produces a prediction pattern multiple times it is likely to be an indication of an underlying phenomenon in the data, and therefore more likely to be correct. Our specific choice of confidence measures is guided by the intuition that unlike structure prediction (i.e., solving the inference problem) which requires taking statistics over complex and intricate patterns, identifying high quality predictions can be done using much simpler patterns that are significantly easier to capture.

In the reminder of this section we describe our

Algorithm 1 Unsupervised Confidence driven Learning

Input: Sentences $\{\mathbf{x}^l\}_{l=1}^N$,
initial weight vector $\mathbf{w}$

1: **define** $Confidence : \mathcal{X} \times \mathcal{Y} \times \mathcal{Z} \rightarrow \mathcal{R}$,
$i = 0,\ S_i = \emptyset$
2: **repeat**
3: **for** $l = 1, \ldots, N$ **do**
4: $\hat{\mathbf{y}}, \hat{\mathbf{z}} = \arg\max_{\mathbf{y},\mathbf{z}} \mathbf{w}^T \Phi(\mathbf{x}^l, \mathbf{y}, \mathbf{z})$
5: $S_i = S_i \cup \{\mathbf{x}^l, \hat{\mathbf{y}}, \hat{\mathbf{z}}\}$
6: **end for**
7: $Confidence$ = compute confidence statistics
8: S_i^{conf} = select from S_i using $Confidence$
9: $\mathbf{w_i} \leftarrow Learn(\cup_i S_i^{conf})$
10: $i = i + 1$
11: **until** S_i^{conf} has no new unique examples
12: $best = \arg\max_{\mathbf{i}}(\sum_{s \in S_i} Confidence(s))/|S|$
13: **return** $\mathbf{w_{best}}$

learning approach. We begin by introducing the overall learning framework (Sec. 3.1), we then explain the rational behind confidence estimation over self-generated data and introduce the confidence measures used in our experiments (Sec. 3.2). We conclude with a description of the specific learning algorithms used for updating the model (Sec. 3.3).

3.1 Unsupervised Confidence-Driven Learning

Our learning framework works in an EM-like manner, iterating between two stages: making predictions based on its current set of parameters and then retraining the model using a subset of the predictions, assigned high confidence. The learning process "discovers" new high confidence training examples to add to its training set over multiple iterations, and converges when the model no longer adds new training examples.

While this is a natural convergence criterion, it provides no performance guarantees, and in practice it is very likely that the quality of the model (i.e., its performance) fluctuates during the learning process. We follow the observation that confidence estimation can be used to approximate the performance of the entire model and return the model with the highest overall prediction confidence.

We describe this algorithmic framework in detail in Alg. 1. Our algorithm takes as input a set of natural language sentences and a set of parameters used for making the initial predictions[1]. The algorithm then iterates between the two stages - predicting the output structure for each sentence (line 4), and updating the set of parameters (line 9). The specific learning algorithms used are discussed in Sec. 3.3. The training examples required for learning are obtained by selecting high confidence examples - the algorithm first takes statistics over the current predicted set of output structures (line 7), and then based on these statistics computes a confidence score for each structure, selecting the top ranked ones as positive training examples, and if needed, the bottom ones as negative examples (line 8). The set of top confidence examples (for either correct or incorrect prediction), at iteration i of the algorithm, is denoted S_i^{conf}. The exact nature of the confidence computation is discussed in Sec. 3.2.

The algorithm iterates between these two stages, at each iteration it adds more self-annotated examples to its training set, learning therefore converges when no new examples are added (line 11). The algorithm keeps track of the models it trained at each stage throughout this process, and returns the one with the highest averaged overall confidence score (lines 12-13). At each stage, the overall confidence score is computed by averaging over all the confidence scores of the predictions made at that stage.

3.2 Unsupervised Confidence Estimation

Confidence estimation is calculated over a batch of input ($\mathbf{x}$) - output ($\mathbf{z}$) pairs. Each pair decomposes into smaller first order and second order decisions (defined Sec. 2.2). Confidence estimation is done by computing the statistics of these decisions, over the entire set of predicted structures. In the rest of this section we introduce the confidence measures used by our system.

Translation Model The first approach essentially constructs a simplified translation model, capturing word-to-predicate mapping patterns. This can be considered as an abstraction of the prediction model: we collapse the intricate feature representation into

[1] Since we commit to the max-score output prediction, rather than summing over all possibilities, we require a reasonable initialization point. We initialized the weight vector using simple, straight-forward heuristics described in Sec. 5.

high level decisions and take statistics over these decisions. Since it takes statistics over considerably less variables than the actual prediction model, we expect this model to make reliable confidence predictions. We consider two variations of this approach, the first constructs a unigram model over the first order decisions and the second a bigram model over the second order decisions. Formally, given a set of predicted structures we define the following confidence scores:

Unigram Score:

$$p(\mathbf{z}|\mathbf{x}) = \prod_{i=1}^{|z|} p(s_i|y(s_i))$$

Bigram Score:

$$p(\mathbf{z}|\mathbf{x}) = \prod_{i=1}^{|z|} p(s_{i-1}(s_i)|y(s_{i-1}), y(s_i))$$

Structural Proportion Unlike the first approach which decomposes the predicted structure into individual decisions, this approach approximates the model's performance by observing global properties of the structure. We take statistics over the proportion between the number of predicates in $\mathbf{z}$ and the number of words in $\mathbf{x}$.

Given a set of structure predictions S, we compute this proportion for each structure (denoted as $Prop(\mathbf{x}, \mathbf{z})$) and calculate the average proportion over the entire set (denoted as $AvProp(S)$). The confidence score assigned to a given structure $(\mathbf{x}, \mathbf{y})$ is simply the difference between its proportion and the averaged proportion, or formally

$$PropScore(S, (\mathbf{x}, \mathbf{z})) = AvProp(S) - Prop(x, z)$$

This measure captures the global complexity of the predicted structure and penalizes structures which are too complex (high negative values) or too simplistic (high positive values).

Combined The two approaches defined above capture different views of the data, a natural question is then - *can these two measures be combined to provide a more powerful estimation?* We suggest a third approach which combines the first two approaches. It first uses the score produced by the latter approach to filter out unlikely candidates, and then ranks the remaining ones with the former approach and selects those with the highest rank.

3.3 Learning Algorithms

Given a set of self generated structures, the parameter vector can be updated (line 9 in Alg. 1). We consider two learning algorithm for this purpose.

The first is a **binary learning** algorithm, which considers learning as a classification problem, that is finding a set of weights $\mathbf{w}$ that can best separate correct from incorrect structures. The algorithm decomposes each predicted formula and its corresponding input sentence into a feature vector $\Phi(\mathbf{x}, \mathbf{y}, \mathbf{z})$ normalized by the size of the input sentence $|\mathbf{x}|$, and assigns a binary label to this vector[2]. The learning process is defined over both positive and negative training examples. To accommodate that we modify line 8 in Alg. 1, and use the confidence score to select the top ranking examples as positive examples, and the bottom ranking examples as negative examples. We use a linear kernel SVM with squared-hinge loss as the underlying learning algorithm.

The second is a **structured learning** algorithm which considers learning as a ranking problem, i.e., finding a set of weights $\mathbf{w}$ such that the "gold structure" will be ranked on top, preferably by a large margin to allow generalization.The structured learning algorithm can directly use the top ranking predictions of the model (line 8 in Alg. 1) as training data. In this case the underlying algorithm is a structural SVM with squared-hinge loss, using hamming distance as the distance function. We use the cutting-plane method to efficiently optimize the learning process' objective function.

4 Model

Semantic parsing as formulated in Eq. 1 is an inference procedure selecting the top ranked output logical formula. We follow the inference approach in (Roth and Yih, 2007; Clarke et al., 2010) and formalize this process as an Integer Linear Program (ILP). Due to space consideration we provide a brief description, and refer the reader to that paper for more details.

[2]Without normalization longer sentences would have more influence on binary learning problem. Normalization is therefore required to ensure that each sentence contributes equally to the binary learning problem regardless of its length.

4.1 Inference

The inference decision (Eq. 1) is decomposed into smaller decisions, capturing mapping of input tokens to logical fragments (first order) and their composition into larger fragments (second order). We encode a first-order decision as α_{cs}, a binary variable indicating that constituent c is aligned with the logical symbol $\mathtt{s}$. A second-order decision $\beta_{cs,dt}$, is encoded as a binary variable indicating that the symbol $\mathtt{t}$ (associated with constituent d) is an argument of a function $\mathtt{s}$ (associated with constituent c). We frame the inference problem over these decisions:

$$F_{\mathbf{w}}(\mathbf{x}) = \arg\max_{\alpha,\beta} \sum_{c \in \mathbf{x}} \sum_{s \in D} \alpha_{cs} \cdot \mathbf{w}^T \Phi_1(\mathbf{x}, c, s) + \sum_{c,d \in \mathbf{x}} \sum_{s,t \in D} \beta_{cs,dt} \cdot \mathbf{w}^T \Phi_2(\mathbf{x}, c, s, d, t) \quad (2)$$

We restrict the possible assignments to the decision variables, forcing the resulting output formula to be *syntactically* legal, for example by restricting active β-variables to be type consistent, and force the resulting functional composition to be acyclic. We take advantage of the flexible ILP framework, and encode these restrictions as global constraints over Eq. 2. We refer the reader to (Clarke et al., 2010) for a full description of the constraints used.

4.2 Features

The inference problem defined in Eq. (2) uses two feature functions: Φ_1 and Φ_2.

First-order decision features Φ_1 Determining if a logical symbol is aligned with a specific constituent depends mostly on lexical information. Following previous work (e.g., (Zettlemoyer and Collins, 2005)) we create a small lexicon, mapping logical symbols to surface forms.[3] Existing approaches rely on annotated data to extend the lexicon. Instead we rely on external knowledge (Miller et al., 1990) and add features which measure the lexical similarity between a constituent and a logical symbol's surface forms (as defined by the lexicon).

[3]The lexicon contains on average 1.42 words per function and 1.07 words per constant.

Model	Description
INITIAL MODEL	Manually set weights (Sec. 5.1)
PRED. SCORE	normalized prediction (Sec. 5.1)
ALL EXAMPLES	All top structures (Sec. 5.1)
UNIGRAM	Unigram score (Sec. 3.2)
BIGRAM	Bigram score (Sec. 3.2)
PROPORTION	Words-predicate prop (Sec. 3.2)
COMBINED	Combined estimators (Sec. 3.2)
RESPONSE BASED	Supervised (binary) (Sec. 5.1)
SUPERVISED	Fully Supervised (Sec. 5.1)

Table 1: Compared systems and naming conventions.

Second-order decision features Φ_2 Second order decisions rely on syntactic information. We use the dependency tree of the input sentence. Given a second-order decision $\beta_{cs,dt}$, the dependency feature takes the normalized distance between the head words in the constituents c and d. In addition, a set of features indicate which logical symbols are usually composed together, without considering their alignment to the text.

5 Experiments

In this section we describe our experimental evaluation. We compare several confidence measures and analyze their properties. Tab. 1 defines the naming conventions used throughout this section to refer to the different models we evaluated. We begin by describing our experimental setup and then proceed to describe the experiments and their results. For the sake of clarity we focus on the best performing models (COMBINED using BIGRAM and PROPORTION) first and discuss other models later in the section.

5.1 Experimental Settings

In all our experiments we used the Geoquery dataset (Zelle and Mooney, 1996), consisting of U.S. geography NL questions and their corresponding Prolog logical MR. We used the data split described in (Clarke et al., 2010), consisting of 250 queries for evaluation purposes. We compared our system to several supervised models, which were trained using a disjoint set of queries. Our learning system had access only to the NL questions, and the logical forms were only used to evaluate the system's performance. We report the proportion of correct structures (accuracy). Note that this evaluation cor-

responds to the 0/1 loss over the predicted structures.

Initialization Our learning framework requires an initial weight vector as input. We use a straight forward heuristic and provide uniform positive weights to three features. This approach is similar in spirit to previous works (Clarke et al., 2010; Zettlemoyer and Collins, 2007). We refer to this system as INITIAL MODEL throughout this section.

Competing Systems We compared our system to several other systems:

(1) **PRED. SCORE**: An unsupervised framework using the model's internal prediction score ($\mathbf{w}^T\Phi(\mathbf{x},\mathbf{y},\mathbf{z})$) for confidence estimation.

(2) **ALL EXAMPLES**: Treating all predicted structures as correct, i.e., at each iteration the model is trained over all the predictions it made. The reported score was obtained by selecting the model at the training iteration with the highest overall confidence score (see line 12 in Alg. 1).

(3) **RESPONSE BASED**: A natural upper bound to our framework is the approach used in (Clarke et al., 2010). While our approach is based on assessing the correctness os the model's predictions according to unsupervised confidence estimation, their framework is provided with external supervision for these decisions, indicating if the predicted structures are correct.

(4) **SUPERVISED**: A fully supervised framework trained over 250 $(\mathbf{x},\mathbf{z})$ pairs using structured SVM.

5.2 Results

Our experiments aim to clarify three key points:

(1) Can a semantic parser indeed be trained without any form of external supervision? this is our key question, as this is the first attempt to approach this task with an unsupervised learning protocol.[4] In order to answer it, we report the overall performance of our system in Tab. 2.

The manually constructed model INITIALMODEL achieves a performance of 0.22. We can expect learning to improve on this baseline. We compare three self-trained systems, ALL EXAMPLES, PREDICTIONSCORE and COMBINED, which differ in their sample selection strategy, but all use confidence estimation for selecting the final semantic parsing model. The ALL EXAMPLES approach achieves an accuracy score of 0.656. PREDICTIONSCORE only achieves a performance of 0.164 using the binary learning algorithm and 0.348 using the structured learning algorithm. Finally, our confidence-driven technique COMBINED achieved a score of 0.536 for the binary case and 0.664 for the structured case, the best performing models in both cases. As expected, the supervised systems RESPONSE BASED and SUPERVISED achieve the best performance.

These results show that training the model with training examples selected carefully will improve learning - as the best performance is achieved with perfect knowledge of the predictions correctness (RESPONSE BASED). Interestingly the difference between the structured version of our system and that of RESPONSE BASED is only 0.07, suggesting that we can recover the binary feedback signal with high precision. The low performance of the PREDICTIONSCORE model is also not surprising, and it demonstrates one of the key principles in confidence estimation - the score should be comparable across predictions done over different inputs, and not the same input, as done in PREDICTIONSCORE model.

(2) How does confidence driven sample selection contribute to the learning process? Comparing the systems driven by confidence sample-selection to the ALL EXAMPLES approach uncovers an interesting tradeoff between training with more (noisy) data and selectively training the system with higher quality examples. We argue that carefully selecting high quality training examples will result in better performance. The empirical results indeed support our argument, as the best performing model (RESPONSE BASED) is achieved by sample selection with perfect knowledge of prediction correctness. The confidence-based sample selection system (COMBINED) is the best performing system out of all the self-trained systems. Nonetheless, the ALL EXAMPLES strategy performs well when compared to COMBINED, justifying a closer look at that aspect of our system.

We argue that different confidence measures capture different properties of the data, and hypothe-

[4] While unsupervised learning for various semantic tasks has been widely discussed, this is the first attempt to tackle this task. We refer the reader to Sec. 6 for further discussion of this point.

size that combining their scores will improve the resulting model. In Tab. 3 we compare the results of the COMBINED measure to the results of its individual components - PROPORTION and BIGRAM. We compare these results both when using the binary and structured learning algorithms. Results show that using the COMBINED measure leads to an improved performance, better than any of the individual measures, suggesting that it can effectively exploit the properties of each confidence measure. Furthermore, COMBINED is the only sample selection strategy that outperforms ALL EXAMPLES.

(3) Can confidence measures serve as a good proxy for the model's performance? In the unsupervised settings we study the learning process may not converge to an optimal model. We argue that by selecting the model that maximizes the averaged confidence score, a better model can be found. We validate this claim empirically in Tab. 4. We compare the performance of the model selected using the confidence score to the performance of the final model considered by the learning algorithm (see Sec. 3.1 for details). We also compare it to the best model achieved in any of the learning iterations.

Since these experiments required running the learning algorithm many times, we focused on the binary learning algorithm as it converges considerably faster. In order to focus the evaluation on the effects of learning, we ignore the initial model generated manually (INITIAL MODEL) in these experiments. In order to compare models performance across the different iterations fairly, a uniform scale, such as UNIGRAM and BIGRAM, is required. In the case of the COMBINED measure we used the BIGRAM measure for performance estimation, since it is one of its underlying components. In the PRED. SCORE and PROPORTION models we used both their confidence prediction, and the simple UNIGRAM confidence score to evaluate *model* performance (the latter appear in parentheses in Tab. 4).

Results show that the over overall confidence score serves as a reliable proxy for the model performance - using UNIGRAM and BIGRAM the framework can select the best performing model, far better than the performance of the default model to which the system converged.

Algorithm	Supervision	Acc.
INITIAL MODEL	—	0.222
SELF-TRAIN: (*Structured*)		
PRED. SCORE	—	0.348
ALL EXAMPLES	—	0.656
COMBINED	—	**0.664**
SELF-TRAIN: (*Binary*)		
PRED. SCORE	—	0.164
COMBINED	—	0.536
RESPONSE BASED		
BINARY	250 (binary)	0.692
STRUCTURED	250 (binary)	0.732
SUPERVISED		
STRUCTURED	250 (struct.)	0.804

Table 2: Comparing our *Self-trained* systems with Response-based and supervised models. Results show that our COMBINED approach outperforms all other unsupervised models.

Algorithm	Accuracy
SELF-TRAIN: (*Structured*)	
PROPORTION	0.6
BIGRAM	0.644
COMBINED	0.664
SELF-TRAIN: (*Binary*)	
BIGRAM	0.532
PROPORTION	0.504
COMBINED	0.536

Table 3: Comparing COMBINED to its components BIGRAM and PROPORTION. COMBINED results in a better score than any of its components, suggesting that it can exploit the properties of each measure effectively.

Algorithm	Best	Conf. estim.	Default
PRED. SCORE	0.164	0.128 (0.164)	0.134
UNIGRAM	0.52	0.52	0.4
BIGRAM	0.532	0.532	0.472
PROPORTION	0.504	0.27 (0.504)	0.44
COMBINED	0.536	0.536	0.328

Table 4: Using confidence to approximate model performance. We compare the best result obtained in any of the learning algorithm iterations (Best), the result obtained by approximating the best result using the averaged prediction confidence (Conf. estim.) and the result of using the default convergence criterion (Default). Results in parentheses are the result of using the UNIGRAM confidence to approximate the model's performance.

6 Related Work

Semantic parsing has attracted considerable interest in recent years. Current approaches employ various machine learning techniques for this task, such as Inductive Logic Programming in earlier systems (Zelle and Mooney, 1996; Tang and Mooney, 2000) and statistical learning methods in modern ones (Ge and Mooney, 2005; Nguyen et al., 2006; Wong and Mooney, 2006; Kate and Mooney, 2006; Zettlemoyer and Collins, 2005; Zettlemoyer and Collins, 2007; Zettlemoyer and Collins, 2009).

The difficulty of providing the required supervision motivated learning approaches using weaker forms of supervision. (Chen and Mooney, 2008; Liang et al., 2009; Branavan et al., 2009; Titov and Kozhevnikov, 2010) ground NL in an external world state directly referenced by the text. The NL input in our setting is not restricted to such grounded settings and therefore we cannot exploit this form of supervision. Recent work (Clarke et al., 2010; Liang et al., 2011) suggest using response-based learning protocols, which alleviate some of the supervision effort. This work takes an additional step in this direction and suggest an unsupervised protocol.

Other approaches to unsupervised semantic analysis (Poon and Domingos, 2009; Titov and Klementiev, 2011) take a different approach to semantic representation, by clustering semantically equivalent dependency tree fragments, and identifying their predicate-argument structure. While these approaches have been applied successfully to semantic tasks such as question answering, they do not ground the input in a well defined output language, an essential component in our task.

Our unsupervised approach follows a self training protocol (Yarowsky, 1995; McClosky et al., 2006; Reichart and Rappoport, 2007b) enhanced with constraints restricting the output space (Chang et al., 2007; Chang et al., 2009). A Self training protocol uses its own predictions for training. We estimate the quality of the predictions and use only high confidence examples for training. This selection criterion provides an additional view, different than the one used by the prediction model. Multi-view learning is a well established idea, implemented in methods such as co-training (Blum and Mitchell, 1998).

Quality assessment of a learned model output was explored by many previous works (see (Caruana and Niculescu-Mizil, 2006) for a survey), and applied to several NL processing tasks such as syntactic parsing (Reichart and Rappoport, 2007a; Yates et al., 2006), machine translation (Ueffing and Ney, 2007), speech (Koo et al., 2001), relation extraction (Rosenfeld and Feldman, 2007), IE (Culotta and McCallum, 2004), QA (Chu-Carroll et al., 2003) and dialog systems (Lin and Weng, 2008).

In addition to sample selection we use confidence estimation as a way to approximate the overall quality of the model and use it for model selection. This use of confidence estimation was explored in (Reichart et al., 2010), to select between models trained with different random starting points. In this work we integrate this estimation deeper into the learning process, thus allowing our training procedure to return the best performing model.

7 Conclusions

We introduced an unsupervised learning algorithm for semantic parsing, the first for this task to the best of our knowledge. To compensate for the lack of training data we use a self-training protocol, driven by unsupervised confidence estimation. We demonstrate empirically that our approach results in a high preforming semantic parser and show that confidence estimation plays a vital role in this success, both by identifying good training examples as well as identifying good over all performance, used to improve the final model selection.

In future work we hope to further improve unsupervised semantic parsing performance. Particularly, we intend to explore new approaches for confidence estimation and their usage in the unsupervised and semi-supervised versions of the task.

Aspect Ranking: Identifying Important Product Aspects from Online Consumer Reviews

Jianxing Yu, Zheng-Jun Zha, Meng Wang, Tat-Seng Chua
School of Computing
National University of Singapore
{jianxing, zhazj, wangm, chuats}@comp.nus.edu.sg

Abstract

In this paper, we dedicate to the topic of aspect ranking, which aims to automatically identify important product aspects from online consumer reviews. The important aspects are identified according to two observations: (a) the important aspects of a product are usually commented by a large number of consumers; and (b) consumers' opinions on the important aspects greatly influence their overall opinions on the product. In particular, given consumer reviews of a product, we first identify the product aspects by a shallow dependency parser and determine consumers' opinions on these aspects via a sentiment classifier. We then develop an aspect ranking algorithm to identify the important aspects by simultaneously considering the aspect frequency and the influence of consumers' opinions given to each aspect on their overall opinions. The experimental results on 11 popular products in four domains demonstrate the effectiveness of our approach. We further apply the aspect ranking results to the application of document-level sentiment classification, and improve the performance significantly.

1 Introduction

The rapidly expanding e-commerce has facilitated consumers to purchase products online. More than $156 million online product retail sales have been done in the US market during 2009 (Forrester Research, 2009). Most retail Web sites encourage consumers to write reviews to express their opinions on various aspects of the products. This gives rise to huge collections of consumer reviews on the Web. These reviews have become an important resource for both consumers and firms. Consumers commonly seek quality information from online consumer reviews prior to purchasing a product, while many firms use online consumer reviews as an important resource in their product development, marketing, and consumer relationship management. As illustrated in Figure 1, most online reviews express consumers' overall opinion ratings on the product, and their opinions on multiple aspects of the product. While a product may have hundreds of aspects, we argue that some aspects are more important than the others and have greater influence on consumers' purchase decisions as well as firms' product development strategies. Take *iPhone 3GS* as an example, some aspects like "*battery*" and "*speed*," are more important than the others like "*moisture sensor*." Generally, identifying the important product aspects will benefit both consumers and firms. Consumers can conveniently make wise purchase decision by paying attentions on the important aspects, while firms can focus on improving the quality of

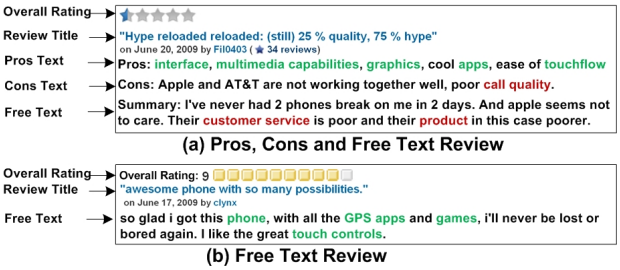

Figure 1: Sample reviews on *iPhone 3GS* product

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1496–1505,
Portland, Oregon, June 19-24, 2011.

these aspects and thus enhance the product reputation effectively. However, it is impractical for people to identify the important aspects from the numerous reviews manually. Thus, it becomes a compelling need to automatically identify the important aspects from consumer reviews.

A straightforward solution for important aspect identification is to select the aspects that are frequently commented in consumer reviews as the important ones. However, consumers' opinions on the frequent aspects may not influence their overall opinions on the product, and thus not influence consumers' purchase decisions. For example, most consumers frequently criticize the bad "*signal connection*" of *iPhone 4*, but they may still give high overall ratings to *iPhone 4*. On the other hand, some aspects, such as "*design*" and "*speed*," may not be frequently commented, but usually more important than "*signal connection*." Hence, the frequency-based solution is not able to identify the truly important aspects.

Motivated by the above observations, in this paper, we propose an effective approach to automatically identify the important product aspects from consumer reviews. Our assumption is that the important aspects of a product should be the aspects that are frequently commented by consumers, and consumers' opinions on the important aspects greatly influence their overall opinions on the product. Given the online consumer reviews of a specific product, we first identify the aspects in the reviews using a shallow dependency parser (Wu et al., 2009), and determine consumers' opinions on these aspects via a sentiment classifier. We then design an aspect ranking algorithm to identify the important aspects by simultaneously taking into account the aspect frequency and the influence of consumers' opinions given to each aspect on their overall opinions. Specifically, we assume that consumer's overall opinion rating on a product is generated based on a weighted sum of his/her specific opinions on multiple aspects of the product, where the weights essentially measure the degree of importance of the aspects. A probabilistic regression algorithm is then developed to derive these importance weights by leveraging the aspect frequency and the consistency between the overall opinions and the weighted sum of opinions on various aspects. We conduct experiments on 11 popular products in four domains. The consumer reviews on these products are crawled from the prevalent forum Web sites (e.g., cnet.com and viewpoint.com etc.) More details of our review corpus are discussed in Section 3. The experimental results demonstrate the effectiveness of our approach on important aspects identification. Furthermore, we apply the aspect ranking results to the application of document-level sentiment classification by carrying out the term-weighting based on the aspect importance. The results show that our approach can improve the performance significantly.

The main contributions of this paper include,

1) We dedicate to the topic of aspect ranking, which aims to automatically identify important aspects of a product from consumer reviews.

2) We develop an aspect ranking algorithm to identify the important aspects by simultaneously considering the aspect frequency and the influence of consumers' opinions given to each aspect on their overall opinions.

3) We apply aspect ranking results to the application of document-level sentiment classification, and improve the performance significantly.

There is another work named aspect ranking (Snyder et al., 2007). The task in this work is different from ours. This work mainly focuses on predicting opinionated ratings on aspects rather than identifying important aspects.

The rest of this paper is organized as follows. Section 2 elaborates our aspect ranking approach. Section 3 presents the experimental results, while Section 4 introduces the application of document-level sentiment classification. Section 5 reviews related work and Section 6 concludes this paper with future works.

2 Aspect Ranking Framework

In this section, we first present some notations and then elaborate the key components of our approach, including the aspect identification, sentiment classification, and aspect ranking algorithm.

2.1 Notations and Problem Formulation

Let $\mathcal{R} = \{r_1, \cdots, r_{|\mathcal{R}|}\}$ denotes a set of online consumer reviews of a specific product. Each review $r \in \mathcal{R}$ is associated with an overall opinion rating

$\mathcal{O}_r$, and covers several aspects with consumer comments on these aspects. Suppose there are m aspects $\mathcal{A} = \{a_1, \cdots, a_m\}$ involved in the review corpus $\mathcal{R}$, where a_k is the k-th aspect. We define o_{rk} as the opinion on aspect a_k in review r. We assume that the overall opinion rating $\mathcal{O}_r$ is generated based on a weighted sum of the opinions on specific aspects o_{rk} (Wang et al., 2010). The weights are denoted as $\{\omega_{rk}\}_{k=1}^{m}$, each of which essentially measures the degree of importance of the aspect a_k in review r. Our task is to derive the important weights of aspects, and identify the important aspects.

Next, we will introduce the key components of our approach, including aspect identification that identifies the aspects a_k in each review r, aspect sentiment classification which determines consumers' opinions o_{rk} on various aspects, and aspect ranking algorithm that identifies the important aspects.

2.2 Aspect Identification

As illustrated in Figure 1, there are usually two types of reviews, *Pros and Cons* review and free text reviews on the Web. For *Pros* and *Cons* reviews, the aspects are identified as the frequent noun terms in the reviews, since the aspects are usually noun or noun phrases (Liu, 2009), and it has been shown that simply extracting the frequent noun terms from the *Pros* and *Cons* reviews can get high accurate aspect terms (Liu el al., 2005). To identify the aspects in free text reviews, we first parse each review using the Stanford parser [1], and extract the noun phrases (*NP*) from the parsing tree as aspect candidates. While these candidates may contain much noise, we leverage the *Pros* and *Cons* reviews to assist identify aspects from the candidates. In particular, we explore the frequent noun terms in *Pros* and *Cons* reviews as features, and train a one-class *SVM* (Manevitz et al., 2002) to identify aspects in the candidates. While the obtained aspects may contain some synonym terms, such as "*earphone*" and "*headphone*," we further perform synonym clustering to get unique aspects. Specifically, we first expand each aspect term with its synonym terms obtained from the synonym terms Web site [2], and then cluster the terms to obtain unique aspects based on unigram feature.

[1] http://nlp.stanford.edu/software/lex-parser.shtml

[2] http://thesaurus.com

2.3 Aspect Sentiment Classification

Since the *Pros* and *Cons* reviews explicitly express positive and negative opinions on the aspects, respectively, our task is to determine the opinions in free text reviews. To this end, we here utilize *Pros* and *Cons* reviews to train a *SVM* sentiment classifier. Specifically, we collect sentiment terms in the *Pros* and *Cons* reviews as features and represent each review into feature vector using Boolean weighting. Note that we select sentiment terms as those appear in the sentiment lexicon provided by *MPQA* project (Wilson et al., 2005). With these features, we then train a *SVM* classifier based on *Pros* and *Cons* reviews. Given a free text review, since it may cover various opinions on multiple aspects, we first locate the opinionated expression modifying each aspect, and determine the opinion on the aspect using the learned *SVM* classifier. In particular, since the opinionated expression on each aspect tends to contain sentiment terms and appear closely to the aspect (Hu and Liu, 2004), we select the expressions which contain sentiment terms and are at the distance of less than 5 from the aspect *NP* in the parsing tree.

2.4 Aspect Ranking

Generally, consumer's opinion on each specific aspect in the review influences his/her overall opinion on the product. Thus, we assume that the consumer gives the overall opinion rating $\mathcal{O}_r$ based on the weighted sum of his/her opinion o_{rk} on each aspect a_k: $\sum_{k=1}^{m} \omega_{rk} o_{rk}$, which can be rewritten as $\boldsymbol{\omega_r}^T \boldsymbol{o_r}$, where $\boldsymbol{\omega_r}$ and $\boldsymbol{o_r}$ are the weight and opinion vectors. Inspired by the work of Wang et al. (2010), we view $\mathcal{O}_r$ as a sample drawn from a *Gaussian Distribution*, with mean $\boldsymbol{\omega_r}^T \boldsymbol{o_r}$ and variance σ^2,

$$p(\mathcal{O}_r) = \frac{1}{\sqrt{2\pi\sigma^2}} exp[-\frac{(\mathcal{O}_r - \boldsymbol{\omega_r}^T \boldsymbol{o_r})^2}{2\sigma^2}]. \quad (1)$$

To model the uncertainty of the importance weights $\boldsymbol{\omega_r}$ in each review, we assume $\boldsymbol{\omega_r}$ as a sample drawn from a *Multivariate Gaussian Distribution*, with $\boldsymbol{\mu}$ as the mean vector and $\boldsymbol{\Sigma}$ as the covariance matrix,

$$p(\boldsymbol{\omega_r}) = \frac{1}{(2\pi)^{n/2}|\boldsymbol{\Sigma}|^{1/2}} exp[-\frac{1}{2}(\boldsymbol{\omega_r} - \boldsymbol{\mu})^T \boldsymbol{\Sigma}^{-1} (\boldsymbol{\omega_r} - \boldsymbol{\mu})]. \quad (2)$$

We further incorporate aspect frequency as a prior knowledge to define the distribution of $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$. Specifically, the distribution of $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ is defined based on its Kullback-Leibler (KL) divergence to a prior distribution with a mean vector $\boldsymbol{\mu_0}$ and an identity covariance matrix $\boldsymbol{I}$ in Eq.3. Each element in $\boldsymbol{\mu_0}$ is defined as the frequency of the corresponding aspect: $frequency(a_k)/\sum_{i=1}^{m} frequency(a_i)$.

$$p(\boldsymbol{\mu}, \boldsymbol{\Sigma}) = exp[-\varphi \cdot KL(Q(\boldsymbol{\mu}, \boldsymbol{\Sigma})||Q(\boldsymbol{\mu_0}, \boldsymbol{I}))], \tag{3}$$

where $KL(\cdot,\cdot)$ is the *KL* divergence, $Q(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ denotes a *Multivariate Gaussian Distribution*, and φ is a tradeoff parameter.

Base on the above definition, the probability of generating the overall opinion rating $\mathcal{O}_r$ on review r is given as,

$$\begin{aligned} p(\mathcal{O}_r|\Psi, r) = \int & p(\mathcal{O}_r|\boldsymbol{\omega_r}^T\boldsymbol{o_r}, \sigma^2) \\ & \cdot p(\boldsymbol{\omega_r}|\boldsymbol{\mu}, \boldsymbol{\Sigma}) \cdot p(\boldsymbol{\mu}, \boldsymbol{\Sigma}) d\boldsymbol{\omega_r}, \end{aligned} \tag{4}$$

where $\Psi = \{\boldsymbol{\omega}, \boldsymbol{\mu}, \boldsymbol{\Sigma}, \sigma^2\}$ are the model parameters.

Next, we utilize Maximum Log-likelihood (*ML*) to estimate the model parameters given the consumer reviews corpus. In particular, we aim to find an optimal $\hat{\Psi}$ to maximize the probability of observing the overall opinion ratings in the reviews corpus.

$$\begin{aligned} \hat{\Psi} &= \arg\max_{\Psi} \sum_{r\in\mathcal{R}} log(p(\mathcal{O}_r|\Psi, r)) \\ &= \arg\min_{\Psi} (|\mathcal{R}| - 1)\log\det(\boldsymbol{\Sigma}) + \sum_{r\in\mathcal{R}} [\log\sigma^2 + \\ &\frac{(\mathcal{O}_r - \boldsymbol{\omega_r}^T\boldsymbol{o_r})^2}{\sigma^2} + (\boldsymbol{\omega_r} - \boldsymbol{\mu})^T\boldsymbol{\Sigma}^{-1}(\boldsymbol{\omega_r} - \boldsymbol{\mu})] + \\ &(tr(\boldsymbol{\Sigma}) + (\boldsymbol{\mu_0} - \boldsymbol{\mu})^T\boldsymbol{I}(\boldsymbol{\mu_0} - \boldsymbol{\mu})). \end{aligned} \tag{5}$$

For the sake of simplicity, we denote the objective function $\sum_{r\in\mathcal{R}} log(p(\mathcal{O}_r|\Psi, r))$ as $\Gamma(\Psi)$.

The derivative of the objective function with respect to each model parameter vanishes at the minimizer:

$$\begin{aligned} \frac{\partial\Gamma(\Psi)}{\partial\boldsymbol{\omega_r}} &= -\frac{(\boldsymbol{\omega_r}^T\boldsymbol{o_r} - \mathcal{O}_r)\boldsymbol{o_r}}{\sigma^2} - \boldsymbol{\Sigma}^{-1}(\boldsymbol{\omega_r} - \boldsymbol{\mu}) \\ &= 0; \end{aligned} \tag{6}$$

$$\begin{aligned} \frac{\partial\Gamma(\Psi)}{\partial\boldsymbol{\mu}} &= \sum_{r\in\mathcal{R}} [-\boldsymbol{\Sigma}^{-1}(\boldsymbol{\omega_r} - \boldsymbol{\mu})] - \varphi \cdot \boldsymbol{I}(\boldsymbol{\mu_0} - \boldsymbol{\mu}) \\ &= 0; \end{aligned} \tag{7}$$

$$\begin{aligned} \frac{\partial\Gamma(\Psi)}{\partial\boldsymbol{\Sigma}} &= \sum_{r\in\mathcal{R}} \{-(\boldsymbol{\Sigma}^{-1})^T - [-(\boldsymbol{\Sigma}^{-1})^T(\boldsymbol{\omega_r} - \boldsymbol{\mu}) \\ &(\boldsymbol{\omega_r} - \boldsymbol{\mu})^T(\boldsymbol{\Sigma}^{-1})^T]\} + \varphi \cdot \left[(\boldsymbol{\Sigma}^{-1})^T - \boldsymbol{I}\right] = 0; \end{aligned} \tag{8}$$

$$\begin{aligned} \frac{\partial\Gamma(\Psi)}{\partial\sigma^2} &= \sum_{r\in\mathcal{R}} (-\frac{1}{\sigma^2} + \frac{(\mathcal{O}_r - \boldsymbol{\omega_r}^T\boldsymbol{o_r})^2}{\sigma^4}) = 0, \end{aligned} \tag{9}$$

which lead to the following solutions:

$$\hat{\boldsymbol{\omega}}_{\boldsymbol{r}} = (\frac{\boldsymbol{o_r}\boldsymbol{o_r}^T}{\sigma^2} + \boldsymbol{\Sigma}^{-1})^{-1}(\frac{\mathcal{O}_r\boldsymbol{o_r}}{\sigma^2} + \boldsymbol{\Sigma}^{-1}\boldsymbol{\mu}); \tag{10}$$

$$\hat{\boldsymbol{\mu}} = (|\mathcal{R}|\boldsymbol{\Sigma}^{-1} + \varphi \cdot \boldsymbol{I})^{-1}(\boldsymbol{\Sigma}^{-1}\sum_{r\in\mathcal{R}} \boldsymbol{\omega_r} + \varphi \cdot \boldsymbol{I}\boldsymbol{\mu_0}); \tag{11}$$

$$\begin{aligned} \hat{\boldsymbol{\Sigma}} = \{&[\frac{1}{\varphi}\sum_{r\in\mathcal{R}} \left[(\boldsymbol{\omega_r} - \boldsymbol{\mu})(\boldsymbol{\omega_r} - \boldsymbol{\mu})^T\right] + \\ &(\frac{|\mathcal{R}| - \varphi}{2\varphi})^2\boldsymbol{I}]^{1/2} - \frac{(|\mathcal{R}| - \varphi)}{2\varphi}\boldsymbol{I}\}^T; \end{aligned} \tag{12}$$

$$\hat{\sigma}^2 = \frac{1}{|\mathcal{R}|}\sum_{r\in\mathcal{R}} (\mathcal{O}_r - \boldsymbol{\omega_r}^T\boldsymbol{o_r})^2. \tag{13}$$

We can see that the above parameters are involved in each other's solution. We here utilize *Alternating Optimization* technique to derive the optimal parameters in an iterative manner. We first hold the parameters $\boldsymbol{\mu}$, $\boldsymbol{\Sigma}$ and σ^2 fixed and update the parameters $\boldsymbol{\omega_r}$ for each review $r \in \mathcal{R}$. Then, we update the parameters $\boldsymbol{\mu}$, $\boldsymbol{\Sigma}$ and σ^2 with fixed $\boldsymbol{\omega_r}$ ($r \in \mathcal{R}$). These two steps are alternatively iterated until the Eq.5 converges. As a result, we obtain the optimal importance weights $\boldsymbol{\omega_r}$ which measure the importance of aspects in review $r \in \mathcal{R}$. We then compute the final importance score ϖ_k for each aspect a_k by integrating its importance score in all the reviews as,

$$\varpi_k = \frac{1}{|\mathcal{R}|}\sum\nolimits_{r\in\mathcal{R}} \omega_{rk}, \quad k = 1, \cdots, m \tag{14}$$

It is worth noting that the aspect frequency is considered again in this integration process. According to the importance score ϖ_k, we can identify important aspects.

3 Evaluations

In this section, we evaluate the effectiveness of our approach on aspect identification, sentiment classification, and aspect ranking.

3.1 Data and Experimental Setting

The details of our product review data set is given in Table 1. This data set contains consumer reviews on 11 popular products in 4 domains. These reviews were crawled from the prevalent forum Web sites, including cnet.com, viewpoints.com, reevoo.com and gsmarena.com. All of the reviews were posted

between June, 2009 and Sep 2010. The aspects of the reviews, as well as the opinions on the aspects were manually annotated as the gold standard for evaluations.

Product Name	*Domain*	*Review#*	*Sentence#*
Canon EOS 450D (Canon EOS)	camera	440	628
Fujifilm Finepix AX245W (Fujifilm)	camera	541	839
Panasonic Lumix DMC-TZ7 (Panasonic)	camera	650	1,546
Apple MacBook Pro (MacBook)	laptop	552	4,221
Samsung NC10 (Samsung)	laptop	2,712	4,946
Apple iPod Touch 2nd (iPod Touch)	MP3	4,567	10,846
Sony NWZ-S639 16GB (Sony NWZ)	MP3	341	773
BlackBerry Bold 9700 (BlackBerry)	phone	4,070	11,008
iPhone 3GS 16GB (iPhone 3GS)	phone	12,418	43,527
Nokia 5800 XpressMusic (Nokia 5800)	phone	28,129	75,001
Nokia N95	phone	15,939	44,379

Table 1: Statistics of the Data Sets, # denotes the size of the reviews/sentences.

To examine the performance on aspect identification and sentiment classification, we employed F_1-measure, which was the combination of *precision* and *recall*, as the evaluation metric. To evaluate the performance on aspect ranking, we adopted *Normalized Discounted Cumulative Gain* at top *k* (NDCG@*k*) (Jarvelin and Kekalainen, 2002) as the performance metric. Given an aspect ranking list $a_1, \cdots, a_k$, NDCG@*k* is calculated by

$$NDCG@k = \frac{1}{Z}\sum_{i=1}^{k}\frac{2^{t(i)}-1}{\log(1+i)}, \qquad (15)$$

where $t(i)$ is the function that represents the reward given to the aspect at position i, Z is a normalization term derived from the top k aspects of a perfect ranking, so as to normalize NDCG@*k* to be within $[0, 1]$. This evaluation metric will favor the ranking which ranks the most important aspects at the top. For the reward $t(i)$, we labeled each aspect as one of the three scores: *Un-important* (score 1), *Ordinary* (score 2) and *Important* (score 3). Three volunteers were invited in the annotation process as follows. We first collected the top *k* aspects in all the rankings produced by various evaluated methods (maximum *k* is 15 in our experiment). We then sampled some reviews covering these aspects, and provided the reviews to each annotator to read. Each review contains the overall opinion rating, the highlighted aspects, and opinion terms. Afterward, the annotators were required to assign an importance score to each aspect. Finally, we took the average of their scorings as the corresponding importance scores of the aspects. In addition, there is only one parameter φ that needs to be tuned in our approach. Throughout the experiments, we empirically set φ as 0.001.

3.2 Evaluations on Aspect Identification

We compared our aspect identification approach against two baselines: a) the method proposed by Hu and Liu (2004), which was based on the association rule mining, and b) the method proposed by Wu et al. (2009), which was based on a dependency parser.

The results are presented in Table 2. On average, our approach significantly outperforms Hu's method and Wu' method in terms of F_1-measure by over 5.87% and 3.27%, respectively. In particular, our approach obtains high precision. Such results imply that our approach can accurately identify the aspects from consumer reviews by leveraging the *Pros* and *Cons* reviews.

Data set	*Hu's Method*	*Wu's Method*	*Our Method*
Canon EOS	0.681	0.686	**0.728**
Fujifilm	0.685	0.666	**0.710**
Panasonic	0.636	0.661	**0.706**
MacBook	0.680	0.733	**0.747**
Samsung	0.594	0.631	**0.712**
iPod Touch	0.650	0.660	**0.718**
Sony NWZ	0.631	0.692	**0.760**
BlackBerry	0.721	0.730	**0.734**
iPhone 3GS	0.697	0.736	**0.740**
Nokia 5800	0.715	0.745	**0.747**
Nokia N95	0.700	0.737	**0.741**

Table 2: Evaluations on Aspect Identification. * significant t-test, p-values$<$0.05.

3.3 Evaluations on Sentiment Classification

In this experiment, we implemented the following sentiment classification methods (Pang and Lee, 2008):

1) Unsupervised method. We employed one unsupervised method which was based on opinionated term counting via *SentiWordNet* (Ohana et al., 2009).

2) Supervised method. We employed three supervised methods proposed in Pang et al. (2002), including Naïve Bayes (*NB*), Maximum Entropy (*ME*), *SVM*. These classifiers were trained based on the *Pros* and *Cons* reviews as described in Section 2.3.

The comparison results are showed in Table 3. We can see that supervised methods significantly outperform unsupervised method. For example, the *SVM* classifier outperforms the unsupervised method in terms of average F_1-measure by over 10.37%. Thus, we can deduce from such results that the *Pros* and *Cons* reviews are useful for sentiment classification. In addition, among the supervised classifiers, *SVM* classifier performs the best in most products, which is consistent with the previous research (Pang et al., 2002).

Data set	*Senti*	*NB*	*SVM*	*ME*
Canon EOS	0.628	0.720	**0.739**	0.726
Fujifilm	0.690	0.781	**0.791**	0.778
Panasonic	0.625	0.694	**0.719**	0.697
MacBook	0.708	0.820	**0.828**	0.797
Samsung	0.675	**0.723**	0.717	0.714
iPod Touch	0.711	0.792	**0.805**	0.791
Sony NWZ	0.621	0.722	**0.737**	0.725
BlackBerry	0.699	**0.819**	0.794	0.788
iPhone 3GS	0.717	0.811	**0.829**	0.822
Nokia 5800	0.736	0.840	**0.851**	0.817
Nokia N95	0.706	0.829	**0.849**	0.826

Table 3: Evaluations on Sentiment Classification. Senti denotes the method based on SentiWordNet. * significant t-test, p-values$<$0.05.

3.4 Evaluations on Aspect Ranking

In this section, we compared our aspect ranking algorithm against the following three methods.

1) Frequency-based method. The method ranks the aspects based on aspect frequency.

2) Correlation-based method. This method measures the correlation between the opinions on specific aspects and the overall opinion. It counts the number of the cases when such two kinds of opinions are consistent, and ranks the aspects based on the number of the consistent cases.

3) Hybrid method. This method captures both the aspect frequency and correlation by a linear combination, as $\lambda\cdot$ *Frequency-based Ranking* $+ (1-\lambda)\cdot$ *Correlation-based Ranking*, where λ is set to 0.5.

The comparison results are showed in Table 4. On average, our approach outperforms the frequency-based method, correlation-based method, and hybrid method in terms of NDCG@*5* by over 6.24%, 5.79% and 5.56%, respectively. It improves the performance over such three methods in terms of NDCG@*10* by over 3.47%, 2.94% and 2.58%, respectively, while in terms of NDCG@*15* by over 4.08%, 3.04% and 3.49%, respectively. We can deduce from the results that our aspect ranking algorithm can effectively identify the important aspects from consumer reviews by leveraging the aspect frequency and the influence of consumers' opinions given to each aspect on their overall opinions. Table 5 shows the aspect ranking results of these four methods. Due to the space limitation, we here only show top 10 aspects of the product *iphone 3GS*. We can see that our approach performs better than the others. For example, the aspect "*phone*" is ranked at the top by the other methods. However, "*phone*" is a general but not important aspect.

#	*Frequency*	*Correlated*	*Hybrid*	*Our Method*
1	Phone	Phone	Phone	Usability
2	Usability	Usability	Usability	Apps
3	3G	Apps	Apps	3G
4	Apps	3G	3G	Battery
5	Camera	Camera	Camera	Looking
6	Feature	Looking	Looking	Storage
7	Looking	Feature	Feature	Price
8	Battery	Screen	Battery	Software
9	Screen	Battery	Screen	Camera
10	Flash	Bluetooth	Flash	Call quality

Table 5: iPhone 3GS Aspect Ranking Results.

To further investigate the reasonability of our ranking results, we refer to one of the public user feedback reports, the "*china unicom 100 customers iPhone user feedback report*" (Chinaunicom Report, 2009). The report demonstrates that the top four aspects of *iPhone* product, which users most concern with, are "*3G Network*" (30%), "*usability*" (30%), "*out-looking design*" (26%), "*application*" (15%). All of these aspects are in the top 10 of our ranking results.

Therefore, we can conclude that our approach is able to automatically identify the important aspects from numerous consumer reviews.

4 Applications

The identification of important aspects can support a wide range of applications. For example, we can

	Frequency			*Correlation*			*Hybrid*			*Our Method*		
Data set	*@5*	*@10*	*@15*	*@5*	*@10*	*@15*	*@5*	*@10*	*@15*	*@5*	*@10*	*@15*

provide product comparison on the important aspects to users, so that users can make wise purchase decisions conveniently.

In the following, we apply the aspect ranking results to assist document-level review sentiment classification. Generally, a review document contains consumer's positive/negative opinions on various aspects of the product. It is difficult to get the accurate overall opinion of the whole review without knowing the importance of these aspects. In addition, when we learn a document-level sentiment classifier, the features generated from unimportant aspects lack of discriminability and thus may deteriorate the performance of the classifier (Fang et al., 2010). While the important aspects and the sentiment terms on these aspects can greatly influence the overall opinions of the review, they are highly likely to be discriminative features for sentiment classification. These observations motivate us to utilize aspect ranking results to assist classifying the sentiment of review documents.

Specifically, we randomly sampled 100 reviews of each product as the testing data and used the remaining reviews as the training data. We first utilized our approach to identify the importance aspects from the training data. We then explored the aspect terms and sentiment terms as features, based on which each review is represented as a feature vector. Here, we give more emphasis on the important aspects and the sentiment terms that modify these aspects. In particular, we set the term-weighting as $1 + \varphi \cdot \varpi_k$, where ϖ_k is the importance score of the aspect a_k, φ is set to 100. Based on the weighted features, we then trained a *SVM* classifier using the training reviews to determine the overall opinions on the testing reviews. For the performance comparison, we compared our approach against two baselines, including Boolean weighting method and frequency weighting (*tf*) method (Paltoglou et al., 2010) that do not utilize the importance of aspects. The comparison results are shown in Table 6. We can see that our approach (*IA*) significantly outperforms the other methods in terms of average F_1-measure by over 2.79% and 4.07%, respectively. The results also show that the Boolean weighting method outperforms the frequency weighting method in terms of average F_1-measure by over 1.25%, which are consistent with the previous research by Pang et al. (2002). On the other hand, from the *IA* weighting formula, we observe that without using the important aspects, our term-weighting function will be equal to Boolean weighting. Thus, we can speculate that the identification of important aspects is beneficial to improving the performance of document-level sentiment classification.

5 Related Work

Existing researches mainly focused on determining opinions on the reviews, or identifying aspects from these reviews. They viewed each aspect equally without distinguishing the important ones. In this section, we review existing researches related to our work.

Analysis of the opinion on whole review text had

been extensively studied (Pang and Lee, 2008). Earlier research had been studied unsupervised (Kim et al., 2004), supervised (Pang et al., 2002; Pang et al., 2005) and semi-supervised approaches (Goldberg et al., 2006) for the classification. For example, Mullen et al. (2004) proposed an unsupervised classification method which exploited pointwise mutual information (*PMI*) with syntactic relations and other attributes. Pang et al. (2002) explored several machine learning classifiers, including Naïve Bayes, Maximum Entropy, SVM, for sentiment classification. Goldberg et al. (2006) classified the sentiment of the review using the graph-based semi-supervised learning techniques, while Li el al. (2009) tackled the problem using matrix factorization techniques with lexical prior knowledge.

Since the consumer reviews usually expressed opinions on multiple aspects, some works had drilled down to the aspect-level sentiment analysis, which aimed to identify the aspects from the reviews and to determine the opinions on the specific aspects instead of the overall opinion. For the topic of aspect identification, Hu and Liu (2004) presented the association mining method to extract the frequent terms as the aspects. Subsequently, Popescu et al. (2005) proposed their system *OPINE*, which extracted the aspects based on the *KnowItAll* Web information extraction system (Etzioni et al., 2005). Liu el al. (2005) proposed a supervised method based on language pattern mining to identify the aspects in the reviews. Later, Mei et al. (2007) proposed a probabilistic topic model to capture the mixture of aspects and sentiments simultaneously. Afterwards, Wu et al. (2009) utilized the dependency parser to extract the noun phrases and verb phrases from the reviews as the aspect candidates. They then trained a language model to refine the candidate set, and to obtain the aspects. On the other hand, for the topic of sentiment classification on the specific aspect, Snyder et al. (2007) considered the situation when the consumers' opinions on one aspect could influence their opinions on others. They thus built a graph to analyze the meta-relations between opinions, such as agreement and contrast. And they proposed a Good Grief algorithm to leveraging such meta-relations to improve the prediction accuracy of aspect opinion ratings. In addition, Wang et al. (2010) proposed the topic of latent aspect rating which aimed to infer the opinion rating on the aspect. They first employed a bootstrapping-based algorithm to identify the major aspects via a few seed word aspects. They then proposed a generative Latent Rating Regression model (LRR) to infer aspect opinion ratings based on the review content and the associated overall rating.

While there were usually huge collection of reviews, some works had concerned the topic of aspect-based sentiment summarization to combat the information overload. They aimed to summarize all the reviews and integrate major opinions on various aspects for a given product. For example, Titov et al. (2008) explored a topic modeling method to generate a summary based on multiple aspects. They utilized topics to describe aspects and incor-

porated a regression model fed by the ground-truth opinion ratings. Additionally, Lu el al. (2009) proposed a structured PLSA method, which modeled the dependency structure of terms, to extract the aspects in the reviews. They then aggregated opinions on each specific aspects and selected representative text segment to generate a summary.

In addition, some works proposed the topic of product ranking which aimed to identify the best products for each specific aspect (Zhang et al., 2010). They used a PageRank style algorithm to mine the aspect-opinion graph, and to rank the products for each aspect.

Different from previous researches, we dedicate our work to identifying the important aspects from the consumer reviews of a specific product.

6 Conclusions and Future Works

In this paper, we have proposed to identify the important aspects of a product from online consumer reviews. Our assumption is that the important aspects of a product should be the aspects that are frequently commented by consumers and consumers' opinions on the important aspects greatly influence their overall opinions on the product. Based on this assumption, we have developed an aspect ranking algorithm to identify the important aspects by simultaneously considering the aspect frequency and the influence of consumers' opinions given to each aspect on their overall opinions. We have conducted experiments on 11 popular products in four domains. Experimental results have demonstrated the effectiveness of our approach on important aspects identification. We have further applied the aspect ranking results to the application of document-level sentiment classification, and have significantly improved the classification performance. In the future, we will apply our approach to support other applications.

University of Melbourne, VIC 3010, Australia
{cburfoot, sb, tim}@csse.unimelb.edu.au

Abstract

This paper explores approaches to sentiment classification of U.S. Congressional floor-debate transcripts. Collective classification techniques are used to take advantage of the informal citation structure present in the debates. We use a range of methods based on local and global formulations and introduce novel approaches for incorporating the outputs of machine learners into collective classification algorithms. Our experimental evaluation shows that the mean-field algorithm obtains the best results for the task, significantly outperforming the benchmark technique.

1 Introduction

Supervised document classification is a well-studied task. Research has been performed across many document types with a variety of classification tasks. Examples are topic classification of newswire articles (Yang and Liu, 1999), sentiment classification of movie reviews (Pang et al., 2002), and satire classification of news articles (Burfoot and Baldwin, 2009). This and other work has established the usefulness of document classifiers as stand-alone systems and as components of broader NLP systems.

This paper deals with methods relevant to supervised document classification in domains with *network* structures, where *collective classification* can yield better performance than approaches that consider documents in isolation. Simply put, a network structure is any set of relationships between documents that can be used to assist the document classification process. Web encyclopedias and scholarly publications are two examples of document domains where network structures have been used to assist classification (Gantner and Schmidt-Thieme, 2009; Cao and Gao, 2005).

The contribution of this research is in four parts: (1) we introduce an approach that gives better than state of the art performance for collective classification on the ConVote corpus of congressional debate transcripts (Thomas et al., 2006); (2) we provide a comparative overview of collective document classification techniques to assist researchers in choosing an algorithm for collective document classification tasks; (3) we demonstrate effective novel approaches for incorporating the outputs of SVM classifiers into collective classifiers; and (4) we demonstrate effective novel feature models for iterative local classification of debate transcript data.

In the next section (Section 2) we provide a formal definition of collective classification and describe the ConVote corpus that is the basis for our experimental evaluation. Subsequently, we describe and critique the established benchmark approach for congressional floor-debate transcript classification, before describing approaches based on three alternative collective classification algorithms (Section 3). We then present an experimental evaluation (Section 4). Finally, we describe related work (Section 5) and offer analysis and conclusions (Section 6).

2 Task Definition

2.1 Collective Classification

Given a network and an object o in the network, there are three types of correlations that can be used

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1506–1515,
Portland, Oregon, June 19-24, 2011.

to infer a label for o: (1) the correlations between the label of o and its observed attributes; (2) the correlations between the label of o and the observed attributes and labels of nodes connected to o; and (3) the correlations between the label of o and the unobserved labels of objects connected to o (Sen et al., 2008).

Standard approaches to classification generally ignore any network information and only take into account the correlations in (1). Each object is classified as an individual instance with features derived from its observed attributes. Collective classification takes advantage of the network by using all three sources. Instances may have features derived from their source objects or from other objects. Classification proceeds in a joint fashion so that the label given to each instance takes into account the labels given to all of the other instances.

Formally, collective classification takes a graph, made up of nodes $\mathcal{V} = \{V_1, \ldots, V_n\}$ and edges E. The task is to label the nodes $V_i \in \mathcal{V}$ from a label set $\mathcal{L} = \{L_1, \ldots, L_q\}$, making use of the graph in the form of a neighborhood function $\mathcal{N} = \{N_1, \ldots, N_n\}$, where $N_i \subseteq \mathcal{V} \setminus \{V_i\}$.

2.2 The ConVote Corpus

ConVote, compiled by Thomas et al. (2006), is a corpus of U.S. congressional debate transcripts. It consists of 3,857 speeches organized into 53 debates on specific pieces of legislation. Each speech is tagged with the identity of the speaker and a "for" or "against" label derived from congressional voting records. In addition, places where one speaker cites another have been annotated, as shown in Figure 1.

We apply collective classification to ConVote debates by letting $\mathcal{V}$ refer to the individual speakers in a debate and populating $\mathcal{N}$ using the citation graph between speakers. We set $\mathcal{L} = \{y, n\}$, corresponding to "for" and "against" votes respectively. The text of each instance is the concatenation of the speeches by a speaker within a debate. This results in a corpus of 1,699 instances with a roughly even class distribution. Approximately 70% of these are *connected*, i.e. they are the source or target of one or more citations. The remainder are *isolated*.

3 Collective Classification Techniques

In this section we describe techniques for performing collective classification on the ConVote corpus. We differentiate between *dual-classifier* and *iterative-classifier* approaches.

Dual-classifier approach: This approach uses a collective classification algorithm that takes inputs from two classifiers: (1) a *content-only* classifier that determines the likelihood of a y or n label for an instance given its text content; and (2) a *citation* classifier that determines, based on citation information, whether a given pair of instances are "same class" or "different class".

Let Ψ denote a set of functions representing the classification preferences produced by the content-only and citation classifiers:

- For each $V_i \in \mathcal{V}$, $\phi_i \in \Psi$ is a function ϕ_i: $\mathcal{L} \rightarrow \mathbb{R}^+ \cup \{0\}$.
- For each $(V_i, V_j) \in E$, $\psi_{ij} \in \Psi$ is a function ψ_{ij}: $\mathcal{L} \times \mathcal{L} \rightarrow \mathbb{R}^+ \cup \{0\}$.

Later in this section we will describe three collective classification algorithms capable of performing overall classification based on these inputs: (1) the minimum-cut approach, which is the benchmark for collective classification with ConVote, established by Thomas et al.; (2) loopy belief propagation; and (3) mean-field. We will show that these latter two techniques, which are both approximate solutions for Markov random fields, are superior to minimum-cut for the task.

Figure 2 gives a visual overview of the dual-classifier approach.

Iterative-classifier approach: This approach incorporates content-only and citation features into a single *local* classifier that works on the assumption that correct neighbor labels are already known. This approach represents a marked deviation from the dual-classifier approach and offers unique advantages. It is fully described in Section 3.4.

Figure 3 gives a visual overview of the iterative-classifier approach.

For a detailed introduction to collective classification see Sen et al. (2008).

Debate 006

Speaker 400378 [against]

Mr. Speaker, . . . all over Washington and in the country, people are talking today about the majority's last-minute decision to abandon . . .

. . .

Speaker 400115 [for]

. . .

Mr. Speaker, . . . I just want to say to the ***gentlewoman from New York*** *that every single member of this institution . . .*

. . .

Figure 1: Sample speech fragments from the ConVote corpus. The phrase *gentlewoman from New York* by speaker 400115 is annotated as a reference to speaker 400378.

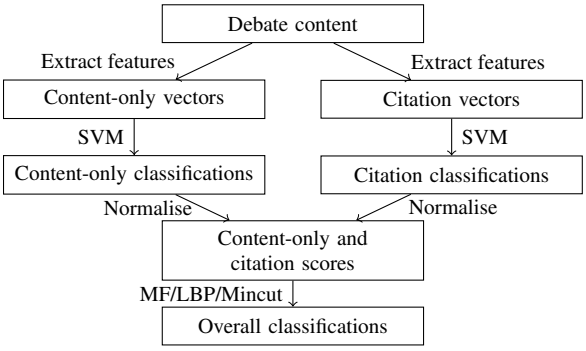

Figure 2: Dual-classifier approach.

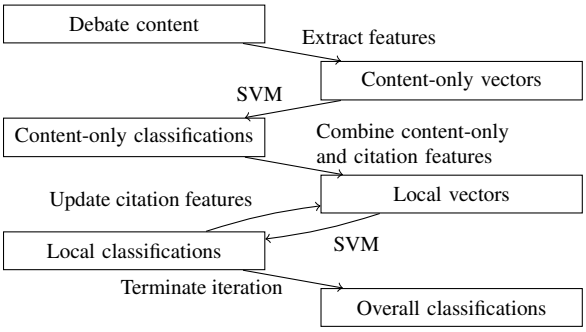

Figure 3: Iterative-classifier approach.

3.1 Dual-classifier Approach with Minimum-cut

Thomas et al. use linear kernel SVMs as their base classifiers. The content-only classifier is trained to predict y or n based on the unigram presence features found in speeches. The citation classifier is trained to predict "same class" or "different class" labels based on the unigram presence features found in the context windows (30 tokens before, 20 tokens after) surrounding citations for each pair of speakers in the debate.

The decision plane distance computed by the content-only SVM is normalized to a positive real number and stripped of outliers:

$$\phi_i(y) = \begin{cases} 1 & d_i > 2\sigma_i; \\ \left(1 + \frac{d_i}{2\sigma_i}\right)/2 & |d_i| \leq 2\sigma_i; \\ 0 & d_i < -2\sigma_i \end{cases}$$

where σ_i is the standard deviation of the decision plane distance, d_i, over all of the instances in the debate and $\phi_i(n) = 1 - \phi_i(y)$. The citation classifier output is processed similarly:[1]

$$\psi_{ij}(y, y) = \begin{cases} 0 & d_{ij} < \theta; \\ \alpha \cdot d_{ij}/4\sigma_{ij} & \theta \leq d_{ij} \leq 4\sigma_{ij}; \\ \alpha & d_{ij} > 4\sigma_{ij} \end{cases}$$

where σ_{ij} is the standard deviation of the decision plane distance, d_{ij} over all of the citations in the debate and $\psi_{ij}(n, n) = \psi_{ij}(y, y)$. The α and θ variables are free parameters.

A given class assignment v is assigned a cost that is the sum of per-instance and per-pair class costs derived from the content-only and citation classifiers respectively:

$$c(v) = \sum_{V_i \in \mathcal{V}} \phi_i(\bar{v}_i) + \sum_{(V_i, V_j) \in E : v_i \neq v_j} \psi_{ij}(v_i, v_i)$$

where v_i is the label of node V_i and $\bar{v}_i$ denotes the complement class of v_i.

[1] Thomas et al. classify each citation context window separately, so their ψ values are actually calculated in a slightly more complicated way. We adopted the present approach for conceptual simplicity and because it gave superior performance in preliminary experiments.

The cost function is modeled in a flow graph where extra source and sink nodes represent the y and n labels respectively. Each node in $\mathcal{V}$ is connected to the source and sink with capacities $\phi_i(y)$ and $\phi_i(n)$ respectively. Pairs classified in the "same class" class are linked with capacities defined by ψ.

An exact optimum and corresponding overall classification is efficiently computed by finding the minimum-cut of the flow graph (Blum and Chawla, 2001). The free parameters are tuned on a set of held-out data.

Thomas et al. demonstrate improvements over content-only classification, without attempting to show that the approach does better than any alternatives; the main appeal is the simplicity of the flow graph model. There are a number of theoretical limitations to the approach, which we now discuss.

As Thomas et al. point out, the model has no way of representing the "different class" output from the citation classifier and these citations must be discarded. This, to us, is the most significant problem with the model. Inspection of the corpus shows that approximately 80% of citations indicate agreement, meaning that for the present task the impact of discarding this information may not be large. However, the primary utility in collective approaches lies in their ability to fill in gaps in information not picked up by content-only classification. All available link information should be applied to this end, so we need models capable of accepting both positive and negative information.

The normalization techniques used for converting SVM outputs to graph weights are somewhat arbitrary. The use of standard deviations appears problematic as, intuitively, the strength of a classification should be independent of its variance. As a case in point, consider a set of instances in a debate all classified as similarly weak positives by the SVM. Use of ψ_i as defined above would lead to these being erroneously assigned the maximum score because of their low variance.

The minimum-cut approach places instances in either the positive or negative class depending on which side of the cut they fall on. This means that no measure of classification *confidence* is available. This extra information is useful at the very least to give a human user an idea of how much to trust the classification. A measure of classification confidence may also be necessary for incorporation into a broader system, e.g., a meta-classifier (Andreevskaia and Bergler, 2008; Li and Zong, 2008).

Tuning the α and θ parameters is likely to become a source of inaccuracy in cases where the tuning and test debates have dissimilar link structures. For example, if the tuning debates tend to have fewer, more accurate links the α parameter will be higher. This will not produce good results if the test debates have more frequent, less accurate links.

3.2 Heuristics for Improving Minimum-cut

Bansal et al. (2008) offer preliminary work describing additions to the Thomas et al. minimum-cut approach to incorporate "different class" citation classifications. They use post hoc adjustments of graph capacities based on simple heuristics. Two of the three approaches they trial appear to offer performance improvements:

The *SetTo* heuristic: This heuristic works through E in order and tries to force V_i and V_j into different classes for every "different class" ($d_{ij} < 0$) citation classifier output where $i < j$. It does this by altering the four relevant content-only preferences, $\phi_i(y)$, $\phi_i(n)$, $\phi_j(y)$, and $\phi_j(n)$. Assume without loss of generality that the largest of these values is $\phi_i(y)$. If this preference is respected, it follows that V_j should be put into class n. Bansal et al. instantiate this chain of reasoning by setting:

- $\phi'_i(y) = \max(\beta, \phi_i(y))$
- $\phi'_j(n) = \max(\beta, \phi_j(n))$

where ϕ' is the replacement content-only function, β is a free parameter $\in (.5, 1]$, $\phi'_i(n) = 1 - \phi'_i(y)$, and $\phi'_j(y) = 1 - \phi'_j(y)$.

The *IncBy* heuristic: This heuristic is a more conservative version of the *SetTo* heuristic. Instead of replacing the content-only preferences with fixed constants, it increments and decrements the previous values so they are somewhat preserved:

- $\phi'_i(y) = \min(1, \phi_i(y) + \beta)$
- $\phi'_j(n) = \min(1, \phi_j(n) + \beta)$

There are theoretical shortcomings with these approaches. The most obvious problem is the arbitrary nature of the manipulations, which produce a flow

graph that has an indistinct relationship to the outputs of the two classifiers.

Bensal et al. trial a range of β values, with varying impacts on performance. No attempt is made to demonstrate a method for choosing a good β value. It is not clear that the tuning approach used to set α and θ would be successful here. In any case, having a third parameter to tune would make the process more time-consuming and increase the risks of incorrect tuning, described above.

As Bansal et al. point out, proceeding through E in order means that earlier changes may be undone for speakers who have multiple "different class" citations.

Finally, we note that the confidence of the citation classifier is not embodied in the graph structure. The most marginal "different class" citation, classified just on the negative side of the decision plane, is treated identically to the most confident one furthest from the decision plane.

3.3 Dual-classifier Approach with Markov Random Field Approximations

A pairwise Markov random field (Taskar et al., 2002) is given by the pair (G, Ψ), where G and Ψ are as previously defined, Ψ being re-termed as a set of *clique potentials*. Given an assignment v to the nodes $\mathcal{V}$, the pairwise Markov random field is associated with the probability distribution:

$$P(v) = \frac{1}{\mathcal{Z}} \prod_{V_i \in \mathcal{V}} \phi_i(v_i) \prod_{(V_i,V_j) \in E} \psi_{ij}(v_i, v_j)$$

where:

$$\mathcal{Z} = \sum_{v'} \prod_{V_i \in \mathcal{V}} \phi_i(v'_i) \prod_{(V_i,V_j) \in E} \psi_{ij}(v'_i, v'_j)$$

and v'_i denotes the label of V_i for an alternative assignment in v'.

In general, exact inference over a pairwise Markov random field is known to be NP-hard. There are certain conditions under which exact inference is tractable, but real-world data is not guaranteed to satisfy these. A class of approximate inference algorithms known as *variational methods* (Jordan et al., 1999) solve this problem by substituting a simpler "trial" distribution which is fitted to the Markov random field distribution.

Loopy Belief Propagation: Applied to a pairwise Markov random field, loopy belief propagation is a message passing algorithm that can be concisely expressed as the following set of equations:

$$\begin{aligned} m_{i \to j}(v_j) &= \alpha \sum_{v_i \in \mathcal{L}} \{\psi_{ij}(v_i, v_j)\phi_i(v_i) \\ &\qquad \prod_{V_k \in \mathcal{N}_i \cap \mathcal{V} \setminus V_j} m_{k \to i}(v_i), \forall v_j \in \mathcal{L}\} \\ b_i(v_i) &= \alpha \phi_i(v_i) \prod_{V_j \in \mathcal{N}_i \cap \mathcal{V}} m_{j \to i}(v_i), \forall v_i \in \mathcal{L} \end{aligned}$$

where $m_{i \to j}$ is a message sent by V_i to V_j and α is a normalization constant that ensures that each message and each set of marginal probabilities sum to 1. The algorithm proceeds by making each node communicate with its neighbors until the messages stabilize. The marginal probability is then derived by calculating $b_i(v_i)$.

Mean-Field: The basic mean-field algorithm can be described with the equation:

$$b_j(v_j) = \alpha \phi_j(v_j) \prod_{V_i \in \mathcal{N}_j \cap \mathcal{V}} \prod_{v_i \in \mathcal{L}} \psi_{ij}^{b_i(v_i)}(v_i, v_j), v_j \in \mathcal{L}$$

where α is a normalization constant that ensures $\sum_{v_j} b_j(v_j) = 1$. The algorithm computes the fixed point equation for every node and continues to do so until the marginal probabilities $b_j(v_j)$ stabilize.

Mean-field can be shown to be a variational method in the same way as loopy belief propagation, using a simpler trial distribution. For details see Sen et al. (2008).

Probabilistic SVM Normalisation: Unlike minimum-cut, the Markov random field approaches have inherent support for the "different class" output of the citation classifier. This allows us to apply a more principled SVM normalisation technique. Platt (1999) describes a technique for converting the output of an SVM classifier to a calibrated posterior probability. Platt finds that the posterior can be fit using a parametric form of a sigmoid:

$$P(y = 1|d) = \frac{1}{1 + \exp(Ad + B)}$$

This is equivalent to assuming that the output of the SVM is proportional to the log odds of a positive example. Experimental analysis shows error rate is

improved over a plain linear SVM and probabilities are of comparable quality to those produced using a regularized likelihood kernel method.

By applying this technique to the base classifiers, we can produce new, simpler Ψ functions, $\phi_i(y) = P_i$ and $\psi_{ij}(y, y) = P_{ij}$ where P_i is the probabilistic normalized output of the content-only classifier and P_{ij} is the probabilistic normalized output of the citation classifier.

This approach addresses the problems with the Thomas et al. method where the use of standard deviations can produce skewed normalizations (see Section 3.1). By using probabilities we also open up the possibility of replacing the SVM classifiers with any other model than can be made to produce a probability. Note also that there are no parameters to tune.

3.4 Iterative Classifier Approach

The dual-classifier approaches described above represent *global* attempts to solve the collective classification problem. We can choose to narrow our focus to the *local* level, in which we aim to produce the best classification for a single instance with the assumption that all other parts of the problem (i.e. the correct labeling of the other instances) are solved.

The Iterative Classification Algorithm (Bilgic et al., 2007), defined in Algorithm 1, is a simple technique for performing collective classification using such a local classifier. After bootstrapping with a content-only classifier, it repeatedly generates new estimates for v_i based on its current knowledge of $\mathcal{N}_i$. The algorithm terminates when the predictions stabilize or a fixed number of iterations is completed. Each iteration is completed using a newly generated ordering $\mathcal{O}$, over the instances $\mathcal{V}$.

We propose three feature models for the local classifier.

Citation presence and Citation count: Given that the majority of citations represent the "same class" relationship (see Section 3.1), we can anticipate that content-only classification performance will be improved if we add features to represent the presence of neighbours of each class.

We define the function $c(i, l) = \sum_{v_j \in \mathcal{N}_i \cap \mathcal{V}} \delta_{v_j, l}$ giving the number of neighbors for node V_i with label l, where δ is the Kronecker delta. We incorporate these *citation count* values, one for the supporting class and one for the opposing class, obtaining a new feature vector $(u_i^1, u_i^2, \ldots, u_i^j, c(i, y), c(i, n))$ where $u_i^1, u_i^2, \ldots, u_i^j$ are the elements of $\vec{u}_i$, the binary unigram feature vector used by the content-only classifier to represent instance i.

Algorithm 1 Iterative Classification Algorithm

```
for each node V_i ∈ V do {bootstrapping}
    compute a_i using only local attributes of node
    v_i ← f(a_i)
end for
repeat {iterative classification}
    randomly generate ordering O over nodes in V
    for each node V_i ∈ O do
        {compute new estimate of v_i}
        compute a_i using current assignments to N_i
        v_i ← f(a_i)
    end for
until labels have stabilized or maximum iterations
reached
```

Alternatively, we can represent neighbor labels using binary *citation presence* values where any non-zero count becomes a 1 in the feature vector.

Context window: We can adopt a more nuanced model for citation information if we incorporate the citation context window features into the feature vector. This is, in effect, a synthesis of the content-only and citation feature models. Context window features come from the product space $\mathcal{L} \times \mathcal{C}$, where $\mathcal{C}$ is the set of unigrams used in citation context windows and $\vec{c}_i$ denotes the context window features for instance i. The new feature vector becomes: $(u_i^1, u_i^2, \ldots, u_i^j, c_i^1, c_i^2, \ldots, c_i^k)$. This approach implements the intuition that speakers indicate their voting intentions by the words they use to refer to speakers whose vote is known. Because neighbor relations are bi-directional the reverse is also true: Speakers indicate other speakers' voting intentions by the words they use to refer to them.

As an example, consider the context window feature `AGREE-FOR`, indicating the presence of the *agree* unigram in the citation window *I agree with the gentleman from Louisiana*, where the label for the *gentleman from Louisiana* instance is y. This feature will be correctly correlated with the y label. Similarly, if the unigram were *disagree* the feature would be correlated with the n label.

4 Experiments

In this section we compare the performance of our dual-classifier and iterative-classifier approaches. We also evaluate the performance of the three feature models for local classification.

All accuracies are given as the percentages of instances correctly classified. Results are macro-averaged using 10 $\times$ 10-fold cross validation, i.e. 10 runs of 10-fold cross validation using different randomly assigned data splits.

Where quoted, statistical significance has been calculated using a two-tailed paired t-test measured over all 100 pairs with 10 degrees of freedom. See Bouckaert (2003) for an experimental justification for this approach.

Note that the results presented in this section are not directly comparable with those reported by Thomas et al. and Bansal et al. because their experiments do not use cross-validation. See Section 4.3 for further discussion of experimental configuration.

4.1 Local Classification

We evaluate three models for local classification: citation presence features, citation count features and context window features. In each case the SVM classifier is given feature vectors with both content-only and citation information, as described in Section 3.4.

Table 1 shows that context window performs the best with 89.66% accuracy, approximately 1.5% ahead of citation count and 3.5% ahead of citation presence. All three classifiers significantly improve on the content-only classifier.

These relative scores seem reasonable. Knowing the words used in citations of each class is better than knowing the number of citations in each class, and better still than only knowing which classes of citations exist.

These results represent an upper-bound for the performance of the iterative classifier, which relies on iteration to produce the reliable information about citations given here by oracle.

4.2 Collective Classification

Table 2 shows overall results for the three collective classification algorithms. The iterative classifier was run separately with citation count and context window citation features, the two best performing local classification methods, both with a threshold of 30 iterations.

Method	Accuracy (%)
Majority	52.46
Content-only	75.29
Citation presence	85.01
Citation count	88.18
Context window	89.66

Table 1: Local classifier accuracy. All three local classifiers are significant over the in-isolation classifier ($p < .001$).

Results are shown for connected instances, isolated instances, and all instances. Collective classification techniques can only have an impact on connected instances, so these figures are most important. The figures for all instances show the performance of the classifiers in our real-world task, where both connected and isolated instances need to be classified and the end-user may not distinguish between the two types.

Each of the four collective classifiers outperform the minimum-cut benchmark over connected instances, with the iterative classifier (context window) (79.05%) producing the smallest gain of less than 1% and mean-field doing best with a nearly 6% gain (84.13%). All show a statistically significant improvement over the content-only classifier. Mean-field shows a statistically significant improvement over minimum-cut.

The dual-classifier approaches based on loopy belief propagation and mean-field do better than the iterative-classifier approaches by an average of about 3%.

Iterative classification performs slightly better with citation count features than with context window features, despite the fact that the context window model performs better in the local classifier evaluation. We speculate that this may be due to citation count performing better when given incorrect neighbor labels. This is an aspect of local classifier performance we do not otherwise measure, so a clear conclusion is not possible. Given the closeness of the results it is also possible that natural statistical variation is the cause of the difference.

The performance of the minimum-cut method is not reliably enhanced by either the *SetTo* or *IncBy* heuristics. Only *IncBy*(.15) gives a very small improvement (0.14%) over plain minimum-cut. All of the other combinations tried diminished performance slightly.

4.3 A Note on Error Propagation and Experimental Configuration

Early in our experimental work we noticed that performance often varied greatly depending on the debates that were allocated to training, tuning and testing. This observation is supported by the per-fold scores that are the basis for the macro-average performance figures reported in Table 2, which tend to have large standard deviations. The absolute standard deviations over the 100 evaluations for the minimum-cut and mean-field methods were 11.19% and 8.94% respectively. These were significantly larger than the standard deviation for the content-only baseline, which was 7.34%. This leads us to conclude that the performance of collective classification methods is highly variable.

Bilgic and Getoor (2008) offer a possible explanation for this. They note that the cost of incorrectly classifying a given instance can be magnified in collective classification, because errors are propagated throughout the network. The extent to which this happens may depend on the random interaction between base classification accuracy and network structure. There is scope for further work to more fully explain this phenomenon.

From these statistical and theoretical factors we infer that more reliable conclusions can be drawn from collective classification experiments that use cross-validation instead of a single, fixed data split.

5 Related work

Somasundaran et al. (2009) use ICA to improve sentiment polarity classification of dialogue acts in a corpus of multi-party meeting transcripts. Link features are derived from annotations giving *frame* relations and *target* relations. Respectively, these relate dialogue acts based on the sentiment expressed and the object towards which the sentiment is expressed. Somasundaran et al. provides another argument for the usefulness of collective classification (specifically ICA), in this case as applied at a dialogue act level and relying on a complex system of annotations for link information.

Somasundaran and Wiebe (2009) propose an unsupervised method for classifying the stance of each contribution to an online debate concerning the merits of competing products. Concessions to other stances are modeled, but there are no overt citations in the data that could be used to induce the network structure required for collective classification.

Pang and Lee (2005) use metric labeling to perform multi-class collective classification of movie reviews. Metric labeling is a multi-class equivalent of the minimum-cut technique in which optimization is done over a cost function incorporating content-only and citation scores. Links are constructed between test instances and a set of k nearest neighbors drawn only from the training set. Restricting the links in this way means the optimization problem is simple. A similarity metric is used to find nearest neighbors.

The Pang and Lee method is an instance of implicit link construction, an approach which is beyond the scope of this paper but nevertheless an important area for future research. A similar technique is used in a variation on the Thomas et al. experiment where additional links between speeches are inferred via a similarity metric (Burfoot, 2008). In cases where both citation and similarity links are present, the overall link score is taken as the sum of the two scores. This seems counter-intuitive, given that the two links are unlikely to be independent. In the framework of this research, the approach would be to train a link meta-classifier to take scores from both link classifiers and output an overall link probability.

Within NLP, the use of LBP has not been restricted to document classification. Examples of other applications are dependency parsing (Smith and Eisner, 2008) and alignment (Cromires and Kurohashi, 2009). Conditional random fields (CRFs) are an approach based on Markov random fields that have been popular for segmenting and labeling sequence data (Lafferty et al., 2001). We rejected linear-chain CRFs as a candidate approach for our evaluation on the grounds that the arbitrarily connected graphs used in collective classification can not be fully represented in graphical format, i.e.

	Connected	Isolated	All
Majority	52.46	46.29	50.51
Content only	75.31	78.90	76.28
Minimum-cut	78.31	78.90	78.40
Minimum-cut (*SetTo*(.6))	78.22	78.90	78.32
Minimum-cut (*SetTo*(.8))	78.01	78.90	78.14
Minimum-cut (*SetTo*(1))	77.71	78.90	77.93
Minimum-cut (*IncBy*(.05))	78.14	78.90	78.25
Minimum-cut (*IncBy*(.15))	78.45	78.90	78.46
Minimum-cut (*IncBy*(.25))	78.02	78.90	78.15
Iterative-classifier (citation count)	80.07⋆	78.90	79.69⋆
Iterative-classifier (context window)	79.05	78.90	78.93
Loopy Belief Propagation	83.37†	78.90	81.93†
Mean-Field	84.12†	78.90	82.45†

Table 2: Speaker classification accuracies (%) over connected, isolated and all instances. The marked results are statistically significant over the content only benchmark ($\star\ p < .01$, $\dagger\ p < .001$). The mean-field results are statistically significant over minimum-cut ($p < .05$).

linear-chain CRFs do not scale to the complexity of graphs used in this research.

6 Conclusions and future work

By applying alternative models, we have demonstrated the best recorded performance for collective classification of ConVote using bag-of-words features, beating the previous benchmark by nearly 6%. Moreover, each of the three alternative approaches trialed are theoretically superior to the minimum-cut approach approach for three main reasons: (1) they support multi-class classification; (2) they support negative and positive citations; (3) they require no parameter tuning.

The superior performance of the dual-classifier approach with loopy belief propagation and mean-field suggests that either algorithm could be considered as a first choice for collective document classification. Their advantage is increased by their ability to output classification confidences as probabilities, while minimum-cut and the local formulations only give absolute class assignments. We do not dismiss the iterative-classifier approach entirely. The most compelling point in its favor is its ability to unify content only and citation features in a single classifier. Conceptually speaking, such an approach should allow the two types of features to inter-relate in more nuanced ways. A case in point comes from our use of a fixed size context window to build a citation classifier. Future approaches may be able to do away with this arbitrary separation of features by training a local classifier to consider all words in terms of their impact on content-only classification and their relations to neighbors.

Probabilistic SVM normalization offers a convenient, principled way of incorporating the outputs of an SVM classifier into a collective classifier. An opportunity for future work is to consider normalization approaches for other classifiers. For example, confidence-weighted linear classifiers (Dredze et al., 2008) have been shown to give superior performance to SVMs on a range of tasks and may therefore be a better choice for collective document classification.

Of the three models trialled for local classifiers, context window features did best when measured in an oracle experiment, but citation count features did better when used in a collective classifier. We conclude that context window features are a more nuanced and powerful approach that is also more likely to suffer from data sparseness. Citation count features would have been the less effective in a scenario where the fact of the citation existing was less informative, for example, if a citation was 50% likely to indicate agreement rather than 80% likely. There is much scope for further research in this area.

Integrating history-length interpolation and classes in language modeling

Hinrich Schütze
Institute for NLP
University of Stuttgart
Germany

Abstract

Building on earlier work that integrates different factors in language modeling, we view (i) backing off to a shorter history and (ii) class-based generalization as two complementary mechanisms of using a larger equivalence class for prediction when the default equivalence class is too small for reliable estimation. This view entails that the classes in a language model should be learned from rare events only and should be preferably applied to rare events. We construct such a model and show that both training on rare events and preferable application to rare events improve perplexity when compared to a simple direct interpolation of class-based with standard language models.

1 Introduction

Language models, probability distributions over strings of words, are fundamental to many applications in natural language processing. The main challenge in language modeling is to estimate string probabilities accurately given that even very large training corpora cannot overcome the inherent sparseness of word sequence data. One way to improve the accuracy of estimation is *class-based generalization*. The idea is that even though a particular word sequence s may not have occurred in the training set (or too infrequently for accurate estimation), the occurrence of sequences similar to s can help us better estimate $p(s)$.

Plausible though this line of reasoning is, the language models most commonly used today do not incorporate class-based generalization. This is partially due to the additional cost of creating classes and using classes as part of the model. But an equally important reason is that most models that integrate class-based information do so by way of a simple interpolation and achieve only a modest improvement in performance.

In this paper, we propose a new type of class-based language model. The key novelty is that we recognize that certain probability estimates are hard to improve based on classes. In particular, the best probability estimate for frequent events is often the maximum likelihood estimator and this estimator is hard to improve by using other information sources like classes or word similarity. We therefore design a model that attempts to focus the effect of class-based generalization on rare events.

Specifically, we propose to employ the same strategy for this that history-length interpolated (HI) models use. We define HI models as models that interpolate the predictions of different-length histories, e.g., $p(w_3|w_1w_2) = \lambda_1(w_1w_2)p'(w_3|w_1w_2) + \lambda_2(w_1w_2)p'(w_3|w_2) + (1 - \lambda_1(w_1w_2) - \lambda_2(w_1w_2))p'(w_3)$ where p' is a simple estimate; in this section, we use $p' = p_{\text{ML}}$, the maximum likelihood estimate, as an example. Jelinek-Mercer (Jelinek and Mercer, 1980) and modified Kneser-Ney (Kneser and Ney, 1995) models are examples of HI models.

HI models address the challenge that frequent events are best estimated by a method close to maximum likelihood by selecting appropriate values for the interpolation weights. For example, if $w_1w_2w_3$ is frequent, then λ_1 will be close to 1, thus ensuring that $p(w_3|w_1w_2) \approx p_{\text{ML}}(w_3|w_1w_2)$ and that the components $p_{\text{ML}}(w_3|w_2)$ and $p_{\text{ML}}(w_3)$, which are unhelpful in this case, will only slightly change the reliable estimate $p_{\text{ML}}(w_3|w_1w_2)$.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1516–1525,
Portland, Oregon, June 19-24, 2011.

The main contribution of this paper is to propose the same mechanism for class language models. In fact, we will use the interpolation weights of a KN model to determine how much weight to give to each component of the interpolation. The difference to a KN model is merely that the lower-order distribution is not the lower-order KN distribution (as in KN), but instead an interpolation of the lower-order KN distribution and a class-based distribution. We will show that this method of integrating history interpolation and classes significantly increases the performance of a language model.

Focusing the effect of classes on rare events has another important consequence: if this is the right way of using classes, then they should not be formed based on *all events* in the training set, but only based on *rare events*. We show that doing this increases performance.

Finally, we introduce a second discounting method into the model that differs from KN. This can be motivated by the fact that with two sources of generalization (history-length and classes) more probability mass should be allocated to these two sources than to the single source used in KN. We propose a *polynomial discount* and show a significant improvement compared to using KN discounting only.

This paper is structured as follows. Section 2 discusses related work. Section 3 reviews the KN model and introduces two models, the Dupont-Rosenfeld model (a "recursive" model) and a top-level interpolated model, that integrate the KN model (a history interpolation model) with a class model. Section 4 details our experimental setup. Results are presented in Section 5. Based on an analysis of strengths and weaknesses of Dupont-Rosenfeld and top-level interpolated models, we present a new polynomial discounting mechanism that does better than either in Section 6. Section 7 presents our conclusions.

2 Related work

A large number of different class-based models have been proposed in the literature. The well-known model by Brown et al. (1992) is a class sequence model, in which $p(u|w)$ is computed as the product of a class transition probability and an emission probability, $p(g(u)|g(w))p(u|g(u))$, where $g(u)$ is the class of u. Other approaches condition the probability of a class on n-grams of lexical items (as opposed to classes) (Whittaker and Woodland, 2001; Emami and Jelinek, 2005; Uszkoreit and Brants, 2008). In this work, we use the Brown type of model: it is simpler and has fewer parameters. Models that condition classes on lexical n-grams could be extended in a way similar to what we propose here.

Classes have been used with good results in a number of applications, e.g., in speech recognition (Yokoyama et al., 2003), sentiment analysis (Wiegand and Klakow, 2008), and question answering (Momtazi and Klakow, 2009). Classes have also been shown to improve the performance of exponential models (Chen, 2009).

Our use of classes of lexical n-grams for $n > 1$ has several precedents in the literature (Suhm and Waibel, 1994; Kuo and Reichl, 1999; Deligne and Sagisaka, 2000; Justo and Torres, 2009). The novelty of our approach is that we integrate phrase-level classes into a KN model.

Hierarchical clustering (McMahon and Smith, 1996; Zitouni and Zhou, 2007; Zitouni and Zhou, 2008) has the advantage that the size of the class to be used in a specific context is not fixed, but can be chosen at an optimal level of the hierarchy. There is no reason why our non-hierarchical flat model could not be replaced with a hierarchical model and we would expect this to improve results.

The key novelty of our clustering method is that clusters are formed based on rare events in the training corpus. This type of clustering has been applied to other problems before, in particular to unsupervised part-of-speech tagging (Schütze, 1995; Clark, 2003; Reichart et al., 2010). However, the importance of rare events for clustering in language modeling has not been investigated before.

Our work is most similar to the lattice-based language models proposed by Dupont and Rosenfeld (1997). Bilmes and Kirchhoff (2003) generalize lattice-based language models further by allowing arbitrary factors in addition to words and classes. We use a special case of lattice-based language models in this paper. Our contributions are that we introduce the novel idea of rare-event clustering into language modeling and that we show that the modified model performs better than a strong word-trigram

symbol	denotation
$\sum[[w]]$	$\sum_w$ (sum over all unigrams w)
$c(w_j^i)$	count of w_j^i
$n_{1+}(\bullet w_j^i)$	# of distinct w occurring before w_j^i

Table 1: Notation used for Kneser-Ney.

baseline.

3 Models

In this section, we introduce the three models that we compare in our experiments: Kneser-Ney model, Dupont-Rosenfeld model, and top-level interpolation model.

3.1 Kneser-Ney model

Our baseline model is the modified Kneser-Ney (KN) trigram model as proposed by Chen and Goodman (1999). We give a comprehensive description of our implementation of KN because the details are important for the integration of the class model given below. We use the notation in Table 1.

We estimate p_{KN} on the training set as follows.

$$\begin{aligned} p_{\text{KN}}(w_3|w_1^2) &= \frac{c(w_1^3) - d'''(c(w_1^3))}{\sum[[w]]\ c(w_1^2 w)} \\ &\quad +\gamma_3(w_1^2) p_{\text{KN}}(w_3|w_2) \end{aligned}$$

$$\gamma_3(w_1^2) = \frac{\sum[[w]]\ d'''(c(w_1^2 w))}{\sum[[w]]\ c(w_1^2 w)}$$

$$\begin{aligned} p_{\text{KN}}(w_3|w_2) &= \frac{n_{1+}(\bullet w_2^3) - d''(n_{1+}(\bullet w_2^3))}{\sum[[w]]\ n_{1+}(\bullet w_2 w)} \\ &\quad +\gamma_2(w_2) p_{\text{KN}}(w_3) \end{aligned}$$

$$\gamma_2(w_2) = \frac{\sum[[w]]\ d''(n_{1+}(\bullet w_2 w))}{\sum[[w]]\ n_{1+}(\bullet w_2 w)}$$

$$p_{\text{KN}}(w_3) = \begin{cases} \frac{n_{1+}(\bullet w_3) - d'(n_{1+}(\bullet w_3))}{\sum[[w]]\ n_{1+}(\bullet w)} & \text{if } c(w_3) > 0 \\ \gamma_1 & \text{if } c(w_3) = 0 \end{cases}$$

$$\gamma_1 = \frac{\sum[[w]]\ d'(n_{1+}(\bullet w))}{\sum[[w]]\ n_{1+}(\bullet w)}$$

The parameters d', d'', and d''' are the discounts for unigrams, bigrams and trigrams, respectively, as defined by Chen and Goodman (1996, p. 20, (26)). Note that our notation deviates from C&G in that they use the single symbol D_1 for the three different values $d'(1)$, $d''(1)$, and $d'''(1)$ etc.

3.2 Dupont-Rosenfeld model

History-interpolated models attempt to find a good tradeoff between using a maximally informative history for accurate prediction of frequent events and generalization for rare events by using lower-order distributions; they employ this mechanism recursively by progressively shortening the history.

The key idea of the improved model we will adopt is that class generalization ought to play the same role in history-interpolated models as the lower-order distributions: they should improve estimates for unseen and rare events. Following Dupont and Rosenfeld (1997), we implement this idea by linearly interpolating the class-based distribution with the lower order distribution, recursively at each level. For a trigram model, this means that we interpolate $p_{\text{KN}}(w_3|w_2)$ and $p_{\text{B}}(w_3|w_1 w_2)$ on the first backoff level and $p_{\text{KN}}(w_3)$ and $p_{\text{B}}(w_3|w_2)$ on the second backoff level, where p_{B} is the (Brown) class model (see Section 4 for details on p_{B}). We call this model p_{DR} for Dupont-Rosenfeld model and define it as follows:

$$\begin{aligned} p_{\text{DR}}(w_3|w_1^2) = & \frac{c(w_1^3) - d'''(c(w_1^3))}{\sum[[w]]\ c(w_1^2 w)} \\ + & \gamma_3(w_1^2)[\beta_1(w_1^2) p_{\text{B}}(w_3|w_1^2) \\ & +(1 - \beta_1(w_1^2)) p_{\text{DR}}(w_3|w_2)] \end{aligned}$$

$$\begin{aligned} p_{\text{DR}}(w_3|w_2) = & \frac{n_{1+}(\bullet w_2^3) - d''(n_{1+}(\bullet w_2^3))}{\sum[[w]]\ n_{1+}(\bullet w_2 w)} \\ + & \gamma_2(w_2)[\beta_2(w_2) p_{\text{B}}(w_3|w_2) \\ & +(1 - \beta_2(w_2)) p_{\text{DR}}(w_3)] \end{aligned}$$

where $\beta_i(v)$ is equal to a parameter α_i if the history (w_1^2 or w_2) is part of a cluster and 0 otherwise:

$$\beta_i(v) = \begin{cases} \alpha_i & \text{if } v \in \mathcal{B}_{2-(i-1)} \\ 0 & \text{otherwise} \end{cases}$$

$\mathcal{B}_1$ (resp. $\mathcal{B}_2$) is the set of unigram (resp. bigram) histories that is covered by the clusters. We cluster bigram histories and unigram histories separately and write $p_{\text{B}}(w_3|w_1 w_2)$ for the bigram cluster model and $p_{\text{B}}(w_3|w_2)$ for the unigram cluster model. Clustering and the estimation of these two distributions are described in Section 4.

The unigram distribution of the Dupont-Rosenfeld model is set to the unigram distribution of the KN model: $p_{\text{DR}}(w) = p_{\text{KN}}(w)$.

The model (or family of models) defined by Dupont and Rosenfeld (1997) is more general than our version p_{DR}. Most importantly, it allows a truly parallel backoff whereas in our model the recursive backoff distribution p_{DR} is interpolated with a class distribution p_{B} that is not backed off. We prefer this version because it makes it easier to understand the contribution that unique-event vs. all-event classes make to improved language modeling; the parameters β are a good indicator of this effect.

An alternative way of setting up the Dupont-Rosenfeld model would be to interpolate $p_{\text{KN}}(w_3|w_1w_2)$ and $p_{\text{B}}(w_3|w_1w_2)$ etc – but this is undesirable. The strength of history interpolation is that estimates for frequent events are close to ML, e.g., $p_{\text{KN}}(\text{share}|\text{cents a}) \approx p_{\text{ML}}(\text{share}|\text{cents a})$ for our corpus. An ML estimate is accurate for large counts and we should not interpolate it directly with $p_{\text{B}}(w_3|w_1w_2)$. For p_{DR}, the discount d''' that is subtracted from $c(w_1w_2w_3)$ is small relative to $c(w_1w_2w_3)$ and therefore $p_{\text{DR}} \approx p_{\text{ML}}$ in this case (exactly as in p_{KN}).

3.3 Top-level interpolation

Class-based models are often combined with other models by interpolation, starting with the work by Brown et al. (1992). Since we cluster both unigrams and bigrams, we interpolate three models:

$$\begin{aligned} & p_{\text{TOP}}(w_3|w_1w_2) \\ = \; & \mu_1(w_1w_2)p_{\text{B}}(w_3|w_1w_2) + \mu_2(w_2)p_{\text{B}}(w_3|w_2) \\ + \; & (1 - \mu_1(w_1w_2) - \mu_2(w_2))p_{\text{KN}}(w_3|w_1w_2) \end{aligned}$$

where $\mu_1(w_1w_2) = \lambda_1$ if $w_1w_2 \in \mathcal{B}_2$ and 0 otherwise, $\mu_2(w_2) = \lambda_2$ if $w_2 \in \mathcal{B}_1$ and 0 otherwise and λ_1 and λ_2 are parameters. We call this the *top-level model* p_{TOP} because it interpolates the three models at the top level. Most previous work on class-based model has employed some form of top-level interpolation.

4 Experimental Setup

We run experiments on a Wall Street Journal (WSJ) corpus of 50M words, split 8:1:1 into training, validation and test sets. The training set contains 256,873 unique unigrams and 4,494,222 unique bigrams. Unknown words in validation and test sets are mapped to a special unknown word u.

We use the SRILM toolkit (Stolcke, 2002) for clustering. An important parameter of the class-based model is size $|\mathcal{B}_i|$ of the base set, i.e., the total number of n-grams (or rather i-grams) to be clustered. As part of the experiments we vary $|\mathcal{B}_i|$ systematically to investigate the effect of base set size. We cluster unigrams ($i = 1$) and bigrams ($i = 2$). For all experiments, $|\mathcal{B}_1| = |\mathcal{B}_2|$ (except in cases where $|\mathcal{B}_2|$ exceeds the number of unigrams, see below). SRILM does not directly support bigram clustering. We therefore represent a bigram as a hyphenated word in bigram clustering; e.g., *Pan Am* is represented as *Pan-Am*.

The input to the clustering is the vocabulary $\mathcal{B}_i$ and the cluster training corpus. For a particular base set size b, the unigram input vocabulary $\mathcal{B}_1$ is set to the b most frequent unigrams in the training set and the bigram input vocabulary $\mathcal{B}_2$ is set to the b most frequent bigrams in the training set.

In this section, we call the WSJ training corpus the *raw corpus* and the cluster training corpus the *cluster corpus* to be able to distinguish them. We run four different clusterings for each base set size (except for the large sets, see below). The cluster corpora are constructed as follows.

- **All-event unigram clustering.** The cluster corpus is simply the raw corpus.
- **All-event bigram clustering.** The cluster corpus is constructed as follows. A sentence of the raw corpus that contains s words is included twice, once as a sequence of the $\lfloor s/2 \rfloor$ bigrams "w_1–w_2 w_3–w_4 w_5–w_6 ..." and once as a sequence of the $\lfloor (s-1)/2 \rfloor$ bigrams "w_2–w_3 w_4–w_5 w_6–w_7 ...".
- **Unique-event unigram clustering.** The cluster corpus is the set of all sequences of two unigrams $\in \mathcal{B}_1$ that occur in the raw corpus, one sequence per line. Each sequence occurs only once in this cluster corpus.
- **Unique-event bigram clustering.** The cluster corpus is the set of all sequences of two bigrams $\in \mathcal{B}_2$ that occur in the training corpus,

one sequence per line. Each sequence occurs only once in this cluster corpus.

As mentioned above, we need both unigram and bigram clusters because we want to incorporate class-based generalization for histories of lengths 1 *and* 2. As we will show below this significantly increases performance. Since the focus of this paper is not on clustering algorithms, reformatting the training corpus as described above (as a sequence of hyphenated bigrams) is a simple way of using SRILM for bigram clustering.

The unique-event clusterings are motivated by the fact that in the Dupont-Rosenfeld model, frequent events are handled by discounted ML estimates. Classes are only needed in cases where an event was not seen or was not frequent enough in the training set. Consequently, we should form clusters not based on all events in the training corpus, but only on events that are rare – because this is the type of event that classes will then be applied to in prediction.

The two unique-event corpora can be thought of as reweighted collections in which each unique event receives the same weight. In practice this means that clustering is mostly influenced by rare events since, on the level of types, most events are rare. As we will see below, rare-event clusterings perform better than all-event clusterings. This is not surprising as the class-based component of the model can only benefit rare events and it is therefore reasonable to estimate this component based on a corpus dominated by rare events.

We started experimenting with reweighted corpora because class sizes become very lopsided in regular SRILM clustering as the size of the base set increases. The reason is that the objective function maximizes mutual information. Highly differentiated classes for frequent words contribute substantially to this objective function whereas putting all rare words in a few large clusters does not hurt the objective much. However, our focus is on using clustering for improving prediction for rare events; this means that the objective function is counterproductive when contexts are frequency-weighted as they occur in the corpus. After overweighting rare contexts, the objective function is more in sync with what we use clusters for in our model.

p_{TOP}	top-level interpolation
p_{POLKN}	KN and polynomial discounting
p_{POL0}	polynomial discounting only

Table 2: Key to probability distributions

It is important to note that the same intuition underlies unique-event clustering that also motivates using the "unique-event" distributions $n_{1+}(\bullet w_2^3)/(\sum n_{1+}(\bullet w_2 w))$ and $n_{1+}(\bullet w_3)/(\sum n_{1+}(\bullet w))$ for the backoff distributions in KN. Viewed this way, the basic KN model also uses a unique-event corpus (although a different one) for estimating backoff probabilities.

In all cases, we set the number of clusters to $k = 512$. Our main goal in this paper is to compare different ways of setting up history-length/class interpolated models and we do not attempt to optimize k. We settled on a fixed number of $k = 512$ because Brown et al. (1992) used a total of 1000 classes. 512 unigram classes and 512 bigram classes roughly correspond to this number. We prefer powers of 2 to facilitate efficient storage of cluster ids (one such cluster id must be stored for each unigram and each bigram) and therefore choose $k = 512$. Clustering was performed on an Opteron 8214 processor and took from several minutes for the smallest base sets to more than a week for the largest set of 400,000 items.

To estimate n-gram emission probabilities p_{E}, we first introduce an additional cluster for all unigrams that are not in the base set; emission probabilities are then estimated by maximum likelihood. Cluster transition probabilities p_{T} are computed using add-one smoothing. Both p_{E} and p_{T} are estimated on the raw corpus. The two class distributions are then defined as follows:

$$p_{\text{B}}(w_3|w_1w_2) = p_{\text{T}}(g(w_3)|g(w_1w_2))p_{\text{E}}(w_3|g(w_3))$$
$$p_{\text{B}}(w_3|w_2) = p_{\text{T}}(g(w_3)|g(w_2))p_{\text{E}}(w_3|g(w_3))$$

where $g(v)$ is the class of the uni- or bigram v.

Perplexity of KN model: 88.03

Table 3: Optimal parameters for Dupont-Rosenfeld (left) and top-level (right) models on the validation set and perplexity on the validation set. The two tables compare performance when using a class model trained on all events vs a class model trained on unique events. $|\mathcal{B}_1| = |\mathcal{B}_2|$ is the number of unigrams and bigrams in the clusters; e.g., lines 1a and 1b are for models that cluster 10,000 unigrams and 10,000 bigrams.

Table 2 is a key to the probability distributions we use.

5 Results

Table 3 shows the performance of p_{DR} and p_{TOP} for a range of base set sizes $|\mathcal{B}_i|$ and for classes trained on all events and on unique events. Parameters α_i and λ_i are optimized on the validation set. Perplexity is reported for the validation set. All following tables also optimize on the validation set and report results on the validation set. The last table, Table 7, also reports perplexity for the test set.

Table 3 confirms previous findings that classes improve language model performance. All models have a perplexity that is lower than KN (88.03).

When comparing all-event and unique-event clusterings, a clear tendency is apparent. In all-event clustering, the best performance is reached for $|\mathcal{B}_i| = 20000$: perplexity is 86.97 with this base set size for p_{DR} (line 2a) and 87.43 for p_{TOP} (line 2b). In unique-event clustering, performance keeps improving with larger and larger base sets; the best perplexities are obtained for $|\mathcal{B}_i| = 60000$: 85.96 for p_{DR} and 87.09 for p_{TOP} (lines 6a, 6b).

The parameter values also reflect this difference between all-event and unique-event clustering. For unique-event results of p_{DR}, we have $\alpha_1 \geq .2$ and $\alpha_2 \geq .4$ (1a–6a). This indicates that classes and history interpolation are both valuable when the model is backing off. But for all-event clustering, the values of α_i decrease: from a peak of .20 and .50 (2a) to .01 and .30 (6a), indicating that with larger base sets, less and less value can be derived from classes. This again is evidence that rare-event clustering is the correct approach: only clusters derived in rare-event clustering receive high weights α_i in the interpolation.

This effect can also be observed for p_{TOP}: the value of λ_1 (the weight of bigrams) is higher for unique-event clustering than for all-event clustering (with the exception of lines 1b&2b). The quality of bigram clusters seems to be low in all-event clustering when the base set becomes too large.

Perplexity is generally lower for unique-event clustering than for all-event clustering: this is the case for all values of $|\mathcal{B}_i|$ for p_{DR} (1a–6a); and for $|\mathcal{B}_i| > 20000$ for p_{TOP} (3b–6b).

Table 4 compares the two models in two different conditions: (i) b-: using unigram clusters only and (ii) b+: using unigram clusters and bigram clusters. For all events, there is no difference in performance. However, for unique events, the model that includes bigrams (b+) does better than the model without bigrams (b-). The effect is larger for p_{DR} than for p_{TOP} because (for unique events) a larger weight for the unigram model ($\lambda_2 = .05$ instead of $\lambda_2 = .04$) apparently partially compensates for the missing bigram clusters.

Table 3 shows that rare-event models do better than all-event models. Given that training large class models with SRILM on all events would take several weeks or even months, we restrict our direct

Table 5: Dupont-Rosenfeld and top-level models for $|\mathcal{B}_i| \in \{60000, 100000, 200000, 400000\}$. Clustering trained on unique-event corpora.

comparison of all-event and rare-event models to $|\mathcal{B}_i| \leq 60,000$ in Tables 3-4 and report only rare-event numbers for $|\mathcal{B}_i| > 60,000$ in what follows.

As we can see in Table 5, the trends observed in Table 3 continue as $|\mathcal{B}_i|$ is increased further. For both models, perplexity steadily decreases as $|\mathcal{B}_i|$ is increased from 60,000 to 400,000. (Note that for $|\mathcal{B}_i| = 400000$, the actual size of $\mathcal{B}_1$ is 256,873 since there are only that many words in the training corpus.) The improvements in perplexity become smaller for larger base set sizes, but it is reassuring to see that the general trend continues for large base set sizes. Our explanation is that the class component is focused on rare events and the items that are being added to the clustering for large base sets are all rare events.

The perplexity for p_{DR} is clearly lower than that of p_{TOP}, indicating the superiority of the Dupont-Rosenfeld model.[1]

[1]Dupont and Rosenfeld (1997) found a relatively large improvement of the "global" linear interpolation model – p_{top} in our terminology – compared to the baseline whereas p_{top} performs less well in our experiments. One possible explanation is that our KN baseline is stronger than the word trigram baseline they used.

6 Polynomial discounting

Further comparative analysis of p_{DR} and p_{TOP} revealed that p_{DR} is not uniformly better than p_{TOP}. We found that p_{TOP} does poorly on frequent events. For example, for the history $w_1w_2 =$ *cents a*, the continuation $w_3 =$ *share* dominates. p_{DR} deals well with this situation because $p_{\text{DR}}(w_3|w_1w_2)$ is the discounted ML estimate, with a discount that is small relative to the 10,768 occurrences of *cents a share* in the training set. In the p_{TOP} model on the last line in Table 5, the discounted ML estimate is multiplied by $1 - .05 - .04 = .91$, which results in a much less accurate estimate of $p_{\text{TOP}}(\text{share}|\text{cents a})$.

In contrast, p_{TOP} does well for productive histories, for which it is likely that a continuation unseen in the training set will occur. An example is the history *in the* – almost any adjective or noun can follow. There are 6251 different words that (i) occur after *in the* in the validation set, (ii) did not occur after *in the* in the training set, and (iii) occurred at least 10 times in the training set. Because their training set unigram frequency is at least 10, they have a good chance of being assigned to a class that captures their distributional behavior well and $p_{\text{B}}(w_3|w_1w_2)$ is then likely to be a good estimate. For a history with these properties, it is advantageous to further discount the discounted ML estimates by multiplying them with .91. p_{TOP} then gives the remaining probability mass of .09 to words w_3 whose probability would otherwise be underestimated.

What we have just described is already partially addressed by the KN model – $\gamma(v)$ will be relatively large for a productive history like $v =$ *in the*. However, it looks like the KN discounts are not large enough for productive histories, at least not in a combined history-length/class model. Apparently, when incorporating the strengths of a class-based model into KN, the default discounting mechanism does not reallocate enough probability mass

from high-frequency to low-frequency events. We conclude from this analysis that we need to increase the discount values d for large counts.

We could add a constant to d, but one of the basic premises of the KN model, derived from the assumption that n-gram marginals should be equal to relative frequencies, is that the discount is larger for more frequent n-grams although in many implementations of KN only the cases $c(w_1^3) = 1$, $c(w_1^3) = 2$, and $c(w_1^3) \geq 3$ are distinguished.

This suggests that the ideal discount $d(x)$ in an integrated history-length/class language model should grow monotonically with $c(v)$. The simplest way of implementing this heuristically is a polynomial of form ρx^r where ρ and r are parameters. r controls the rate of growth of the discount as a function of x; ρ is a factor that can be scaled for optimal performance.

The incorporation of the additional polynomial discount into KN is straightforward. We use a discount function $e(x)$ that is the sum of $d(x)$ and the polynomial:

$$e(x) = d(x) + \begin{cases} \rho x^r & \text{for } x \geq 4 \\ 0 & \text{otherwise} \end{cases}$$

where $(e, d) \in \{(e', d'), (e'', d''), (e''', d''')\}$. This model is identical to p_{DR} except that d is replaced with e. We call this model p_{POLKN}. p_{POLKN} directly implements the insight that, when using class-based generalization, discounts for counts $x \geq 4$ should be larger than they are in KN.

We also experiment with a second version of the model:

$$e(x) = \rho x^r$$

This second model, called p_{POL0}, is simpler and does not use KN discounts. It allows us to determine whether a polynomial discount by itself (without using KN discounts in addition) is sufficient.

Results for the two models are shown in Table 6 and compared with the two best models from Table 5, for $|\mathcal{B}_i| = 400{,}000$, classes trained on unique events. p_{POLKN} and p_{POL0} achieve a small improvement in perplexity when compared to p_{DR} (line 3&4 vs 2). This shows that using discounts that are larger than KN discounts for large counts is potentially advantageous.

		α_1/λ_1	α_2/λ_2	ρ	r	perp.

Table 7: Performance of key models on validation and test sets. tb:l = Table and line the validation result is taken from. ae/ue = all-event/unique-event. b- = unigrams only. b+ = bigrams and unigrams.

The linear interpolation $\alpha p + (1 - \alpha) q$ of two distributions p and q is a form of linear discounting: p is discounted by $1 - \alpha$ and q by α. See (Katz, 1987; Jelinek, 1990; Ney et al., 1994). It can thus be viewed as polynomial discounting for $r = 1$. Absolute discounting could be viewed as a form of polynomial discounting for $r = 0$. We know of no other work that has explored exponents between 0 and 1 and shown that for this type of exponent, one obtains competitive discounts that could be argued to be simpler than more complex discounts like KN discounts.

6.1 Test set performance

We report the test set performance of the key models we have developed in this paper in Table 7. The experiments were run with the optimal parameters

on the validation set as reported in the table referenced in column "tb:l"; e.g., on line 2 of Table 7, $(\alpha_1, \alpha_2) = (.01, .3)$ as reported on line 6a of Table 3.

There is an almost constant difference between validation and test set perplexities, ranging from +.2 to +.3, indicating that test set results are consistent with validation set results. To test significance, we assigned the 2.8M positions in the test set to 48 different bins according to the majority part-of-speech tag of the word in the training set.[2] We can then compute perplexity for each bin, compare perplexities for different experiments and use the sign test for determining significance. We indicate results that were significant at $p < .05$ ($n = 48$, $k \geq 32$ successes) using a star, e.g., $3 <^* 2$ means that test set perplexity on line 3 is significantly lower than test set perplexity on line 2.

The main findings on the validation set also hold for the test set: (i) Trained on unique events and with a sufficiently large $|\mathcal{B}_i|$, both p_{DR} and p_{TOP} are better than KN: $10 <^* 1$, $11 <^* 1$. (ii) Training on unique events is better than training on all events: $3 <^* 2$, $5 <^* 4$, $7 <^* 6$, $9 <^* 8$. (iii) For unique events, using bigram and unigram classes gives better results than using unigram classes only: $3 <^* 7$. Not significant: $5 < 9$. (iv) The Dupont-Rosenfeld model p_{DR} is better than the top-level model p_{TOP}: $10 <^* 11$. (v) The model POL0 (polynomial discounting) is the best model overall: Not significant: $13 < 12$. (vi) Polynomial discounting is significantly better than KN discounting for the Dupont-Rosenfeld model p_{DR} although the absolute difference in perplexity is small: $13 <^* 10$.

Overall, p_{DR} and p_{POL0} achieve considerable reductions in test set perplexity from 88.28 to 85.39 and 85.22, respectively. The main result of the experiments is that Dupont-Rosenfeld models (which focus on rare events) are better than the standardly used top-level models; and that training classes on unique events is better than training classes on all events.

[2] Words with a rare majority tag (e.g., FW 'foreign word') and unknown words were assigned to a special class OTHER.

7 Conclusion

Our hypothesis was that classes are a generalization mechanism for rare events that serves the same function as history-length interpolation and that classes should therefore be (i) primarily trained on rare events and (ii) receive high weight only if it is likely that a rare event will follow and be weighted in a way analogous to the weighting of lower-order distributions in history-length interpolation.

We found clear statistically significant evidence for both (i) and (ii). (i) Classes trained on unique-event corpora perform better than classes trained on all-event corpora. (ii) The p_{DR} model (which adjusts the interpolation weight given to classes based on the prevalence of nonfrequent events following) is better than top-level model p_{TOP} (which uses a fixed weight for classes). Most previous work on class-based models has employed top-level interpolation. Our results strongly suggest that the Dupont-Rosenfeld model is a superior model.

A comparison of Dupont-Rosenfeld and top-level results suggested that the KN discount mechanism does not discount high-frequency events enough. We empirically determined that better discounts are obtained by letting the discount grow as a function of the count of the discounted event and implemented this as polynomial discounting, an arguably simpler way of discounting than Kneser-Ney discounting. The improvement of polynomial discounts vs. KN discounts was small, but statistically significant.

In future work, we would like to find a theoretical justification for the surprising fact that polynomial discounting does at least as well as Kneser-Ney discounting. We also would like to look at other backoff mechanisms (in addition to history length and classes) and incorporate them into the model, e.g., similarity and topic. Finally, training classes on unique events is an extreme way of highly weighting rare events. We would like to explore training regimes that lie between unique-event clustering and all-event clustering and upweight rare events less.

Structural Topic Model for Latent Topical Structure Analysis

Abstract

Topic models have been successfully applied to many document analysis tasks to discover topics embedded in text. However, existing topic models generally cannot capture the latent topical structures in documents. Since languages are intrinsically cohesive and coherent, modeling and discovering latent topical transition structures within documents would be beneficial for many text analysis tasks.

In this work, we propose a new topic model, Structural Topic Model, which simultaneously discovers topics and reveals the latent topical structures in text through explicitly modeling topical transitions with a latent first-order Markov chain. Experiment results show that the proposed Structural Topic Model can effectively discover topical structures in text, and the identified structures significantly improve the performance of tasks such as sentence annotation and sentence ordering.

1 Introduction

A great amount of effort has recently been made in applying statistical topic models (Hofmann, 1999; Blei et al., 2003) to explore word co-occurrence patterns, i.e. topics, embedded in documents. Topic models have become important building blocks of many interesting applications (see e.g., (Blei and Jordan, 2003; Blei and Lafferty, 2007; Mei et al., 2007; Lu and Zhai, 2008)).

In general, topic models can discover word clustering patterns in documents and project each document to a latent topic space formed by such word clusters. However, the topical structure in a document, i.e., the internal dependency between the topics, is generally not captured due to the exchangeability assumption (Blei et al., 2003), i.e., the document generation probabilities are invariant to content permutation. In reality, natural language text rarely consists of isolated, unrelated sentences, but rather collocated, structured and coherent groups of sentences (Hovy, 1993). Ignoring such latent topical structures inside the documents means wasting valuable clues about topics and thus would lead to non-optimal topic modeling.

Taking apartment rental advertisements as an example, when people write advertisements for their apartments, it's natural to first introduce *"size"* and *"address"* of the apartment, and then *"rent"* and *"contact"*. Few people would talk about *"restriction"* first. If this kind of topical structures are captured by a topic model, it would not only improve the topic mining results, but, more importantly, also help many other document analysis tasks, such as sentence annotation and sentence ordering.

Nevertheless, very few existing topic models attempted to model such structural dependency among topics. The Aspect HMM model introduced in (Blei and Moreno, 2001) combines pLSA (Hofmann, 1999) with HMM (Rabiner, 1989) to perform document segmentation over text streams. However, Aspect HMM separately estimates the topics in the training set and depends on heuristics to infer the transitional relations between topics. The Hidden Topic Markov Model (HTMM) proposed by (Gruber et al., 2007) extends the traditional topic models by assuming words in each sentence share the same topic assignment, and topics transit between adjacent sentences. However, the transitional structures among topics, i.e., how likely one topic would follow another topic, are not captured in this model.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1526–1535,
Portland, Oregon, June 19-24, 2011.

In this paper, we propose a new topic model, named Structural Topic Model (strTM) to model and analyze both latent topics and topical structures in text documents. To do so, strTM assumes: 1) words in a document are either drawn from a content topic or a *functional* (i.e., background) topic; 2) words in the same sentence share the same content topic; and 3) content topics in the adjacent sentences follow a topic transition that satisfies the first order Markov property. The first assumption distinguishes the semantics of the occurrence of each word in the document, the second requirement confines the unrealistic "bag-of-word" assumption into a tighter unit, and the third assumption exploits the connection between adjacent sentences.

To evaluate the usefulness of the identified topical structures by strTM, we applied strTM to the tasks of sentence annotation and sentence ordering, where correctly modeling the document structure is crucial. On the corpus of 8,031 apartment advertisements from craiglist (Grenager et al., 2005) and 1,991 movie reviews from IMDB (Zhuang et al., 2006), strTM achieved encouraging improvement in both tasks compared with the baseline methods that don't explicitly model the topical structure. The results confirm the necessity of modeling the latent topical structures inside documents, and also demonstrate the advantages of the proposed strTM over existing topic models.

2 Related Work

Topic models have been successfully applied to many problems, e.g., sentiment analysis (Mei et al., 2007), document summarization (Lu and Zhai, 2008) and image annotation (Blei and Jordan, 2003). However, in most existing work, the dependency among the topics is loosely governed by the prior topic distribution, e.g., Dirichlet distribution.

Some work has attempted to capture the interrelationship among the latent topics. Correlated Topic Model (Blei and Lafferty, 2007) replaces Dirichlet prior with logistic Normal prior for topic distribution in each document in order to capture the correlation between the topics. HMM-LDA (Griffiths et al., 2005) distinguishes the short-range syntactic dependencies from long-range semantic dependencies among the words in each document. But in HMM-LDA, only the latent variables for the syntactic classes are treated as a locally dependent sequence, while latent topics are treated the same as in other topic models. Chen et al. introduced the generalized Mallows model to constrain the latent topic assignments (Chen et al., 2009). In their model, they assume there exists a canonical order among the topics in the collection of related documents and the same topics are forced not to appear in disconnected portions of the topic sequence in one document (sampling without replacement). Our method relaxes this assumption by only postulating transitional dependency between topics in the adjacent sentences (sampling with replacement) and thus potentially allows a topic to appear multiple times in disconnected segments. As discussed in the previous section, HTMM (Gruber et al., 2007) is the most similar model to ours. HTMM models the document structure by assuming words in the same sentence share the same topic assignment and successive sentences are more likely to share the same topic. However, HTMM only loosely models the transition between topics as a binary relation: the same as the previous sentence's assignment or draw a new one with a certain probability. This simplified coarse modeling of dependency could not fully capture the complex structure across different documents. In contrast, our strTM model explicitly captures the regular topic transitions by postulating the first order Markov property over the topics.

Another line of related work is discourse analysis in natural language processing: discourse segmentation (Sun et al., 2007; Galley et al., 2003) splits a document into a linear sequence of multi-paragraph passages, where lexical cohesion is used to link together the textual units; discourse parsing (Soricut and Marcu, 2003; Marcu, 1998) tries to uncover a more sophisticated hierarchical coherence structure from text to represent the entire discourse. One work in this line that shares a similar goal as ours is the content models (Barzilay and Lee, 2004), where an HMM is defined over text spans to perform information ordering and extractive summarization. A deficiency of the content models is that the identification of clusters of text spans is done separately from transition modeling. Our strTM addresses this deficiency by defining a generative process to simultaneously capture the topics and the transitional re-

lationship among topics: allowing topic modeling and transition modeling to reinforce each other in a principled framework.

3 Structural Topic Model

In this section, we formally define the Structural Topic Model (strTM) and discuss how it captures the latent topics and topical structures within the documents simultaneously. From the theory of linguistic analysis (Kamp, 1981), we know that document exhibits internal structures, where structural segments encapsulate semantic units that are closely related. In strTM, we treat a sentence as the basic structure unit, and assume all the words in a sentence share the same topical aspect. Besides, two adjacent segments are assumed to be highly related (capturing cohesion in text); specifically, in strTM we pose a strong transitional dependency assumption among the topics: the choice of topic for each sentence directly depends on the previous sentence's topic assignment, i.e., first order Markov property. Moveover, taking the insights from HMM-LDA that not all the words are content conveying (some of them may just be a result of syntactic requirement), we introduce a dummy *functional* topic z_B for every sentence in the document. We use this functional topic to capture the document-independent word distribution, i.e., corpus background (Zhai et al., 2004). As a result, in strTM, every sentence is treated as a mixture of content and functional topics.

Formally, we assume a corpus consists of *D* documents with a vocabulary of size *V*, and there are *k* content topics embedded in the corpus. In a given document *d*, there are *m* sentences and each sentence *i* has N_i words. We assume the topic transition probability $p(z|z')$ is drawn from a Multinomial distribution *Mul(*$\alpha_{z'}$*)*, and the word emission probability under each topic $p(w|z)$ is drawn from a Multinomial distribution *Mul(*β_z*)*.

To get a unified description of the generation process, we add another dummy topic *T-START* in strTM, which is the initial topic with position "-1" for every document but does not emit any words. In addition, since our functional topic is assumed to occur in all the sentences, we don't need to model its transition with other content topics. We use a Binomial variable π to control the proportion between content and functional topics in each sentence. Therefore, there are *k*+1 topic transitions, one for *T-START* and others for *k* content topics; and *k* emission probabilities for the content topics, with an additional one for the functional topic z_B (in total *k*+1 emission probability distributions).

Conditioned on the model parameters $\Theta = (\alpha, \beta, \pi)$, the generative process of a document in strTM can be described as follows:

1. For each sentence s_i in document *d*:
   (a) Draw topic z_i from Multinomial distribution conditioned on the previous sentence s_{i-1}'s topic assignment z_{i-1}:
   $z_i \sim Mul(\alpha_{z_{i-1}})$
   (b) Draw each word w_{ij} in sentence s_i from the mixture of content topic z_i and functional topic z_B:
   $w_{ij} \sim \pi p(w_{ij}|\beta, z_i) + (1-\pi)p(w_{ij}|\beta, z_B)$

The joint probability of sentences and topics in one document defined by strTM is thus given by:

$$p(S_0, S_1, \ldots, S_m, \mathbf{z}|\alpha, \beta, \pi) = \prod_{i=1}^{m} p(z_i|\alpha, z_{i-1}) p(S_i|z_i) \quad (1)$$

where the topic to sentence emission probability is defined as:

$$p(S_i|z_i) = \prod_{j=0}^{N_i} \left[\pi p(w_{ij}|\beta, z_i) + (1-\pi) p(w_{ij}|\beta, z_B)\right] \quad (2)$$

This process is graphically illustrated in Figure 1.

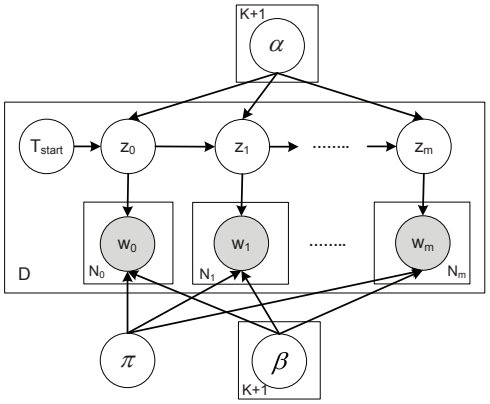

Figure 1: Graphical Representation of strTM.

From the definition of strTM, we can see that the document structure is characterized by a document-specific topic chain, and forcing the words in one

sentence to share the same content topic ensures semantic cohesion of the mined topics. Although we do not directly model the topic mixture for each document as the traditional topic models do, the word co-occurrence patterns within the same document are captured by topic propagation through the transitions. This can be easily understood when we write down the posterior probability of the topic assignment for a particular sentence:

$$\begin{aligned}
&p(z_i|S_0, S_1, \ldots, S_m, \Theta) \\
=&\frac{p(S_0, S_1, \ldots, S_m|z_i, \Theta)p(z_i)}{p(S_0, S_1, \ldots, S_m)} \\
\propto& p(S_0, S_1, \ldots, S_i, z_i) \times p(S_{i+1}, S_{i+2}, \ldots, S_m|z_i) \\
=&\sum_{z_{i-1}} p(S_0, \ldots, S_{i-1}, z_{i-1})p(z_i|z_{i-1})p(S_i|z_i) \\
&\times \sum_{z_{i+1}} p(S_{i+1}, \ldots, S_m|z_{i+1})p(z_{i+1}|z_i) \qquad (3)
\end{aligned}$$

The first part of Eq(3) describes the recursive influence on the choice of topic for the i*th* sentence from its preceding sentences, while the second part captures how the succeeding sentences affect the current topic assignment. Intuitively, when we need to decide a sentence's topic, we will look "backward" and "forward" over all the sentences in the document to determine a "suitable" one. In addition, because of the first order Markov property, the local topical dependency gets more emphasis, i.e., they are interacting directly through the transition probabilities $p(z_i|z_{i-1})$ and $p(z_{i+1}|z_i)$. And such interaction on sentences farther away would get damped by the multiplication of such probabilities. This result is reasonable, especially in a long document, since neighboring sentences are more likely to cover similar topics than two sentences far apart.

4 Posterior Inference and Parameter Estimation

The chain structure in strTM enables us to perform exact inference: posterior distribution can be efficiently calculated by the forward-backward algorithm, the optimal topic sequence can be inferred using the Viterbi algorithm, and parameter estimation can be solved by the Expectation Maximization (EM) algorithm. More technical details can be found in (Rabiner, 1989). In this section, we only discuss strTM-specific procedures.

In the E-Step of EM algorithm, we need to collect the expected count of a sequential topic pair (z, z') and a topic-word pair (z, w) to update the model parameters α and β in the M-Step. In strTM, $E[c(z, z')]$ can be easily calculated by forward-backward algorithm. But we have to go one step further to fetch the required sufficient statistics for $E[c(z, w)]$, because our emission probabilities are defined over sentences.

Through forward-backward algorithm, we can get the posterior probability $p(s_i, z|d, \Theta)$. In strTM, words in one sentence are independently drawn from either a specific content topic z or functional topic z_B according to the mixture weight π. Therefore, we can accumulate the expected count of (z, w) over all the sentences by:

$$E[c(z, w)] = \sum_{d, s \in d} \frac{\pi p(w|z)p(s, z|d, \Theta)c(w, s)}{\pi p(w|z) + (1 - \pi)p(w|z_B)} \qquad (4)$$

where $c(w, s)$ indicates the frequency of word w in sentence s.

Eq(4) can be easily explained as follows. Since we already observe topic z and sentence s co-occur with probability $p(s, z|d, \Theta)$, each word w in s should share the same probability of being observed with content topic z. Thus the expected count of $c(z, w)$ in this sentence would be $p(s, z|d, \Theta)c(w, s)$. However, since each sentence is also associated with the functional topic z_B, the word w may also be drawn from z_B. By applying the Bayes' rule, we can properly reallocate the expected count of $c(z, w)$ by Eq(4). The same strategy can be applied to obtain $E[c(z_B, w)]$.

As discussed in (Johnson, 2007), to avoid the problem that EM algorithm tends to assign a uniform word/state distribution to each hidden state, which deviates from the heavily skewed word/state distributions empirically observed, we can apply a Bayesian estimation approach for strTM. Thus we introduce prior distributions over the topic transition *Mul($\alpha_{z'}$)* and emission probabilities *Mul(β_z)*, and use the Variational Bayesian (VB) (Jordan et al., 1999) estimator to obtain a model with more skewed word/state distributions.

Since both the topic transition and emission probabilities are Multinomial distributions in strTM, the conjugate Dirichlet distribution is the natural

choice for imposing a prior on them (Diaconis and Ylvisaker, 1979). Thus, we further assume:

$$\alpha_z \sim Dir(\eta) \quad (5)$$

$$\beta_z \sim Dir(\gamma) \quad (6)$$

where we use exchangeable Dirichlet distributions to control the sparsity of α_z and β_z. As η and γ approach zero, the prior strongly favors the models in which each hidden state emits as few words/states as possible. In our experiments, we empirically tuned η and γ on different training corpus to optimize log-likelihood.

The resulting VB estimation only requires a minor modification to the M-Step in the original EM algorithm:

$$\bar{\alpha}_z = \frac{\Phi(E[c(z', z)] + \eta)}{\Phi(E[c(z)] + k\eta)} \quad (7)$$

$$\bar{\beta}_z = \frac{\Phi(E[c(w, z)] + \gamma)}{\Phi(E[c(z)] + V\gamma)} \quad (8)$$

where $\Phi(x)$ is the exponential of the first derivative of the log-gamma function.

The optimal setting of π for the proportion of content topics in the documents is empirically tuned by cross-validation over the training corpus to maximize the log-likelihood.

5 Experimental Results

In this section, we demonstrate the effectiveness of strTM in identifying latent topical structures from documents, and quantitatively evaluate how the mined topic transitions can help the tasks of sentence annotation and sentence ordering.

5.1 Data Set

We used two different data sets for evaluation: apartment advertisements (Ads) from (Grenager et al., 2005) and movie reviews (Review) from (Zhuang et al., 2006).

The Ads data consists of 8,767 advertisements for apartment rentals crawled from Craigslist website. 302 of them have been labeled with 11 fields, including *size*, *feature*, *address*, etc., on the sentence level. The review data contains 2,000 movie reviews discussing 11 different movies from IMDB. These reviews are manually labeled with 12 movie feature labels (We didn't use the additional opinion annotations in this data set.) , e.g., *VP* (vision effects), *MS* (music and sound effects), etc., also on the sentences, but the annotations in the review data set is much sparser than that in the Ads data set (see in Table 1). The sentence-level annotations make it possible to quantitatively evaluate the discovered topic structures.

We performed simple preprocessing on these two data sets: 1) removed a standard list of stop words, terms occurring in less than 2 documents; 2) discarded the documents with less than 2 sentences; 3) aggregated sentence-level annotations into document-level labels (binary vector) for each document. Table 1 gives a brief summary on these two data sets after the processing.

	Ads	*Review*
Document Size	8,031	1,991
Vocabulary Size	21,993	14,507
Avg Stn/Doc	8.0	13.9
Avg Labeled Stn/Doc	7.1*	5.1
Avg Token/Stn	14.1	20.0

*Only in 302 labeled ads

Table 1: Summary of evaluation data set

5.2 Topic Transition Modeling

First, we qualitatively demonstrate the topical structure identified by strTM from Ads data[1]. We trained strTM with 11 content topics in Ads data set, used word distribution under each class (estimated by maximum likelihood estimator on document-level labels) as priors to initialize the emission probability *Mul(β_z)* in Eq(6), and treated document-level labels as the prior for transition from T-START in each document, so that the mined topics can be aligned with the predefined class labels. Figure 2 shows the identified topics and the transitions among them. To get a clearer view, we discarded the transitions below a threshold of 0.1 and removed all the isolated nodes.

From Figure 2, we can find some interesting topical structures. For example, people usually start with *"size"*, *"features"* and *"address"*, and end with *"contact"* information when they post an apart-

[1]Due to the page limit, we only show the result in Ads data set.

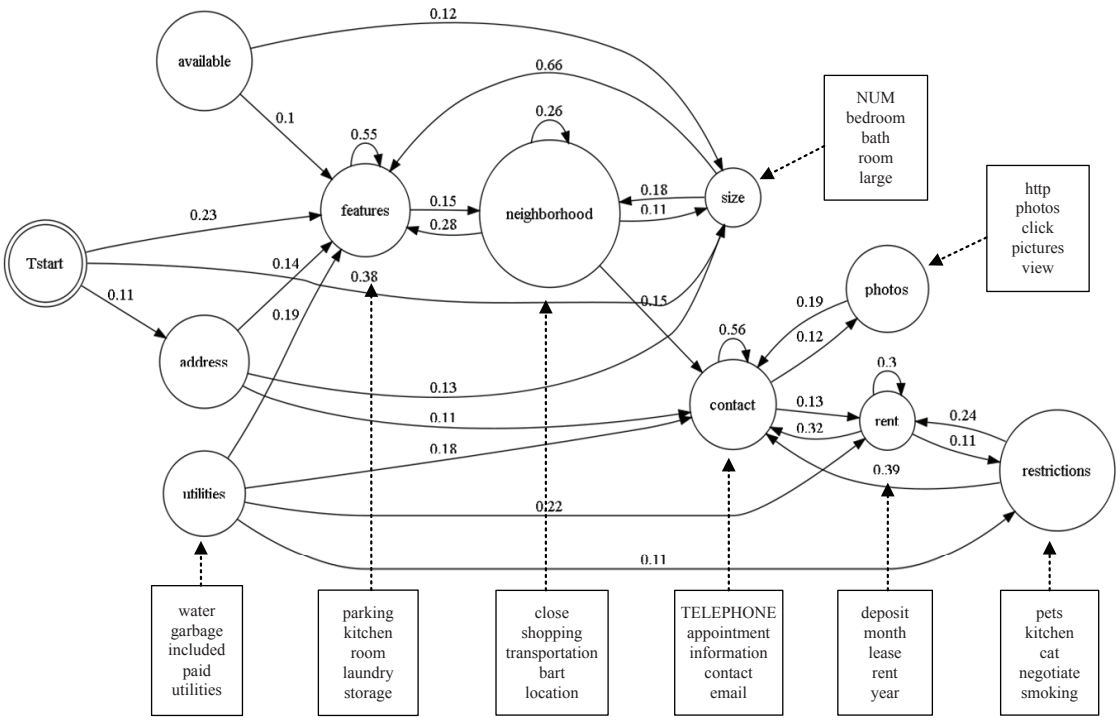

Figure 2: Estimated topics and topical transitions in Ads data set

ment ads. Also, we can discover a strong transition from *"size"* to *"features"*. This intuitively makes sense because people usually write "it's a two bedrooms apartment" first, and then describe other *"features"* about the apartment. The mined topics are also quite meaningful. For example, *"restrictions"* are usually put over pets and smoking, and parking and laundry are always the major *"features"* of an apartment.

To further quantitatively evaluate the estimated topic transitions, we used *Kullback-Leibler* (*KL*) divergency between the estimated transition matrix and the "ground-truth" transition matrix as the metric. Each element of the "ground-truth" transition matrix was calculated by Eq(9), where $c(z, z')$ denotes how many sentences annotated by z' immediately precede one annotated by z. δ is a smoothing factor, and we fixed it to 0.01 in the experiment.

$$\bar{p}(z|z') = \frac{c(z, z') + \delta}{c(z) + k\delta} \tag{9}$$

The *KL* divergency between two transition matrices is defined in Eq(10). Because we have a $k \times k$ transition matrix (T_{start} is not included), we calculated the average *KL* divergency against the ground-truth over all the topics:

$$avgKL = \frac{\sum_{i=1}^{k} KL(p(z|z'_i)||\bar{p}(z|z'_i)) + KL(\bar{p}(z|z'_i)||p(z|z'_i))}{2k} \tag{10}$$

where $\bar{p}(z|z')$ is the ground-truth transition probability estimated by Eq(9), and $p(z|z')$ is the transition probability given by the model.

We used pLSA (Hofmann, 1999), latent permutation model (lPerm) (Chen et al., 2009) and HTMM (Gruber et al., 2007) as the baseline methods for the comparison. Because none of these three methods can generate a topic transition matrix directly, we extended them a little bit to achieve this goal. For pLSA, we used the document-level labels as priors for the topic distribution in each document, so that the estimated topics can be aligned with the predefined class labels. After the topics were estimated, for each sentence we selected the topic that had the highest posterior probability to generate the sentence as its class label. For lPerm and HTMM, we used Kuhn-Munkres algorithm (Lovász and Plummer, 1986) to find the optimal topic-to-class alignment based on the sentence-level annotations. After the sentences were annotated with class labels, we estimated the topic transition matrices for all of these three methods by Eq(9).

Since only a small portion of sentences are annotated in the Review data set, very few neighboring sentences are annotated at the same time, which introduces many noisy transitions. As a result, we only performed the comparison on the Ads data set. The "ground-truth" transition matrix was estimated based on all the 302 annotated ads.

	pLSA+prior	lPerm	HTMM	strTM
avgKL	0.743	1.101	0.572	0.372
p-value	0.023	1e-4	0.007	–

Table 2: Comparison of estimated topic transitions on Ads data set

In Table 2, the p-value was calculated based on t-test of the *KL* divergency between each topic's transition probability against strTM. From the results, we can see that avgKL of strTM is smaller than the other three baseline methods, which means the estimated transitional relation by strTM is much closer to the ground-truth transition. This demonstrates that strTM captures the topical structure well, compared with other baseline methods.

5.3 Sentence Annotation

In this section, we demonstrate how the identified topical structure can benefit the task of sentence annotation. Sentence annotation is one step beyond the traditional document classification task: in sentence annotation, we want to predict the class label for each sentence in the document, and this will be helpful for other problems, including extractive summarization and passage retrieval. However, the lack of detailed annotations on sentences greatly limits the effectiveness of the supervised classification methods, which have been proved successful on document classifications.

In this experiment, we propose to use strTM to address this annotation task. One advantage of strTM is that it captures the topic transitions on the sentence level within documents, which provides a regularization over the adjacent predictions.

To examine the effectiveness of such structural regularization, we compared strTM with four baseline methods: pLSA, lPerm, HTMM and Naive Bayes model. The sentence labeling approaches for strTM, pLSA, lPerm and HTMM have been discussed in the previous section. As for Naive Bayes model, we used EM algorithm [2] with both labeled and unlabeled data for the training purpose (we used the same unigram features as in topics models). We set weights for the unlabeled data to be 10^{-3} in Naive Bayes with EM.

The comparison was performed on both data sets. We set the size of topics in each topic model equal to the number of classes in each data set accordingly. To tackle the situation where some sentences in the document are not strictly associated with any classes, we introduced an additional *NULL* content topic in all the topic models. During the training phase, none of the methods used the sentence-level annotations in the documents, so that we treated the whole corpus as the training and testing set.

To evaluate the prediction performance, we calculated accuracy, recall and precision based on the correct predictions over the sentences, and averaged over all the classes as the criterion.

Model	Accuracy	Recall	Precison
pLSA+prior	0.432	0.649	0.457
lPerm	0.610	0.514	0.471
HTMM	0.606	0.588	0.443
NB+EM	0.528	0.337	0.612
strTM	**0.747**	**0.674**	**0.620**

Table 3: Sentence annotation performance on Ads data set

Model	Accuracy	Recall	Precison
pLSA+prior	0.342	0.278	0.250
lPerm	0.286	0.205	0.184
HTMM	0.369	0.131	0.149
NB+EM	0.341	0.354	**0.431**
strTM	**0.541**	**0.398**	0.323

Table 4: Sentence annotation performance on Review data set

Annotation performance on the two data sets is shown in Table 3 and Table 4. We can see that strTM outperformed all the other baseline methods on most of the metrics: strTM has the best accuracy and recall on both of the two data sets. The improvement confirms our hypothesis that besides solely depending on the local word patterns to perform predic-

[2]Mallet package: `http://mallet.cs.umass.edu/`

tions, adjacent sentences provide a structural regularization in strTM (see Eq(3)). Compared with lPerm, which postulates a strong constrain over the topic assignment (sampling without replacement), strTM performed much better on both of these two data sets. This validates the benefit of modeling local transitional relation compared with the global ordering. Besides, strTM achieved over 46% accuracy improvement compared with the second best HTMM in the review data set. This result shows the advantage of explicitly modeling the topic transitions between neighbor sentences instead of using a binary relation to do so as in HTMM.

To further testify how the identified topical structure can help the sentence annotation task, we first randomly removed 100 annotated ads from the training corpus and used them as the testing set. Then, we used the ground-truth topic transition matrix estimated from the training data to order those 100 ads according to their fitness scores under the ground-truth topic transition matrix, which is defined in Eq(11). We tested the prediction accuracy of different models over two different partitions, top 50 and bottom 50, according to this order.

$$fitness(d) = \frac{1}{|d|}\sum_{i=0}^{|d|}\log \bar{p}(t_i|t_{i-1}) \qquad (11)$$

where t_i is the class label for i*th* sentence in document d, $|d|$ is the number of sentences in document d, and $\bar{p}(t_i|t_{i-1})$ is the transition probability estimated by Eq(9).

	Top 50	p-value	Bot 50	p-value
pLSA+prior	0.496	4e-12	0.542	0.004
lPerm	0.669	0.003	0.505	8e-4
HTMM	0.683	0.004	0.579	0.003
NB + EM	0.492	1e-12	0.539	0.002
strTM	0.752	–	0.644	–

Table 5: Sentence annotation performance according to structural fitness

The results are shown in Table 5. From this table, we can find that when the testing documents follow the regular patterns as in the training data, i.e., top 50 group, strTM performs significantly better than the other methods; when the testing documents don't share such structure, i.e., bottom 50 group, strTM's performance drops. This comparison confirms that when a testing document shares similar topic structure as the training data, the topical transitions captured by strTM can help the sentence annotation task a lot. In contrast, because pLSA and Naive Bayes don't depend on the document's structure, their performance does not change much over these two partitions.

5.4 Sentence Ordering

In this experiment, we illustrate how the learned topical structure can help us better arrange sentences in a document. Sentence ordering, or text planning, is essential to many text synthesis applications, including multi-document summarization (Goldstein et al., 2000) and concept-to-text generation (Barzilay and Lapata, 2005).

In strTM, we evaluate all the possible orderings of the sentences in a given document and selected the optimal one which gives the highest generation probability:

$$\bar{\sigma}(m) = \arg\max_{\sigma(m)} \sum_{\mathbf{z}} p(S_{\sigma[0]}, S_{\sigma[1]}, \ldots, S_{\sigma[m]}, \mathbf{z}|\Theta) \qquad (12)$$

where $\sigma(m)$ is a permutation of 1 to m, and $\sigma[i]$ is the i*th* element in this permutation.

To quantitatively evaluate the ordering result, we treated the original sentence order (OSO) as the perfect order and used *Kendall's* $\tau(\sigma)$ (Lapata, 2006) as the evaluation metric to compute the divergency between the optimum ordering given by the model and OSO. *Kendall's* $\tau(\sigma)$ is widely used in information retrieval domain to measure the correlation between two ranked lists and it indicates how much an ordering differs from OSO, which ranges from 1 (perfect matching) to -1 (totally mismatching).

Since only the HTMM and lPerm take the order of sentences in the document into consideration, we used them as the baselines in this experiment. We ranked OSO together with candidate permutations according to the corresponding model's generation probability. However, when the size of documents becomes larger, it's infeasible to permutate all the orderings, therefore we randomly permutated 200 possible orderings of sentences as candidates when there were more than 200 possible candidates. Table 6: Sample results for document ordering by strTM

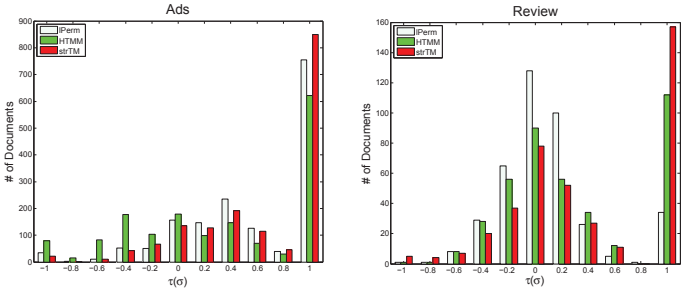
experiment was performed on both data sets with 80% data for training and the other 20% for testing.

We calculated the $\tau(\sigma)$ of all these models for each document in the two data sets and visualized the distribution of $\tau(\sigma)$ in each data set with histogram in Figure 3. From the results, we could observe that strTM's $\tau(\sigma)$ is more skewed towards the positive range (with mean 0.619 in Ads data set and 0.398 in review data set) than lPerm's results (with mean 0.566 in Ads data set and 0.08 in review data set) and HTMM's results (with mean 0.332 in Ads data set and 0.286 in review data set). This indicates that strTM better captures the internal structure within the documents.



(a) Ads (b) Review

Figure 3: Document Ordering Performance in $\tau(\sigma)$.

We see that all methods performed better on the Ads data set than the review data set, suggesting that the topical structures are more coherent in the Ads data set than the review data. Indeed, in the Ads data, strTM perfectly recovered 52.9% of the original sentence order. When examining some mismatched results, we found that some of them were due to an "outlier" order given by the original document (in comparison to the "regular" patterns in the set). In Table 6, we show two such examples where we see the learned structure "suggested" to move the contact information to the end, which intuitively gives us a more regular organization of the ads. It's hard to say that in this case, the system's ordering is inferior to that of the original; indeed, the system order is arguably more natural than the original order.

6 Conclusions

In this paper, we proposed a new structural topic model (strTM) to identify the latent topical structure in documents. Different from the traditional topic models, in which exchangeability assumption precludes them to capture the structure of a document, strTM captures the topical structure explicitly by introducing transitions among the topics. Experiment results show that both the identified topics and topical structure are intuitive and meaningful, and they are helpful for improving the performance of tasks such as sentence annotation and sentence ordering, where correctly recognizing the document structure is crucial. Besides, strTM is shown to outperform not only the baseline topic models that fail to model the dependency between the topics, but also the semi-supervised Naive Bayes model for the sentence annotation task.

Our work can be extended by incorporating richer features, such as named entity and co-reference, to enhance the model's capability of structure finding. Besides, advanced NLP techniques for document analysis, e.g., shallow parsing, may also be used to further improve structure finding.

Abstract

We propose a method for automatically labelling topics learned via LDA topic models. We generate our label candidate set from the top-ranking topic terms, titles of Wikipedia articles containing the top-ranking topic terms, and sub-phrases extracted from the Wikipedia article titles. We rank the label candidates using a combination of association measures and lexical features, optionally fed into a supervised ranking model. Our method is shown to perform strongly over four independent sets of topics, significantly better than a benchmark method.

1 Introduction

Topic modelling is an increasingly popular framework for simultaneously soft-clustering terms and documents into a fixed number of "topics", which take the form of a multinomial distribution over terms in the document collection (Blei et al., 2003). It has been demonstrated to be highly effective in a wide range of tasks, including multi-document summarisation (Haghighi and Vanderwende, 2009), word sense discrimination (Brody and Lapata, 2009), sentiment analysis (Titov and McDonald, 2008), information retrieval (Wei and Croft, 2006) and image labelling (Feng and Lapata, 2010).

One standard way of interpreting a topic is to use the marginal probabilities $p(w_i|t_j)$ associated with each term w_i in a given topic t_j to extract out the 10 terms with highest marginal probability. This results in term lists such as:[1]

stock market investor fund trading investment firm exchange companies share

[1]Here and throughout the paper, we will represent a topic t_j via its ranking of top-10 topic terms, based on $p(w_i|t_j)$.

which are clearly associated with the domain of stock market trading. The aim of this research is to automatically generate topic labels which explicitly identify the semantics of the topic, i.e. which take us from a list of terms requiring interpretation to a single label, such as STOCK MARKET TRADING in the above case.

The approach proposed in this paper is to first generate a topic label candidate set by: (1) sourcing topic label candidates from Wikipedia by querying with the top-N topic terms; (2) identifying the top-ranked document titles; and (3) further post-processing the document titles to extract sub-strings. We translate each topic label into features extracted from Wikipedia, lexical association with the topic terms in Wikipedia documents, and also lexical features for the component terms. This is used as the basis of a support vector regression model, which ranks each topic label candidate.

Our contributions in this work are: (1) the generation of a novel evaluation framework and dataset for topic label evaluation; (2) the proposal of a method for both generating and scoring topic label candidates; and (3) strong in- and cross-domain results across four independent document collections and associated topic models, demonstrating the ability of our method to automatically label topics with remarkable success.

2 Related Work

Topics are conventionally interpreted via their top-N terms, ranked based on the marginal probability $p(w_i|t_j)$ in that topic (Blei et al., 2003; Griffiths and Steyvers, 2004). This entails a significant cognitive load in interpretation, prone to subjectivity. Topics are also sometimes presented with manual post-hoc labelling for ease of interpretation in research publications (Wang and McCallum, 2006; Mei et al.,

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1536–1545,
Portland, Oregon, June 19-24, 2011.

2006). This has obvious disadvantages in terms of subjectivity, and lack of reproducibility/automation.

The closest work to our method is that of Mei et al. (2007), who proposed various unsupervised approaches for automatically labelling topics, based on: (1) generating label candidates by extracting either bigrams or noun chunks from the document collection; and (2) ranking the label candidates based on KL divergence with a given topic. Their proposed methodology generates a generic list of label candidates for *all* topics using only the document collection. The best method uses bigrams exclusively, in the form of the top-1000 bigrams based on the Student's t-test. We reimplement their method and present an empirical comparison in Section 5.3.

In other work, Magatti et al. (2009) proposed a method for labelling topics induced by a hierarchical topic model. Their label candidate set is the Google Directory (gDir) hierarchy, and label selection takes the form of ontological alignment with gDir. The experiments presented in the paper are highly preliminary, although the results certainly show promise. However, the method is only applicable to a hierarchical topic model and crucially relies on a pre-existing ontology and the class labels contained therein.

Pantel and Ravichandran (2004) addressed the more specific task of labelling a semantic class by applying Hearst-style lexico-semantic patterns to each member of that class. When presented with semantically homogeneous, fine-grained near-synonym clusters, the method appears to work well. With topic modelling, however, the top-ranking topic terms tended to be *associated* and not lexically *similar* to one another. It is thus highly questionable whether their method could be applied to topic models, but it would certainly be interesting to investigate whether our model could conversely be applied to the labelling of sets of near-synonyms.

In recent work, Lau et al. (2010) proposed to approach topic labelling via best term selection, i.e. selecting one of the top-10 topic terms to label the overall topic. While it is often possible to label topics with topic terms (as is the case with the stock market topic above), there are also often cases where topic terms are not appropriate as labels. We reuse a selection of the features proposed by Lau et al. (2010), and return to discuss it in detail in Section 3.

While not directly related to topic labelling, Chang et al. (2009) were one of the first to propose human labelling of topic models, in the form of synthetic intruder word and topic detection tasks. In the intruder word task, they include a term w with low marginal probability $p(w|t)$ for topic t into the top-N topic terms, and evaluate how well both humans and their model are able to detect the intruder.

The potential applications for automatic labelling of topics are many and varied. In document collection visualisation, e.g., the topic model can be used as the basis for generating a two-dimensional representation of the document collection (Newman et al., 2010a). Regions where documents have a high marginal probability $p(d_i|t_j)$ of being associated with a given topic can be explicitly labelled with the learned label, rather than just presented as an unlabelled region, or presented with a dense "term cloud" from the original topic. In topic model-based selectional preference learning (Ritter et al., 2010; Ò Séaghdha, 2010), the learned topics can be translated into semantic class labels (e.g. DAYS OF THE WEEK), and argument positions for individual predicates can be annotated with those labels for greater interpretability/portability. In dynamic topic models tracking the diachronic evolution of topics in time-sequenced document collections (Blei and Lafferty, 2006), labels can greatly enhance the interpretation of what topics are "trending" at any given point in time.

3 Methodology

The task of automatic labelling of topics is a natural progression from the best topic term selection task of Lau et al. (2010). In that work, the authors use a reranking framework to produce a ranking of the top-10 topic terms based on how well each term – in isolation – represents a topic. For example, in our *stock market investor fund trading ...* topic example, the term *trading* could be considered as a more representative term of the overall semantics of the topic than the top-ranked topic term *stock*.

While the best term could be used as a topic label, topics are commonly ideas or concepts that are better expressed with multiword terms (for example STOCK MARKET TRADING), or terms that might not be in the top-10 topic terms (for example, COLOURS

would be a good label for a topic of the form *red green blue cyan ...*).

In this paper, we propose a novel method for automatic topic labelling that first generates topic label candidates using English Wikipedia, and then ranks the candidates to select the best topic labels.

3.1 Candidate Generation

Given the size and diversity of English Wikipedia, we posit that the vast majority of (coherent) topics or concepts are encapsulated in a Wikipedia article. By making this assumption, the difficult task of generating potential topic labels is transposed to finding relevant Wikipedia articles, and using the title of each article as a topic label candidate.

We first use the top-10 topic terms (based on the marginal probabilities from the original topic model) to query Wikipedia, using: (a) Wikipedia's native search API; and (b) a site-restricted Google search. The combined set of top-8 article titles returned from the two search engines for each topic constitutes the initial set of *primary* candidates.

Next we chunk parse the primary candidates using the OpenNLP chunker,[2] and extract out all noun chunks. For each noun chunk, we generate all component n-grams (including the full chunk), out of which we remove all n-grams which are not in themselves article titles in English Wikipedia. For example, if the Wikipedia document title were the single noun chunk *United States Constitution*, we would generate the bigrams *United States* and *States Constitution*, and prune the latter; we would also generate the unigrams *United*, *States* and *Constitution*, all of which exist as Wikipedia articles and are preserved.

In this way, an average of 30–40 *secondary* labels are produced for each topic based on noun chunk n-grams. A good portion of these labels are commonly stopwords or unigrams that are only marginally related to the topic (an artifact of the n-gram generation process). To remove these outlier labels, we use the RACO lexical association method of Grieser et al. (2011).

RACO (Related Article Conceptual Overlap) uses Wikipedia's link structure and category membership to identify the strength of relationship between articles via their category overlap. The set of categories related to an article is defined as the union of the category membership of all outlinks in that article. The category overlap of two articles (a and b) is the intersection of the related category sets of each article. The formal definition of this measure is as follows:

$$|(\cup_{p \in O(a)} C(p)) \cap (\cup_{p \in O(b)} C(p))|$$

where $O(a)$ is the set of outlinks from article a, and $C(p)$ is the set of categories of which article p is a member. This is then normalised using Dice's coefficient to generate a similarity measure. In the instance that a term maps onto multiple Wikipedia articles via a disambiguation page, we return the best RACO score across article pairings for a given term pair. The final score for each secondary label candidate is calculated as the average RACO score with each of the primary label candidates. All secondary labels with an average RACO score of 0.1 and above are added to the label candidate set.

Finally, we add the top-5 topic terms to the set of candidates, based on the marginals from the original topic model. Doing this ensures that there are always label candidates for all topics (even if the Wikipedia searches fail), and also allows the possibility of labeling a topic using its own topic terms, which was demonstrated by Lau et al. (2010) to be a baseline source of topic label candidates.

3.2 Candidate Ranking

After obtaining the set of topic label candidates, the next step is to rank the candidates to find the best label for each topic. We will first describe the features that we use to represent label candidates.

3.2.1 Features

A good label should be strongly associated with the topic terms. To learn the association of a label candidate with the topic terms, we use several lexical association measures: pointwise mutual information (PMI), Student's t-test, Dice's coefficient, Pearson's χ^2 test, and the log likelihood ratio (Pecina, 2009). We also include conditional probability and reverse conditional probability measures, based on the work of Lau et al. (2010). To calculate the association measures, we parse the full collection of English Wikipedia articles using a sliding window of width

[2] http://opennlp.sourceforge.net/

20, and obtain term frequencies for the label candidates and topic terms. To measure the association between a label candidate and a list of topic terms, we average the scores of the top-10 topic terms.

In addition to the association measures, we include two lexical properties of the candidate: the raw number of terms, and the relative number of terms in the label candidate that are top-10 topic terms.

We also include a search engine score for each label candidate, which we generate by querying a local copy of English Wikipedia with the top-10 topic terms, using the Zettair search engine (based on BM25 term similarity).[3] For a given label candidate, we return the average score for the Wikipedia article(s) associated with it.

3.2.2 Unsupervised and Supervised Ranking

Each of the proposed features can be used as the basis for an unsupervised model for label candidate selection, by ranking the label candidates for a given topic and selecting the top-N. Alternatively, they can be combined in a supervised model, by training over topics where we have gold-standard labelling of the label candidates. For the supervised method, we use a support vector regression (SVR) model (Joachims, 2006) over all of the features.

4 Datasets

We conducted topic labelling experiments using document collections constructed from four distinct domains/genres, to test the domain/genre independence of our method:

BLOGS : 120,000 blog articles dated from August to October 2008 from the Spinn3r blog dataset[4]

BOOKS : 1,000 English language books from the Internet Archive American Libraries collection

NEWS : 29,000 New York Times news articles dated from July to September 1999, from the English Gigaword corpus

PUBMED : 77,000 PubMed biomedical abstracts published in June 2010

[3] http://www.seg.rmit.edu.au/zettair/

[4] http://www.icwsm.org/data/

The BLOGS dataset contains blog posts that cover a diverse range of subjects, from product reviews to casual, conversational messages. The BOOKS topics, coming from public-domain out-of-copyright books (with publication dates spanning more than a century), relate to a wide range of topics including furniture, home decoration, religion and art, and have a more historic feel to them. The NEWS topics reflect the types and range of subjects one might expect in news articles such as health, finance, entertainment, and politics. The PUBMED topics frequently contain domain-specific terms and are sharply differentiated from the topics for the other corpora. We are particularly interested in the performance of the method over PUBMED, as it is a highly specialised domain where we may expect lower coverage of appropriate topic labels within Wikipedia.

We took a standard approach to topic modelling each of the four document collections: we tokenised, lemmatised and stopped each document,[5] and created a vocabulary of terms that occurred at least ten times. From this processed data, we created a bag-of-words representation of each document, and learned topic models with $T = 100$ topics in each case.

To focus our experiments on topics that were relatively more coherent and interpretable, we first used the method of Newman et al. (2010b) to calculate the average PMI-score for each topic, and filtered all topics that had an average PMI-score lower than 0.4. We additionally filtered any topics where less than 5 of the top-10 topic terms are default nominal in Wikipedia.[6] The filtering criteria resulted in 45 topics for BLOGS, 38 topics for BOOKS, 60 topics for NEWS, and 85 topics for PUBMED. Manual inspection of the discarded topics indicated that they were predominantly hard-to-label junk topics or mixed topics, with limited utility for document/term clustering.

Applying our label candidate generation methodology to these 228 topics produced approximately 6000 labels — an average of 27 labels per topic.

[5] OpenNLP is used for tokenization, Morpha for lemmatization (Minnen et al., 2001).

[6] As determined by POS tagging English Wikipedia with OpenNLP, and calculating the coarse-grained POS priors (noun, verb, etc.) for each term.

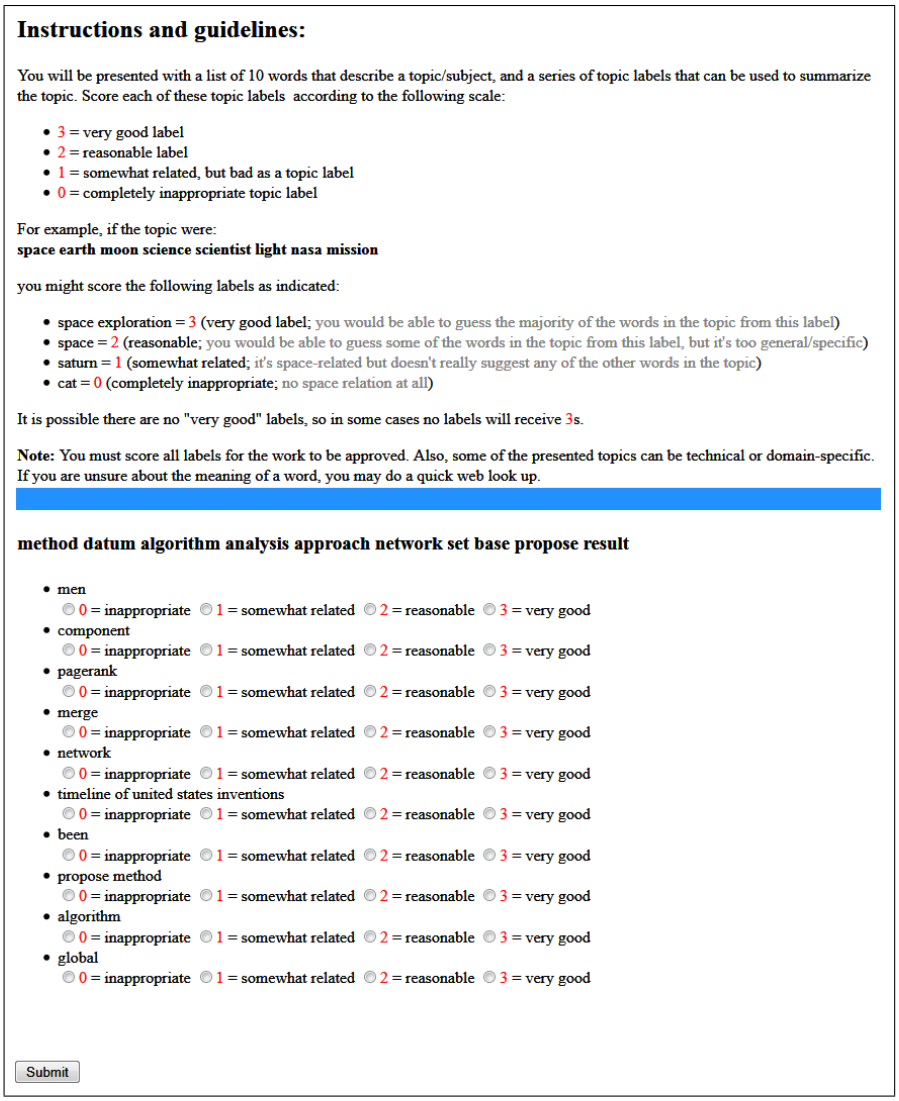

Figure 1: A screenshot of the topic label evaluation task on Amazon Mechanical Turk. This screen constitutes a *Human Intelligence Task* (HIT); it contains a topic followed by 10 suggested topic labels, which are to be rated. Note that *been* would be the stopword label in this example.

4.1 Topic Candidate Labelling

To evaluate our methods and train the supervised method, we require gold-standard ratings for the label candidates. To this end, we used Amazon Mechanical Turk to collect annotations for our labels.

In our annotation task, each topic was presented in the form of its top-10 terms, followed by 10 suggested labels for the topic. This constitutes a *Human Intelligence Task* (HIT); annotators are paid based on the number of HITs they have completed. A screenshot of a HIT seen by annotator is presented in Figure 1.

In each HIT, annotators were asked to rate the labels based on the following ordinal scale:

3: Very good label; a perfect description of the topic.

2: Reasonable label, but does not completely capture the topic.

1: Label is semantically related to the topic, but would not make a good topic label.

0: Label is completely inappropriate, and unrelated to the topic.

To filter annotations from workers who did not perform the task properly or from spammers, we ap-

Domain	Topic Terms	Label Candidate	Average Rating
BLOGS	china chinese olympics gold olympic team win beijing medal sport	2008 summer olympics	2.60
BOOKS	church arch wall building window gothic nave side vault tower	gothic architecture	2.40
NEWS	israel peace barak israeli minister palestinian agreement prime leader palestinians	israeli-palestinian conflict	2.63
PUBMED	cell response immune lymphocyte antigen cytokine t-cell induce receptor immunity	immune system	2.36

Table 1: A sample of topics and topic labels, along with the average rating for each label candidate

plied a few heuristics to automatically detect these workers. Additionally, we inserted a small number of stopwords as label candidates in each HIT and recorded workers who gave high ratings to these stopwords. Annotations from workers who failed to passed these tests are removed from the final set of gold ratings.

Each label candidate was rated in this way by at least 10 annotators, and ratings from annotators who passed the filter were combined by averaging them. A sample of topics, label candidates, and the average rating is presented in Table 1.[7]

Finally, we train the regression model over all the described features, using the human rating-based ranking.

5 Experiments

In this section we present our experimental results for the topic labelling task, based on both the unsupervised and supervised methods, and the methodology of Mei et al. (2007), which we denote MSZ for the remainder of the paper.

5.1 Evaluation

We use two basic measures to evaluate the performance of our predictions. **Top-1 average rating** is the average annotator rating given to the top-ranked system label, and has a maximum value of 3 (where annotators unanimously rated all top-ranked system labels with a 3). This is intended to give a sense of the *absolute* utility of the top-ranked candidates.

The second measure is normalized discounted cumulative gain (nDCG: Jarvelin and Kekalainen (2002), Croft et al. (2009)), computed for the top-1 (**nDCG-1**), top-3 (**nDCG-3**) and top-5 ranked system labels (**nDCG-5**). For a given ordered list of scores, this measure is based on the difference between the original order, and the order when the list is sorted by score. That is, if items are ranked optimally in descending order of score at position N, nDCG-N is equal to 1. nDCG is a normalised score, and indicates how close the candidate label ranking is to the optimal ranking within the set of annotated candidates, noting that an nDCG-N score of 1 tells us nothing about absolute values of the candidates. This second evaluation measure is thus intended to reflect the *relative* quality of the ranking, and complements the top-1 average rating.

Note that conventional precision- and recall-based evaluation is not appropriate for our task, as each label candidate has a real-valued rating.

As a baseline for the task, we use the unsupervised label candidate ranking method based on Pearson's χ^2 test, as it was overwhelmingly found to be the pick of the features for candidate ranking.

5.2 Results for the Supervised Method

For the supervised model, we present both in-domain results based on 10-fold cross-validation, and cross-domain results where we learn a model from the ratings for the topic model from a given domain, and apply it to a second domain. In each case, we learn an SVR model over the full set of features described in Section 3.2.1. In practical terms, in-domain results make the unreasonable assumption that we have labelled 90% of labels in order to be able to label the remaining 10%, and cross-domain results are thus the more interesting data point in terms of the expected results when applying our method to a novel topic model. It is valuable to compare the two, however, to gauge the relative impact of domain on the results.

We present the results for the supervised method in Table 2, including the unsupervised baseline and an upper bound estimate for comparison purposes. The upper bound is calculated by ranking the candi-

[7] The dataset is available for download from `http://www.csse.unimelb.edu.au/research/lt/resources/acl2011-topic/`.

	Upper bound	2.31	2.17	2.22	2.01	1.00	1.00	1.00

Table 2: Supervised results for all domains

dates based on the annotated human ratings. The upper bound for top-1 average rating is thus the highest average human rating of all label candidates for a given topic, while the upper bound for the nDCG measures will always be 1.

In addition to results for the combined candidate set, we include results for each of the three candidate subsets, namely the primary Wikipedia labels ("1°"), the secondary Wikipedia labels ("2°") and the top-5 topic terms ("Top5"); the nDCG results are over the full candidate set only, as the numbers aren't directly comparable over the different subsets (due to differences in the number of candidates and the distribution of ratings).

Comparing the in-domain and cross-domain results, we observe that they are largely comparable, with the exception of BOOKS, where there is a noticeable drop in both top-1 average rating and nDGC-1 when we use cross-domain training. We see an appreciable drop in scores when we train BOOKS against BLOGS (or vice versa), which we analyse as being due to incompatibility in document content and structure between these two domains. Overall though, the results are very encouraging, and point to the plausibility of using labelled topic models from independent domains to learn the best topic labels for a new domain.

Returning to the question of the suitability of label candidates for the highly specialised PUBMED document collection, we first notice that the upper bound top-1 average rating is comparable to the other domains, indicating that our method has been able to extract equivalent-quality label candidates from Wikipedia. The top-1 average ratings of the supervised method are lower than the other domains. We hypothesise that the cause of the drop is that the lexical association measures are trained over highly diverse Wikipedia data rather than biomedical-specific data, and predict that the results would improve if we trained our features over PubMed.

The results are uniformly better than the unsupervised baselines for all four corpora, although there is quite a bit of room for improvement relative to the upper bound. To better gauge the quality of these results, we carry out a direct comparison of our proposed method with the best-performing method of MSZ in Section 5.3.

Looking to the top-1 average score results over the different candidate sets, we observe first that the upper bound for the combined candidate set ("All") is higher than the scores for the candidate subsets in all cases, underlining the complementarity of the different candidate sets. We also observe that the top-5 topic term candidate set is the lowest performer out of the three subsets across all four corpora, in terms of both upper bound and the results for the supervised method. This reinforces our comments about the inferiority of the topic word selection method of Lau et al. (2010) for topic labelling purposes. For NEWS and PUBMED, there is a noticeable difference between the results of the supervised method over the full candidate set and each of the candidate subsets. In contrast, for BOOKS and BLOGS, the results for the primary candidate subset are at times actually higher than those over the full candidate set in most cases (but not for the upper bound). This is due to the larger search space in the full candidate set, and the higher median quality of candidates in the primary candidate set.

5.3 Comparison with MSZ

The best performing method out of the suite of approaches proposed by MSZ method exclusively uses bigrams extracted from the document collection, ranked based on Student's t-test. The potential drawbacks to this approach are: all labels must be bigrams, there must be explicit token instances of a given bigram in the document collection for it to be considered as a label candidate, and furthermore, there must be *enough* token instances in the document collection for it to have a high t score.

To better understand the performance difference of our approach to that of MSZ, we perform direct comparison of our proposed method with the benchmark method of MSZ.

5.3.1 Candidate Ranking

First, we compare the candidate ranking methodology of our method with that of MSZ, using the label candidates extracted by the MSZ method.

We first extracted the top-2000 bigrams using the N-gram Statistics Package (Banerjee and Pedersen, 2003). We then ranked the bigrams for each topic using the Student's t-test. We included the top-5 labels generated for each topic by the MSZ method in our Mechanical Turk annotation task, and use the annotations to directly compare the two methods.

To measure the performance of candidate ranking between our supervised method and MSZ's, we re-rank the top-5 labels extracted by MSZ using our SVR methodology (in-domain) and compare the top-1 average rating and nDCG scores. Results are shown in Table 3. We do not include results for the BOOKS domain because the text collection is much larger than the other domains, and the computation for the MSZ relevance score ranking is intractable due to the number of n-grams (a significant shortcoming of the method).

Looking at the results for the other domains, it is clear that our ranking system has the upper hand: it consistently outperforms MSZ over every evaluation metric.[8] Comparing the top-1 average rating results back to those in Table 2, we observe that for all three domains, the results for MSZ are below those of the unsupervised baseline, and well below those of our supervised method. The nDCG results are more competitive, and the nDCG-3 results are actually higher than our original results in Table 2. It is important to bear in mind, however, that the numbers are in each case relative to a different label candidate set. Additionally, the results in Table 3 are based on only 5 candidates, with a relatively flat gold-standard rating distribution, making it easier to achieve higher nDCG-5 scores.

5.3.2 Candidate Generation

The method of MSZ makes the implicit assumption that good bigram labels are discoverable within the document collection. In our method, on the other hand, we (efficiently) access the much larger and variable n-gram length set of English Wikipedia article titles, in addition to the top-5 topic terms. To better understand the differences in label candidate sets, and the relative coverage of the full label candidate set in each case, we conducted another survey where human users were asked to suggest one topic label for each topic presented.

The survey consisted, once again, of presenting annotators with a topic, but in this case, we gave them the open task of proposing the ideal label for

[8] Based on a single ANOVA, the difference in results is statistically significant at the 5% level for BLOGS, and 1% for NEWS and PUBMED.

Test Domain	Candidate Ranking System	Top-1 Avg. Rating	nDCG-1	nDCG-3	nDCG-5
BLOGS	MSZ	1.26	0.65	0.76	0.87
	SVR	1.41	0.75	0.85	0.92
	Upper bound	1.87	1.00	1.00	1.00
NEWS	MSZ	1.37	0.73	0.81	0.90
	SVR	1.66	0.88	0.90	0.95
	Upper bound	1.86	1.00	1.00	1.00
PUBMED	MSZ	1.53	0.77	0.85	0.93
	SVR	1.73	0.87	0.91	0.96
	Upper bound	1.98	1.00	1.00	1.00

Table 3: Comparison of results for our proposed supervised ranking method (SVR) and that of MSZ

the topic. In this, we did not enforce any restrictions on the type or size of label (e.g. the number of terms in the label).

Of the manually-generated gold-standard labels, approximately 36% were contained in the original document collection, but 60% were Wikipedia article titles. This indicates that our method has greater potential to generate a label of the quality of the ideal proposed by a human in a completely open-ended task.

6 Discussion

On the subject of suitability of using Amazon Mechanical Turk for natural language tasks, Snow et al. (2008) demonstrated that the quality of annotation is comparable to that of expert annotators. With that said, the PUBMED topics are still a subject of interest, as these topics often contain biomedical terms which could be difficult for the general populace to annotate.

As the number of annotators per topic and the number of annotations per annotator vary, there is no immediate way to calculate the inter-annotator agreement. Instead, we calculated the MAE score for each candidate, which is an average of the absolute difference between an annotator's rating and the average rating of a candidate, summed across all candidates to get the MAE score for a given corpus. The MAE scores for each corpus are shown in Table 4, noting that a smaller value indicates higher agreement.

As the table shows, the agreement for the PUBMED domain is comparable with the other datasets. BLOGS and NEWS have marginally better agreement, almost certainly because of the greater immediacy of the topics, covering everyday areas such as lifestyle and politics. BOOKS topics are occasionally difficult to label due to the breadth of the domain; e.g. consider a topic containing terms extracted from Shakespeare sonnets.

Corpus	MAE
BLOGS	0.50
BOOKS	0.56
NEWS	0.52
PUBMED	0.56

Table 4: Average MAE score for label candidate rating over each corpus

7 Conclusion

This paper has presented the task of topic labelling, that is the generation and scoring of labels for a given topic. We generate a set of label candidates from the top-ranking topic terms, titles of Wikipedia articles containing the top-ranking topic terms, and also a filtered set of sub-phrases extracted from the Wikipedia article titles. We rank the label candidates using a combination of association measures, lexical features and an Information Retrieval feature. Our method is shown to perform strongly over four independent sets of topics, and also significantly better than a competitor system.

Using Bilingual Information for Cross-Language Document Summarization

Abstract

Cross-language document summarization is defined as the task of producing a summary in a target language (e.g. Chinese) for a set of documents in a source language (e.g. English). Existing methods for addressing this task make use of either the information from the original documents in the source language or the information from the translated documents in the target language. In this study, we propose to use the bilingual information from both the source and translated documents for this task. Two summarization methods (SimFusion and CoRank) are proposed to leverage the bilingual information in the graph-based ranking framework for cross-language summary extraction. Experimental results on the DUC2001 dataset with manually translated reference Chinese summaries show the effectiveness of the proposed methods.

1 Introduction

Cross-language document summarization is defined as the task of producing a summary in a different target language for a set of documents in a source language (Wan et al., 2010). In this study, we focus on English-to-Chinese cross-language summarization, which aims to produce Chinese summaries for English document sets. The task is very useful in the field of multilingual information access. For example, it is beneficial for most Chinese readers to quickly browse and understand English news documents or document sets by reading the corresponding Chinese summaries.

A few pilot studies have investigated the task in recent years and exiting methods make use of either the information in the source language or the information in the target language after using machine translation. In particular, for the task of English-to-Chinese cross-language summarization, one method is to directly extract English summary sentences based on English features extracted from the English documents, and then automatically translate the English summary sentences into Chinese summary sentences. The other method is to automatically translate the English sentences into Chinese sentences, and then directly extract Chinese summary sentences based on Chinese features. The two methods make use of the information from only one language side.

However, it is not very reliable to use only the information in one language, because the machine translation quality is far from satisfactory, and thus the translated Chinese sentences usually contain some errors and noises. For example, the English sentence "*Many destroyed power lines are thought to be uninsured, as are trees and shrubs uprooted across a wide area.*" is automatically translated into the Chinese sentence "*许多破坏电源线被认为是保险的，因为是连根拔起的树木和灌木，在广泛的领域。*" by using Google Translate[1], but the Chinese sentence contains a few translation errors. Therefore, on the one side, if we rely only on the English-side information to extract Chinese

[1] http://translate.google.com/. Note that the translation service is updated frequently and the current translation results may be different from that presented in this paper.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1546–1555,
Portland, Oregon, June 19-24, 2011.

summary sentences, we cannot guarantee that the automatically translated Chinese sentences for salient English sentences are really salient when these sentences may contain many translation errors and other noises. On the other side, if we rely only on the Chinese-side information to extract Chinese summary sentences, we cannot guarantee that the selected sentences are really salient because the features for sentence ranking based on the incorrectly translated sentences are not very reliable, either.

In this study, we propose to leverage both the information in the source language and the information in the target language for cross-language document summarization. In particular, we propose two graph-based summarization methods (SimFusion and CoRank) for using both English-side and Chinese-side information in the task of English-to-Chinese cross-document summarization. The SimFusion method linearly fuses the English-side similarity and the Chinese-side similarity for measuring Chinese sentence similarity. The CoRank method adopts a co-ranking algorithm to simultaneously rank both English sentences and Chinese sentences by incorporating mutual influences between them.

We use the DUC2001 dataset with manually translated reference Chinese summaries for evaluation. Experimental results based on the ROUGE metrics show the effectiveness of the proposed methods. Three important conclusions for this task are summarized below:

1) The Chinese-side information is more beneficial than the English-side information.
2) The Chinese-side information and the English-side information can complement each other.
3) The proposed CoRank method is more reliable and robust than the proposed SimFusion method.

The rest of this paper is organized as follows: Section 2 introduces related work. In Section 3, we present our proposed methods. Evaluation results are shown in Section 4. Lastly, we conclude this paper in Section 5.

2 Related Work

2.1 General Document Summarization

Document summarization methods can be extraction-based, abstraction-based or hybrid methods. We focus on extraction-based methods in this study, and the methods directly extract summary sentences from a document or document set by ranking the sentences in the document or document set.

In the task of single document summarization, various features have been investigated for ranking sentences in a document, including term frequency, sentence position, cue words, stigma words, and topic signature (Luhn 1969; Lin and Hovy, 2000). Machine learning techniques have been used for sentence ranking (Kupiec et al., 1995; Amini and Gallinari, 2002). Litvak et al. (2010) present a language-independent approach for extractive summarization based on the linear optimization of several sentence ranking measures using a genetic algorithm. In recent years, graph-based methods have been proposed for sentence ranking (Erkan and Radev, 2004; Mihalcea and Tarau, 2004). Other methods include mutual reinforcement principle (Zha 2002; Wan et al., 2007).

In the task of multi-document summarization, the centroid-based method (Radev et al., 2004) ranks the sentences in a document set based on such features as cluster centroids, position and TFIDF. Machine Learning techniques have also been used for feature combining (Wong et al., 2008). Nenkova and Louis (2008) investigate the influences of input difficulty on summarization performance. Pitler et al. (2010) present a systematic assessment of several diverse classes of metrics designed for automatic evaluation of linguistic quality of multi-document summaries. Celikyilmaz and Hakkani-Tur (2010) formulate extractive summarization as a two-step learning problem by building a generative model for pattern discovery and a regression model for inference. Aker et al. (2010) propose an A* search algorithm to find the best extractive summary up to a given length, and they propose a discriminative training algorithm for directly maximizing the quality of the best summary. Graph-based methods have also been used to rank sentences for multi-document summarization (Mihalcea and Tarau, 2005; Wan and Yang, 2008).

2.2 Cross-Lingual Document Summarization

Several pilot studies have investigated the task of cross-language document summarization. The existing methods use only the information in either language side. Two typical translation schemes are document translation or summary translation. The document translation scheme first translates the source documents into the corresponding documents in the target language, and then extracts summary sentences based only on the information on the target side. The summary translation scheme first extracts summary sentences from the source documents based only on the information on the source side, and then translates the summary sentences into the corresponding summary sentences in the target language.

For example Leuski et al. (2003) use machine translation for English headline generation for Hindi documents. Lim et al. (2004) propose to generate a Japanese summary by using Korean summarizer. Chalendar et al. (2005) focus on semantic analysis and sentence generation techniques for cross-language summarization. Orasan and Chiorean (2008) propose to produce summaries with the MMR method from Romanian news articles and then automatically translate the summaries into English. Cross language query based summarization has been investigated in (Pingali et al., 2007), where the query and the documents are in different languages. Wan et al. (2010) adopt the summary translation scheme for the task of English-to-Chinese cross-language summarization. They first extract English summary sentences by using English-side features and the machine translation quality factor, and then automatically translate the English summary into Chinese summary. Other related work includes multilingual summarization (Lin et al., 2005; Siddharthan and McKeown, 2005), which aims to create summaries from multiple sources in multiple languages.

3 Our Proposed Methods

As mentioned in Section 1, existing methods rely only on one-side information for sentence ranking, which is not very reliable. In order to leveraging both-side information for sentence ranking, we propose the following two methods to incorporate the bilingual information in different ways.

3.1 SimFusion

This method uses the English-side information for Chinese sentence ranking in the graph-based framework. The sentence similarities in the two languages are fused in the method. In other words, when we compute the similarity value between two Chinese sentences, the similarity value between the corresponding two English sentences is used by linear fusion. Since sentence similarity evaluation plays a very important role in the graph-based ranking algorithm, this method can leverage both-side information through similarity fusion.

Formally, given the Chinese document set D^{cn} translated from an English document set, let $G^{cn}=(V^{cn}, E^{cn})$ be an undirected graph to reflect the relationships between the sentences in the Chinese document set. V^{cn} is the set of vertices and each vertex s^{cn}_i in V^{cn} represents a Chinese sentence. E^{cn} is the set of edges. Each edge e^{cn}_{ij} in E^{cn} is associated with an affinity weight $f(s^{cn}_i, s^{cn}_j)$ between sentences s^{cn}_i and s^{cn}_j $(i \neq j)$. The weight is computed by linearly combining the similarity value $sim_{cosine}(s^{cn}_i, s^{cn}_j)$ between the Chinese sentences and the similarity value $sim_{cosine}(s^{en}_i, s^{en}_j)$ between the corresponding English sentences.

$$f(s_i^{cn}, s_j^{cn}) = \lambda \cdot sim_{\cos ine}(s_i^{cn}, s_j^{cn}) + (1-\lambda) \cdot sim_{\cos ine}(s_i^{en}, s_j^{en})$$

where s^{en}_j and s^{en}_i are the source English sentences for s^{cn}_j and s^{cn}_i. $\lambda \in [0, 1]$ is a parameter to control the relative contributions of the two similarity values. The similarity values $sim_{cosine}(s^{cn}_i, s^{cn}_j)$ and $sim_{cosine}(s^{en}_i, s^{en}_j)$ are computed by using the standard cosine measure. The weight for each term is computed based on the TFIDF formula. For Chinese similarity computation, Chinese word segmentation is performed. Here, we have $f(s^{cn}_i, s^{cn}_j)=f(s^{cn}_j, s^{cn}_i)$ and let $f(s^{cn}_i, s^{cn}_i)=0$ to avoid self transition. We use an affinity matrix M^{cn} to describe G^{cn} with each entry corresponding to the weight of an edge in the graph. $M^{cn}=(M^{cn}_{ij})_{|Vcn|\times|Vcn|}$ is defined as $M^{cn}_{ij}=f(s^{cn}_i,s^{cn}_j)$. Then M^{cn} is normalized to $\tilde{M}^{cn}$ to make the sum of each row equal to 1.

Based on matrix $\tilde{M}^{cn}$, the saliency score $InfoScore(s^{cn}_i)$ for sentence s^{cn}_i can be deduced from those of all other sentences linked with it and it can be formulated in a recursive form as in the PageRank algorithm:

$$InfoScore(s_i^{cn}) = \mu \cdot \sum_{all\ j \neq i} InfoScore(s_j^{cn}) \cdot \widetilde{M}_{ji}^{cn} + \frac{(1-\mu)}{n}$$

where n is the sentence number, i.e. $n= |V^{cn}|$. μ is the damping factor usually set to 0.85, as in the PageRank algorithm.

For numerical computation of the saliency scores, we can iteratively run the above equation until convergence.

For multi-document summarization, some sentences are highly overlapping with each other, and thus we apply the same greedy algorithm in Wan et al. (2006) to penalize the sentences highly overlapping with other highly scored sentences, and finally the salient and novel Chinese sentences are directly selected as summary sentences.

3.2 CoRank

This method leverages both the English-side information and the Chinese-side information in a co-ranking way. The source English sentences and the translated Chinese sentences are simultaneously ranked in a unified graph-based algorithm. The saliency of each English sentence relies not only on the English sentences linked with it, but also on the Chinese sentences linked with it. Similarly, the saliency of each Chinese sentence relies not only on the Chinese sentences linked with it, but also on the English sentences linked with it. More specifically, the proposed method is based on the following assumptions:

Assumption 1: A Chinese sentence would be salient if it is heavily linked with other salient Chinese sentences; and an English sentence would be salient if it is heavily linked with other salient English sentences.

Assumption 2: A Chinese sentence would be salient if it is heavily linked with salient English sentences; and an English sentence would be salient if it is heavily linked with salient Chinese sentences.

The first assumption is similar to PageRank which makes use of mutual "recommendations" between the sentences in the same language to rank sentences. The second assumption is similar to HITS if the English sentences and the Chinese sentences are considered as authorities and hubs, respectively. In other words, the proposed method aims to fuse the ideas of PageRank and HITS in a unified framework. The mutual influences between the Chinese sentences and the English sentences are incorporated in the method.

Figure 1 gives the graph representation for the method. Three kinds of relationships are exploited: the CN-CN relationships between Chinese sentences, the EN-EN relationships between English sentences, and the EN-CN relationships between English sentences and Chinese sentences.

Formally, given an English document set D^{en} and the translated Chinese document set D^{cn}, let $G=(V^{en}, V^{cn}, E^{en}, E^{cn}, E^{encn})$ be an undirected graph to reflect all the three kinds of relationships between the sentences in the two document sets. $V^{en} =\{s^{en}_i \mid 1\le i\le n\}$ is the set of English sentences. $V^{cn}=\{s^{cn}_i \mid 1\le i\le n\}$ is the set of Chinese sentences. s^{cn}_i is the corresponding Chinese sentence translated from s^{en}_i. n is the number of the sentences. E^{en} is the edge set to reflect the relationships between the English sentences. E^{cn} is the edge set to reflect the relationships between the Chinese sentences. E^{encn} is the edge set to reflect the relationships between the English sentences and the Chinese sentences. Based on the graph representation, we compute the following three affinity matrices to reflect the three kinds of sentence relationships:

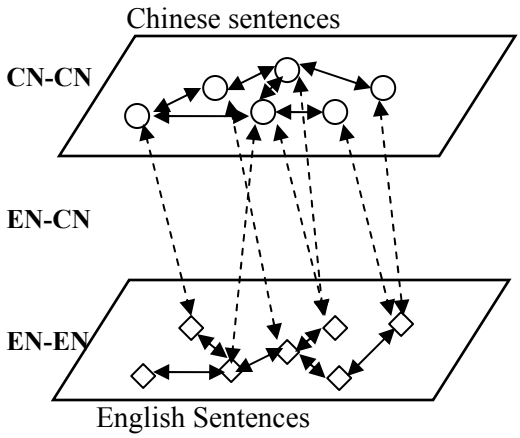

Figure 1. The three kinds of sentence relationships

1) $\boldsymbol{M}^{cn}=(M^{cn}_{ij})_{n\times n}$: This affinity matrix aims to reflect the relationships between the Chinese sentences. Each entry in the matrix corresponds to the cosine similarity between the two Chinese sentences.

$$M_{ij}^{cn} = \begin{cases} sim_{\cos ine}(s_i^{cn}, s_j^{cn}), & if\ i \neq j \\ 0, & otherwise \end{cases}$$

Then $\boldsymbol{M}^{cn}$ is normalized to $\tilde{\boldsymbol{M}}^{\boldsymbol{cn}}$ to make the sum of each row equal to 1.

2) $\boldsymbol{M}^{en}=(M^{en}{}_{i,j})_{n\times n}$: This affinity matrix aims to reflect the relationships between the English sentences. Each entry in the matrix corresponds to the cosine similarity between the two English sentences.

$$M_{ij}^{en}=\begin{cases} sim_{\cos ine}(s_i^{en},s_j^{en}), & if\ i\neq j \\ 0, & otherwise \end{cases}$$

Then $\boldsymbol{M}^{en}$ is normalized to $\tilde{\boldsymbol{M}}^{\boldsymbol{en}}$ to make the sum of each row equal to 1.

3) $\boldsymbol{M}^{encn}=(M^{encn}{}_{ij})_{n\times n}$: This affinity matrix aims to reflect the relationships between the English sentences and the Chinese sentences. Each entry $M^{encn}{}_{ij}$ in the matrix corresponds to the similarity between the English sentence $s^{en}{}_i$ and the Chinese sentence $s^{cn}{}_j$. It is hard to directly compute the similarity between the sentences in different languages. In this study, the similarity value is computed by fusing the following two similarity values: the cosine similarity between the sentence $s^{en}{}_i$ and the corresponding source English sentence $s^{en}{}_j$ for $s^{cn}{}_j$, and the cosine similarity between the corresponding translated Chinese sentence $s^{cn}{}_i$ for $s^{en}{}_i$ and the sentence $s^{cn}{}_j$. We use the geometric mean of the two values as the affinity weight.

$$M_{ij}^{encn}=\sqrt{sim_{\cos ine}(s_i^{en},s_j^{en})\times sim_{\cos ine}(s_i^{cn},s_j^{cn})}$$

Note that we have $M^{encn}{}_{ij}=M^{encn}{}_{ji}$ and $\boldsymbol{M}^{encn}=(\boldsymbol{M}^{encn})^{\mathrm{T}}$. Then $\boldsymbol{M}^{encn}$ is normalized to $\tilde{\boldsymbol{M}}^{\boldsymbol{encn}}$ to make the sum of each row equal to 1.

We use two column vectors $\boldsymbol{u}=[u(s^{cn}{}_i)]_{n\times 1}$ and $\boldsymbol{v}=[v(s^{en}{}_j)]_{n\times 1}$ to denote the saliency scores of the Chinese sentences and the English sentences, respectively. Based on the three kinds of relationships, we can get the following four assumptions:

$$u(s_i^{cn})\propto\sum\nolimits_j \tilde{M}_{ji}^{cn}u(s_j^{cn})$$

$$v(s_j^{en})\propto\sum\nolimits_i \tilde{M}_{ij}^{en}v(s_i^{en})$$

$$u(s_i^{cn})\propto\sum\nolimits_j \tilde{M}_{ji}^{encn}v(s_j^{en})$$

$$v(s_j^{en})\propto\sum\nolimits_i \tilde{M}_{ij}^{encn}u(s_i^{cn})$$

After fusing the above equations, we can obtain the following iterative forms:

$$u(s_i^{cn})=\alpha\sum\nolimits_j \tilde{M}_{ji}^{cn}u(s_j^{cn})+\beta\sum\nolimits_j \tilde{M}_{ji}^{encn}v(s_j^{en})$$

$$v(s_j^{en})=\alpha\sum\nolimits_i \tilde{M}_{ij}^{en}v(s_i^{en})+\beta\sum\nolimits_i \tilde{M}_{ij}^{encn}u(s_i^{cn})$$

And the matrix form is:

$$\boldsymbol{u}=\alpha(\tilde{\boldsymbol{M}}^{\boldsymbol{cn}})^T\boldsymbol{u}+\beta(\tilde{\boldsymbol{M}}^{encn})^T\boldsymbol{v}$$

$$\boldsymbol{v}=\alpha(\tilde{\boldsymbol{M}}^{\boldsymbol{en}})^T\boldsymbol{v}+\beta(\tilde{\boldsymbol{M}}^{encn})^T\boldsymbol{u}$$

where α and β specify the relative contributions to the final saliency scores from the information in the same language and the information in the other language and we have $\alpha+\beta=1$.

For numerical computation of the saliency scores, we can iteratively run the two equations until convergence. Usually the convergence of the iteration algorithm is achieved when the difference between the scores computed at two successive iterations for any sentences and words falls below a given threshold. In order to guarantee the convergence of the iterative form, $\boldsymbol{u}$ and $\boldsymbol{v}$ are normalized after each iteration.

After we get the saliency scores $\boldsymbol{u}$ for the Chinese sentences, we apply the same greedy algorithm for redundancy removing. Finally, a few highly ranked sentences are selected as summary sentences.

4 Experimental Evaluation

4.1 Evaluation Setup

There is no benchmark dataset for English-to-Chinese cross-language document summarization, so we built our evaluation dataset based on the DUC2001 dataset by manually translating the reference summaries.

DUC2001 provided 30 English document sets for generic multi-document summarization. The average document number per document set was 10. The sentences in each article have been separated and the sentence information has been stored into files. Three or two generic reference English summaries were provided by NIST annotators for each document set. Three graduate students were employed to manually translate the reference English summaries into reference Chinese summaries. Each student manually translated one third of the reference summaries. It was much easier and more reliable to provide the reference Chinese summaries by manual translation than by manual summarization.

	ROUGE-2 Average_F	ROUGE-W Average_F	ROUGE-L Average_F	ROUGE-SU4 Average_F
Baseline(EN)	0.03723	0.05566	0.13259	0.07177
Baseline(CN)	0.03805	0.05886	0.13871	0.07474
SimFusion	0.04017	0.06117	0.14362	0.07645
CoRank	0.04282	0.06158	0.14521	0.07805

Table 1: Comparison Results

All the English sentences in the document set were automatically translated into Chinese sentences by using *Google Translate*, and the Stanford Chinese Word Segmenter[2] was used for segmenting the Chinese documents and summaries into words. For comparative study, the summary length was limited to five sentences, i.e. each Chinese summary consisted of five sentences.

We used the ROUGE-1.5.5 (Lin and Hovy, 2003) toolkit for evaluation, which has been widely adopted by DUC and TAC for automatic summarization evaluation. It measured summary quality by counting overlapping units such as the n-gram, word sequences and word pairs between the candidate summary and the reference summary. We showed three of the ROUGE F-measure scores in the experimental results: ROUGE-2 (bigram-based), ROUGE-W (based on weighted longest common subsequence, weight=1.2), ROUGE-L (based on longest common subsequences), and ROUGE-SU4 (based on skip bigram with a maximum skip distance of 4). Note that the ROUGE toolkit was performed for Chinese summaries after using word segmentation.

Two graph-based baselines were used for comparison.

Baseline(EN): This baseline adopts the summary translation scheme, and it relies on the English-side information for English sentence ranking. The extracted English summary is finally automatically translated into the corresponding Chinese summary. The same sentence ranking algorithm with the SimFusion method is adopted, and the affinity weight is computed based only on the cosine similarity between English sentences.

Baseline(CN): This baseline adopts the document translation scheme, and it relies on the Chinese-side information for Chinese sentence ranking. The Chinese summary sentences are directly extracted from the translated Chinese documents. The same sentence ranking algorithm with the SimFusion method is adopted, and the affinity weight is computed based only on the cosine similarity between Chinese sentences.

For our proposed methods, the parameter values are empirically set as λ=0.8 and α=0.5.

4.2 Results and Discussion

Table 1 shows the comparison results for our proposed methods and the baseline methods. Seen from the tables, Baseline(CN) performs better than Baseline(EN) over all the metrics. The results demonstrate that the Chinese-side information is more beneficial than the English-side information for cross-document summarization, because the summary sentences are finally selected from the Chinese side. Moreover, our proposed two methods can outperform the two baselines over all the metrics. The results demonstrate the effectiveness of using bilingual information for cross-language document summarization. It is noteworthy that the ROUGE scores in the table are not high due to the following two reasons: 1) The use of machine translation may introduce many errors and noises in the peer Chinese summaries; 2) The use of Chinese word segmentation may introduce more noises and mismatches in the ROUGE evaluation based on Chinese words.

We can also see that the CoRank method can outperform the SimFusion method over all metrics. The results show that the CoRank method is more suitable for the task by incorporating the bilingual information into a unified ranking framework.

In order to show the influence of the value of the combination parameter λ on the performance of the SimFusion method, we present the performance curves over the four metrics in Figures 2 through 5, respectively. In the figures, λ ranges from 0 to 1, and λ=1 means that SimFusion is the same with Baseline(CN), and λ=0 means that only English-side information is used for Chinese sentence ranking. We can see that when λ is set to a value larger than 0.5, SimFusion can outperform the two baselines over most metrics. The results show that λ can be set in a relatively wide range. Note that

[2] http://nlp.stanford.edu/software/segmenter.shtml

λ>0.5 means that SimFusion relies more on the Chinese-side information than on the English-side information. Therefore, the Chinese-side information is more beneficial than the English-side information.

In order to show the influence of the value of the combination parameter α on the performance of the CoRank method, we present the performance curves over the four metrics in Figures 6 through 9, respectively. In the figures, α ranges from 0.1 to 0.9, and a larger value means that the information from the same language side is more relied on, and a smaller value means that the information from the other language side is more relied on. We can see that CoRank can always outperform the two baselines over all metrics with different value of α. The results show that α can be set in a very wide range. We also note that a very large value or a very small value of α can lower the performance values. The results demonstrate that CoRank relies on both the information from the same language side and the information from the other language side for sentence ranking. Therefore, both the Chinese-side information and the English-side information can complement each other, and they are beneficial to the final summarization performance.

Comparing Figures 2 through 5 with Figures 6 through 9, we can further see that the CoRank method is more stable and robust than the SimFusion method. The CoRank method can outperform the SimFusion method with most parameter settings. The bilingual information can be better incorporated in the unified ranking framework of the CoRank method.

Finally, we show one running example for the document set D59 in the DUC2001 dataset. The four summaries produced by the four methods are listed below:

Baseline(EN): *周日的崩溃是 24 年来第一次乘客在涉及西北飞机事故中丧生。有乘客和观察员的报告，这架飞机的右翼引擎也坠毁前失败。在坠机现场联邦航空局官员表示不会揣测关于崩溃或在飞机上的发动机评论的原因。美国联邦航空局的记录显示，除了那些涉及的飞机坠毁，与 JT8D 涡轮路段-200 系列发动机问题的三个共和国在过去四年的航班发生的事件。1988 年 7 月，一个联合国的 DC-10 坠毁的苏城，艾奥瓦州后，发动机在飞行中发生外，造成 112 人。*

Baseline(CN): *第二，在美国历史上最严重的事故是 1987 年 8 月 16 日，坠毁，造成 156 人时，美国西北航空公司飞机上的底特律都市机场起飞时坠毁。据美国联邦航空管理局的纪录，麦道公司的 MD-82 飞机在 1985 年和 1986 年紧急降落后，在其两个引擎之一是失去权力。周日的崩溃是 24 年来第一次乘客在涉及西北飞机事故中丧生。今年 4 月，国家运输安全委员会敦促美国联邦航空局后进行一些危险，发动机故障，飞机的一个发动机的 200 系列 JT8D 安全调查。目前，机组人员发现了一个黑人师谁说，他可以引导飞机在附近的人们听到了他们的区域。*

SimFusion: *第二，在美国历史上最严重的事故是 1987 年 8 月 16 日，坠毁，造成 156 人时，美国西北航空公司飞机上的底特律都市机场起飞时坠毁。周日的崩溃是 24 年来第一次乘客在涉及西北飞机事故中丧生。在坠机现场联邦航空局官员表示不会揣测关于崩溃或在飞机上的发动机评论的原因。有乘客和观察员的报告，这架飞机的右翼引擎也坠毁前失败。据美国联邦航空管理局的纪录，麦道公司的 MD-82 飞机在 1985 年和 1986 年紧急降落后，在其两个引擎之一是失去权力。*

5 Conclusion and Future Work

In this paper, we propose two methods (SimFusion and CoRank) to address the cross-language document summarization task by leveraging the bilingual information in both the source and target language sides. Evaluation results demonstrate the effectiveness of the proposed methods. The Chinese-side information is validated to be more beneficial than the English-side information, and the CoRank method is more robust than the SimFusion method.

In future work, we will investigate to use the machine translation quality factor to further improve the fluency of the Chinese summary, as in Wan et al. (2010). Though our attempt to use GIZA++ for evaluating the similarity between Chinese sentences and English sentences failed, we will exploit more advanced measures based on statistical alignment model for cross-language similarity computation.

Exploiting Web-Derived Selectional Preference to Improve Statistical Dependency Parsing

Abstract

In this paper, we present a novel approach which incorporates the web-derived selectional preferences to improve statistical dependency parsing. Conventional selectional preference learning methods have usually focused on word-to-class relations, e.g., a verb selects as its subject a given nominal class. This paper extends previous work to word-to-word selectional preferences by using web-scale data. Experiments show that web-scale data improves statistical dependency parsing, particularly for long dependency relationships. There is no data like more data, performance improves log-linearly with the number of parameters (unique N-grams). More importantly, when operating on new domains, we show that using web-derived selectional preferences is essential for achieving robust performance.

1 Introduction

Dependency parsing is the task of building dependency links between words in a sentence, which has recently gained a wide interest in the natural language processing community. With the availability of large-scale annotated corpora such as Penn Treebank (Marcus et al., 1993), it is easy to train a high-performance dependency parser using supervised learning methods.

However, current state-of-the-art statistical dependency parsers (McDonald et al., 2005; McDonald and Pereira, 2006; Hall et al., 2006) tend to have lower accuracies for longer dependencies (McDonald and Nivre, 2007). The length of a dependency from word w_i to word w_j is simply equal to $|i-j|$. Longer dependencies typically represent the modifier of the root or the main verb, internal dependencies of longer NPs or PP-attachment in a sentence. Figure 1 shows the F_1 score[1] relative to the dependency length on the development set by using the graph-based dependency parsers (McDonald et al., 2005; McDonald and Pereira, 2006). We note that the parsers provide very good results for adjacent dependencies (96.89% for dependency length =1), while the dependency length increases, the accuracies degrade sharply. These longer dependencies are therefore a major opportunity to improve the overall performance of dependency parsing. Usually, these longer dependencies can be parsed dependent on the specific words involved due to the limited range of features (e.g., a verb and its modifiers). Lexical statistics are therefore needed for resolving ambiguous relationships, yet the lexicalized statistics are sparse and difficult to estimate directly. To solve this problem, some information with different granularity has been investigated. Koo et al. (2008) proposed a semi-supervised dependency parsing by introducing lexical intermediaries at a coarser level than words themselves via a cluster method. This approach, however, ignores the selectional preference for word-to-word interactions, such as head-modifier relationship. Extra resources

Portland, Oregon, June 19-24, 2011.

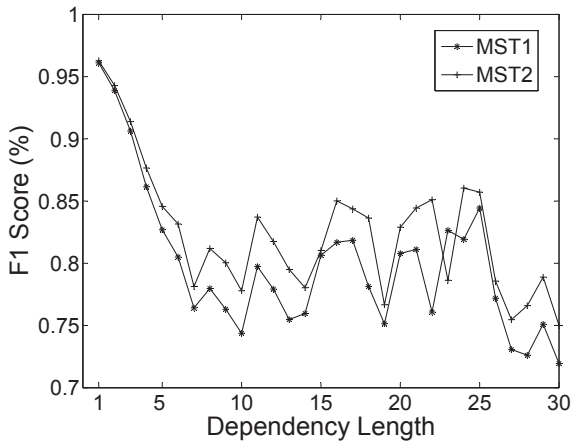

Figure 1: F score relative to dependency length.

beyond the annotated corpora are needed to capture the bi-lexical relationship at the word-to-word level.

Our purpose in this paper is to exploit web-derived selectional preferences to improve the supervised statistical dependency parsing. All of our lexical statistics are derived from two kinds of web-scale corpus: one is the web, which is the largest data set that is available for NLP (Keller and Lapata, 2003). Another is a web-scale N-gram corpus, which is a N-gram corpus with N-grams of length 1-5 (Brants and Franz, 2006), we call it **Google V1** in this paper. The idea is very simple: web-scale data have large coverage for word pair acquisition. By leveraging some assistant data, the dependency parsing model can directly utilize the additional information to capture the word-to-word level relationships. We address two natural and related questions which some previous studies leave open:

Question I: Is there a benefit in incorporating web-derived selectional preference features for statistical dependency parsing, especially for longer dependencies?

Question II: How well do web-derived selectional preferences perform on new domains?

For Question I, we systematically assess the value of using web-scale data in state-of-the-art supervised dependency parsers. We compare dependency parsers that include or exclude selectional preference features obtained from web-scale corpus. To the best of our knowledge, none of the existing studies directly address long dependencies of dependency parsing by using web-scale data.

Most statistical parsers are highly domain dependent. For example, the parsers trained on WSJ text perform poorly on Brown corpus. Some studies have investigated domain adaptation for parsers (McClosky et al., 2006; Daumé III, 2007; McClosky et al., 2010). These approaches assume that the parsers know which domain it is used, and that it has access to representative data in that domain. However, in practice, these assumptions are unrealistic in many real applications, such as when processing the heterogeneous genre of web texts. In this paper we incorporate the web-derived selectional preference features to design our parsers for robust open-domain testing.

We conduct the experiments on the English Penn Treebank (PTB) (Marcus et al., 1993). The results show that web-derived selectional preference can improve the statistical dependency parsing, particularly for long dependency relationships. More importantly, when operating on new domains, the web-derived selectional preference features show great potential for achieving robust performance (Section 4.3).

The remainder of this paper is divided as follows. Section 2 gives a brief introduction of dependency parsing. Section 3 describes the web-derived selectional preference features. Experimental evaluation and results are reported in Section 4. Finally, we discuss related work and draw conclusion in Section 5 and Section 6, respectively.

2 Dependency Parsing

In dependency parsing, we attempt to build head-modifier (or head-dependent) relations between words in a sentence. The discriminative parser we used in this paper is based on the *part-factored* model and features of the MSTParser (McDonald et al., 2005; McDonald and Pereira, 2006; Carreras, 2007). The parsing model can be defined as a conditional distribution $p(y|\mathbf{x};\mathbf{w})$ over each projective parse tree y for a particular sentence $\mathbf{x}$, parameterized by a vector $\mathbf{w}$. The probability of a parse tree is

$$p(y|\mathbf{x};\mathbf{w}) = \frac{1}{Z(\mathbf{x};\mathbf{w})}\exp\Big\{\sum_{\rho\in y}\mathbf{w}\cdot\mathbf{\Phi}(\mathbf{x},\rho)\Big\} \quad (1)$$

where $Z(\mathbf{x};\mathbf{w})$ is the partition function and $\mathbf{\Phi}$ are *part-factored* feature functions that include *head-*

modifier parts, *sibling* parts and *grandchild* parts. Given the training set $\{(\mathbf{x}_i, y_i)\}_{i=1}^N$, parameter estimation for log-linear models generally resolve around optimization of a regularized conditional log-likelihood objective $\mathbf{w}^* = \arg\min_{\mathbf{w}} L(\mathbf{w})$ where

$$L(\mathbf{w}) = -C \sum_{i=1}^{N} \log p(y_i|\mathbf{x}_i; \mathbf{w}) + \frac{1}{2}||\mathbf{w}||^2 \quad (2)$$

The parameter $C > 0$ is a constant dictating the level of regularization in the model. Since objective function $L(\mathbf{w})$ is smooth and convex, which is convenient for standard gradient-based optimization techniques. In this paper we use the dual exponentiated gradient (EG)[2] descent, which is a particularly effective optimization algorithm for log-linear models (Collins et al., 2008).

3 Web-Derived Selectional Preference Features

In this paper, we employ two different feature sets: a baseline feature set[3] which draw upon "normal" information source, such as word forms and part-of-speech (POS) without including the web-derived selectional preference[4] features, a feature set conjoins the baseline features and the web-derived selectional preference features.

3.1 Web-scale resources

All of our selectional preference features described in this paper rely on probabilities derived from unlabeled data. To use the largest amount of data possible, we exploit web-scale resources. one is web, N-gram counts are approximated by **Google hits**. Another we use is **Google V1** (Brants and Franz, 2006). This N-gram corpus records how often each unique sequence of words occurs. N-grams appearing 40 times or more (1 in 25 billion) are kept, and appear in the n-gram tables. All n-grams with lower counts are discarded. Co-occurrence probabilities can be calculated directly from the N-gram counts.

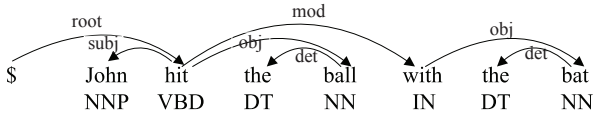

Figure 2: An example of a labeled dependency tree. The tree contains a special token "$" which is always the root of the tree. Each arc is directed from head to modifier and has a label describing the function of the attachment.

3.2 Web-derived N-gram features

3.2.1 PMI

Previous work on noun compounds bracketing has used *adjacency model* (Resnik, 1993) and *dependency model* (Lauer, 1995) to compute association statistics between pairs of words. In this paper we generalize the adjacency and dependency models by including the pointwise mutual information (Church and Hanks, 1900) between all pairs of words in the dependency tree:

$$\text{PMI}(x, y) = \log \frac{p(\text{“x y”})}{p(\text{“x”})p(\text{“y”})} \quad (3)$$

where $p(\text{“x y”})$ is the co-occurrence probabilities. When use the **Google V1** corpus, this probabilities can be calculated directly from the N-gram counts, while using the **Google hits**, we send the queries to the search engine *Google*[5] and all the search queries are performed as exact matches by using quotation marks.[6]

The value of these features is the PMI, if it is defined. If the PMI is undefined, following the work of (Pitler et al., 2010), we include one of two binary features:

$$p(\text{“x y”}) = 0 \text{ or } p(\text{“x”}) \vee p(\text{“y”}) = 0$$

Besides, we also consider the trigram features be-

[2] http://groups.csail.mit.edu/nlp/egstra/

[3] This kind of feature sets are similar to other feature sets in the literature (McDonald et al., 2005; Carreras, 2007), so we will not attempt to give a exhaustive description.

[4] Selectional preference tells us which arguments are plausible for a particular predicate, one way to determine the selectional preference is from co-occurrences of predicates and arguments in text (Bergsma et al., 2008). In this paper, the selectional preferences have the same meaning with N-grams, which model the word-to-word relationships, rather than only considering the predicates and arguments relationships.

[5] http://www.google.com/

[6] Google only allows automated querying through the Google Web API, this involves obtaining a license key, which then restricts the number of queries to a daily quota of 1000. However, we obtained a quota of 20,000 queries per day by sending a request to api-support@google.com for research purposes.

tween the three words in the dependency tree:

$$\text{PMI}(x, y, z) = \log \frac{p(\text{"x y z"})}{p(\text{"x y"})p(\text{"y z"})} \quad (4)$$

This kinds of trigram features, for example in MSTParser, which can directly capture the sibling and grandchild features.

We illustrate the PMI features with an example of dependency parsing tree in Figure 2. In deciding the dependency between the main verb *hit* and its argument headed preposition *with*, an example of the N-gram PMI features and the conjoin features with the baseline are shown in Table 1.

3.2.2 PP-attachment

Propositional phrase (PP) attachment is one of the hardest problems in English dependency parsing. An English sentence consisting of a subject, a verb, and a nominal object followed by a prepositional phrase is often ambiguous. Ambiguity resolution reflects the selectional preference between the verb and noun with their prepositional phrase. For example, considering the following two examples:

(1) John **hit** the ball **with** the *bat*.

(2) John hit the **ball with** the red *stripe*.

In sentence (1), the preposition **with** depends on the main verb **hit**; but in sentence (2), the prepositional phrase is a noun attribute and the preposition **with** needs to depends on the word **ball**. To resolve this kind of ambiguity, there needs to measure the attachment preference. We thus have PP-attachment features that determine the PMI association across the preposition word "*IN*"[7]:

$$\text{PMI}_{IN}(x, z) = \log \frac{p(\text{"x } IN \text{ z"})}{p(\text{x})} \quad (5)$$

[7]Here, the preposition word "*IN*" (e.g., "with", "in", ...) is any token whose part-of-speech is IN

N-gram feature templates
hw, mw, PMI(hw,mw)
hw, ht, mw, PMI(hw,mw)
hw, mw, mt, PMI(hw,mw)
hw, ht, mw, mt, PMI(hw,mw)
...
hw, mw, sw
hw, mw, sw, PMI(hw, mw, sw)
hw, mw, gw
hw, mw, gw, PMI(hw, mw, gw)

Table 2: Examples of N-gram feature templates. Each entry represents a class of indicator for tuples of information. For example, "hw, mw" reprsents a class of indicator features with one feature for each possible combination of head word and modifier word. Abbreviations: hw=head word, ht= head POS. st, gt=likewise for sibling and grandchild.

$$\text{PMI}_{IN}(y, z) = \log \frac{p(\text{"y } IN \text{ z"})}{p(\text{y})} \quad (6)$$

where the word x and y are usually verb and noun, z is a noun which directly depends on the preposition word "*IN*". For example in sentence (1), we would include the features $\text{PMI}_{with}(hit, bat)$ and $\text{PMI}_{with}(ball, bat)$. If both PMI features exist and $\text{PMI}_{with}(hit, bat) > \text{PMI}_{with}(ball, bat)$, indicating to our dependency parsing model that the preposition word *with* depends on the verb *hit* is a good choice. While in sentence (2), the features include $\text{PMI}_{with}(hit, stripe)$ and $\text{PMI}_{with}(ball, stripe)$.

3.3 N-gram feature templates

We generate N-gram features by mimicking the template structure of the original baseline features. For example, the baseline feature set includes indicators for word-to-word and tag-to-tag interactions between the head and modifier of a dependency. In the N-gram feature set, we correspondingly introduce N-gram PMI for word-to-word interactions.

The N-gram feature set for MSTParser is shown in Table 2. Following McDonald et al. (2005), all features are conjoined with the direction of attachment as well as the distance between the two words creating the dependency. In between N-gram features, we include the form of word trigrams and PMI of the trigrams. The surrounding word N-gram features represent the local context of the selectional preference. Besides, we also present the second-order feature templates, including the sibling and grandchild features. These features are designed to disambiguate cases like coordinating conjunctions and prepositional attachment. Consider the examples we have shown in section 3.2.2, for sentence (1), the dependency graph path feature $ball \rightarrow with \rightarrow bat$ should have a lower weight since *ball* rarely is modified by *bat*, but is often seen through them (e.g., a higher weight should be associated with $hit \rightarrow with \rightarrow bat$). In contrast, for sentence (2), our N-gram features will tell us that the prepositional phrase is much more likely to attach to the noun since the dependency graph path feature $ball \rightarrow with \rightarrow stripe$ should have a high weight due to the high strength of selectional preference between *ball* and *stripe*.

Web-derived selectional preference features based on PMI values are trickier to incorporate into the dependency parsing model because they are continuous rather than discrete. Since all the baseline features used in the literature (McDonald et al., 2005; Carreras, 2007) take on binary values of 0 or 1, there is a "mis-match" between the continuous and binary features. Log-linear dependency parsing model is sensitive to inappropriately scaled feature. To solve this problem, we transform the PMI values into a more amenable form by replacing the PMI values with their $z\text{-}score$. The $z\text{-}score$ of a PMI value x is $\frac{x-\mu}{\sigma}$, where μ and σ are the mean and standard deviation of the PMI distribution, respectively.

4 Experiments

In order to evaluate the effectiveness of our proposed approach, we conducted dependency parsing experiments in English. The experiments were performed on the Penn Treebank (PTB) (Marcus et al., 1993), using a standard set of head-selection rules (Yamada and Matsumoto, 2003) to convert the phrase structure syntax of the Treebank into a dependency tree representation, dependency labels were obtained via the "Malt" hard-coded setting.[8] We split the Treebank into a training set (Sections 2-21), a development set (Section 22), and several test sets (Sections 0,[9] 1, 23, and 24). The part-of-speech tags for the development and test set were automatically assigned by the MXPOST tagger[10], where the tagger was trained on the entire training corpus.

Web page hits for word pairs and trigrams are obtained using a simple heuristic query to the search engine *Google*.[11] Inflected queries are performed by expanding a bigram or trigram into all its morphological forms. These forms are then submitted as literal queries, and the resulting hits are summed up. John Carroll's suite of morphological tools[12] is used to generate inflected forms of verbs and nouns. All the search terms are performed as exact matches by using quotation marks and submitted to the search engines in lower case.

We measured the performance of the parsers using the following metrics: unlabeled attachment score (UAS), labeled attachment score (LAS) and complete match (CM), which were defined by Hall et al. (2006). All the metrics are calculated as mean scores per word, and punctuation tokens are consistently excluded.

4.1 Main results

There are some clear trends in the results of Table 3. First, performance increases with the order of the parser: *edge-factored* model (dep1) has the lowest performance, adding sibling and grandchild relationships (dep2) significantly increases performance. Similar observations regarding the effect of model order have also been made by Carreras (2007) and Koo et al. (2008).

Second, note that the parsers incorporating the N-gram feature sets consistently outperform the models using the baseline features in all test data sets, regardless of model order or label usage. Another

Table 3: Unlabeled accuracies (UAS) and labeled accuracies (LAS) on Section 0, 1, 23, 24. Abbreviation: dep1/dep2=first-order parser and second-order parser with the baseline features; +hits=N-gram features derived from the Google hits; +V1=N-gram features derived from the Google V1; suffix-L=labeled parser. Unlabeled parsers are scored using unlabeled parent predictions, and labeled parsers are scored using labeled parent predictions.

finding is that the N-gram features derived from Google hits are slightly better than Google V1 due to the large N-gram coverage, we will discuss later. As a final note, all the comparisons between the integration of N-gram features and the baseline features in Table 3 are mildly significant using the Z-test of Collins et al. (2005) ($p < 0.08$).

Table 4: Comparison of our final results with other best-performing systems on the whole Section 23. Type D, C and S denote discriminative, combined and semi-supervised systems, respectively. † These papers were not directly reported the results on this data set, we implemented the experiments in this paper.

To put our results in perspective, we also compare them with other best-performing systems in Table 4. To facilitate comparisons with previous work, we only use Section 23 as the test data. The results show that our second order model incorporating the N-gram features (92.64) performs better than most previously reported discriminative systems trained on the Treebank. Carreras et al. (2008) reported a very high accuracy using information of constituent structure of TAG grammar formalism, while in our system, we do not use such knowledge. When compared to the combined systems, our system is better than Nivre and McDonald (2008) and Zhang and Clark (2008), but a slightly worse than Martins et al. (2008). We also compare our method with the semi-supervised approaches, the semi-supervised approaches achieved very high accuracies by leveraging on large unlabeled data directly into the systems for joint learning and decoding, while in our method, we only explore the N-gram features to further improve supervised dependency parsing performance.

Table 5 shows the details of some other N-gram sources, where **NEWS**: created from a large set of news articles including the Reuters and Gigword (Graff, 2003) corpora. For a given number of unique N-gram, using any of these sources does not have significant difference in Figure 3. Google hits is the largest N-gram data and shows the best performance. The other two are smaller ones, accuracies increase linearly with the log of the number of types in the auxiliary data set. Similar observations have been made by Pitler et al. (2010). We see that the relationship between accuracy and the number of N-gram is not monotonic for Google V1. The reason may be that Google V1 does not make detailed preprocessing, containing many mistakes in the corpus. Although Google hits is noisier, it has very much larger coverage of bigrams or trigrams.

Some previous studies also found a log-linear relationship between unlabeled data (Suzuki and Isozaki, 2008; Suzuki et al., 2009; Bergsma et al., 2010; Pitler et al., 2010). We have shown that this trend continues well for dependency parsing by using web-scale data (NEWS and Google V1).

[13]Google indexes about more than 8 billion pages and each contains about 1,000 words on average.

Corpus	# of tokens	θ	# of types
NEWS	3.2B	1	3.7B
Google V1	1,024.9B	40	3.4B
Google hits[13]	8,000B	100	-

Table 5: N-gram data, with total number of words in the original corpus (in billions, B). Following (Brants and Franz, 2006; Pitler et al., 2010), we set the frequency threshold to filter the data θ, and total number of unique N-gram (types) remaining in the data.

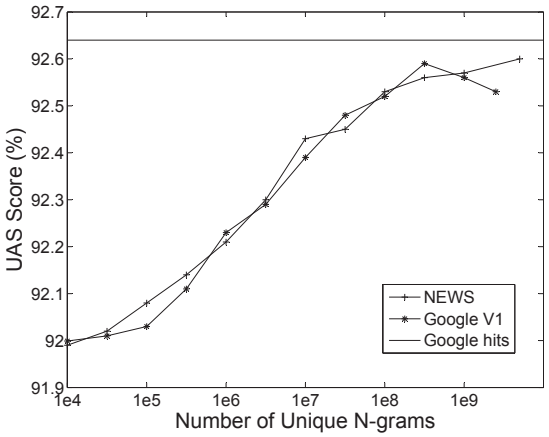

Figure 3: There is no data like more data. UAS accuracy improves with the number of unique N-grams but still lower than the Google hits.

4.2 Improvement relative to dependency length

The experiments in (McDonald and Nivre, 2007) showed a negative impact on the dependency parsing performance from too long dependencies. For our proposed approach, the improvement relative to dependency length is shown in Figure 4. From the Figure, it is seen that our method gives observable better performance when dependency lengths are larger than 3. The results here show that the proposed approach improves the dependency parsing performance, particularly for long dependency relationships.

4.3 Cross-genre testing

In this section, we present the experiments to validate the robustness the web-derived selectional preferences. The intent is to understand how well the web-derived selectional preferences transfer to other sources.

The English experiment evaluates the performance of our proposed approach when it is trained

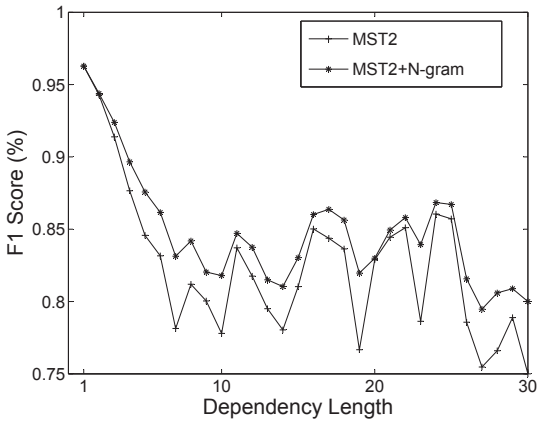

Figure 4: Dependency length vs. F_1 score.

on annotated data from one genre of text (WSJ) and is used to parse a test set from a different genre: the biomedical domain related to cancer (PennBioIE., 2005) with 2,600 parsed sentences. We divided the data into 500 for training, 100 for development and others for testing. We created five sets of training data with 100, 200, 300, 400, and 500 sentences respectively. Figure 5 plots the UAS accuracy as function of training instances. *WSJ* is the performance of our second-order dependency parser trained on section 2-21; WSJ+N-gram is the performance of our proposed approach trained on section 2-21; *WSJ+BioMed* is the performance of the parser trained on WSJ and biomedical data. *WSJ+BioMed+N-gram* is the performance of our proposed approach trained on WSJ and biomedical data. The results show that incorporating the web-scale N-gram features can significantly improve the dependency parsing performance, and the improvement is much larger than the in-domain testing presented in Section 4.1, the reason may be that web-derived N-gram features do not depend directly on training data and thus work better on new domains.

4.4 Discussion

In this paper, we present a novel method to improve dependency parsing by using web-scale data. Despite the success, there are still some problems which should be discussed.

(1) Google hits is less sparse than Google V1 in modeling the word-to-word relationships, but Google hits are likely to be noisier than Google V1. It is very appealing to carry out a correlation anal-

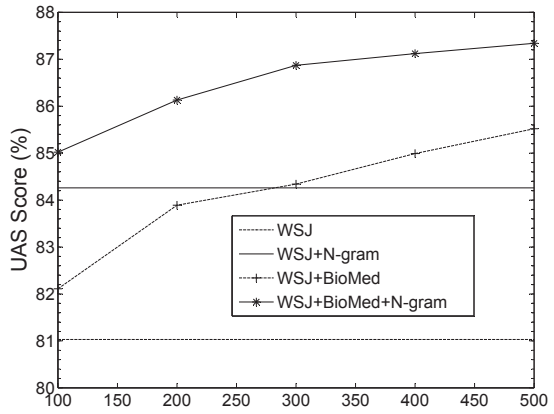

Figure 5: Adapting a WSJ parser to biomedical text. *WSJ*: performance of parser trained only on WSJ; *WSJ+N-gram*: performance of our proposed approach trained only on WSJ; *WSJ+BioMed*: parser trained on WSJ and biomedical text; *WSJ+BioMed+N-gram*: our approach trained on WSJ and biomedical text.

ysis to determine whether Google hits and Google V1 are highly correlated. We will leave it for future research.

(2) Veronis (2005) pointed out that there had been a debate about reliability of Google hits due to the inconsistencies of page hits estimates. However, this estimate is scale-invariant. Assume that when the number of pages indexed by Google grows, the number of pages containing a given search term goes to a fixed fraction. This means that if pages indexed by Google doubles, then so do the bigrams or trigrams frequencies. Therefore, the estimate becomes stable when the number of indexed pages grows unboundedly. Some details are presented in Cilibrasi and Vitanyi (2007).

5 Related Work

Our approach is to exploit web-derived selectional preferences to improve the dependency parsing. The idea of this paper is inspired by the work of Suzuki et al. (2009) and Pitler et al. (2010). The former uses the web-scale data explicitly to create more data for training the model; while the latter explores the web-scale N-grams data (Lin et al., 2010) for compound bracketing disambiguation. Our research, however, applies the web-scale data (**Google hits** and **Google V1**) to model the word-to-word dependency relationships rather than compound bracketing disambiguation.

Several previous studies have exploited the web-scale data for word pair acquisition. Keller and Lapata (2003) evaluated the utility of using web search engine statistics for unseen bigram. Nakov and Hearst (2005) demonstrated the effectiveness of using search engine statistics to improve the noun compound bracketing. Volk (2001) exploited the WWW as a corpus to resolve PP attachment ambiguities. Turney (2007) measured the semantic orientation for sentiment classification using co-occurrence statistics obtained from the search engines. Bergsma et al. (2010) created robust supervised classifiers via web-scale N-gram data for adjective ordering, spelling correction, noun compound bracketing and verb part-of-speech disambiguation. Our approach, however, extends these techniques to dependency parsing, particularly for long dependency relationships, which involves more challenging tasks than the previous work.

Besides, there are some work exploring the word-to-word co-occurrence derived from the web-scale data or a fixed size of corpus (Calvo and Gelbukh, 2004; Calvo and Gelbukh, 2006; Yates et al., 2006; Drabek and Zhou, 2000; van Noord, 2007) for PP attachment ambiguities or shallow parsing. Johnson and Riezler (2000) incorporated the lexical selectional preference features derived from British National Corpus (Graff, 2003) into a stochastic unification-based grammar. Abekawa and Okumura (2006) improved Japanese dependency parsing by using the co-occurrence information derived from the results of automatic dependency parsing of large-scale corpora. However, we explore the web-scale data for dependency parsing, the performance improves log-linearly with the number of parameters (unique N-grams). To the best of our knowledge, web-derived selectional preference has not been successfully applied to dependency parsing.

6 Conclusion

In this paper, we present a novel method which incorporates the web-derived selectional preferences to improve statistical dependency parsing. The results show that web-scale data improves the dependency parsing, particularly for long dependency relationships. There is no data like more data, performance improves log-linearly with the num-

ber of parameters (unique N-grams). More importantly, when operating on new domains, the web-derived selectional preferences show great potential for achieving robust performance.

Effective Measures of Domain Similarity for Parsing

Barbara Plank

Abstract

It is well known that parsing accuracy suffers when a model is applied to out-of-domain data. It is also known that the most beneficial data to parse a given domain is data that matches the domain (Sekine, 1997; Gildea, 2001). Hence, an important task is to select appropriate domains. However, most previous work on domain adaptation relied on the implicit assumption that domains are somehow given. As more and more data becomes available, automatic ways to select data that is beneficial for a new (unknown) target domain are becoming attractive. This paper evaluates various ways to automatically acquire related training data for a given test set. The results show that an unsupervised technique based on topic models is effective – it outperforms random data selection on both languages examined, English and Dutch. Moreover, the technique works better than manually assigned labels gathered from meta-data that is available for English.

1 Introduction and Motivation

Previous research on domain adaptation has focused on the task of adapting a system trained on one domain, say newspaper text, to a particular new domain, say biomedical data. Usually, some amount of (labeled or unlabeled) data from the new domain was given – which has been determined by a human.

However, with the growth of the web, more and more data is becoming available, where each document "is potentially its own domain" (McClosky et al., 2010). It is not straightforward to determine which data or model (in case we have several source domain models) will perform best on a new (unknown) target domain. Therefore, an important issue that arises is *how to measure domain similarity*, i.e. whether we can find a simple yet effective method to determine which model or data is most beneficial for an arbitrary piece of new text. Moreover, if we had such a measure, a related question is whether it can tell us something more about what is actually meant by "domain". So far, it was mostly arbitrarily used to refer to some kind of coherent unit (related to topic, style or genre), e.g.: newspaper text, biomedical abstracts, questions, fiction.

Most previous work on domain adaptation, for instance Hara et al. (2005), McClosky et al. (2006), Blitzer et al. (2006), Daumé III (2007), sidestepped this problem of automatic domain selection and adaptation. For parsing, to our knowledge only one recent study has started to examine this issue (McClosky et al., 2010) – we will discuss their approach in Section 2. Rather, an implicit assumption of all of these studies is that domains are given, i.e. that they are represented by the respective corpora. Thus, a corpus has been considered a homogeneous unit. As more data is becoming available, it is unlikely that domains will be 'given'. Moreover, a given corpus might not always be as homogeneous as originally thought (Webber, 2009; Lippincott et al., 2010). For instance, recent work has shown that the well-known Penn Treebank (PT) Wall Street Journal (WSJ) actually contains a variety of genres, including letters, wit and short verse (Webber, 2009).

In this study we take a different approach. Rather than viewing a given corpus as a monolithic entity,

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1566–1576,
Portland, Oregon, June 19-24, 2011.

we break it down to the article-level and disregard corpora boundaries. Given the resulting set of documents (articles), we evaluate various ways to automatically acquire related training data for a given test set, to find answers to the following questions:

- Given a pool of data (a collection of articles from unknown domains) and a test article, is there a way to automatically select data that is relevant for the new domain? If so:
- Which similarity measure is good for parsing?
- How does it compare to human-annotated data?
- Is the measure also useful for other languages and/or tasks?

To this end, we evaluate measures of domain similarity and feature representations and their impact on dependency parsing accuracy. Given a collection of annotated articles, and a new article that we want to parse, we want to select the most similar articles to train the best parser for that new article.

In the following, we will first compare automatic measures to human-annotated labels by examining parsing performance within subdomains of the Penn Treebank WSJ. Then, we extend the experiments to the domain adaptation scenario. Experiments were performed on two languages: English and Dutch. The empirical results show that a simple measure based on topic distributions is effective for both languages and works well also for Part-of-Speech tagging. As the approach is based on plain surface-level information (words) and it finds related data in a completely unsupervised fashion, it can be easily applied to other tasks or languages for which annotated (or automatically annotated) data is available.

2 Related Work

The work most related to ours is McClosky et al. (2010). They try to find the best combination of source models to parse data from a new domain, which is related to Plank and Sima'an (2008). In the latter, unlabeled data was used to create several parsers by weighting trees in the WSJ according to their similarity to the subdomain. McClosky et al. (2010) coined the term *multiple source domain adaptation*. Inspired by work on parsing accuracy prediction (Ravi et al., 2008), they train a linear regression model to predict the best (linear interpolation) of source domain models. Similar to us, McClosky et al. (2010) regard a target domain as mixture of source domains, but they focus on phrase-structure parsing. Furthermore, our approach differs from theirs in two respects: we do not treat source corpora as one entity and try to mix models, but rather consider articles as base units and try to find subsets of related articles (the most similar articles); moreover, instead of creating a supervised model (in their case to predict parsing accuracy), our approach is 'simplistic': we apply measures of domain similarity directly (in an unsupervised fashion), without the necessity to train a supervised model.

Two other related studies are (Lippincott et al., 2010; Van Asch and Daelemans, 2010). Van Asch and Daelemans (2010) explore a measure of domain difference (Renyi divergence) between pairs of domains and its correlation to Part-of-Speech tagging accuracy. Their empirical results show a linear correlation between the measure and the performance loss. Their goal is different, but related: rather than finding related data for a new domain, they want to estimate the loss in accuracy of a PoS tagger when applied to a new domain. We will briefly discuss results obtained with the Renyi divergence in Section 5.1. Lippincott et al. (2010) examine subdomain variation in biomedicine corpora and propose awareness of NLP tools to such variation. However, they did not yet evaluate the effect on a practical task, thus our study is somewhat complementary to theirs.

The issue of data selection has recently been examined for Language Modeling (Moore and Lewis, 2010). A subset of the available data is automatically selected as training data for a Language Model based on a scoring mechanism that compares cross-entropy scores. Their approach considerably outperformed random selection and two previous proposed approaches both based on perplexity scoring.[1]

3 Measures of Domain Similarity

3.1 Measuring Similarity Automatically

Feature Representations A similarity function may be defined over any set of events that are con-

[1] We tested data selection by perplexity scoring, but found the Language Models too small to be useful in our setting.

sidered to be relevant for the task at hand. For parsing, these might be words, characters, n-grams (of words or characters), Part-of-Speech (PoS) tags, bilexical dependencies, syntactic rules, etc. However, to obtain more abstract types such as PoS tags or dependency relations, one would first need to gather respective labels. The necessary tools for this are again trained on particular corpora, and will suffer from domain shifts, rendering labels noisy.

Therefore, we want to gauge the effect of the simplest representation possible: plain surface characteristics (unlabeled text). This has the advantage that we do not need to rely on additional supervised tools; moreover, it is interesting to know how far we can get with this level of information only.

We examine the following feature representations: relative frequencies of words, relative frequencies of character tetragrams, and topic models. Our motivation was as follows. Relative frequencies of words are a simple and effective representation used e.g. in text classification (Manning and Schütze, 1999), while character n-grams have proven successful in genre classification (Wu et al., 2010). Topic models (Blei et al., 2003; Steyvers and Griffiths, 2007) can be considered an advanced model over word distributions: every article is represented by a topic distribution, which in turn is a distribution over words. Similarity between documents can be measured by comparing topic distributions.

Similarity Functions There are many possible similarity (or distance) functions. They fall broadly into two categories: probabilistically-motivated and geometrically-motivated functions. The similarity functions examined in this study will be described in the following.

The *Kullback-Leibler (KL) divergence* $D(q||r)$ is a classical measure of 'distance'[2] between two probability distributions, and is defined as: $D(q||r) = \sum_y q(y) \log \frac{q(y)}{r(y)}$. It is a non-negative, additive, asymmetric measure, and 0 iff the two distributions are identical. However, the KL-divergence is undefined if there exists an event y such that $q(y) > 0$ but $r(y) = 0$, which is a property that "makes it unsuitable for distributions derived via maximum-likelihood estimates" (Lee, 2001).

[2]It is not a proper distance metric since it is asymmetric.

One option to overcome this limitation is to apply smoothing techniques to gather non-zero estimates for all y. The alternative, examined in this paper, is to consider an approximation to the KL divergence, such as the Jensen-Shannon (JS) divergence (Lin, 1991) and the skew divergence (Lee, 2001).

The *Jensen-Shannon divergence*, which is symmetric, computes the KL-divergence between q, r, and the average between the two. We use the JS divergence as defined in Lee (2001): $JS(q,r) = \frac{1}{2}[D(q||\text{avg}(q,r)) + D(r||\text{avg}(q,r))]$. The asymmetric *skew divergence* s_α, proposed by Lee (2001), mixes one distribution with the other by a degree defined by $\alpha \in [0,1)$: $s_\alpha(q,r,\alpha) = D(q||\alpha r + (1-\alpha)q)$. As α approaches 1, the skew divergence approximates the KL-divergence.

An alternative way to measure similarity is to consider the distributions as vectors and apply geometrically-motivated distance functions. This family of similarity functions includes the *cosine* $cos(q,r) = q(y) \cdot r(y)/||q(y)||||r(y)||$, *euclidean* $euc(q,r) = \sqrt{\sum_y (q(y) - r(y))^2}$ and *variational* (also known as L1 or Manhattan) distance function, defined as $var(q,r) = \sum_y |q(y) - r(y)|$.

3.2 Human-annotated data

In contrast to the automatic measures devised in the previous section, we might have access to human annotated data. That is, use label information such as topic or genre to define the set of similar articles.

Genre For the Penn Treebank (PT) Wall Street Journal (WSJ) section, more specifically, the subset available in the Penn Discourse Treebank, there exists a partition of the data by *genre* (Webber, 2009). Every article is assigned one of the following genre labels: news, letters, highlights, essays, errata, wit and short verse, quarterly progress reports, notable and quotable. This classification has been made on the basis of meta-data (Webber, 2009). It is well-known that there is no meta-data directly associated with the individual WSJ files in the Penn Treebank. However, meta-data can be obtained by looking at the articles in the ACL/DCI corpus (LDC99T42), and a mapping file that aligns document numbers of DCI (DOCNO) to WSJ keys (Webber, 2009). An example document is given in Figure 1. The meta-data field `HL` contains headlines, `SO` source info, and

the IN field includes topic markers.

```
<DOC><DOCNO>  891102-0186. </DOCNO>
<WSJKEY> wsj_0008 </WSJKEY>
<AN> 891102-0186. </AN>
<HL> U.S. Savings Bonds Sales
@  Suspended by Debt Limit </HL>
<DD> 11/02/89 </DD>
<SO> WALL STREET JOURNAL (J) </SO>
<IN> FINANCIAL, ACCOUNTING, LEASING (FIN)
BOND MARKET NEWS (BON) </IN>
<GV> TREASURY DEPARTMENT (TRE) </GV>
<DATELINE> WASHINGTON  </DATELINE>
<TXT>
<p><s>
The federal government suspended sales of U.S.
savings bonds because Congress hasn't lifted
the ceiling on government debt.</s></p> [...]
```

Figure 1: Example of ACL/DCI article. We have augmented it with the WSJ filename (WSJKEY).

Topic On the basis of the same meta-data, we devised a classification of the Penn Treebank WSJ by *topic*. That is, while the genre division has been mostly made on the basis of headlines, we use the information of the IN field. Every article is assigned one, more than one or none of a predefined set of keywords. While their origin remains unclear,[3] these keywords seem to come from a controlled vocabulary. There are 76 distinct topic markers. The three most frequent keywords are: TENDER OFFERS, MERGERS, ACQUISITIONS (TNM), EARNINGS (ERN), STOCK MARKET, OFFERINGS (STK). This reflects the fact that a lot of articles come from the financial domain. But the corpus also contains articles from more distant domains, like MARKETING, ADVERTISING (MKT), COMPUTERS AND INFORMATION TECHNOLOGY (CPR), HEALTH CARE PROVIDERS, MEDICINE, DENTISTRY (HEA), PETROLEUM (PET).

4 Experimental Setup

4.1 Tools & Evaluation

The parsing system used in this study is the MST parser (McDonald et al., 2005), a state-of-the-art data-driven graph-based dependency parser. It is a system that can be trained on a variety of languages given training data in CoNLL format (Buchholz and Marsi, 2006). Additionally, the parser implements both projective and non-projective parsing algorithms. The projective algorithm is used for the experiments on English, while the non-projective variant is used for Dutch. We train the parser using default settings. MST takes PoS-tagged data as input; we use gold-standard tags in the experiments.

We estimate topic models using Latent Dirichlet Allocation (Blei et al., 2003) implemented in the MALLET[4] toolkit. Like Lippincott et al. (2010), we set the number of topics to 100, and otherwise use standard settings (no further optimization). We experimented with the removal of stopwords, but found no deteriorating effect while keeping them. Thus, all experiments are carried out on data where stopwords were not removed.

We implemented the similarity measures presented in Section 3.1. For skew divergence, that requires parameter α, we set $\alpha = .99$ (close to KL divergence) since that has shown previously to work best (Lee, 2001). Additionally, we evaluate the approach on English PoS tagging using two different taggers: MXPOST, the MaxEnt tagger of Ratnaparkhi[5] and Citar,[6] a trigram HMM tagger.

In all experiments, parsing performance is measured as *Labeled Attachment Score* (LAS), the percentage of tokens with correct dependency edge and label. To compute LAS, we use the CoNLL 2007 evaluation script[7] with punctuation tokens excluded from scoring (as was the default setting in CoNLL 2006). PoS tagging accuracy is measured as the percentage of correctly labeled words out of all words. Statistical significance is determined by *Approximate Randomization Test* (Noreen, 1989; Yeh, 2000) with 10,000 iterations.

4.2 Data

English - WSJ For English, we use the portion of the Penn Treebank Wall Street Journal (WSJ) that has been made available in the CoNLL 2008 shared

[3] It is not known what IN stands for, as also stated in Mark Liberman's notes in the readme of the ACL/DCI corpus. However, a reviewer suggested that IN might stand for "index terms" which seems plausible.

[4] http://mallet.cs.umass.edu/

[5] ftp://ftp.cis.upenn.edu/pub/adwait/jmx/

[6] Citar has been implemented by Daniël de Kok and is available at: https://github.com/danieldk/citar

[7] http://nextens.uvt.nl/depparse-wiki/

task. This data has been automatically converted[8] into dependency structure, and contains three files: the training set (sections 02-21), development set (section 24) and test set (section 23).

Since we use articles as basic units, we actually split the data to get back original article boundaries.[9] This led to a total of 2,034 articles (1 million words). Further statistics on the datasets are given in Table 1. In the first set of experiments on WSJ subdomains, we consider articles from section 23 and 24 that contain at least 50 sentences as test sets (target domains). This amounted to 22 test articles.

	EN: WSJ	WSJ+G+B	Dutch
articles	2,034	3,776	51,454
sentences	43,117	77,422	1,663,032
words	1,051,997	1,784,543	20,953,850

Table 1: Overview of the datasets for English and Dutch.

To test whether we have a reasonable system, we performed a sanity check and trained the MST parser on the training section (02-21). The result on the standard test set (section 23) is identical to previously reported results (excluding punctuation tokens: LAS 87.50, Unlabeled Attachment Score (UAS) 90.75; with punctuation tokens: LAS 87.07, UAS 89.95). The latter has been reported in (Surdeanu and Manning, 2010).

English - Genia (G) & Brown (B) For the Domain Adaptation experiments, we added 1,552 articles from the GENIA[10] treebank (biomedical abstracts from Medline) and 190 files from the Brown corpus to the pool of data. We converted the data to CoNLL format with the LTH converter (Johansson and Nugues, 2007). The size of the test files is, respectively: Genia 1,360 sentences with an average number of 26.20 words per sentence; the Brown test set is the same as used in the CoNLL 2008 shared task and contains 426 sentences with a mean of 16.80 words.

[8]Using the LTH converter: `http://nlp.cs.lth.se/software/treebank_converter/`

[9]This was a non-trivial task, as we actually noticed that some sentences have been omitted from the CoNLL 2008 shared task.

[10]We use the GENIA distribution in Penn Treebank format available at `http://bllip.cs.brown.edu/download/genia1.0-division-rel1.tar.gz`

5 Experiments on English

5.1 Experiments within the WSJ

In the first set of experiments, we focus on the WSJ and evaluate the similarity functions to gather related data for a given test article. We have 22 WSJ articles as test set, sampled from sections 23 and 24. Regarding feature representations, we examined three possibilities: relative frequencies of words, relative frequencies of character tetragrams (both unsmoothed) and document topic distributions.

In the following, we only discuss representations based on words or topic models as we found character tetragrams less stable; they performed sometimes like their word-based counterparts but other times, considerably worse.

Results of Similarity Measures Table 2 compares the effect of the different ways to select related data in comparison to the random baseline for increasing amounts of training data. The table gives the average over 22 test articles (rather than showing individual tables for the 22 articles). We select articles up to various thresholds that specify the total number of sentences selected in each round (e.g. 0.3k, 1.2k, etc.).[11] In more detail, Table 2 shows the result of applying various similarity functions (introduced in Section 3.1) over the two different feature representations (w: words; tm: topic model) for increasing amounts of data. We additionally provide results of using the Renyi divergence.[12]

Clearly, as more and more data is selected, the differences become smaller, because we are close to the data limit. However, for all data points less than 38k (97%), selection by jensen-shannon, variational and cosine similarity outperform random data selection significantly for both types of feature representations (words and topic model). For selection by topic models, this additionally holds for the euclidean measure.

From the various measures we can see that selection by jensen-shannon divergence and variational distance perform best, followed by cosine similarity, skew divergence, euclidean and renyi.

[11]Rather than choosing k articles, as article length may differ.

[12]The *Renyi divergence* (Rényi, 1961), also used by Van Asch and Daelemans (2010), is defined as $D_\alpha(q,r) = 1/(\alpha - 1)\log(\sum q^\alpha r^{1-\alpha})$.

	1% (0.3k)	**3%** (1.2k)	**25%** (9.6k)	**49%** (19.2k)	**97%** (38k)
random	70.61	77.21	82.98	84.48	85.51

tm-ryi	71.26	78.64⋆	83.79⋆	84.85	85.58

Table 2: Comparison of similarity measures based on words (w) and topic model (tm): parsing accuracy for increasing amounts of training data as average over 22 WSJ articles (js=jensen-shannon; cos=cosine; skw=skew; var=variational; euc=euclidean; ryi=renyi). Best score (per representation) underlined, best overall score bold; ⋆ indicates significantly better ($p < 0.05$) than random.

Renyi divergence does not perform as well as other probabilistically-motivated functions. Regarding feature representations, the representation based on topic models works slightly better than the respective word-based measure (cf. Table 2) and often achieves the overall best score (boldface).

Overall, the differences in accuracy between the various similarity measures are small; but interestingly, the overlap between them is not that large. Table 3 and Table 4 show the overlap (in terms of proportion of identically selected articles) between pairs of similarity measures. As shown in Table 3, for all measures there is only a small overlap with the random baseline (around 10%-14%). Despite similar performance, topic model selection has interestingly no substantial overlap with any other word-based similarity measures: their overlap is at most 41.6%. Moreover, Table 4 compares the overlap of the various similarity functions within a certain feature representation (here x stands for either topic model – left value – or words – right value). The table shows that there is quite some overlap between jensen-shannon, variational and skew divergence on one side, and cosine and euclidean on the other side, i.e. between probabilistically- and geometrically-motivated functions. Variational has a higher overlap with the probabilistic functions. Interestingly, the 'peaks' in Table 4 (underlined, i.e. the highest pair-wise overlaps) are the same for the different feature representations.

In the following we analyze selection by topic model and words, as they are relatively different from each other, despite similar performance. For the word-based model, we use jensen-shannon as similarity function, as it turned out to be the best measure. For topic model, we use the simpler variational metric. However, very similar results were achieved using jensen-shannon. Cosine and euclidean did not perform as well.

	ran	w-js	w-var	w-skw	w-cos	w-euc
ran	–	10.3	10.4	10.0	10.4	10.2
tm-js	12.1	41.6	39.6	36.0	29.3	28.6
tm-var	12.3	40.8	39.3	34.9	29.3	28.5

Table 3: Average overlap (in %) of similarity measure: random selection (ran) vs. measures based on words (w) and topic model (tm).

x=tm/w	x-js	x-var	x-skw	x-cos	x-euc
tm/w-var	76/74	–	60/63	55/48	49/47
tm/w-skw	69/72	60/63	–	48/41	42/42
tm/w-cos	57/42	55/48	48/41	–	62/71
tm/w-euc	47/41	49/47	42/42	62/71	–

Table 4: Average overlap (in %) for different feature representations x as tm/w, where tm=topic model and w=words. Highest pair-wise overlap is underlined.

Automatic Measure vs. Human labels The next question is how these automatic measures compare to human-annotated data. We compare word-based and topic model selection (by using jensen-shannon and variational, respectively) to selection based on human-given labels: genre and topic. For genre, we randomly select larger amounts of training data for a given test article from the same genre. For topic, the approach is similar, but as an article might have

several topic markers (keywords in the IN field), we rank articles by proportion of overlapping keywords.

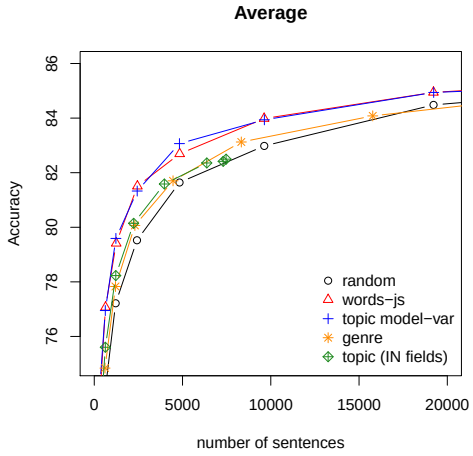

Figure 2: Comparison of automatic measures (words using jensen-shannon and topic model using variational) with human-annotated labels (genre/topic). Automatic measures outperform human labels ($p < 0.05$).

Figure 2 shows that human-labels do actually not perform better than the automatic measures. Both are close to random selection. Moreover, the line of selection by topic marker (IN fields) stops early – we believe the reason for this is that the IN fields are too fine-grained, which limits the number of articles that are considered relevant for a given test article. However, manually aggregating articles on similar topics did not improve topic-based selection either. We conclude that the automatic selection techniques perform significantly better than human-annotated data, at least within the WSJ domain considered here.

5.2 Domain Adaptation Results

Until now, we compared similarity measures by restricting ourselves to articles from the WSJ. In this section, we extend the experiments to the domain adaptation scenario. We augment the pool of WSJ articles with articles coming from two other corpora: Genia and Brown. We want to gauge the effectiveness of the domain similarity measures in the multi-domain setting, where articles are selected from the pool of data without knowing their identity (which corpus the articles came from).

The test sets are the standard evaluation sets from the three corpora: the standard WSJ (section 23) and Brown test set from CoNLL 2008 (they contain 2,399 and 426 sentences, respectively) and the Genia test set (1,370 sentences). As a reference, we give results of models trained on the respective corpora (*per-corpus* models; i.e. if we consider corpora boundaries and train a model on the respective domain – this model is 'supervised' in the sense that it knows from which corpus the test article came from) as well as a baseline model trained on all data, i.e. the *union* of all three corpora (wsj+genia+brown), which is a standard baseline in domain adaptation (Daumé III, 2007; McClosky et al., 2010).

	WSJ (38k)	**Brown** (28k)	**Genia** (19k)
random	86.58	73.81	83.77
per-corpus	87.50	81.55	86.63
union	87.05	79.12	81.57
topic model (var)	87.11⋆	81.76♢	86.77♢
words (js)	86.30	81.47♢	86.44♢

Table 5: Domain Adaptation Results on English (significantly better: ⋆ than random; ♢ than random and union).

The learning curves are shown in Figure 3, the scores for a specific amount of data are given in Table 5. The performance of the reference models (per-corpus and union in Table 5) are indicated in Figure 3 with horizontal lines: the dashed line represents the per-corpus performance ('supervised' model); the solid line shows the performance of the union baseline trained on all available data (77k sentences). For the former, the vertical dashed lines indicate the amount of data the model was trained on (e.g. 23k sentences for Brown).

Simply taking all available data has a deteriorating effect: on all three test sets, the performance of the union model is below the presumably best performance of a model trained on the respective corpus (per-corpus model).

The empirical results show that automatic data selection by topic model outperforms random selection on all three test sets and the union baseline in two out of three cases. More specifically, selection by topic model outperforms random selection significantly on all three test sets and all points in the graph ($p < 0.001$). Selection by the word-based measure (words-js) achieves a significant improve-

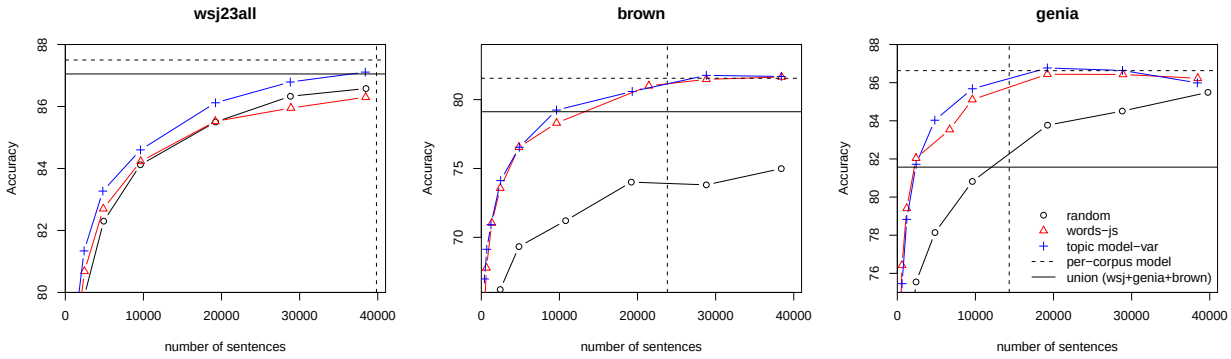

Figure 3: Domain Adaptation Results for English Parsing with Increasing Amounts of Training Data. The vertical line represents the amount of data the per-corpus model is trained on.

ment over the random baseline on two out of the three test sets – it falls below the random baseline on the WSJ test set. Thus, selection by topic model performs best – it achieves better performance than the union baseline with comparatively little data (Genia: 4k; Brown: 19k – in comparison: union has 77k). Moreover, it comes very close to the supervised per-corpus model performance[13] with a similar amount of data (cf. vertical dashed line). This is a very good result, given that the technique disregards the origin of the articles and just uses plain words as information. It automatically finds data that is beneficial for an unknown target domain.

So far we examined domain similarity measures for parsing, and concluded that selection by topic model performs best, closely followed by word-based selection using the jensen-shannon divergence. The question that remains is whether the measure is more widely applicable: How does it perform on another language and task?

PoS tagging We perform similar Domain Adaptation experiments on WSJ, Genia and Brown for PoS tagging. We use two taggers (HMM and MaxEnt) and the same three test articles as before. The results are shown in Figure 4 (it depicts the average over the three test sets, WSJ, Genia, Brown, for space reasons). The left figure shows the performance of the HMM tagger; on the right is the MaxEnt tagger. The graphs show that automatic training data selection outperforms random data selection, and again topic model selection performs best, closely followed by words-js. This confirms previous findings and shows that the domain similarity measures are effective also for this task.

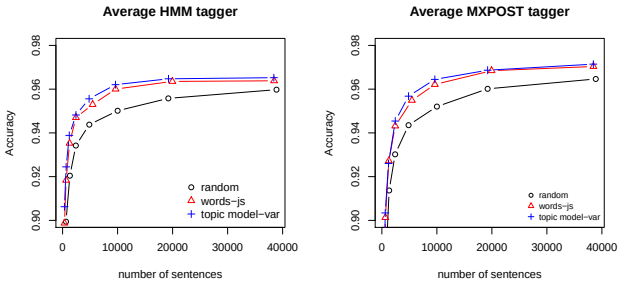

Figure 4: PoS tagging results, average over 3 test sets.

6 Experiments on Dutch

For Dutch, we evaluate the approach on a bigger and more varied dataset. It contains in total over 50k articles and 20 million words (cf. Table 1). In contrast to the English data, only a small portion of the dataset is manually annotated: 281 articles.[14]

Since we want to evaluate the performance of different similarity measures, we want to keep the influence of noise as low as possible. Therefore, we annotated the remaining articles with a parsing system that is more accurate (Plank and van Noord, 2010), the Alpino parser (van Noord, 2006). Note that using a more accurate parsing system to train another parser has recently also been proposed by Petrov et al. (2010) as *uptraining*. Alpino is a

[13] On Genia and Brown (cf. Table 5) there is no significant difference between topic model and per-corpus model.

[14] http://www.let.rug.nl/vannoord/Lassy/

parser tailored to Dutch, that has been developed over the last ten years, and reaches an accuracy level of 90% on general newspaper text. It uses a conditional MaxEnt model as parse selection component. Details of the parser are given in (van Noord, 2006).

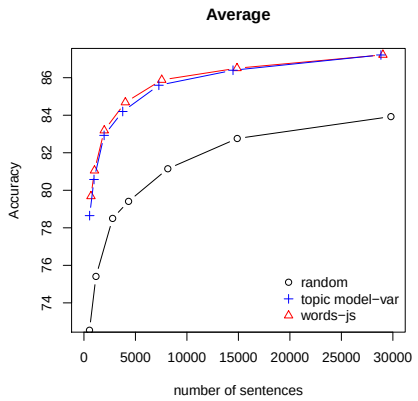

Figure 5: Result on Dutch; average over 30 articles.

Data and Results The Dutch dataset contains articles from a variety of sources: Wikipedia[15], EMEA[16] (documents from the European Medicines Agency) and the Dutch parallel corpus[17] (DPC), that covers a variety of subdomains. The Dutch articles were parsed with Alpino and automatically converted to CoNLL format with the treebank conversion software from CoNLL 2006, where PoS tags have been replaced with more fine-grained Alpino tags as that had a positive effect on MST. The 281 annotated articles come from all three sources. As with English, we consider as test set articles with at least 50 sentences, from which 30 are randomly sampled.

The results on Dutch are shown in Figure 5. Domain similarity measures clearly outperform random data selection also in this setting with another language and a considerably larger pool of data (20 million words; 51k articles).

7 Discussion

In this paper we have shown the effectiveness of a simple technique that considers only plain words as domain selection measure for two tasks, dependency parsing and PoS tagging. Interestingly, human-annotated labels did not perform better than the automatic measures. The best technique is based on topic models, and compares document topic distributions estimated by LDA (Blei et al., 2003) using the variational metric (very similar results were obtained using jensen-shannon). Topic model selection significantly outperforms random data selection on both examined languages, English and Dutch, and has a positive effect on PoS tagging. Moreover, it outperformed a standard Domain Adaptation baseline (union) on two out of three test sets. Topic model is closely followed by the word-based measure using jensen-shannon divergence. By examining the overlap between word-based and topic model-based techniques, we found that despite similar performance their overlap is rather small. Given these results and the fact that no optimization has been done for the topic model itself, results are encouraging: there might be an even better measure that exploits the information from both techniques. So far, we tested a simple combination of the two by selecting half of the articles by a measure based on words and the other half by a measure based on topic models (by testing different metrics). However, this simple combination technique did not improve results yet – topic model alone still performed best.

Overall, plain surface characteristics seem to carry important information of what kind of data is relevant for a given domain. Undoubtedly, parsing accuracy will be influenced by more factors than lexical information. Nevertheless, as we have seen, lexical differences constitute an important factor.

Applying divergence measures over syntactic patterns, adding additional articles to the pool of data (by uptraining (Petrov et al., 2010), selftraining (McClosky et al., 2006) or active learning (Hwa, 2004)), gauging the effect of weighting instances according to their similarity to the test data (Jiang and Zhai, 2007; Plank and Sima'an, 2008), as well as analyzing differences between gathered data are venues for further research.

Efficient CCG Parsing: A* versus Adaptive Supertagging

Abstract

We present a systematic comparison and combination of two orthogonal techniques for efficient parsing of Combinatory Categorial Grammar (CCG). First we consider adaptive supertagging, a widely used approximate search technique that prunes most lexical categories from the parser's search space using a separate sequence model. Next we consider several variants on A*, a classic exact search technique which to our knowledge has not been applied to more expressive grammar formalisms like CCG. In addition to standard hardware-independent measures of parser effort we also present what we believe is the first evaluation of A* parsing on the more realistic but more stringent metric of CPU time. By itself, A* substantially reduces parser effort as measured by the number of edges considered during parsing, but we show that for CCG this does not always correspond to improvements in CPU time over a CKY baseline. Combining A* with adaptive supertagging decreases CPU time by 15% for our best model.

1 Introduction

Efficient parsing of Combinatorial Categorial Grammar (CCG; Steedman, 2000) is a longstanding problem in computational linguistics. Even with practical CCG that are strongly context-free (Fowler and Penn, 2010), parsing can be much harder than with Penn Treebank-style context-free grammars, since the number of nonterminal categories is generally much larger, leading to increased grammar constants. Where a typical Penn Treebank grammar may have fewer than 100 nonterminals (Hockenmaier and Steedman, 2002), we found that a CCG grammar derived from CCGbank contained nearly 1600. The same grammar assigns an average of 26 lexical categories per word, resulting in a very large space of possible derivations.

The most successful strategy to date for efficient parsing of CCG is to first prune the set of lexical categories considered for each word, using the output of a *supertagger*, a sequence model over these categories (Bangalore and Joshi, 1999; Clark, 2002). Variations on this approach drive the widely-used, broad coverage C&C parser (Clark and Curran, 2004; Clark and Curran, 2007). However, pruning means approximate search: if a lexical category used by the highest probability derivation is pruned, the parser will not find that derivation (§2). Since the supertagger enforces no grammaticality constraints it may even prefer a sequence of lexical categories that cannot be combined into *any* derivation (Figure 1). Empirically, we show that supertagging improves efficiency by an order of magnitude, but the tradeoff is a significant loss in accuracy (§3).

Can we improve on this tradeoff? The line of investigation we pursue in this paper is to consider more efficient *exact* algorithms. In particular, we test different variants of the classical A* algorithm (Hart et al., 1968), which has met with success in Penn Treebank parsing with context-free grammars (Klein and Manning, 2003; Pauls and Klein, 2009a; Pauls and Klein, 2009b). We can substitute A* for standard CKY on either the unpruned set of lexical categories, or the pruned set resulting from su-

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1577–1585,
Portland, Oregon, June 19-24, 2011.

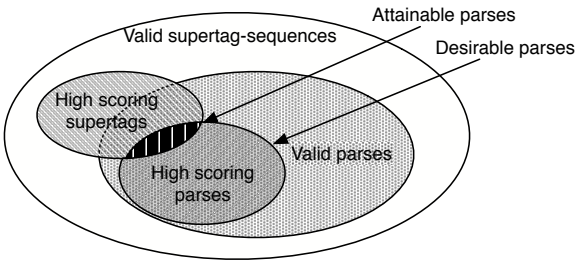

Figure 1: The relationship between supertagger and parser search spaces based on the intersection of their corresponding tag sequences.

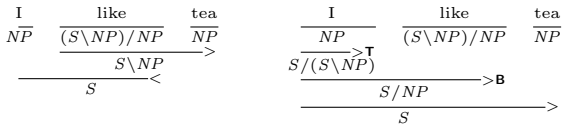
pertagging. Our empirical results show that on the unpruned set of lexical categories, heuristics employed for context-free grammars show substantial speedups in hardware-independent metrics of parser effort (§4). To understand how this compares to the CKY baseline, we conduct a carefully controlled set of timing experiments. Although our results show that improvements on hardware-independent metrics do not always translate into improvements in CPU time due to increased processing costs that are hidden by these metrics, they also show that when the lexical categories are pruned using the output of a supertagger, then we can still improve efficiency by 15% with A* techniques (§5).

2 CCG and Parsing Algorithms

CCG is a lexicalized grammar formalism encoding for each word lexical categories which are either basic (eg. NN, JJ) or complex. Complex lexical categories specify the number and directionality of arguments. For example, one lexical category (of over 100 in our model) for the transitive verb *like* is $(S\backslash NP_2)/NP_1$, specifying the first argument as an NP to the right and the second as an NP to the left. In parsing, adjacent spans are combined using a small number of binary combinatory rules like forward application or composition on the spanning categories (Steedman, 2000; Fowler and Penn, 2010). In the first derivation below, $(S\backslash NP)/NP$ and NP combine to form the spanning category $S\backslash NP$, which only requires an NP to its left to form a complete sentence-spanning S. The second derivation uses type-raising to change the category type of *I*.



Because of the number of lexical categories and their complexity, a key difficulty in parsing CCG is that the number of analyses for each span of the sentence quickly becomes extremely large, even with efficient dynamic programming.

2.1 Adaptive Supertagging

Supertagging (Bangalore and Joshi, 1999) treats the assignment of lexical categories (or *supertags*) as a sequence tagging problem. Once the supertagger has been run, lexical categories that apply to each word in the input sentence are pruned to contain only those with high posterior probability (or other figure of merit) under the supertagging model (Clark and Curran, 2004). The posterior probabilities are then discarded; it is the extensive pruning of lexical categories that leads to substantially faster parsing times.

Pruning the categories in advance this way has a specific failure mode: sometimes it is not possible to produce a sentence-spanning derivation from the tag sequences preferred by the supertagger, since it does not enforce grammaticality. A workaround for this problem is the *adaptive supertagging* (AST) approach of Clark and Curran (2004). It is based on a step function over supertagger beam ratios, relaxing the pruning threshold for lexical categories whenever the parser fails to find an analysis. The process either succeeds and returns a parse after some iteration or gives up after a predefined number of iterations. As Clark and Curran (2004) show, most sentences can be parsed with a very small number of supertags per word. However, the technique is inherently approximate: it will return a lower probability parse under the parsing model if a higher probability parse can only be constructed from a supertag sequence returned by a subsequent iteration. In this way it prioritizes speed over accuracy, although the tradeoff can be modified by adjusting the beam step function.

2.2 A* Parsing

Irrespective of whether lexical categories are pruned in advance using the output of a supertagger, the CCG parsers we are aware of all use some vari-

ant of the CKY algorithm. Although CKY is easy to implement, it is *exhaustive*: it explores all possible analyses of all possible spans, irrespective of whether such analyses are likely to be part of the highest probability derivation. Hence it seems natural to consider exact algorithms that are more efficient than CKY.

A* search is an agenda-based best-first graph search algorithm which finds the lowest cost parse exactly without necessarily traversing the entire search space (Klein and Manning, 2003). In contrast to CKY, items are not processed in topological order using a simple control loop. Instead, they are processed from a priority queue, which orders them by the product of their inside probability and a heuristic estimate of their outside probability. Provided that the heuristic never underestimates the true outside probability (i.e. it is *admissible*) the solution is guaranteed to be exact. Heuristics are model specific and we consider several variants in our experiments based on the CFG heuristics developed by Klein and Manning (2003) and Pauls and Klein (2009a).

3 Adaptive Supertagging Experiments

Parser. For our experiments we used the generative CCG parser of Hockenmaier and Steedman (2002). Generative parsers have the property that all edge weights are non-negative, which is required for A* techniques.[1] Although not quite as accurate as the discriminative parser of Clark and Curran (2007) in our preliminary experiments, this parser is still quite competitive. It is written in Java and implements the CKY algorithm with a global pruning threshold of 10^{-4} for the models we use. We focus on two parsing models: `PCFG`, the baseline of Hockenmaier and Steedman (2002) which treats the grammar as a PCFG (Table 1); and `HWDep`, a headword dependency model which is the best performing model of the parser. The PCFG model simply generates a tree top down and uses very simple structural probabilities while the `HWDep` model conditions node expansions on headwords and their lexical categories.

Supertagger. For supertagging we used Dennis Mehay's implementation, which follows Clark (2002).[2] Due to differences in smoothing of the supertagging and parsing models, we occasionally drop supertags returned by the supertagger because they do not appear in the parsing model [3].

Evaluation. All experiments were conducted on CCGBank (Hockenmaier and Steedman, 2007), a right-most normal-form CCG version of the Penn Treebank. Models were trained on sections 2-21, tuned on section 00, and tested on section 23. Parsing accuracy is measured using labelled and unlabelled predicate argument structure recovery (Clark and Hockenmaier, 2002); we evaluate on *all* sentences and thus penalise lower coverage. All timing experiments reported in the paper were run on a 2.5 GHz Xeon machine with 32 GB memory and are averaged over ten runs[4].

3.1 Results

Supertagging has been shown to improve the speed of a generative parser, although little analysis has been reported beyond the speedups (Clark, 2002) We ran experiments to understand the time/accuracy tradeoff of adaptive supertagging, and to serve as baselines.

Adaptive supertagging is parametrized by a beam size β and a dictionary cutoff k that bounds the number of lexical categories considered for each word (Clark and Curran, 2007). Table 3 shows both the standard beam levels (`AST`) used for the C&C parser and looser beam levels: `AST-covA`, a simple extension of `AST` with increased coverage and `AST-covB`, also increasing coverage but with better performance for the `HWDep` model.

Parsing results for the AST settings (Tables 4 and 5) confirm that it improves speed by an order of magnitude over a baseline parser without AST. Perhaps surprisingly, the number of parse failures decreases with AST in some cases. This is because the parser prunes more aggressively as the search space increases.[5]

[1] Indeed, all of the past work on A* parsing that we are aware of uses generative parsers (Pauls and Klein, 2009b, *inter alia*).

[2] http://code.google.com/p/statopenccg

[3] Less than 2% of supertags are affected by this.

[4] The timing results reported differ from an earlier draft since we used a different machine

[5] Hockenmaier and Steedman (2002) saw a similar effect.

Table 4: Results on CCGbank section 00 when applying adaptive supertagging (AST) to two models of a generative CCG parser. Performance is measured in terms of parse failures, labelled and unlabelled precision (LP/UP), recall (LR/UR) and F-score (LF/UF). Evaluation is based only on sentences for which each parser returned an analysis.

3.2 Efficiency versus Accuracy

The most interesting result is the effect of the speedup on accuracy. As shown in Table 6, the vast majority of sentences are actually parsed with a very tight supertagger beam, raising the question of whether many higher-scoring parses are pruned.[6] Despite this, labeled F-score improves by up to 1.6 F-measure for the PCFG model, although it harms accuracy for HWDep as expected.

In order to understand this effect, we filtered section 00 to include only sentences of between 18 and 26 words (resulting in 610 sentences) for which

[6]Similar results are reported by Clark and Curran (2007).

	Time(sec)	Sent/sec	Cats/word	Fail	UP	UR	UF	LP	LR	LF

Fail		16	0.9

Table 6: Breakdown of the number of sentences parsed for the HWDep (AST) model (see Table 4) at each of the supertagger beam levels from the most to the least restrictive setting.

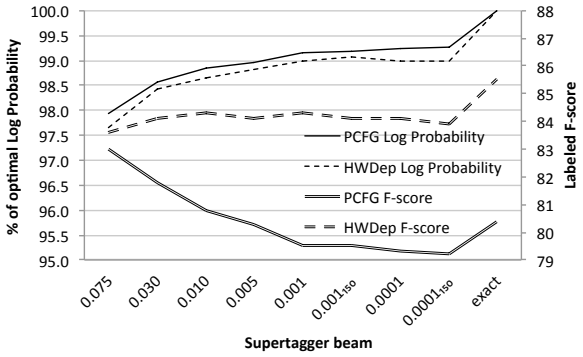

Figure 2: Log-probability of parses relative to exact solution vs. labelled F-score at each supertagging beam-level.

we can perform exhaustive search without pruning[7], and for which we could parse without failure at all of the tested beam settings. We then measured the log probability of the highest probability parse found under a variety of beam settings, relative to the log probability of the unpruned exact parse, along with the labeled F-Score of the Viterbi parse under these settings (Figure 2). The results show that PCFG actually finds worse results as it considers more of the search space. In other words, the supertagger can actually "fix" a bad parsing model by restricting it to a small portion of the search space. With the more accurate HWDep model, this does not appear to be a problem and there is a clear opportunity for improvement by considering the larger search space. The next question is whether we can exploit this larger search space without paying as high a cost in efficiency.

[7]The fact that only a subset of short sentences could be exhaustively parsed demonstrates the need for efficient search algorithms.

4 A* Parsing Experiments

To compare approaches, we extended our baseline parser to support A* search. Following (Klein and Manning, 2003) we restrict our experiments to sentences on which we can perform exact search via using the same subset of section 00 as in §3.2. Before considering CPU time, we first evaluate the amount of work done by the parser using three hardware-independent metrics. We measure the number of *edges pushed* (Pauls and Klein, 2009a) and *edges popped*, corresponding to the insert/decrease-key operations and remove operation of the priority queue, respectively. Finally, we measure the number of *traversals*, which counts the number of edge weights computed, regardless of whether the weight is discarded due to the prior existence of a better weight. This latter metric seems to be the most accurate account of the work done by the parser.

Due to differences in the PCFG and HWDep models, we considered different A* variants: for the PCFG model we use a simple A* with a precom-

puted heuristic, while for the the more complex HWDep model, we used a hierarchical A* algorithm (Pauls and Klein, 2009a; Felzenszwalb and McAllester, 2007) based on a simple grammar projection that we designed.

4.1 Hardware-Independent Results: PCFG

For the PCFG model, we compared three agenda-based parsers: EXH prioritizes edges by their span length, thereby simulating the exhaustive CKY algorithm; NULL prioritizes edges by their inside probability; and SX is an A* parser that prioritizes edges by their inside probability times an admissible outside probability estimate.[8] We use the SX estimate devised by Klein and Manning (2003) for CFG parsing, where they found it offered very good performance for relatively little computation. It gives a bound on the outside probability of a nonterminal P with i words to the right and j words to the left, and can be computed from a grammar using a simple dynamic program.

The parsers are tested with and without adaptive supertagging where the former can be seen as performing exact search (via A*) over the pruned search space created by AST.

Table 7 shows that A* with the SX heuristic decreases the number of edges pushed by up to 39% on the unpruned search space. Although encouraging, this is not as impressive as the 95% speedup obtained by Klein and Manning (2003) with this heuristic on their CFG. On the other hand, the NULL heuristic works better for CCG than for CFG, with speedups of 29% and 11%, respectively. These results carry over to the AST setting which shows that A* can improve search even on the highly pruned search graph. Note that A* only saves work in the final iteration of AST, since for earlier iterations it must process the entire agenda to determine that there is no spanning analysis.

Since there are many more categories in the CCG grammar we might have expected the SX heuristic to work better than for a CFG. Why doesn't it? We can measure how well a heuristic bounds the true cost in terms of *slack*: the difference between the true and estimated outside cost. Lower slack means that the heuristic bounds the true cost better and guides us to the exact solution more quickly. Figure 3 plots the average slack for the SX heuristic against the number of words in the outside context. Comparing this with an analysis of the same heuristic when applied to a CFG by Klein and Manning (2003), we find that it is less effective in our setting[9]. There is a steep increase in slack for outside contexts with size more than one. The main reason for this is because a single word in the outside context is in many cases the full stop at the end of the sentence, which is very predictable. However for longer spans the flexibility of CCG to analyze spans in many different ways means that the outside estimate for a nonterminal can be based on many high probability outside derivations which do not bound the true probability very well.

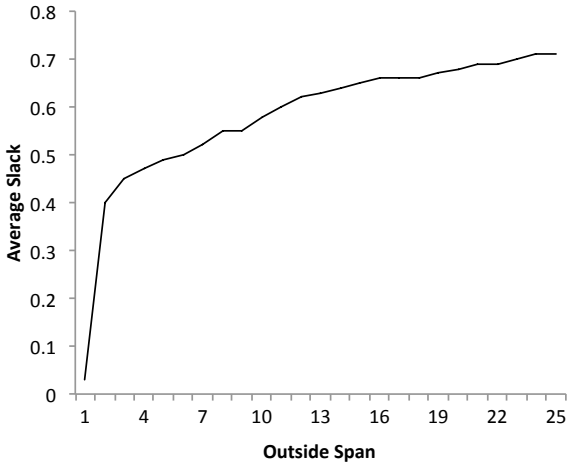

Figure 3: Average slack of the SX heuristic. The figure aggregates the ratio of the difference between the estimated outside cost and true outside costs relative to the true cost across the development set.

4.2 Hardware-Independent Results: HWDep

Lexicalization in the HWDep model makes the precomputed SX estimate impractical, so for this model we designed two hierarchical A* (HA*) variants based on simple grammar projections of the model. The basic idea of HA* is to compute Viterbi inside probabilities using the easier-to-parse projected

[8] The NULL parser is a special case of A*, also called uniform cost search, which in the case of parsing corresponds to Knuth's algorithm (Knuth, 1977; Klein and Manning, 2001), the extension of Dijkstra's algorithm to hypergraphs.

[9] Specifically, we refer to Figure 9 of their paper which uses a slightly different representation of estimate sharpness

Parser	Edges pushed				Edges popped				Traversals			
	Std	%	AST	%	Std	%	AST	%	Std	%	AST	%
EXH	34	100	6.3	100	15.7	100	4.2	100	133.4	100	13.3	100
NULL	24.3	71	4.9	78	13.5	86	3.5	83	113.8	85	11.1	83
SX	**20.9**	**61**	**4.3**	**68**	**10.0**	**64**	**2.6**	**62**	**96.5**	**72**	**9.7**	**73**

Table 7: Exhaustive search (EXH), A* with no heuristic (NULL) and with the SX heuristic in terms of millions of edges pushed, popped and traversals computed using the PCFG grammar with and without adaptive supertagging.

grammar, use these to compute Viterbi outside probabilities for the simple grammar, and then use these as outside estimates for the true grammar; all computations are prioritized in a single agenda following the algorithm of Felzenszwalb and McAllester (2007) and Pauls and Klein (2009a). We designed two simple grammar projections, each simplifying the HWDep model: PCFGProj completely removes lexicalization and projects the grammar to a PCFG, while as LexcatProj removes only the headwords but retains the lexical categories.

Figure 4 compares exhaustive search, A* with no heuristic (NULL), and HA*. For HA*, parsing effort is broken down into the different edge types computed at each stage: We distinguish between the work carried out to compute the inside and outside edges of the projection, where the latter represent the heuristic estimates, and finally, the work to compute the edges of the target grammar. We find that A* NULL saves about 44% of edges pushed which makes it slightly more effective than for the PCFG model. However, the effort to compute the grammar projections outweighs their benefit. We suspect that this is due to the large difference between the target grammar and the projection: The PCFG projection is a simple grammar and so we improve the probability of a traversal less often than in the target grammar.

The Lexcat projection performs worst, for two reasons. First, the projection requires about as much work to compute as the target grammar without a heuristic (NULL). Second, the projection itself does not save a large amount of work as can be seen in the statistics for the target grammar.

5 CPU Timing Experiments

Hardware-independent metrics are useful for understanding agenda-based algorithms, but what we actually care about is CPU time. We were not aware of any past work that measures A* parsers in terms of CPU time, but as this is the real objective we feel that experiments of this type are important. This is especially true in real implementations because the savings in edges processed by an agenda parser come at a cost: operations on the priority queue data structure can add significant runtime.

Timing experiments of this type are very implementation-dependent, so we took care to implement the algorithms as cleanly as possible and to reuse as much of the existing parser code as we could. An important implementation decision for agenda-based algorithms is the data structure used to implement the priority queue. Preliminary experiments showed that a Fibonacci heap implementation outperformed several alternatives: Brodal queues (Brodal, 1996), binary heaps, binomial heaps, and pairing heaps.[10]

We carried out timing experiments on the best A* parsers for each model (SX and NULL for PCFG and HWDep, respectively), comparing them with our CKY implementation and the agenda-based CKY simulation EXH; we used the same data as in §3.2. Table 8 presents the cumulative running times with and without adaptive supertagging average over ten runs, while Table 9 reports F-scores.

The results (Table 8) are striking. Although the timing results of the agenda-based parsers track the hardware-independent metrics, they start at a significant disadvantage to exhaustive CKY with a simple control loop. This is most evident when looking at the timing results for EXH, which in the case of the full PCFG model requires more than twice the time than the CKY algorithm that it simulates. A*

[10] We used the Fibonacci heap implementation at http://www.jgrapht.org

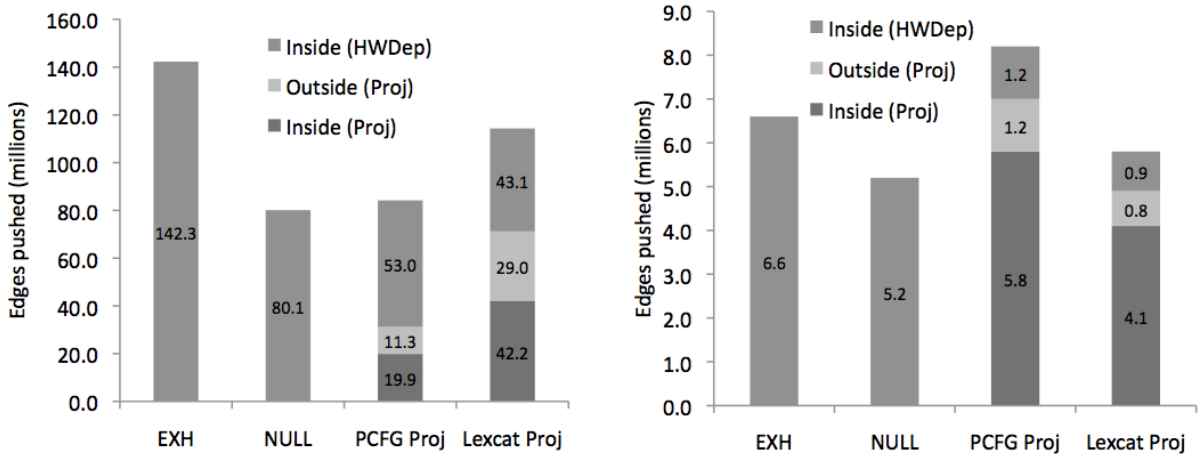

Figure 4: Comparsion between a CKY simulation (EXH), A* with no heuristic (NULL), hierarchical A* (HA*) using two grammar projections for standard search (left) and AST (right). The breakdown of the inside/outside edges for the grammar projection as well as the target grammar shows that the projections, serving as the heuristic estimates for the target grammar, are costly to compute.

	Standard		AST	
	PCFG	HWDep	PCFG	HWDep
CKY	536	24489	34	143
EXH	1251	26889	41	155
A* NULL	1032	21830	36	121
A* SX	889	-	34	-

Table 8: Parsing time in seconds of CKY and agenda-based parsers with and without adaptive supertagging.

	Standard		AST	
	PCFG	HWDep	PCFG	HWDep
CKY	80.4	85.5	81.7	83.8
EXH	79.4	85.5	80.3	83.8
A* NULL	79.6	85.5	80.7	83.8
A* SX	79.4	-	80.4	-

Table 9: Labelled F-score of exact CKY and agenda-based parsers with/without adaptive supertagging. All parses have the same probabilities, thus variances are due to implementation-dependent differences in tiebreaking.

makes modest CPU-time improvements in parsing the full space of the HWDep model. Although this decreases the time required to obtain the highest accuracy, it is still a substantial tradeoff in speed compared with AST.

On the other hand, the AST tradeoff improves significantly: by combining AST with A* we observe a decrease in running time of 15% for the A* NULL parser of the HWDep model over CKY. As the CKY baseline with AST is very strong, this result shows that A* holds real promise for CCG parsing.

6 Conclusion and Future Work

Adaptive supertagging is a strong technique for efficient CCG parsing. Our analysis confirms tremendous speedups, and shows that for weak models, it can even result in improved accuracy. However, for better models, the efficiency gains of adaptive supertagging come at the cost of accuracy. One way to look at this is that the supertagger has good precision with respect to the parser's search space, but low recall. For instance, we might combine both parsing and supertagging models in a principled way to exploit these observations, eg. by making the supertagger output a soft constraint on the parser rather than a hard constraint. Principled, efficient search algorithms will be crucial to such an approach.

To our knowledge, we are the first to measure A* parsing speed both in terms of running time and commonly used hardware-independent metrics. It is clear from our results that the gains from A* do not come as easily for CCG as for CFG, and that agenda-based algorithms like A* must make very large reductions in the number of edges processed to result in realtime savings, due to the added expense of keeping a priority queue. However, we

have shown that A* can yield real improvements even over the highly optimized technique of adaptive supertagging: in this pruned search space, a 44% reduction in the number of edges pushed results in a 15% speedup in CPU time. Furthermore, just as A* can be combined with adaptive supertagging, it should also combine easily with other search-space pruning methods, such as those of Djordjevic et al. (2007), Kummerfeld et al. (2010), Zhang et al. (2010) and Roark and Hollingshead (2009). In future work we plan to examine better A* heuristics for CCG, and to look at principled approaches to combine the strengths of A*, adaptive supertagging, and other techniques to the best advantage.

Abstract

We explore the contribution of morphological features – both lexical and inflectional – to dependency parsing of Arabic, a morphologically rich language. Using controlled experiments, we find that definiteness, person, number, gender, and the undiacritzed lemma are most helpful for parsing on automatically tagged input. We further contrast the contribution of form-based and functional features, and show that functional gender and number (e.g., "broken plurals") and the related rationality feature improve over form-based features. It is the first time functional morphological features are used for Arabic NLP.

1 Introduction

Parsers need to learn the syntax of the modeled language in order to project structure on newly seen sentences. Parsing model design aims to come up with features that best help parsers to learn the syntax and choose among different parses. One aspect of syntax, which is often not explicitly modeled in parsing, involves morphological constraints on syntactic structure, such as agreement, which often plays an important role in morphologically rich languages. In this paper, we explore the role of morphological features in parsing Modern Standard Arabic (MSA). For MSA, the space of possible morphological features is fairly large. We determine which morphological features help and why. We also explore going beyond the easily detectable, regular form-based ("surface") features, by representing *functional* values for some morphological features. We expect that representing lexical abstractions and inflectional features participating in agreement relations would help parsing quality, but other inflectional features would not help. We further expect functional features to be superior to surface-only features.

The paper is structured as follows. We first present the corpus we use (Section 2), then relevant Arabic linguistic facts (Section 3); we survey related work (Section 4), describe our experiments (Section 5), and conclude with an analysis of parsing error types (Section 6).

2 Corpus

We use the Columbia Arabic Treebank (CATiB) (Habash and Roth, 2009). Specifically, we use the portion converted automatically from part 3 of the Penn Arabic Treebank (PATB) (Maamouri et al., 2004) to the CATiB format, which enriches the CATiB dependency trees with full PATB morphological information. CATiB's dependency representation is based on traditional Arabic grammar and emphasizes syntactic case relations. It has a reduced POS tagset (with six tags only – henceforth CATIB6), but a standard set of eight dependency relations: **SBJ** and **OBJ** for subject and (direct or indirect) object, respectively, (whether they appear pre- or post-verbally); **IDF** for the idafa (possessive) relation; **MOD** for most other modifications; and other less common relations that we will not discuss here. For more information, see Habash et al. (2009). The CATiB treebank uses the word segmentation of the PATB: it splits off several categories of orthographic clitics, but not the definite article ال *Al*. In all of the experiments reported in this paper, we use the gold

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1586–1596,
Portland, Oregon, June 19-24, 2011.

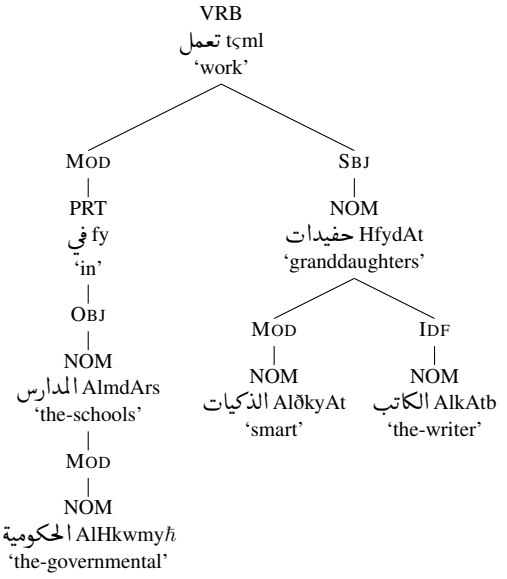

Figure 1: CATiB Annotation example (tree display from right to left). تعمل حفيدات الكاتب الذكيات في المدارس الحكومية *tçml HfydAt AlkAtb AlðkyAt fy AlmdArs AlHkwmyħ* 'The writer's smart granddaughters work for public schools.'

segmentation. An example CATiB dependency tree is shown in Figure 1.

3 Relevant Linguistic Concepts

In this section, we present the linguistic concepts relevant to our discussion of Arabic parsing.

Orthography The Arabic script uses optional diacritics to represent short vowels, consonantal doubling and the indefininteness morpheme (*nunation*). For example, the word كَتَبَ *kataba* 'he wrote' is often written as كتب *ktb*, which can be ambiguous with other words such as كُتُبٌ *kutubũ* 'books'. In news text, only around 1.6% of all words have any diacritic (Habash, 2010). As expected, the lack of diacritics contributes heavily to Arabic's morphological ambiguity. In this work, we only use undiacritized text; however, some of our parsing features which are derived through morphological disambiguation include diacritics (specifically, *lemmas*, see below).

Morphemes Words can be described in terms of their morphemes; in Arabic, in addition to concatenative prefixes and suffixes, there are templatic morphemes called *root* and *pattern*. For example, the word يكاتبون *yu+kAtib+uwn* 'they correspond' has one prefix and one suffix, in addition to a stem composed of the root كتب *k-t-b* 'writing related' and the pattern *1A2i3*.[1]

Lexeme and features Alternatively, Arabic words can be described in terms of lexemes and inflectional features. The set of word forms that only vary inflectionally among each other is called the *lexeme*. A *lemma* is a specific word form chosen to represent the lexeme word set; for example, Arabic verb lemmas are third person masculine singular perfective. We explore using both the diacritized lemma and the undiacritized lemma (hereafter LMM). Just as the lemma abstracts over inflectional morphology, the *root* abstracts over both inflectional and derivational morphology and thus provides a deeper level of lexical abstraction, indicating the "core" meaning of the word. The *pattern* is a generally complementary abstraction sometimes indicating sematic notions such causation and reflexiveness. We use the pattern of the lemma, not of the word form. We group the ROOT, PATTERN, LEMMA and LMM in our discussion as *lexical features*. Nominal lexemes can also be classified into two groups: rational (i.e., human) or irrational (i.e.,, non-human).[2] The rationality feature interacts with syntactic agreement and other inflectional features (discussed next); as such, we group it with those features in this paper's experiments.

The *inflectional features* define the the space of variations of the word forms associated with a lexeme. PATB-tokenized words vary along nine dimensions: GENDER and NUMBER (for nominals and verbs); PERSON, ASPECT, VOICE and MOOD (for verbs); and CASE, STATE, and the attached definite article proclitic DET (for nominals). Inflectional features abstract away from the specifics of morpheme forms. Some inflectional features affect more than one morpheme in the same word. For example, changing the value of the ASPECT feature in the example above from imperfective to perfective yields the word form كاتبوا *kAtab+uwA* 'they corresponded', which differs in terms of prefix, suffix and pattern.

[1]The digits in the pattern correspond to the positions root radicals are inserted.

[2]Note that rationality ('human-ness' 'عاقل/غير عاقل') is narrower than animacy; its expression is wide-spead in Arabic, but less so English, where it mainly shows in pronouns (*he/she* vs. *it*) and relativizers (*the student who...* vs. *the desk/bird which...*).

Surface vs. functional features Additionally, some inflectional features, specifically gender and number, are expressed using different morphemes in different words (even within the same part-of-speech). There are four *sound* gender-number suffixes in Arabic:[3] $+\phi$ *(null morpheme)* for masculine singular, ة+ $+\hbar$ for feminine singular, ون+ *+wn* for masculine plural and ات+ *+At* for feminine plural. Plurality can be expressed using *sound plural* suffixes or using a pattern change together with *singular* suffixes. A sound plural example is the word pair حفيدة/حفيدات *Hafiyd+aħ/Hafiyd+At* 'granddaughter/granddaughters'. On the other hand, the plural of the inflectionally and morphemically feminine singular word مدرسة *madras+aħ* 'school' is the word مدارس *madAris+*ϕ 'schools', which is feminine and plural inflectionally, but has a masculine singular suffix. This irregular inflection, known as *broken plural*, is similar to the English *mouse/mice*, but is much more common in Arabic (over 50% of plurals in our training data). A similar inconsistency appears in feminine nouns that are not inflected using *sound* gender suffixes, e.g., the feminine form of the masculine singular adjective أزرق *Âzraq+*ϕ 'blue' is زرقاء *zarqA'+*ϕ not أزرقة* **Âzraq+aħ*. To address this inconsistency in the correspondence between inflectional features and morphemes, and inspired by (Smrž, 2007), we distinguish between two types of inflectional features: surface (or form-based)[4] features and functional features.

Most available Arabic NLP tools and resources model morphology using surface inflectional features and do not mark rationality; this includes the PATB (Maamouri et al., 2004), the Buckwalter morphological analyzer (BAMA) (Buckwalter, 2004) and tools using them such as the Morphological Analysis and Disambiguation for Arabic (MADA) system (Habash and Rambow, 2005). The Elixir-FM analyzer (Smrž, 2007) readily provides the functional inflectional number feature, but not full functional gender (only for adjectives and verbs but not for nouns), nor rationality. Most recently, Alkuhlani and Habash (2011) present a version of the PATB (part 3) that is annotated for functional gender, number and rationality features for Arabic. We use this resource in modeling these features in Section 5.5.

Morpho-syntactic interactions Inflectional features and rationality interact with syntax in two ways. In **agreement relations**, two words in a specific syntactic configuration have coordinated values for specific sets of features. MSA has standard (i.e., matching value) agreement for subject-verb pairs on PERSON, GENDER, and NUMBER, and for noun-adjective pairs on NUMBER, GENDER, CASE, and DET. There are three very common cases of exceptional agreement: verbs preceding subjects are always singular, adjectives of irrational plural nouns are always feminine singular, and verbs whose subjects are irrational plural are also always feminine singular. See the example in Figure 1: the adjective, الذكيات *Alðkyat* 'smart', of the feminine plural (and rational) حفيدات *HafiydAt* 'granddaughters' is feminine plural; but the adjective, الحكومية *AlHkwmyħ* 'the-governmental', of the feminine plural (and irrational) مدارس *madAris* 'schools' is feminine singular. These agreement rules always refer to functional morphology categories; they are orthogonal to the morpheme-feature inconsistency discussed above.

MSA exhibits **marking relations** in CASE and STATE marking. Different types of dependents have different CASE, e.g., verbal subjects are always marked NOMINATIVE. CASE and STATE are rarely explicitly manifested in undiacritized MSA. The DET feature plays an important role in distinguishing between the N-N *idafa* (possessive) construction, in which only the last noun may bear the definite article, and the N-A modifier construction, in which both elements generally exhibit agreement in definiteness.

Lexical features do not constrain syntactic structure as inflectional features do. Instead, bilexical dependencies are used to model semantic relations which often are the only way to disambiguate among different possible syntactic structures. Lexical abstraction also reduces data sparseness.

The core POS tagsets Words also have associated part-of-speech (POS) tags, e.g., "verb", which further abstract over morphologically and syntactically similar lexemes. Traditional Arabic grammars often describe a very general three-way distinction into verbs, nominals and particles. In com-

[3] We ignore duals, which are regular in Arabic, and case/state variations in this discussion for simplicity.

[4] Smrž (2007) uses the term *illusory* for surface features.

parison, the tagset of the Buckwalter Morphological Analyzer (Buckwalter, 2004) used in the PATB has a core POS set of 44 tags (before morphological extension). Cross-linguistically, a core set containing around 12 tags is often assumed, including: noun, proper noun, verb, adjective, adverb, preposition, particles, connectives, and punctuation. Henceforth, we reduce CORE44 to such a tagset, and dub it CORE12. The CATIB6 tagset can be viewed as a further reduction, with the exception that CATIB6 contains a passive voice tag; however, this tag constitutes only 0.5% of the tags in the training.

Extended POS tagsets The notion of "POS tagset" in natural language processing usually does *not* refer to a core set. Instead, the Penn English Treebank (PTB) uses a set of 46 tags, including not only the core POS, but also the complete set of morphological features (this tagset is still fairly small since English is morphologically impoverished). In PATB-tokenized MSA, the corresponding type of tagset (core POS extended with a complete description of morphology) would contain upwards of 2,000 tags, many of which are extremely rare (in our training corpus of about 300,000 words, we encounter only 430 of such POS tags with complete morphology). Therefore, researchers have proposed tagsets for MSA whose size is similar to that of the English PTB tagset, as this has proven to be a useful size computationally. These tagsets are hybrids in the sense that they are neither simply the core POS, nor the complete morphologically enriched tagset, but instead they selectively enrich the core POS tagset with only certain morphological features. A full dicussion of how these tagsets affect parsing is presented in Marton et al. (2010); we summarize the main points here.

The following are the various tagsets we use in this paper: **(a)** the core POS tagset CORE12; **(b)** the CATiB treebank tagset CATIBEX, a newly introduced extension of CATIB6 (Habash and Roth, 2009) by simple regular expressions of the word form, indicating particular morphemes such as the prefix ال *Al+* or the suffix ون *+wn*; this tagset is the best-performing tagset for Arabic on predicted values. **(c)** the PATB full tagset (BW), size ≈2000+ (Buckwalter, 2004); We only discuss here the best performing tagsets (on predicted values), and BW for comparison.

4 Related Work

Much work has been done on the use of morphological features for parsing of morphologically rich languages. Collins et al. (1999) report that an optimal tagset for parsing Czech consists of a basic POS tag plus a CASE feature (when applicable). This tagset (size 58) outperforms the basic Czech POS tagset (size 13) and the complete tagset (size ≈3000+). They also report that the use of gender, number and person features did not yield any improvements. We got similar results for CASE in the gold experimental setting (Marton et al., 2010) but not when using predicted POS tags (POS tagger output). This may be a result of CASE tagging having a lower error rate in Czech (5.0%) (Hajič and Vidová-Hladká, 1998) compared to Arabic (≈14.0%, see Table 2). Similarly, Cowan and Collins (2005) report that the use of a subset of Spanish morphological features (number for adjectives, determiners, nouns, pronouns, and verbs; and mode for verbs) outperforms other combinations. Our approach is comparable to their work in terms of its systematic exploration of the space of morphological features. We also find that the number feature helps for Arabic. Looking at Hebrew, a Semitic language related to Arabic, Tsarfaty and Sima'an (2007) report that extending POS and phrase structure tags with definiteness information helps unlexicalized PCFG parsing.

As for work on Arabic, results have been reported on PATB (Kulick et al., 2006; Diab, 2007; Green and Manning, 2010), the Prague Dependency Treebank (PADT) (Buchholz and Marsi, 2006; Nivre, 2008) and the Columbia Arabic Treebank (CATiB) (Habash and Roth, 2009). Recently, Green and Manning (2010) analyzed the PATB for annotation consistency, and introduced an enhanced split-state constituency grammar, including labels for short *Idafa* constructions and verbal or equational clauses.

Nivre (2008) reports experiments on Arabic parsing using his MaltParser (Nivre et al., 2007), trained on the PADT. His results are not directly comparable to ours because of the different treebanks' representations, even though all the experiments reported here were performed using MaltParser. Our results agree with previous work on Arabic and Hebrew in that marking the definite article is helpful for parsing. However, we go beyond previous work in that

we also extend this morphologically enhanced feature set to include additional lexical and inflectional features. Previous work with MaltParser in Russian, Turkish and Hindi showed gains with case but not with agreement features (Nivre et al., 2008; Eryigit et al., 2008; Nivre, 2009). Our work is the first using MaltParser to show gains using agreement-oriented features (Marton et al., 2010), and the first to use functional features for this task (this paper).

5 Experiments

Throughout this section, we only report results using *predicted* input feature values (e.g., generated automatically by a POS tagger). After presenting the parser we use (Section 5.1), we examine a large space of settings in the following order: the contribution of numerous inflectional features in a controlled fashion (Section 5.2);[5] the contribution of the lexical features in a similar fashion, as well as the combination of lexical and inflectional features (Section 5.3); an extension of the DET feature (Section 5.4); using functional NUMBER and GENDER feature values, as well as the RATIONALITY feature (Section 5.5); finally, putting best feature combinations to test with the best-performing POS tagset, and on an unseen test set (Section 5.6). All results are reported mainly in terms of labeled attachment accuracy score (parent word and the dependency relation to it, a.k.a. LAS). Unlabeled attachment accuracy score (UAS) is also given. We use McNemar's statistical significance test as implemented by Nilsson and Nivre (2008), and denote $p < 0.05$ and $p < 0.01$ with $^{+}$ and $^{++}$, respectively.

5.1 Parser

For all experiments reported here we used the syntactic dependency parser MaltParser v1.3 (Nivre, 2003; Nivre, 2008; Kübler et al., 2009) – a transition-based parser with an input buffer and a stack, using SVM classifiers to predict the next state in the parse derivation. All experiments were done using the Nivre "eager" algorithm.[6] For training, development and testing, we follow the splits used by Roth et al. (2008) for PATB part 3 (Maamouri et al., 2004). We kept the test unseen during training.

There are five default *attributes*, in the MaltParser terminology, for each token in the text: word ID (ordinal position in the sentence), word form, POS tag, head (parent word ID), and deprel (the dependency relation between the current word and its parent). There are default *MaltParser features* (in the machine learning sense),[7] which are the values of functions over these attributes, serving as input to the MaltParser internal classifiers. The most commonly used feature functions are the top of the input buffer (next word to process, denoted buf[0]), or top of the stack (denoted stk[0]); following items on buffer or stack are also accessible (buf[1], buf[2], stk[1], etc.). Hence MaltParser features are defined as POS tag at stk[0], word form at buf[0], etc. Kübler et al. (2009) describe a "typical" MaltParser model configuration of attributes and features.[8] Starting with it, in a series of initial controlled experiments, we settled on using buf[0-1] + stk[0-1] for wordforms, and buf[0-3] + stk[0-2] for POS tags. For features of new MaltParser-attributes (discussed later), we used buf[0] + stk[0]. We did not change the features for deprel. This new MaltParser configuration resulted in gains of 0.3-1.1% in labeled attachment accuracy (depending on the POS tagset) over the default MaltParser configuration.[9] All experiments reported below were conducted using this new configuration.

5.2 Inflectional features

In order to explore the contribution of inflectional and lexical information in a controlled manner, we focused on the best performing core ("morphology-free") POS tagset, CORE12, as baseline; using three

[5] In this paper, we do not examine the contribution of different POS tagsets, see Marton et al. (2010) for details.

[6] Nivre (2008) reports that non-projective and pseudo-projective algorithms outperform the "eager" projective algorithm in MaltParser, but our training data did not contain any non-projective dependencies. The Nivre "standard" algorithm is also reported to do better on Arabic, but in a preliminary experimentation, it did similarly or slightly worse than the "eager" one, perhaps due to high percentage of right branching (left headed structures) in our Arabic training set – an observation already noted in Nivre (2008).

[7] The terms "feature" and "attribute" are overloaded in the literature. We use them in the linguistic sense, unless specifically noted otherwise, e.g., "MaltParser feature(s)".

[8] It is slightly different from the default configuration.

[9] We also experimented with normalizing word forms (*Alif Maqsura* conversion to *Ya*, and *hamza* removal from *Alif* forms) as is common in parsing and statistical machine translation literature – but it resulted in a similar or slightly decreased performance, so we settled on using non-normalized word forms.

different setups, we added nine morphological features with values predicted by MADA: DET (presence of the definite determiner), PERSON, ASPECT, VOICE, MOOD, GENDER, NUMBER, STATE (morphological marking as head of an *idafa* construction), and CASE. In setup ***All***, we augmented the baseline model with all nine MADA features (as nine additional MaltParser attributes); in setup ***Sep***, we augmented the baseline model with the MADA features, one at a time; and in setup ***Greedy***, we combined them in a greedy heuristic (since the entire feature space is too vast to exhaust): starting with the most gainful feature from *Sep*, adding the next most gainful feature, keeping it if it helped, or discarding it otherwise, and continuing through the least gainful feature. See Table 1.

Somewhat surprisingly, setup *All* hurts performance. This can be explained if one examines the prediction accuracy of each feature (top of Table 2). Features which are not predicted with very high accuracy, such as CASE (86.3%), can dominate the negative contribution, even though they are top contributors when provided as gold input (Marton et al., 2010); when all features are provided as gold input, *All* actually does better than individual features, which puts to rest a concern that its decrease here

is due to data sparseness. Here, when features are predicted, the DET feature (determiner), followed by the STATE (construct state, *idafa*) feature, are top individual contributors in setup *Sep*. Adding DET and the so-called ϕ-features (PERSON, NUMBER, GENDER, also shorthanded PNG) in the *Greedy* setup, yields 1.43% gain over the CORE12 baseline.

5.3 Lexical features

Next, we experimented with adding the lexical features, which involve semantic abstraction to some degree: LEMMA, LMM (the undiacritized lemma), and ROOT. We experimented with the same setups as above: *All*, *Sep*, and *Greedy*. Adding all four features yielded a minor gain in setup *All*. LMM was the best single contributor, closely followed by ROOT in *Sep*. CORE12+LMM+ROOT (with or with-

out LEMMA) was the best greedy combination in setup *Greedy*. See Table 3. All lexical features are predicted with high accuracy (bottom of Table 2).

Following the same greedy heuristic, we augmented the best inflection-based model CORE12+DET+PNG with lexical features, and found that only the undiacritized lemma (LMM) alone improved performance (80.23%). See Table 4.

5.4 Inflectional feature engineering

So far we experimented with morphological feature values as predicted by MADA. However, it is likely that from a machine-learning perspective, representing similar categories with the same tag may be useful for learning. Therefore, we next experimented with modifying inflectional features that proved most useful.

As DET may help distinguish the N-N *idafa* construction from the N-A modifier construction, we attempted modeling also the DET values of previous and next elements (as MaltParser's stk[1] + buf[1], in addition to stk[0] + buf[0]). This variant, denoted DET2, indeed helps: when added to the CORE12, DET2 improves non-gold parsing quality by more than 0.3%, compared to DET (Table 5). This improvement unfortunately does not carry over to our best feature combination to date, CORE12+DET+PNG+LMM. However, in subsequent feature combinations, we see that DET2 helps again, or at least, doesn't hurt: LAS goes up by 0.06% in conjunction with features LMM+PERSON +FN*NGR in Table 6.

CORE12 + ...	LAS	LAS_{diff}	UAS

+DET2+LMM +PERSON+FN*NGR	**74.40**$^{++}$	1.76	79.40

Table 6: Functional features: gender, number, rationality.

We also experimented with PERSON. We changed the values of proper names from "N/A" to "3" (third person), but it resulted in a similar or slightly decreased performance, so it was abandoned.

5.5 Functional feature values

The NUMBER and GENDER features we have used so far only reflect *surface* (as opposed to *functional*) values, e.g., broken plurals are marked as singular. This might have a negative effect on learning generalizations over the complex agreement patterns in MSA (see Section 3), beyond memorization of word pairs seen together in training.

Predicting functional features To predict functional GENDER, functional NUMBER and RATIONALITY, we build a simple maximum likelihood estimate (MLE) model using these annotations in the corpus created by Alkuhlani and Habash (2011). We train using the same training data we use throughout this paper. For all three features, we select the most seen value in training associated with the triple *word*-CATIBEX-*lemma*; we back off to CATIBEX-*lemma* and then to *lemma*. For gender and number, we further back off to the surface values; for rationality, we back off to the most common value (*irrational*). On our predicted dev set, the overall accuracy baseline of predicting correct functional *gender-number-rationality* using surface features is

85.1% (for all POS tags). Our MLE model reduces the error by two thirds reaching an overall accuracy of 95.5%. The high accuracy may be a result of the low percentage of words in the dev set that do not appear in training (around 4.6%).

Digit tokens (e.g., "4") are also marked singular by default. They don't show surface agreement, even though the corresponding number-word token (*Arbς ħ* 'four.fem.sing') would. We further observe that MSA displays complex agreement patterns with numbers (Dada, 2007). Therefore, we alternatively experimented with binning the digit tokens' NUMBER value accordingly:

- the number 0 and numbers ending with 00
- the number 1 and numbers ending with 01
- the number 2 and numbers ending with 02
- the numbers 3-10 and those ending with 03-10
- the numbers, and numbers ending with, 11-99
- all other number tokens (e.g., 0.35 or 7/16)

and denoted these experiments with NUMDGTBIN. Almost 1.5% of the tokens are digit tokens in the training set, and 1.2% in the dev set.[10]

Results using these new features are shown in Table 6. The first part repeats the CORE12 baseline. The second part repeats previous experiments with surface morphological features. The third part uses the new functional morphological features instead. The performance using NUMBER and GENDER increases by 0.21% and 0.22%, respectively, as we replace surface features with functional features. (Recall that there is no functional PERSON.) We then see that the change in the representation of digits does not help; in the large space of experiments we have performed, we saw some improvement through the use of this alternative representation, but not in any of the feature combinations that performed best and that we report on in this paper. We then use just the RATIONALITY feature, which results in an increase over the baseline. The combination of all three functional features (NUMBER, GENDER, RATIONALITY) provides for a nice cumulative effect. Adding PERSON hardly improves further.

In the fourth part of the table, we include the other features which we found previously to be helpful, namely DET and LMM. Here, using DET2 instead of DET (see Section 5.4) gives us a slight improvement, providing our best result using the CORE12 POS tagset: 80.53%. This is a 1.85% improvement over using only the CORE12 POS tags (an 8.7% error reduction); of this improvement, 0.3% absolute (35% relative) is due to the use of functional features. We then use the best configuration, but without the RATIONALITY feature; we see that this feature on its own contributes 0.1% absolute, confirming its place in Arabic syntax. In gold experiments which we do not report here, the contribution was even higher (0.6-0.7%). The last row in the fourth part of Table 6 shows that using both surface and functional variants of NUMBER and GENDER does not help (hurts, in fact); the functional morphology features carry sufficient information for syntactic disambiguation.

The last part of the table revalidates the gains achieved of the best feature combination using the two other POS tagsets mentioned in Section 3: CATIBEX (the best performing tagset with predicted values), and BW (the best POS tagset with gold values in Marton et al. (2010), but results shown here are with predicted values). The CATIBEX result of 80.83% is our overall best result. The result using BW reconfirms that BW is not the best tagset to use for parsing Arabic with current prediction ability.

5.6 Validating results on unseen test set

Once experiments on the development set were done, we ran the best performing models on the previously unseen test set (Section 5.1). Table 7 shows that the same trends hold on this set as well.

Model	LAS	LAS_{diff}	UAS
CATIBEX	78.46	—	81.81
+DET2+LMM+PER+FN*NGR	**79.45**$^{++}$	**0.99**	**82.56**

Table 7: Results on unseen test set for models which performed best on dev set – predicted input.

6 Error Analysis

We analyze the attachment accuracy by attachment type. We show the accuracy for selected attachment types in Table 8. Using just CORE12, we see that some attachments (subject, modifications) are harder than others (objects, idafa). We see that by

[10] We didn't mark the number-words since in our training data there were less than 30 lemmas of less than 2000 such tokens, so presumably their agreement patterns can be more easily learned.

Features	SBJ	OBJ	MN	MP	IDF	Tot.
CORE12	67.9	90.4	72.0	70.3	94.5	78.7
CORE12 + LMM	68.8	90.4	72.6	70.9	94.6	79.0
CORE12 + DET2 +LMM+PNG	71.7	91.0	74.9	72.4	95.5	80.2
CORE12 + DET2 +LMM+PERS +FN*NGR	72.3	91.0	76.0	73.3	95.4	80.5

Table 8: Error analysis: Accuracy by attachment type (selected): subject, object, modification by a noun, modification (of a verb or a noun) by a preposition, idafa, and overall results (which match previously shown results)

adding LMM, all attachment types improve a little bit; this is as expected, since this feature provides a slight lexical abstraction. We then add features designed to improve idafa and those relations subject to agreement, subject and nominal modification (DET2, PERSON, NUMBER, GENDER). We see that as expected, subject, nominal modification (MN), and idafa reduce error by substantial margins (error reduction over CORE12+LMM greater than 8%, in the case of idafa the error reduction is 16.7%), while object and prepositional attachment (MP) improve to a lesser degree (error reduction of 6.2% or less). We assume that the relations not subject to agreement (object and prepositional attachment) improve because of the overall improvement in the parse due to the improvements in the other relations.

When we move to the functional features, we again see a reduction in the attachments which are subject to agreement, namely subject and nominal modification (error reductions over surface features of 2.1% and 4.4%, respectively). Idafa decreases slightly (since this relation is not affected by the functional features), while object stays the same. Surprisingly, prepositional attachment also improves, with an error reduction of 3.3%. Again, we can only explain this by proposing that the improvement in nominal modification attachment has the indirect effect of ruling out some bad prepositional attachments as well.

In summary, we see that not only do morphological features – and functional morphology features in particular – improve parsing, but they improve parsing in the way that we expect: those relations subject to agreement improve more than those that are not.

Last, we point out that MaltParser does not model generalized feature checking or matching directly, i.e., it has not learned that certain syntactic relations require identical (functional) morphological feature values. The gains in parsing quality reflect that the MaltParser SVM classifier has learned that the pairing of specific morphological feature values – e.g., *fem.sing.* for both the verb and its subject – is useful, with no generalization from each specific value to other values, or to general pair-wise value matching.

7 Conclusions and Future Work

We explored the contribution of different morphological (inflectional and lexical) features to dependency parsing of Arabic. We find that definiteness (DET), ϕ-features (PERSON, NUMBER, GENDER), and undiacritized lemma (LMM) are most helpful for Arabic dependency parsing on predicted input. We further find that functional morphology features and rationality improve over surface morphological features, as predicted by the complex agreement rules of Arabic. To our knowledge, this is the first result in Arabic NLP that uses functional morphology features, and that shows an improvement over surface features.

In future work, we intend to improve the prediction of functional morphological features in order to improve parsing accuracy. We also intend to investigate how these features can be integrated into other parsing frameworks; we expect them to help independently of the framework. We plan to make our parser available to other researchers. Please contact the authors if interested.

Abstract

Recent work has shown how a parallel corpus can be leveraged to build syntactic parser for a target language by projecting automatic source parse onto the target sentence using word alignments. The projected target dependency parses are not always fully connected to be useful for training traditional dependency parsers. In this paper, we present a greedy non-directional parsing algorithm which doesn't need a fully connected parse and can learn from partial parses by utilizing available structural and syntactic information in them. Our parser achieved statistically significant improvements over a baseline system that trains on only fully connected parses for Bulgarian, Spanish and Hindi. It also gave a significant improvement over previously reported results for Bulgarian and set a benchmark for Hindi.

1 Introduction

Parallel corpora have been used to transfer information from source to target languages for Part-Of-Speech (POS) tagging, word sense disambiguation (Yarowsky et al., 2001), syntactic parsing (Hwa et al., 2005; Ganchev et al., 2009; Jiang and Liu, 2010) and machine translation (Koehn, 2005; Tiedemann, 2002). Analysis on the source sentences was induced onto the target sentence via projections across word aligned parallel corpora.

Equipped with a source language parser and a word alignment tool, parallel data can be used to build an automatic treebank for a target language. The parse trees given by the parser on the source sentences in the parallel data are projected onto the target sentence using the word alignments from the alignment tool. Due to the usage of automatic source parses, automatic word alignments and differences in the annotation schemes of source and target languages, the projected parses are not always fully connected and can have edges missing (Hwa et al., 2005; Ganchev et al., 2009). Non-literal translations and divergences in the syntax of the two languages also lead to incomplete projected parse trees.

Figure 1 shows an English-Hindi parallel sentence with correct source parse, alignments and target dependency parse. For the same sentence, Figure 2 is a sample partial dependency parse projected using an automatic source parser on aligned text. This parse is not fully connected with the words *banaa*, *kottaige* and *dikhataa* left without any parents.

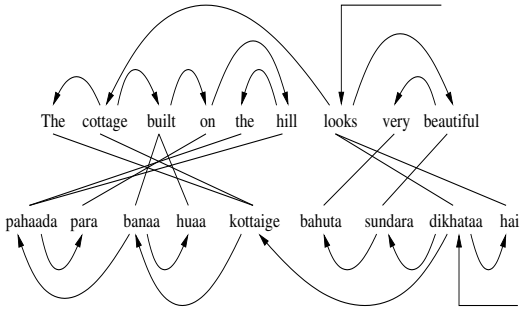

Figure 1: Word alignment with dependency parses for an English-Hindi parallel sentence

To train the traditional dependency parsers (Yamada and Matsumoto, 2003; Eisner, 1996; Nivre, 2003), the dependency parse has to satisfy four constraints: *connectedness*, *single-headedness*, *acyclicity* and *projectivity* (Kuhlmann and Nivre, 2006). Projectivity can be relaxed in some parsers (McDonald et al., 2005; Nivre, 2009). But these parsers can not directly be used to learn from partially connected parses (Hwa et al., 2005; Ganchev et al., 2009).

In the projected Hindi treebank (section 4) that was extracted from English-Hindi parallel text, only 5.9% of the sentences had full trees. In

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1597–1606,
Portland, Oregon, June 19-24, 2011.

Spanish and Bulgarian projected data extracted by Ganchev et al. (2009), the figures are 3.2% and 12.9% respectively. Learning from data with such high proportions of partially connected dependency parses requires special parsing algorithms which are not bound by *connectedness*. Its only during learning that the constraint doesn't satisfy. For a new sentence (i.e. during inference), the parser should output fully connected dependency tree.

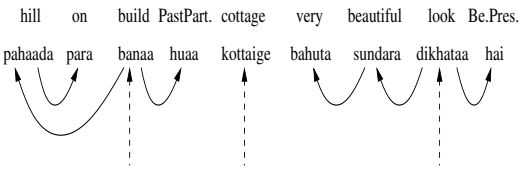

Figure 2: A sample dependency parse with partial parses

In this paper, we present a dependency parsing algorithm which can train on partial projected parses and can take rich syntactic information as features for learning. The parsing algorithm constructs the partial parses in a bottom-up manner by performing a greedy search over all possible relations and choosing the best one at each step without following either left-to-right or right-to-left traversal. The algorithm is inspired by earlier non-directional parsing works of Shen and Joshi (2008) and Goldberg and Elhadad (2010). We also propose an extended partial parsing algorithm that can learn from partial parses whose yields are partially contiguous.

Apart from bitext projections, this work can be extended to other cases where learning from partial structures is required. For example, while bootstrapping parsers high confidence parses are extracted and trained upon (Steedman et al., 2003; Reichart and Rappoport, 2007). In cases where these parses are few, learning from partial parses might be beneficial.

We train our parser on projected Hindi, Bulgarian and Spanish treebanks and show statistically significant improvements in accuracies between training on fully connected trees and learning from partial parses.

2 Related Work

Learning from partial parses has been dealt in different ways in the literature. Hwa et al. (2005) used post-projection completion/transformation rules to get full parse trees from the projections and train Collin's parser (Collins, 1999) on them. Ganchev et al. (2009) handle partial projected parses by avoiding committing to entire projected tree during training. The posterior regularization based framework constrains the projected syntactic relations to hold approximately and only in expectation. Jiang and Liu (2010) refer to alignment matrix and a dynamic programming search algorithm to obtain better projected dependency trees. They deal with partial projections by breaking down the projected parse into a set of edges and training on the set of projected relations rather than on trees.

While Hwa et al. (2005) requires full projected parses to train their parser, Ganchev et al. (2009) and Jiang and Liu (2010) can learn from partially projected trees. However, the discriminative training in (Ganchev et al., 2009) doesn't allow for richer syntactic context and it doesn't learn from all the relations in the partial dependency parse. By treating each relation in the projected dependency data independently as a classification instance for parsing, Jiang and Liu (2010) sacrifice the context of the relations such as global structural context, neighboring relations that are crucial for dependency analysis. Due to this, they report that the parser suffers from local optimization during training.

The parser proposed in this work (section 3) learns from partial trees by using the available structural information in it and also in neighboring partial parses. We evaluated our system (section 5) on Bulgarian and Spanish projected dependency data used in (Ganchev et al., 2009) for comparison. The same could not be carried out for Chinese (which was the language (Jiang and Liu, 2010) worked on) due to the unavailability of projected data used in their work. Comparison with the traditional dependency parsers (McDonald et al., 2005; Yamada and Matsumoto, 2003; Nivre, 2003; Goldberg and Elhadad, 2010) which train on complete dependency parsers is out of the scope of this work.

3 Partial Parsing

A standard dependency graph satisfies four graph constraints: *connectedness*, *single-headedness*, *acyclicity* and *projectivity* (Kuhlmann and Nivre, 2006). In our work, we assume the dependency graph for a sentence only satisfies the single-

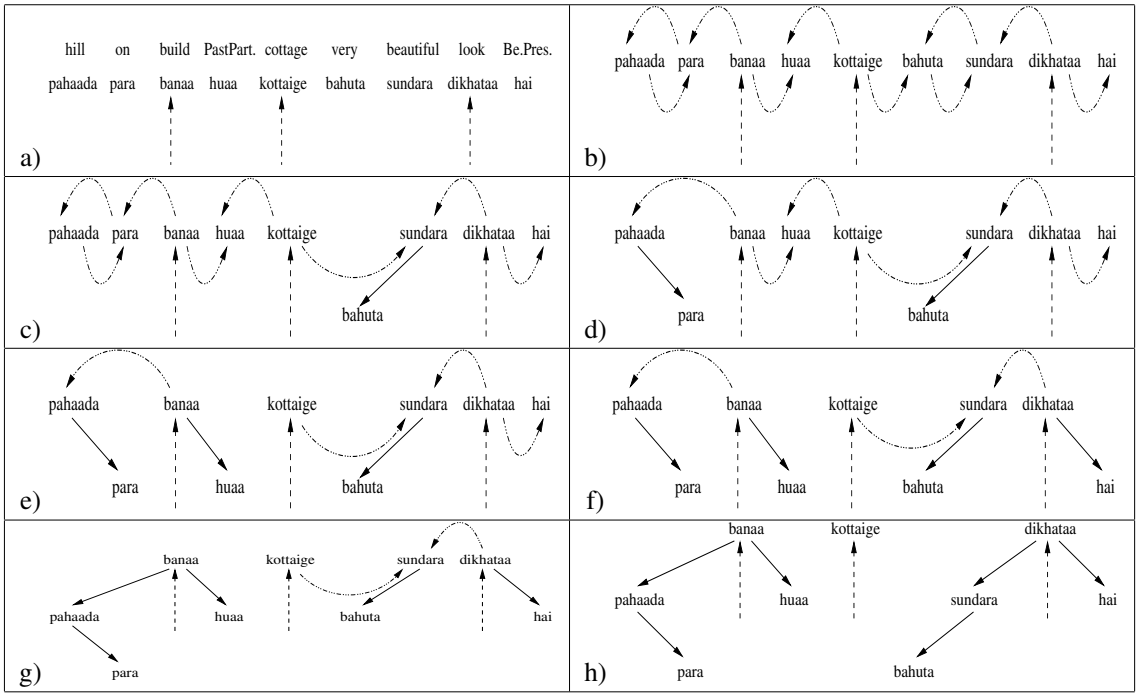

Figure 3: Steps taken by GNPPA. The dashed arcs indicate the unconnected words in *unConn*. The dotted arcs indicate the candidate arcs in *candidateArcs* and the solid arcs are the high scoring arcs that are stored in *builtPPs*

headedness, acyclicity and projectivity constraints while not necessarily being connected i.e. all the words need not have parents.

Given a sentence W=$w_0 \cdots w_n$ with a set of directed arcs A on the words in W, $w_i \rightarrow w_j$ denotes a dependency arc from w_i to w_j, (w_i,w_j) ϵ A. w_i is the parent in the arc and w_j is the child in the arc. $\stackrel{*}{\rightarrow}$ denotes the reflexive and transitive closure of the arc. $w_i \stackrel{*}{\rightarrow} w_j$ says that w_i *dominates* w_j, i.e. there is (possibly empty) path from w_i to w_j.

A node w_i is *unconnected* if it does not have an incoming arc. R is the set of all such unconnected nodes in the dependency graph. For the example in Figure 2, R={`banaa`, `kottaige`, `dikhataa`}. A *partial parse* rooted at node w_i denoted by $\rho(w_i)$ is the set of arcs that can be traversed from node w_i. The *yield* of a partial parse $\rho(w_i)$ is the set of nodes dominated by it. We use $\pi(w_i)$ to refer to the yield of $\rho(w_i)$ arranged in the linear order of their occurrence in the sentence. The *span* of the partial tree is the first and last words in its yield.

The dependency graph D can now be represented in terms of partial parses by $D = (W, R, \varrho(R))$ where W={$w_0 \cdots w_n$} is the sentence, R={$r_1 \cdots r_m$} is the set of unconnected nodes and $\varrho(R)$= {$\rho(r_1) \cdots \rho(r_m)$} is the set of partial parses rooted at these unconnected nodes. w_0 is a dummy word added at the beginning of W to behave as a root of a fully connected parse. A fully connected dependency graph would have only one element w_0 in R and the dependency graph rooted at w_0 as the only (fully connected) parse in $\varrho(R)$.

We assume the combined yield of $\varrho(R)$ spans the entire sentence and each of the partial parses in $\varrho(R)$ to be contiguous and non-overlapping with one another. A partial parse is *contiguous* if its yield is contiguous i.e. if a node $w_j \epsilon \pi(w_i)$, then all the words between w_i and w_j also belong to $\pi(w_i)$. A partial parse $\rho(w_i)$ is *non-overlapping* if the intersection of its yield $\pi(w_i)$ with yields of all other partial parses is empty.

3.1 Greedy Non-directional Partial Parsing Algorithm (GNPPA)

Given the sentence W and the set of unconnected nodes R, the parser follows a non-directional greedy approach to establish relations in a bottom up manner. The parser does a greedy search over all the possible relations and picks the one with

the highest score at each stage. This process is repeated until parents for all the nodes that do not belong to R are chosen.

Algorithm 1 lists the outline of the greedy non-directional partial parsing algorithm (GNPPA). *builtPPs* maintains a list of all the partial parses that have been built. It is initialized in line 1 by considering each word as a separate partial parse with just one node. *candidateArcs* stores all the arcs that are possible at each stage of the parsing process in a bottom up strategy. It is initialized in line 2 using the method *initCandidateArcs(*$w_0 \cdots w_n$*)*. *initCandidateArcs(*$w_0 \cdots w_n$*)* adds two candidate arcs for each pair of consecutive words with each other as parent (see Figure 3b). If an arc has one of the nodes in R as the child, it isn't included in *candidateArcs*.

Algorithm 1 Partial Parsing Algorithm

Input: sentence $w_0 \cdots w_n$ and set of partial tree roots *unConn*=$\{r_1 \cdots r_m\}$
Output: set of partial parses whose roots are in *unConn* (*builtPPs* = $\{\rho(r_1) \cdots \rho(r_m)\}$)

1: *builtPPs* = $\{\rho(r_1) \cdots \rho(r_n)\} \leftarrow \{w_0 \cdots w_n\}$
2: *candidateArcs* = initCandidateArcs($w_0 \cdots w_n$)
3: **while** *candidateArcs*.isNotEmpty() **do**
4: *bestArc* = $\underset{c_i \in candidateArcs}{\text{argmax}}\ score(c_i, \overrightarrow{w})$
5: *builtPPs*.remove(*bestArc*.child)
6: *builtPPs*.remove(*bestArc*.parent)
7: *builtPPs*.add(*bestArc*)
8: updateCandidateArcs(*bestArc*, *candidateArcs*, *builtPPs*, *unConn*)
9: **end while**
10: **return** builtPPs

Once initialized, the candidate arc with the highest score (line 4) is chosen and accepted into *builtPPs*. This involves replacing the best arc's child partial parse ρ(*arc*.child) and parent partial parse ρ(*arc*.parent) over which the arc has been formed with the arc ρ(*arc*.parent) $\rightarrow$ ρ(*arc*.child) itself in *builtPPs* (lines 5-7). In Figure 3f, to accept the best candidate arc ρ(banaa) $\rightarrow$ ρ(pahaada), the parser would remove the nodes ρ(banaa) and ρ(pahaada) in *builtPPs* and add ρ(banaa) $\rightarrow$ ρ(pahaada) to *builtPPs* (see Figure 3g).

After the best arc is accepted, the *candidateArcs* has to be updated (line 8) to remove the arcs that are no longer valid and add new arcs in the context of the updated *builtPPs*. Algorithm 2 shows the update procedure. First, all the arcs that end on the child are removed (lines 3-7) along with the arc from child to parent. Then, the immediately previous and next partial parses of the best arc in *builtPPs* are retrieved (lines 8-9) to add possible candidate arcs between them and the partial parse representing the best arc (lines 10-23). In the example, between Figures 3b and 3c, the arcs ρ(kottaige) $\rightarrow$ ρ(bahuta) and ρ(bahuta) $\rightarrow$ ρ(sundara) are first removed and the arc ρ(kottaige) $\rightarrow$ ρ(sundara) is added to *candidateArcs*. Care is taken to avoid adding arcs that end on unconnected nodes listed in R.

The entire GNPPA parsing process for the example sentence in Figure 2 is shown in Figure 3.

Algorithm 2 updateCandidateArcs(*bestArc*, *candidateArcs*, *builtPPs*, *unConn*)

1: *baChild* = bestArc.child
2: *baParent* = bestArc.parent
3: **for all** *arc* ϵ *candidateArcs* **do**
4: **if** *arc*.child = *baChild* or (*arc*.parent = *baChild* and *arc*.child = *baParent*) **then**
5: remove *arc*
6: **end if**
7: **end for**
8: *prevPP* = *builtPPs*.previousPP(*bestArc*)
9: *nextPP* = *builtPPs*.nextPP(*bestArc*)
10: **if** *bestArc*.direction == *LEFT* **then**
11: *newArc1* = new Arc(*prevPP*,*baParent*)
12: *newArc2* = new Arc(*baParent*,*prevPP*)
13: **end if**
14: **if** *bestArc*.direction == *RIGHT* **then**
15: *newArc1* = new Arc(*nextPP*,*baParent*)
16: *newArc2* = new Arc(*baParent*,*nextPP*)
17: **end if**
18: **if** *newArc1*.parent $\notin$ *unConn* **then**
19: *candidateArcs*.add(*newArc1*)
20: **end if**
21: **if** newArc2.parent $\notin$ unConn **then**
22: *candidateArcs*.add(*newArc2*)
23: **end if**
24: **return** *candidateArcs*

3.2 Learning

The algorithm described in the previous section uses a weight vector $\overrightarrow{w}$ to compute the best arc from the list of candidate arcs. This weight vector is learned using a simple Perceptron like algorithm similar to the one used in (Shen and Joshi, 2008). Algorithm 3 lists the learning framework for GNPPA.

For a training sample with sentence $w_0 \cdots w_n$, projected partial parses *projectedPPs*=$\{\rho(r_i) \cdots \rho(r_m)\}$, unconnected words *unConn* and weight vector $\overrightarrow{w}$, the *builtPPs* and *candidateArcs* are initiated as in algorithm 1. Then the arc with the highest score is selected. If this arc belongs to the parses in *projectedPPs*, *builtPPs* and *candidateArcs* are updated similar to the operations in

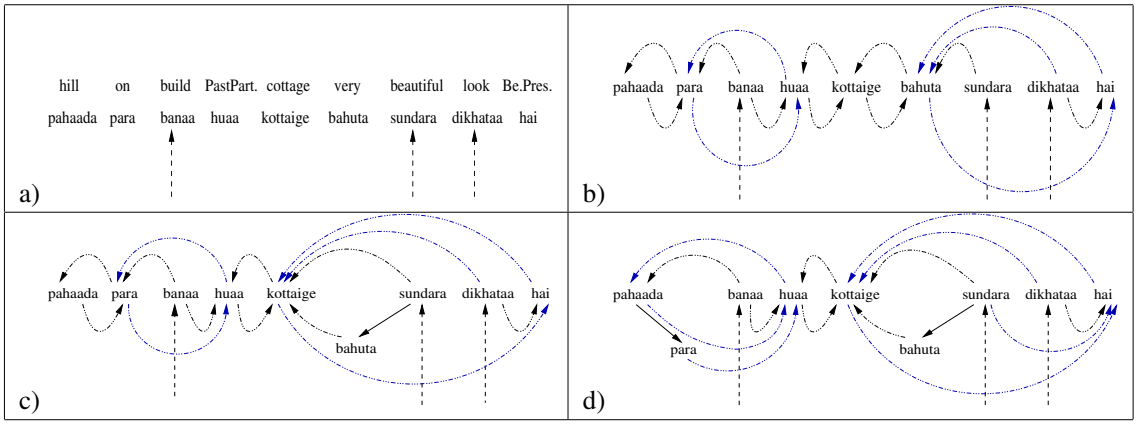

Figure 4: First four steps taken by E-GNPPA. The blue colored dotted arcs are the additional candidate arcs that are added to *candidateArcs*

algorithm 1. If it doesn't, it is treated as a negative sample and a corresponding positive candidate arc which is present both *projectedPPs* and *candidateArcs* is selected (lines 11-12).

The weights of the positive candidate arc are increased while that of the negative sample (best arc) are decreased. To reduce over fitting, we use averaged weights (Collins, 2002) in algorithm 1.

Algorithm 3 Learning for Non-directional Greedy Partial Parsing Algorithm

Input: sentence $w_0 \cdots w_n$, projected partial parses *projectedPPs*, unconnected words *unConn*, current $\overrightarrow{w}$
Output: updated $\overrightarrow{w}$
1: *builtPPs* = $\{\rho(r_1) \cdots \rho(r_n)\} \leftarrow \{w_0 \cdots w_n\}$
2: *candidateArcs* = initCandidateArcs($w_0 \cdots w_n$)
3: **while** *candidateArcs*.isNotEmpty() **do**
4: *bestArc* = $\underset{c_i \in candidateArcs}{\text{argmax}}\ score(c_i, \overrightarrow{w})$
5: **if** *bestArc* $\in$ *projectedPPs* **then**
6: *builtPPs*.remove(*bestArc*.child)
7: *builtPPs*.remove(*bestArc*.parent)
8: *builtPPs*.add(*bestArc*)
9: updateCandidateArcs(*bestArc*, *candidateArcs*, *builtPPs*, *unConn*)
10: **else**
11: allowedArcs = $\{c_i \mid c_i \in$ *candidateArcs* && $c_i \in$ *projectedArcs*$\}$
12: *compatArc* = $\underset{c_i \in allowedArcs}{\text{argmax}}\ score(c_i, \overrightarrow{w})$
13: promote(*compatArc*, $\overrightarrow{w}$)
14: demote(*bestArc*, $\overrightarrow{w}$)
15: **end if**
16: **end while**
17: **return** builtPPs

3.3 Extended GNPPA (E-GNPPA)

The GNPPA described in section 3.1 assumes that the partial parses are contiguous. The example in Figure 5 has a partial tree ρ(dikhataa) which isn't contiguous. Its yield doesn't contain bahuta and sundara. We call such *non-contiguous* partial parses whose yields encompass the yield of an other partial parse as *partially contiguous*. Partially contiguous parses are common in the projected data and would not be parsable by the algorithm 1 (ρ(dikhataa) $\rightarrow$ ρ(kottaige) would not be identified).

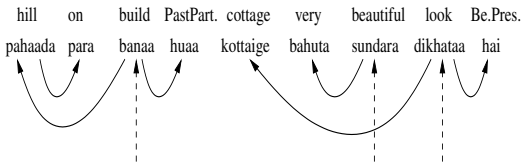

Figure 5: Dependency parse with a partially contiguous partial parse

In order to identify and learn from relations which are part of partially contiguous partial parses, we propose an extension to GNPPA. The extended GNPAA (E-GNPPA) broadens its scope while searching for possible candidate arcs given R and *builtPPs*. If the immediate previous or the next partial parses over which arcs are to be formed are designated unconnected nodes, the parser looks further for a partial parse over which it can form arcs. For example, in Figure 4b, the arc ρ(para) $\rightarrow$ ρ(banaa) can not be added to the *candidateArcs* since banaa is a designated unconnected node in $unConn$. The E-GNPPA looks over the unconnected node and adds the arc ρ(para) $\rightarrow$ ρ(huaa) to the candidate arcs list *candidateArcs*.

E-GNPPA differs from algorithm 1 in lines 2 and 8. The E-GNPPA uses an extended initialization method *initCandidateArcsExtended(w_0)* for

Parent and Child	par.pos, chd.pos, par.lex, chd.lex

end while
··· lines 10 to 24 of Algorithm 2 ···
```

3.4 Features

Features for a relation (candidate arc) are defined on the POS tags and lexical items of the nodes in the relation and those in its context. Two kinds of context are used a) context from the input sentence (*sentence context*) b) context in *builtPPs* i.e. nearby partial parses (*partial parse context*). Information from the partial parses (*structural info*) such as left and right most children of the parent node in the relation, left and right siblings of the child node in the relation are also used. Table 1 lists the information on which features are defined in the various configurations of the three language parsers. The actual features are combinations of the information present in the table. The set varies depending on the language and whether its GNPPA or E-GNPPA approach.

While training, no features are defined on whether a node is unconnected (present in *unConn*) or not as this information isn't available during testing.

4 Hindi Projected Dependency Treebank

We conducted experiments on English-Hindi parallel data by transferring syntactic information from English to Hindi to build a projected dependency treebank for Hindi.

The TIDES English-Hindi parallel data containing 45,000 sentences was used for this purpose [1] (Venkatapathy, 2008). Word alignments for these sentences were obtained using the widely used GIZA++ toolkit in grow-diag-final-and mode (Och and Ney, 2003). Since Hindi is a morphologically rich language, root words were used instead of the word forms. A bidirectional English POS tagger (Shen et al., 2007) was used to POS tag the source sentences and the parses were obtained using the first order MST parser (McDonald et al., 2005) trained on dependencies extracted from Penn treebank using the head rules of Yamada and Matsumoto (2003). A CRF based Hindi POS tagger (PVS. and Gali, 2007) was used to POS tag the target sentences.

English and Hindi being morphologically and syntactically divergent makes the word alignment and dependency projection a challenging task. The source dependencies are projected using an approach similar to (Hwa et al., 2005). While they use post-projection transformations on the projected parse to account for annotation differences, we use pre-projection transformations on the source parse. The projection algorithm pro-

[1] The original data had 50,000 parallel sentences. It was later refined by IIIT-Hyderabad to remove repetitions and other trivial errors. The corpus is still noisy with typographical errors, mismatched sentences and unfaithful translations.

duces acyclic parses which could be unconnected and non-projective.

4.1 Annotation Differences in Hindi and English

Before projecting the source parses onto the target sentence, the parses are transformed to reflect the annotation scheme differences in English and Hindi. While English dependency parses reflect the PTB annotation style (Marcus et al., 1994), we project them to Hindi to reflect the annotation scheme described in (Begum et al., 2008). The differences in the annotation schemes are with respect to three phenomena: a) head of a verb group containing auxiliary and main verbs, b) prepositions in a prepositional phrase (PP) and c) coordination structures.

In the English parses, the auxiliary verb is the head of the main verb while in Hindi, the main verb is the head of the auxiliary in the verb group. For example, in the Hindi parse in Figure 1, `dikhataa` is the head of the auxiliary verb `hai`. The prepositions in English are realized as post-positions in Hindi. While prepositions are the heads in a preposition phrase, post-positions are the modifiers of the preceding nouns in Hindi. In `pahaada para` (*on the hill*), `hill` is the head of `para`. In coordination structures, while English differentiates between how NP coordination and VP coordination structures behave, Hindi annotation scheme is consistent in its handling. Left-most verb is the head of a VP coordination structure in English whereas the rightmost noun is the head in case of NP coordination. In Hindi, the conjunct is the head of the two verbs/nouns in the coordination structure.

These three cases are identified in the source tree and appropriate transformations are made to the source parse itself before projecting the relations using word alignments.

5 Experiments

We carried out all our experiments on parallel corpora belonging to English-Hindi, English-Bulgarian and English-Spanish language pairs. While the Hindi projected treebank was obtained using the method described in section 4, Bulgarian and Spanish projected datasets were obtained using the approach in (Ganchev et al., 2009). The datasets of Bulgarian and Spanish that contributed to the best accuracies for Ganchev et al. (2009) were used in our work (7 rules dataset for Bulgarian and 3 rules dataset for Spanish). The Hindi, Bulgarian and Spanish projected dependency treebanks have 44760, 39516 and 76958 sentences respectively. Since we don't have confidence scores for the projections on the sentences, we picked 10,000 sentences randomly in each of the three datasets for training the parsers[2]. Other methods of choosing the 10K sentences such as those with the max. no. of relations, those with least no. of unconnected words, those with max. no. of contiguous partial trees that can be learned by GNPPA parser etc. were tried out. Among all these, random selection was consistent and yielded the best results. The errors introduced in the projected parses by errors in word alignment, source parser and projection are not consistent enough to be exploited to select the better parses from the entire projected data.

Statistic	Hindi	Bulgarian	Spanish
N(Words)	226852	71986	133124
N(Parent==-1)	44607	30268	54815
P(Parent==-1)	19.7	42.0	41.1
N(Full trees)	593	1299	327
N(GNPPA)	30063	10850	19622
P(GNPPA)	16.4	26.0	25.0
N(E-GNPPA)	35389	12281	24577
P(E-GNPPA)	19.3	29.4	30.0

Table 2: Statistics of the Hindi, Bulgarian and Spanish projected treebanks used for experiments. Each of them has 10,000 randomly picked parses. N(X) denotes *number of X* and P(X) denotes *percentage of X*. N(Words) is the number of words. N(Parents==-1) is the number of words without a parent. N(Full trees) is the number of parses which are fully connected. N(GNPPA) is the number of relations learnt by GNPPA parser and N(E-GNPPA) is the number of relations learnt by E-GNPPA parser. Note that P(GNPPA) is calculated as N(GNPPA)/(N(Words) - N(Parents==-1)).

Table 2 gives an account of the randomly chosen 10k sentences in terms of the number of words, words without parents etc. Around 40% of the words spread over 88% of sentences in Bulgarian and 97% of sentences in Spanish have no parents. Traditional dependency parsers which only train from fully connected trees would not be able to learn from these sentences. P(GNPPA) is the percentage of relations in the data that are learned by the GNPPA parser satisfying the contiguous partial tree constraint and P(E-GNPPA) is the per-

[2]Exactly 10K sentences were selected in order to compare our results with those of (Ganchev et al., 2009).

Parser	Hindi		Bulgarian		Spanish	
	Punct	*NoPunct*	*Punct*	*NoPunct*	*Punct*	*NoPunct*
Baseline	78.70	77.39	51.85	55.15	41.60	45.61
GNPPA	80.03*	78.81*	77.03*	79.06*	65.49*	68.70*
E-GNPPA	**81.10***†	**79.94***†	**78.93***†	**80.11***†	**67.69***†	**70.90***†

Table 3: UAS for Hindi, Bulgarian and Spanish with the baseline, GNPPA and E-GNPPA parsers trained on 10k parses selected randomly. *Punct* indicates evaluation with punctuation whereas *NoPunct* indicates without punctuation. * next to an accuracy denotes statistically significant (McNemar's and $p < 0.05$) improvement over the baseline. † denotes significance over GNPPA

centage that satisfies the partially contiguous constraint. E-GNPPA parser learns around 2-5% more no. of relations than GNPPA due to the relaxation in the constraints.

The Hindi test data that was released as part of the ICON-2010 Shared Task (Husain et al., 2010) was used for evaluation. For Bulgarian and Spanish, we used the same test data that was used in the work of Ganchev et al. (2009). These test datasets had sentences from the training section of the CoNLL Shared Task (Nivre et al., 2007) that had lengths less than or equal to 10. All the test datasets have gold POS tags.

A baseline parser was built to compare learning from partial parses with learning from fully connected parses. Full parses are constructed from partial parses in the projected data by randomly assigning parents to unconnected parents, similar to the work in (Hwa et al., 2005). The unconnected words in the parse are selected randomly one by one and are assigned parents randomly to complete the parse. This process is repeated for all the sentences in the three language datasets. The parser is then trained with the GNPPA algorithm on these fully connected parses to be used as the baseline.

Table 3 lists the accuracies of the baseline, GNPPA and E-GNPPA parsers. The accuracies are unlabeled attachment scores (UAS): the percentage of words with the correct head. Table 4 compares our accuracies with those reported in (Ganchev et al., 2009) for Bulgarian and Spanish.

5.1 Discussion

The baseline reported in (Ganchev et al., 2009) significantly outperforms our baseline (see Table 4) due to the different baselines used in both the works. In our work, while creating the data for the baseline by assigning random parents to unconnected words, acyclicity and projectivity constraints are not enforced. Ganchev et al. (2009)'s baseline is similar to the first iteration of their discriminative model and hence performs better than ours. Our Bulgarian E-GNPPA parser achieved a 1.8% gain over theirs while the Spanish results are lower. Though their training data size is also 10K, the training data is different in both our works due to the difference in the method of choosing 10K sentences from the large projected treebanks.

Parser	Bulgarian	Spanish
Ganchev-Baseline	72.6	69.0
Baseline	55.15	45.61
Ganchev-Discriminative	78.3	**72.3**
GNPPA	79.06	68.70
E-GNPPA	**80.11**	70.90

Table 4: Comparison of baseline, GNPPA and E-GNPPA with baseline and discriminative model from (Ganchev et al., 2009) for Bulgarian and Spanish. Evaluation didn't include punctuation.

The GNPPA accuracies (see table 3) for all the three languages are significant improvements over the baseline accuracies. This shows that learning from partial parses is effective when compared to imposing the connected constraint on the partially projected dependency parse. Even while projecting source dependencies during data creation, it is better to project high confidence relations than look to project more relations and thereby introduce noise.

The E-GNPPA which also learns from partially contiguous partial parses achieved statistically significant gains for all the three languages. The gains across languages is due to the fact that in the 10K data that was used for training, E-GNPPA parser could learn $2 - 5\%$ more relations over GNPPA (see Table 2).

Figure 6 shows the accuracies of baseline and E-

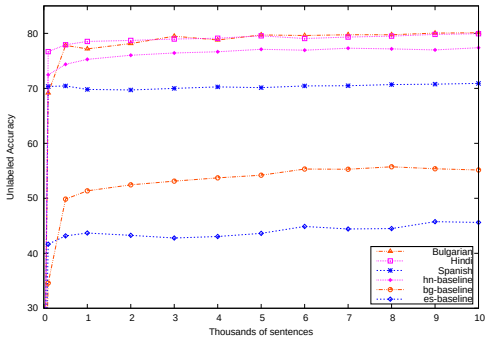

Figure 6: Accuracies (without punctuation) w.r.t varying training data sizes for baseline and E-GNPPA parsers.

GNPPA parser for the three languages when training data size is varied. The parsers peak early with less than 1000 sentences and make small gains with the addition of more data.

6 Conclusion

We presented a non-directional parsing algorithm that can learn from partial parses using syntactic and contextual information as features. A Hindi projected dependency treebank was developed from English-Hindi bilingual data and experiments were conducted for three languages Hindi, Bulgarian and Spanish. Statistically significant improvements were achieved by our partial parsers over the baseline system. The partial parsing algorithms presented in this paper are not specific to bitext projections and can be used for learning from partial parses in any setting.

Ranking Class Labels Using Query Sessions

mars@google.com

Abstract

The role of search queries, as available within query sessions or in isolation from one another, in examined in the context of ranking the class labels (e.g., *brazilian cities*, *business centers*, *hilly sites*) extracted from Web documents for various instances (e.g., *rio de janeiro*). The co-occurrence of a class label and an instance, in the same query or within the same query session, is used to reinforce the estimated relevance of the class label for the instance. Experiments over evaluation sets of instances associated with Web search queries illustrate the higher quality of the query-based, re-ranked class labels, relative to ranking baselines using document-based counts.

1 Introduction

Motivation: The offline acquisition of instances (*rio de janeiro*, *porsche cayman*) and their corresponding class labels (*brazilian cities*, *locations*, *vehicles*, *sports cars*) from text has been an active area of research. In order to extract fine-grained classes of instances, existing methods often apply manually-created (Banko et al., 2007; Talukdar et al., 2008) or automatically-learned (Snow et al., 2006) extraction patterns to text within large document collections.

In Web search, the relative ranking of documents returned in response to a query directly affects the outcome of the search. Similarly, the quality of the relative ranking among class labels extracted for a given instance influences any applications (e.g., query refinements or structured extraction) using the extracted data. But due to noise in Web data and limitations of extraction techniques, class labels acquired for a given instance (e.g., *oil shale*) may fail to properly capture the semantic classes to which the instance may belong (Kozareva et al., 2008). Inevitably, some of the extracted class labels will be less useful (e.g., *sources*, *mutual concerns*) or incorrect (e.g., *plants* for the instance *oil shale*). In previous work, the relative ranking of class labels for an instance is determined mostly based on features derived from the source Web documents from which the data has been extracted, such as variations of the frequency of co-occurrence or diversity of extraction patterns producing a given pair (Etzioni et al., 2005).

Contributions: This paper explores the role of Web search queries, rather than Web documents, in inducing superior ranking among class labels extracted automatically from documents for various instances. It compares two sources of indirect ranking evidence available within anonymized query logs: a) co-occurrence of an instance and its class label in the same query; and b) co-occurrence of an instance and its class label, as separate queries within the same query session. The former source is a noisy attempt to capture queries that narrow the search results to a particular class of the instance (e.g., *jaguar car maker*). In comparison, the latter source noisily identifies searches that specialize from a class (e.g., *car maker*) to an instance (e.g., *jaguar*) or, conversely, generalize from an instance to a class. To our knowledge, this is the first study comparing inherently-noisy queries and query sessions for the purpose of ranking of open-domain, labeled class instances.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1607–1615,
Portland, Oregon, June 19-24, 2011.

The remainder of the paper is organized as follows. Section 2 introduces intuitions behind an approach using queries for ranking class labels of various instances, and describes associated ranking functions. Sections 3 and 4 describe the experimental setting and evaluation results over evaluation sets of instances associated with Web search queries. The results illustrate the higher quality of the query-based, re-ranked lists of class labels, relative to alternative ranking methods using only document-based counts.

2 Instance Class Ranking via Query Logs

Ranking Hypotheses: We take advantage of anonymized query logs, to induce superior ranking among the class labels associated with various class instances within an IsA repository acquired from Web documents. Given a class instance $\mathcal{I}$, the functions used for the ranking of its class labels are chosen following several observations.

• *Hypothesis H_1*: If $\mathcal{C}$ is a prominent class of an instance $\mathcal{I}$, then $\mathcal{C}$ and $\mathcal{I}$ are likely to occur in text in contexts that are indicative of an IsA relation.

• *Hypothesis H_2*: If $\mathcal{C}$ is a prominent class of an instance $\mathcal{I}$, and $\mathcal{I}$ is ambiguous, then a fraction of the queries about $\mathcal{I}$ may also refer to and contain $\mathcal{C}$.

• *Hypothesis H_3*: If $\mathcal{C}$ is a prominent class of an instance $\mathcal{I}$, then a fraction of the queries about $\mathcal{I}$ may be followed by queries about $\mathcal{C}$, and vice-versa.

Ranking Functions: The ranking functions follow directly from the above hypotheses.

• *Ranking based on H_1* (using documents): The first hypothesis H_1 is a reformulation of findings from previous work (Etzioni et al., 2005). In practice, a class label is deemed more relevant for an instance if the pair is extracted more frequently and by multiple patterns, with the scoring formula:

$$Score_{H1}(\mathcal{C},\mathcal{I}) = Freq(\mathcal{C},\mathcal{I}) \times Size(\{Pattern(\mathcal{C})\})^2 \quad (1)$$

where $Freq(\mathcal{C},\mathcal{I})$ is the frequency of extraction of $\mathcal{C}$ for the instance $\mathcal{I}$, and $Size(\{Pattern(\mathcal{C})\})$ is the number of unique patterns extracting the class label $\mathcal{C}$ for the instance $\mathcal{I}$. The patterns are hand-written, following (Hearst, 1992):

⟨[..] $\mathcal{C}$ [such as|including] $\mathcal{I}$ [and|,|.]⟩,

where $\mathcal{I}$ is a potential instance (e.g., *diderot*) and $\mathcal{C}$ is a potential class label (e.g., *writers*). The boundaries are approximated from the part-of-speech tags of the sentence words, for potential class labels $\mathcal{C}$; and identified by checking that $\mathcal{I}$ occurs as an entire query in query logs, for instances $\mathcal{I}$ (Van Durme and Paşca, 2008).

The application of the scoring formula (1) to candidates extracted from the Web produces a ranked list of class labels $L_{H1}(\mathcal{I})$.

• *Ranking based on H_2* (using queries): Intuitively, Web users searching for information about $\mathcal{I}$ sometimes add some or all terms of $\mathcal{C}$ to a search query already containing $\mathcal{I}$, either to further specify their query, or in response to being presented with sets of search results spanning several meanings of an ambiguous instance. Examples of such queries are *happiness emotion* and *diderot philosopher*. Moreover, queries like *happiness positive psychology* and *diderot enlightenment* may be considered to weakly and partially reinforce the relevance of the class labels *positive emotions* and *enlightenment writers* of the instances *happiness* and *diderot* respectively. In practice, a class label is deemed more relevant if its individual terms occur in popular queries containing the instance. More precisely, for each term within any class label from $L_{H1}(\mathcal{I})$, we compute a score $TermQueryScore$. The score is the frequency sum of the term within anonymized queries containing the instance $\mathcal{I}$ as a prefix, and the term anywhere else in the queries. Terms are stemmed before the computation.

Each class label $\mathcal{C}$ is assigned the geometric mean of the scores of its N terms $\mathcal{T}_i$, after ignoring stop words:

$$Score_{H2}(\mathcal{C},\mathcal{I}) = (\prod_{i=1}^{N} TermQueryScore(\mathcal{T}_i))^{1/N} \quad (2)$$

The geometric mean is preferred to the arithmetic mean, because the latter is more strongly affected by outlier values. The class labels are ranked according to the means, resulting in a ranked list $L_{H2}(\mathcal{I})$. In case of ties, $L_{H2}(\mathcal{I})$ keeps the relative ranking from $L_{H1}(\mathcal{I})$.

• *Ranking based on H_3* (using query sessions): Given the third hypothesis H_3, Web users searching for information about $\mathcal{I}$ may subsequently search for more general information about one of its classes $\mathcal{C}$. Conversely, users may specialize their search from a class $\mathcal{C}$ to one of its instances $\mathcal{I}$. Examples of such queries are *happiness* followed later by *emotions*, or *diderot* followed by *philosophers*; or *emo-*

tions followed later by *happiness*, or *philosophers* followed by *diderot*. In practice, a class label is deemed more relevant if its individual terms occur as part of queries that are in the same query session as a query containing only the instance. More precisely, for each term within any class label from $L_{H1}(\mathcal{I})$, we compute a score $TermSessionScore$, equal to the frequency sum of the anonymized queries from the query sessions that contain the term and are: a) either the initial query of the session, with the instance $\mathcal{I}$ being one of the subsequent queries from the same session; or b) one of the subsequent queries of the session, with the instance $\mathcal{I}$ being the initial query of the same session. Before computing the frequencies, the class label terms are stemmed.

Each class label $\mathcal{C}$ is assigned the geometric mean of the scores of its terms, after ignoring stop words:

$$Score_{H3}(\mathcal{C},\mathcal{I}) = (\prod_{i=1}^{N} TermSessionScore(\mathcal{T}_i))^{1/N} \quad (3)$$

The class labels are ranked according to the geometric means, resulting in a ranked list $L_{H3}(\mathcal{I})$. In case of ties, $L_{H3}(\mathcal{I})$ preserves the relative ranking from $L_{H1}(\mathcal{I})$.

Unsupervised Ranking: Given an instance $\mathcal{I}$, the ranking hypotheses and corresponding functions $L_{H1}(\mathcal{I})$, $L_{H2}(\mathcal{I})$ and $L_{H3}(\mathcal{I})$ (or any combination of them) can be used together to generate a merged, ranked list of class labels per instance $\mathcal{I}$. The score of a class label in the merged list is determined by the inverse of the average rank in the lists $L_{H1}(\mathcal{I})$ and $L_{H2}(\mathcal{I})$ and $L_{H3}(\mathcal{I})$, computed with the following formula:

$$Score_{H1+H2+H3}(\mathcal{C},\mathcal{I}) = \frac{N}{\sum_i^N Rank(\mathcal{C}, L_{Hi})} \quad (4)$$

where N is the number of input lists of class labels (in this case, 3), and Rank($\mathcal{C}$, L_{Hi}) is the rank of $\mathcal{C}$ in the input list of class labels L_{Hi} (L_{H1}, L_{H2} or L_{H3}). The rank is set to 1000, if $\mathcal{C}$ is not present in the list L_{Hi}. By using only the relative ranks and not the absolute scores of the class labels within the input lists, the outcome of the merging is less sensitive to how class labels of a given instance are numerically scored within the input lists. In case of ties, the scores of the class labels from $L_{H1}(\mathcal{I})$ serve as a secondary ranking criterion. Thus, every instance $\mathcal{I}$ from the IsA repository is associated with a ranked list of class labels computed according to this ranking formula. Conversely, each class label $\mathcal{C}$ from the IsA repository is associated with a ranked list of class instances computed with the earlier scoring formula (1) used to generate lists $L_{H1}(\mathcal{I})$.

Note that the ranking formula can also consider only a subset of the available input lists. For instance, $Score_{H1+H2}$ would use only $L_{H1}(\mathcal{I})$ and $L_{H2}(\mathcal{I})$ as input lists; $Score_{H1+H3}$ would use only $L_{H1}(\mathcal{I})$ and $L_{H3}(\mathcal{I})$ as input lists; etc.

3 Experimental Setting

Textual Data Sources: The acquisition of the IsA repository relies on unstructured text available within Web documents and search queries. The queries are fully-anonymized queries in English submitted to Google by Web users in 2009, and are available in two collections. The first collection is a random sample of 50 million unique queries that are independent from one another. The second collection is a random sample of 5 million query sessions. Each session has an initial query and a series of subsequent queries. A subsequent query is a query that has been submitted by the same Web user within no longer than a few minutes after the initial query. Each subsequent query is accompanied by its frequency of occurrence in the session, with the corresponding initial query. The document collection consists of a sample of 100 million documents in English.

Experimental Runs: The experimental runs correspond to different methods for extracting and ranking pairs of an instance and a class:

- from the repository extracted here, with class labels of an instance ranked based on the frequency and the number of extraction patterns ($Score_{H1}$ from Equation (1) in Section 2), in run $\underline{\mathbf{R}_d}$;
- from the repository extracted here, with class labels of an instance ranked via the rank-based merging of: $Score_{H1+H2}$ from Section 2, in run $\underline{\mathbf{R}_p}$, which corresponds to re-ranking using co-occurrence of an instance and its class label in the same query; $Score_{H1+H3}$ from Section 2, in run $\underline{\mathbf{R}_s}$, which corresponds to re-ranking using co-occurrence of an instance and its class label, as separate queries within the same query session; and $Score_{H1+H2+H3}$ from Section 2, in run $\underline{\mathbf{R}_u}$, which corresponds to re-ranking using both types of co-occurrences in queries.

Evaluation Procedure: The manual evaluation of open-domain information extraction output is time consuming (Banko et al., 2007). A more practical alternative is an automatic evaluation procedure for ranked lists of class labels, based on existing resources and systems.

Assume that there is a gold standard, containing gold class labels that are each associated with a gold set of their instances. The creation of such gold standards is discussed later. Based on the gold standard, the ranked lists of class labels available within an IsA repository can be automatically evaluated as follows. First, for each gold label, the ranked lists of class labels of individual gold instances are retrieved from the IsA repository. Second, the individual retrieved lists are merged into a ranked list of class labels, associated with the gold label. The merged list can be computed, e.g., using an extension of the $Score_{H1+H2+H3}$ formula (Equation (4)) described earlier in Section 2. Third, the merged list is compared against the gold label, to estimate the accuracy of the merged list. Intuitively, a ranked list of class labels is a better approximation of a gold label, if class labels situated at better ranks in the list are closer in meaning to the gold label.

Evaluation Metric: Given a gold label and a list of class labels, if any, derived from the IsA repository, the rank of the highest class label that matches the gold label determines the score assigned to the gold label, in the form of the reciprocal rank of the match. Thus, if the gold label matches a class label at rank 1, 2 or 3 in the computed list, the gold label receives a score of 1, 0.5 or 0.33 respectively. The score is 0 if the gold label does not match any of the top 20 class labels. The overall score over the entire set of gold labels is the mean reciprocal rank (MRR) score over all gold labels from the set. Two types of MRR scores are automatically computed:

• **MRR**$_f$ considers a gold label and a class label to match, if they are identical;

• **MRR**$_p$ considers a gold label and a class label to match, if one or more of their tokens that are not stop words are identical.

During matching, all string comparisons are case-insensitive, and all tokens are first converted to their singular form (e.g., *european countries* to *european country*) using WordNet (Fellbaum, 1998). Thus, *insurance carriers* and *insurance companies* are considered to not match in MRR$_f$ scores, but match in MRR$_p$ scores. On the other hand, MRR$_p$ scores may give credit to less relevant class labels, such as *insurance policies* for the gold label *insurance carriers*. Therefore, MRR$_p$ is an optimistic, and MRR$_f$ is a pessimistic estimate of the actual usefulness of the computed ranked lists of class labels as approximations of the gold labels.

Query Set: Sample of Queries
Q_e (807 queries): 2009 movies, amino acids, asian countries, bank, board games, buildings, capitals, chemical functional groups, clothes, computer language, dairy farms near modesto ca, disease, egyptian pharaohs, eu countries, fetishes, french presidents, german islands, hawaiian islands, illegal drugs, irc clients, lakes, macintosh models, mobile operator india, nba players, nobel prize winners, orchids, photo editors, programming languages, renaissance artists, roller costers, science fiction tv series, slr cameras, soul singers, states of india, taliban members, thomas edison inventions, u.s. presidents, us president, water slides
Q_m (40 queries): actors, actresses, airlines, american presidents, antibiotics, birds, cars, celebrities, colors, computer languages, digital camera, dog breeds, dogs, drugs, elements, endangered animals, european countries, flowers, fruits, greek gods, horror movies, idioms, ipods, movies, names, netbooks, operating systems, park slope restaurants, planets, presidents, ps3 games, religions, renaissance artists, rock bands, romantic movies, states, universities, university, us cities, vitamins

Table 1: Size and composition of evaluation sets of queries associated with non-filtered (Q_e) or manually-filtered (Q_m) instances

4 Evaluation

IsA Repository: The IsA repository, extracted from the document collection, covers a total of 4.04 million instances associated with 7.65 million class labels. The number of class labels available per instance and vice-versa follows a long-tail distribution, indicating that 2.12 million of the instances each have two or more class labels (with an average of 19.72 class labels per instance).

Evaluation Sets of Queries: Table 1 shows samples of two query sets, introduced in (Paşca, 2010) and used in the evaluation. The first set, denoted $\mathbf{Q}_e$,

Query Set	Min	Max	Avg	Median
Number of Gold Instances:				
Q_e	10	100	70.4	81
Q_m	8	33	16.9	17
Number of Query Tokens:				
Q_e	1	8	2.0	2
Q_m	1	3	1.4	1

Table 2: Number of gold instances (upper part) and number of query tokens (lower part) available per query, over the evaluation sets of queries associated with non-filtered gold instances (Q_e) or manually-filtered gold instances (Q_m)

is obtained from a random sample of anonymized, class-seeking queries submitted by Web users to Google Squared. The set contains 807 queries, each associated with a ranked list of between 10 and 100 gold instances automatically extracted by Google Squared.

Since the gold instances available as input for each query as part of Q_e are automatically extracted, they may or may not be true instances of the respective queries. As described in (Paşca, 2010), the second evaluation set $\mathbf{Q}_m$ is a subset of 40 queries from Q_e, such that the gold instances available for each query in Q_m are found to be correct after manual inspection. The 40 queries from Q_m are associated with between 8 and 33 human-validated instances.

As shown in the upper part of Table 2, the queries from Q_e are up to 8 tokens in length, with an average of 2 tokens per query. Queries from Q_m are comparatively shorter, both in maximum (3 tokens) and average (1.4 tokens) length. The lower part of Table 2 shows the number of gold instances available as input, which average around 70 and 17 per query, for queries from Q_e and Q_m respectively. To provide another view on the distribution of the queries from evaluation sets, Table 3 lists tokens that are not stop words, which occur in most queries from Q_e. Comparatively, few query tokens occur in more than one query in Q_m.

Evaluation Procedure: Following the general evaluation procedure, each query from the sets $\mathbf{Q}_e$ and $\mathbf{Q}_m$ acts as a gold class label associated with the corresponding set of instances. Given a query and its instances $\mathcal{I}$ from the evaluation sets Q_e or Q_m, a merged, ranked lists of class labels is computed out of the ranked lists of class labels available in the underlying IsA repository for each instance $\mathcal{I}$. The evaluation compares the merged lists of class labels, with the corresponding queries from Q_e or Q_m.

Query Token	Cnt.	Examples of Queries Containing the Token
countries	22	african countries, eu countries, poor countries
cities	21	australian cities, cities in california, greek cities
presidents	18	american presidents, korean presidents, presidents of the south korea
restaurants	15	atlanta restaurants, nova scotia restaurants, restaurants 10024
companies	14	agriculture companies, gas utility companies, retail companies
states	14	american states, states of india, united states national parks
prime	11	australian prime ministers, indian prime ministers, prime ministers
cameras	10	cameras, digital cameras olympus, nikon cameras
movies	10	2009 movies, movies, romantic movies
american	9	american authors, american president, american revolution battles
ministers	9	australian prime ministers, indian prime ministers, prime ministers

Table 3: Query tokens occurring most frequently in queries from the Q_e evaluation set, along with the number (Cnt) and examples of queries containing the tokens

Accuracy of Lists of Class Labels: Table 4 summarizes results from comparative experiments, quantifying a) horizontally, the impact of alternative parameter settings on the computed lists of class labels; and b) vertically, the comparative accuracy of the experimental runs over the query sets. The experimental parameters are the number of input instances from the evaluation sets that are used for retrieving class labels, I-per-Q, set to 3, 5, 10; and the number of class labels retrieved per input instance, C-per-I, set to 5, 10, 20.

Four conclusions can be derived from the results. First, the scores over Q_m are higher than those over Q_e, confirming the intuition that the higher-quality

	Accuracy

Table 4: Accuracy of instance set labeling, as full-match (MRR_f) or partial-match (MRR_p) scores over the evaluation sets of queries associated with non-filtered instances (Q_e) or manually-filtered instances (Q_m), for various experimental runs (I-per-Q=number of gold instances available in the input evaluation sets that are used for retrieving class labels; C-per-I=number of class labels retrieved from IsA repository per input instance)

input set of instances available in Q_m relative to Q_e should lead to higher-quality class labels for the corresponding queries. Second, when I-per-Q is fixed, increasing C-per-I leads to small, if any, score improvements. Third, when C-per-I is fixed, even small values of I-per-Q, such as 3 (that is, very small sets of instances provided as input) produce scores that are competitive with those obtained with a higher value like 10. This suggests that useful class labels can be generated even in extreme scenarios, where the number of instances available as input is as small as 3 or 5. Fourth and most importantly, for most combinations of parameter settings and on both query sets, the runs that take advantage of query logs (R_p, R_s, R_u) produce the highest scores. In particular, when I-per-Q is set to 10 and C-per-I to 20, run R_u identifies the original query as an exact match among the top three to four class labels returned (score 0.278); and as a partial match among the top one to two class labels returned (score 0.636), as an average over the Q_e set. The corresponding MRR_f score of 0.278 over the Q_e set obtained with run R_u is 27% higher than with run R_d.

In all experiments, the higher scores of R_p, R_s and R_u can be attributed to higher-quality lists of class labels, relative to R_d. Among combinations of parameter settings described in Table 4, values around 10 for I-per-Q and 20 for C-per-I give the highest scores over both Q_e and Q_m.

Among the query-based runs R_p, R_s and R_u, the highest scores in Table 4 are obtained mostly for run R_s. Thus, between the presence of a class label and an instance either in the same query, or as separate queries within the same query session, it is the latter that provides a more useful signal during the re-ranking of class labels of each instance.

Table 5 illustrates the top class labels from the ranked lists generated in run R_s for various queries from both Q_e and Q_m. The table suggests that the computed class labels are relatively resistant to noise and variation within the input set of gold instances. For example, the top elements of the lists of class la-

Query	Query Set	Gold Instances		Top Labels Generated Using Top 10 Gold Instances
		Cnt.	Sample from Top Gold Instances	
actors	Q_e	100	abe vigoda, ben kingsley, bill hickman	actors, stars, favorite actors, celebrities, movie stars
	Q_m	28	al pacino, christopher walken, danny devito	actors, celebrities, favorite actors, movie stars, stars
computer languages	Q_e	59	acm transactions on mathematical software, applescript, c	languages, programming languages, programs, standard programming languages, computer programming languages
	Q_m	17	applescript, eiffel, haskell	languages, programming languages, computer languages, modern programming languages, high-level languages
european countries	Q_e	60	abkhazia, armenia, bosnia & herzegovina	countries, european countries, eu countries, foreign countries, western countries
	Q_m	19	belgium, finland, greece	countries, european countries, eu countries, foreign countries, western countries
endangered animals	Q_e	98	arkive, arabian oryx, bagheera	species, animals, endangered species, animal species, endangered animals
	Q_m	21	arabian oryx, blue whale, giant hispaniolan galliwasp	animals, endangered species, species, endangered animals, rare animals
park slope restaurants	Q_e	100	12th street bar & grill, aji bar lounge, anthony's	businesses, departments
	Q_m	18	200 fifth restaurant bar, applewood restaurant, beet thai restaurant	(none)

	Q_m	15	arcade fire, faith no more, indigo girls	bands, rock bands, favorite bands, great bands, groups

Table 5: Examples of gold instances available in the input, and actual ranked lists of class labels produced by run R_s for various queries from the evaluation sets of queries associated with non-filtered gold instances (Q_e) or manually-filtered gold instances (Q_m)

bels generated for *computer languages* are relevant and also quite similar for Q_e vs. Q_m, although the list of gold instances in Q_e may contain incorrect items (e.g., *acm transactions on mathematical software*). Similarly, the class labels computed for *european countries* are almost the same for Q_e vs. Q_m, although the overlap of the respective lists of 10 gold instances used as input is not large. The table shows at least one query (*park slope restaurants*) for which the output is less than optimal, either because the class labels (e.g., *businesses*) are quite distant semantically from the query (for Q_e), or because no output is produced at all, due to no class labels being found in the IsA repository for any of the 10 input gold instances (for Q_m). For many queries, however, the computed class labels arguably capture the meaning of the original query, although not necessarily in the exact same lexical form, and sometimes only partially. For example, for the query *endangered animals*, only the fourth class label from Q_m identifies the query exactly. However, class labels preceding *endangered animals* already capture the notion of *animals* or *species* (first and third labels), or that they are *endangered* (second label).

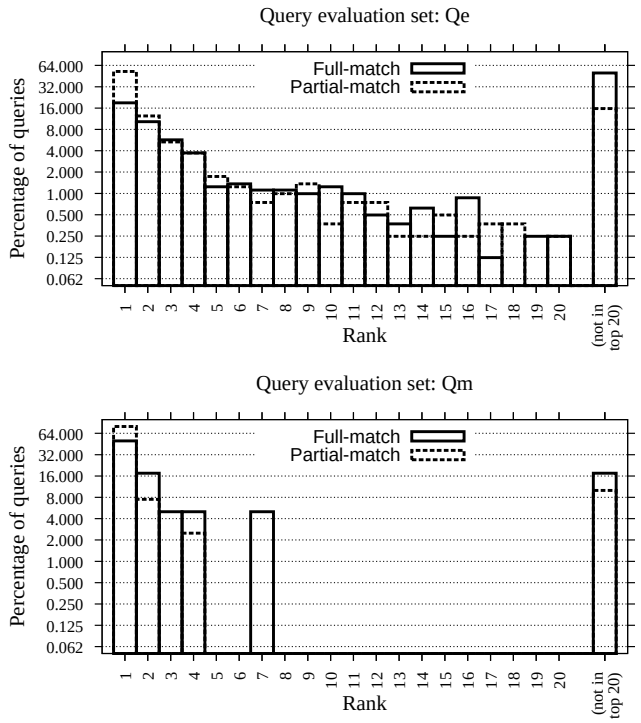

Figure 1: Percentage of queries from the evaluation sets, for which the earliest class labels from the computed ranked lists of class labels, which match the queries, occur at various ranks in the ranked lists returned by run R_s

Figure 1 provides a detailed view on the distribution of queries from the Q_e and Q_m evaluation sets, for which the class label that matches the query occurs at a particular rank in the computed list of class labels. In the first graph of Figure 1, for Q_e, the query matches the automatically-generated class label at ranks 1, 2, 3, 4 and 5 for 18.9%, 10.3%, 5.7%, 3.7% and 1.2% of the queries respectively, with full string matching, i.e., corresponding to MRR_f; and for 52.6%, 12.4%, 5.3%, 3.7% and 1.7% respectively, with partial string matching, corresponding to MRR_p. The second graph confirms that higher MRR scores are obtained for Q_m than for Q_e. In particular, the query matches the class label at rank 1 and 2 for 50.0% and 17.5% (or a combined 67.5%) of the queries from Q_m, with full string matching; and for 52.6% and 12.4% (or a combined 67%), with partial string matching.

Discussion: The quality of lists of items extracted from documents can benefit from query-driven ranking, particularly for the task of ranking class labels of instances within IsA repositories. The use of queries for ranking is generally applicable: it can be seen as a post-processing stage that enhances the ranking of the class labels extracted for various instances by any method into any IsA repository.

Open-domain class labels extracted from text and re-ranked as described in this paper are useful in a variety of applications. Search tools such as Google Squared return a set of instances, in response to class-seeking queries (e.g., *insurance companies*). The labeling of the returned set of instances, using the re-ranked class labels available per instances, allows for the generation of query refinements (e.g., *insurers*). In search over semi-structured data (Cafarella et al., 2008), the labeling of column cells is useful to infer the semantics of a table column, when the subject row of the table in which the column appears is either absent or difficult to detect.

5 Related Work

The role of anonymized query logs in Web-based information extraction has been explored in tasks such as class attribute extraction (Paşca and Van Durme, 2007), instance set expansion (Pennacchiotti and Pantel, 2009) and extraction of sets of similar entities (Jain and Pennacchiotti, 2010). Our work compares the usefulness of queries and query sessions for ranking class labels in extracted IsA repositories. It shows that query sessions produce better-ranked class labels than isolated queries do. A task complementary to class label ranking is entity ranking (Billerbeck et al., 2010), also referred to as ranking for typed search (Demartini et al., 2009).

The choice of search queries and query substitutions is often influenced by, and indicative of, various semantic relations holding among full queries or query terms (Jones et al., 2006). Semantic relations may be loosely defined, e.g., by exploring the acquisition of untyped, similarity-based relations from query logs (Baeza-Yates and Tiberi, 2007). In comparison, queries are used here to re-rank class labels capturing a well-defined type of open-domain relations, namely IsA relations.

6 Conclusion

In an attempt to bridge the gap between information stated in documents and information requested

in search queries, this study shows that inherently-noisy queries are useful in re-ranking class labels extracted from Web documents for various instances, with query sessions leading to higher quality than isolated queries. Current work investigates the impact of ambiguous input instances (Vyas and Pantel, 2009) on the quality of the generated class labels.

Abstract

Text mining and data harvesting algorithms have become popular in the computational linguistics community. They employ patterns that specify the kind of information to be harvested, and usually bootstrap either the pattern learning or the term harvesting process (or both) in a recursive cycle, using data learned in one step to generate more seeds for the next. They therefore treat the source text corpus as a network, in which words are the nodes and relations linking them are the edges. The results of computational network analysis, especially from the world wide web, are thus applicable. Surprisingly, these results have not yet been broadly introduced into the computational linguistics community. In this paper we show how various results apply to text mining, how they explain some previously observed phenomena, and how they can be helpful for computational linguistics applications.

1 Introduction

Text mining / harvesting algorithms have been applied in recent years for various uses, including learning of semantic constraints for verb participants (Lin and Pantel, 2002) related pairs in various relations, such as part-whole (Girju et al., 2003), cause (Pantel and Pennacchiotti, 2006), and other typical information extraction relations, large collections of entities (Soderland et al., 1999; Etzioni et al., 2005), features of objects (Pasca, 2004) and ontologies (Carlson et al., 2010). They generally start with one or more seed terms and employ patterns that specify the desired information as it relates to the seed(s). Several approaches have been developed specifically for learning patterns, including guided pattern collection with manual filtering (Riloff and Shepherd, 1997) automated surface-level pattern induction (Agichtein and Gravano, 2000; Ravichandran and Hovy, 2002) probabilistic methods for taxonomy relation learning (Snow et al., 2005) and kernel methods for relation learning (Zelenko et al., 2003). Generally, the harvesting procedure is recursive, in which data (terms or patterns) gathered in one step of a cycle are used as seeds in the following step, to gather more terms or patterns.

This method treats the source text as a graph or network, consisting of terms (words) as nodes and inter-term relations as edges. Each relation type induces a different network[1]. Text mining is a process of network traversal, and faces the standard problems of handling cycles, ranking search alternatives, estimating yield maxima, etc.

The computational properties of large networks and large network traversal have been studied intensively (Sabidussi, 1966; Freeman, 1979; Watts and Strogatz, 1998) and especially, over the past years, in the context of the world wide web (Page et al., 1999; Broder et al., 2000; Kleinberg and Lawrence, 2001; Li et al., 2005; Clauset et al., 2009). Surprisingly, except in (Talukdar and Pereira, 2010), this work has not yet been related to text mining research in the computational linguistics community.

The work is, however, relevant in at least two ways. It sometimes explains why text mining algo-

[1]These networks are generally far larger and more densely interconnected than the world wide web's network of pages and hyperlinks.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1616–1625,
Portland, Oregon, June 19-24, 2011.

rithms have the limitations and thresholds that are empirically found (or suspected), and it may suggest ways to improve text mining algorithms for some applications.

In Section 2, we review some related work. In Section 3 we describe the general harvesting procedure, and follow with an examination of the various statistical properties of implicit semantic networks in Section 4, using our implemented harvester to provide illustrative statistics. In Section 5 we discuss implications for computational linguistics research.

2 Related Work

The Natural Language Processing knowledge harvesting community has developed a good understanding of how to harvests various kinds of semantic information and use this information to improve the performance of tasks such as information extraction (Riloff, 1993), textual entailment (Zanzotto et al., 2006), question answering (Katz et al., 2003), and ontology creation (Suchanek et al., 2007), among others. Researchers have focused on the automated extraction of semantic lexicons (Hearst, 1992; Riloff and Shepherd, 1997; Girju et al., 2003; Pasca, 2004; Etzioni et al., 2005; Kozareva et al., 2008). While clustering approaches tend to extract general facts, pattern based approaches have shown to produce more constrained but accurate lists of semantic terms. To extract this information, (Lin and Pantel, 2002) showed the effect of using different sizes and genres of corpora such as news and Web documents. The latter has been shown to provide broader and more complete information.

Researchers outside computational linguistics have studied complex networks such as the World Wide Web, the Social Web, the network of scientific papers, among others. They have investigated the properties of these text-based networks with the objective of understanding their structure and applying this knowledge to determine node importance/centrality, connectivity, growth and decay of interest, etc. In particular, the ability to analyze networks, identify influential nodes, and discover hidden structures has led to important scientific and technological breakthroughs such as the discovery of communities of like-minded individuals (Newman and Girvan, 2004), the identification of influential people (Kempe et al., 2003), the ranking of scientists by their citation indexes (Radicchi et al., 2009), and the discovery of important scientific papers (Walker et al., 2006; Chen et al., 2007; Sayyadi and Getoor, 2009). Broder et al. (2000) demonstrated that the Web link structure has a "bow-tie" shape, while (2001) classified Web pages into *authorities* (pages with relevant information) and *hubs* (pages with useful references). These findings resulted in the development of the PageRank (Page et al., 1999) algorithm which analyzes the structure of the hyperlinks of Web documents to find pages with authoritative information. PageRank has revolutionized the whole Internet search society.

However, no-one has studied the properties of the text-based semantic networks induced by semantic relations between terms with the objective of understanding their structure and applying this knowledge to improve concept discovery. Most relevant to this theme is the work of Steyvers and Tenenbaum (Steyvers and Tenenbaum, 2004), who studied three manually built lexical networks (association norms, WordNet, and Roget's Thesaurus (Roget, 1911)) and proposed a model of the growth of the semantic structure over time. These networks are limited to the semantic relations among nouns.

In this paper we take a step further to explore the statistical properties of semantic networks relating *proper names*, *nouns*, *verbs*, and *adjectives*. Understanding the semantics of nouns, verbs, and adjectives has been of great interest to linguists and cognitive scientists such as (Gentner, 1981; Levin and Somers, 1993; Gasser and Smith, 1998). We implement a general harvesting procedure and show its results for these word types. A fundamental difference with the work of (Steyvers and Tenenbaum, 2004) is that we study very large semantic networks built 'naturally' by (millions of) users rather than 'artificially' by a small set of experts. The large networks capture the semantic intuitions and knowledge of the collective mass. It is conceivable that an analysis of this knowledge can begin to form the basis of a large-scale theory of semantic meaning and its interconnections, support observation of the process of lexical development and usage in humans, and even suggest explanations of how knowledge is organized in our brains, especially when performed for differ-

ent languages on the WWW.

3 Inducing Semantic Networks in the Web

Text mining algorithms such as those mentioned above raise certain questions, such as: *Why are some seed terms more powerful (provide a greater yield) than others?*, *How can one find high-yield terms?*, *How many steps does one need, typically, to learn all terms for a given relation?*, *Can one estimate the total eventual yield of a given relation?*, and so on. On the face of it, one would need to know the structure of the network a priori to be able to provide answers. But research has shown that some surprising regularities hold. For example, in the text mining community, (Kozareva and Hovy, 2010b) have shown that one can obtain a quite accurate estimate of the eventual yield of a pattern and seed after only five steps of harvesting. Why is this? They do not provide an answer, but research from the network community does.

To illustrate the properties of networks of the kind induced by semantic relations, and to show the applicability of network research to text harvesting, we implemented a harvesting algorithm and applied it to a representative set of relations and seeds in two languages.

Since the goal of this paper is not the development of a new text harvesting algorithm, we implemented a version of an existing one: the so-called DAP (doubly-anchored pattern) algorithm (Kozareva et al., 2008), because it (1) is easy to implement, (2) requires minimum input (one pattern and one seed example), (3) achieves very high precision compared to existing methods (Pasca, 2004; Etzioni et al., 2005; Pasca, 2007), (4) enriches existing semantic lexical repositories such as WordNet and Yago (Suchanek et al., 2007), (5) can be formulated to learn semantic lexicons and relations for *noun*, *verb* and *verb+preposition* syntactic constructions; (6) functions equally well in different languages. Next we describe the knowledge harvesting procedure and the construction of the text-mined semantic networks.

3.1 Harvesting to Induce Semantic Networks

For a given semantic class of interest say *singers*, the algorithm starts with a *seed* example of the *class*, say *Madonna*. The *seed* term is inserted in the lexico-syntactic pattern "*class* such as *seed* and *", which learns on the position of the $*$ new terms of type *class*. The newly learned terms are then individually placed into the position of the *seed* in the pattern, and the bootstrapping process is repeated until no new terms are found. The output of the algorithm is a set of terms for the semantic class. The algorithm is implemented as a breadth-first search and its mechanism is described as follows:

1. Given:
   a language L={English, Spanish}
   a pattern P_i={such as, including, verb prep, noun}
   a seed term $seed$ for P_i
2. Build a query for P_i using template T_i 'class such as $seed$ and *', 'class including $seed$ and *', '* and $seed$ verb prep', '* and $seed$ noun', '$seed$ and * noun'
3. Submit T_i to Yahoo! or other search engine
4. Extract terms occupying the * position
5. Feed terms from 4. into 2.
6. Repeat steps 2–5. until no new terms are found

The output of the knowledge harvesting algorithm is a network of semantic terms interconnected by the semantic relation captured in the pattern. We can represent the traversed (implicit) network as a directed graph $G(V, E)$ with nodes $V(|V| = n)$ and edges $E(|E| = m)$. A node u in the network corresponds to a term discovered during bootstrapping. An edge $(u, v) \in E$ represents an existing link between two terms. The direction of the edge indicates that the term v was generated by the term u. For example, given the sentence (where the pattern is in italics and the extracted term is underlined) "He loves *singers such as Madonna and* Michael Jackson", two nodes *Madonna* and *Michael Jackson* with an edge e=(*Madonna*, *Michael Jackson*) would be created in the graph G. Figure 1 shows a small example of the singer network. The starting seed term *Madonna* is shown in red color and the harvested terms are in blue.

3.2 Data

We harvested data from the Web for a representative selection of semantic classes and relations, of

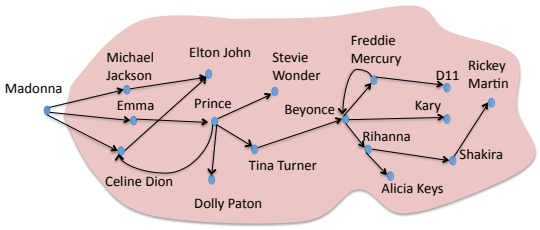

Figure 1: Harvesting Procedure.

the type used in (Etzioni et al., 2005; Pasca, 2007; Kozareva and Hovy, 2010a):

- semantic classes that can be learned using different seeds (e.g., "singers such as **Madonna** and *" and "singers such as **Placido Domingo** and *");
- semantic classes that are expressed through different lexico-syntactic patterns (e.g., "weapons **such as** bombs and *" and "weapons **including** bombs and *");
- verbs and adjectives characterizing the semantic class (e.g., "**expensive** and * car", "dogs **run** and *");
- semantic relations with more complex lexico-syntactic structure (e.g., "* and Easyjet **fly to**", "* and Sam **live in**");
- semantic classes that are obtained in different languages, such as English and Spanish (e.g., "**singers** such as Madonna and *" and "**cantantes** como Madonna y *");

While most of these variations have been explored in individual papers, we have found no paper that covers them all, and none whatsoever that uses verbs and adjectives as seeds.

Using the above procedure to generate the data, each pattern was submitted as a query to Yahoo!Boss. For each query the top 1000 text snippets were retrieved. The algorithm ran until exhaustion. In total, we collected 10GB of data which was part-of-speech tagged with Treetagger (Schmid, 1994) and used for the semantic term extraction. Table 1 summarizes the number of nodes and edges learned for each semantic network using pattern P_i and the initial seed shown in italics.

Lexico-Syntactic Pattern	Nodes	Edges
P_1="**singers** such as *Madonna* and *"	1115	1942
P_2="**singers** such as *Placido Domingo* and *"	815	1114
P_3="**emotions** including *anger* and *"	113	250

4 Statistical Properties of Text-Mined Semantic Networks

In this section we apply a range of relevant measures from the network analysis community to the networks described above.

4.1 Centrality

The first statistical property we explore is centrality. It measures the degree to which the network structure determines the importance of a node in the network (Sabidussi, 1966; Freeman, 1979).

We explore the effect of two centrality measures: $indegree$ and $outdegree$. The $indegree$ of a node u denoted as $indegree(u)$=$\sum(v,u)$ considers the sum of all incoming edges to u and captures the ability of a semantic term to be discovered by other semantic terms. The $outdegree$ of a node u denoted as $outdegree(u)$=$\sum(u,v)$ considers the number of outgoing edges of the node u and measures the ability of a semantic term to discover new terms. Intuitively, the more central the node u is, the more confident we are that it is a correct term.

Since harvesting algorithms are notorious for extracting erroneous information, we use the two centrality measures to rerank the harvested elements. Table 2 shows the accuracy[2] of the singer semantic terms at different ranks using the in and out degree measures. Consistently, $outdegree$ outperforms $indegree$ and reaches higher accuracy. This

[2]Accuracy is calculated as the number of correct terms at rank R divided by the total number of terms at rank R.

shows that for the text-mined semantic networks, the ability of a term to discover new terms is more important than the ability to be discovered.

@rank	in-degree	out-degree
10	.92	1.0
25	.91	1.0
50	.90	.97
75	.90	.96
100	.89	.96
150	.88	.95

Table 2: *Accuracy of the Singer Terms.*

This poses the question "*What are the terms with high and low outdegree?*". Table 3 shows the top and bottom 10 terms of the semantic class.

Semantic Class	top 10 outDegree	bottom 10 outDegree
Singers	Frank Sinatra	Alanis Morisette
	Ella Fitzgerald	Christine Agulera
	Billie Holiday	Buffy Sainte-Marie
	Britney Spears	Cece Winans
	Aretha Franklin	Wolfman Jack
	Michael Jackson	Billie Celebration
	Celine Dion	Alejandro Sanz
	Beyonce	France Gall
	Bessie Smith	Peter
	Joni Mitchell	Sarah

Table 3: *Singer Term Ranking with Centrality Measures.*

The nodes with high outdegree correspond to famous or contemporary singers. The lower-ranked nodes are mostly spelling errors such as *Alanis Morisette* and *Christine Agulera*, less known singers such as *Buffy Sainte-Marie* and *Cece Winans*, non-American singers such as *Alejandro Sanz* and *France Gall*, extractions due to part-of-speech tagging errors such as *Billie Celebration*, and general terms such as *Peter* and *Sarah*. Potentially, knowing which terms have a high *outdegree* allows one to rerank candidate seeds for more effective harvesting.

4.2 Power-law Degree Distribution

We next study the degree distributions of the networks. Similarly to the Web (Broder et al., 2000) and social networks like Orkut and Flickr, the text-mined semantic networks also exhibit a power-law distribution. This means that while a few terms have a significantly high degree, the majority of the semantic terms have small degree. Figure 2 shows the $indegree$ and $outdegree$ distributions for different semantic classes, lexico-syntactic patterns, and languages (English and Spanish). For each semantic network, we plot the best-fitting power-law function (Clauset et al., 2009) which fits well all degree distributions. Table 4 shows the power-law exponent values for all text-mined semantic networks.

Patt.	γ_{in}	γ_{out}	Patt.	γ_{in}	γ_{out}
P_1	2.37	1.27	P_{10}	1.65	1.12
P_2	2.25	1.21	P_{11}	2.42	1.41
P_3	2.20	1.76	P_{12}	1.60	1.13
P_4	2.28	1.18	P_{13}	2.26	1.20
P_5	2.49	1.18	P_{14}	2.43	1.25
P_6	2.42	1.30	P_{15}	2.51	1.43
P_7	1.95	1.20	P_{16}	2.74	1.31
P_8	1.94	1.07	P_{17}	2.90	1.20
P_9	1.96	1.30			

Table 4: *Power-Law Exponents of Semantic Networks.*

It is interesting to note that the $indegree$ power-law exponents for all semantic networks fall within the same range ($\gamma_{in} \approx 2.4$), and similarly for the $outdegree$ exponents ($\gamma_{out} \approx 1.3$). However, the values of the $indegree$ and $outdegree$ exponents differ from each other. This observation is consistent with Web degree distributions (Broder et al., 2000). The difference in the distributions can be explained by the link asymmetry of semantic terms: A discovering B does not necessarily mean that B will discover A. In the text-mined semantic networks, this asymmetry is caused by patterns of language use, such as the fact that people use first adjectives of the size and then of the color (e.g., big red car), or prefer to place male before female proper names. Harvesting patterns should take into account this tendency.

4.3 Sparsity

Another relevant property of the semantic networks concerns sparsity. Following Preiss (Preiss, 1999), a graph is sparse if $|E| = O(|V|^k)$ and $1 < k < 2$, where $|E|$ is the number of edges and $|V|$ is the number of nodes, otherwise the graph is dense. For the studied text-semantic networks, k is ≈ 1.08. Sparsity can be also captured through the density of the semantic network which is computed as $\frac{|E|}{V(V-1)}$. All networks have low density which suggests that the networks exhibit a sparse connectivity pattern. On average a node (semantic term) is connected to a very small percentage of other nodes. Similar behavior was reported for the WordNet and Roget's semantic networks (Steyvers and Tenenbaum, 2004).

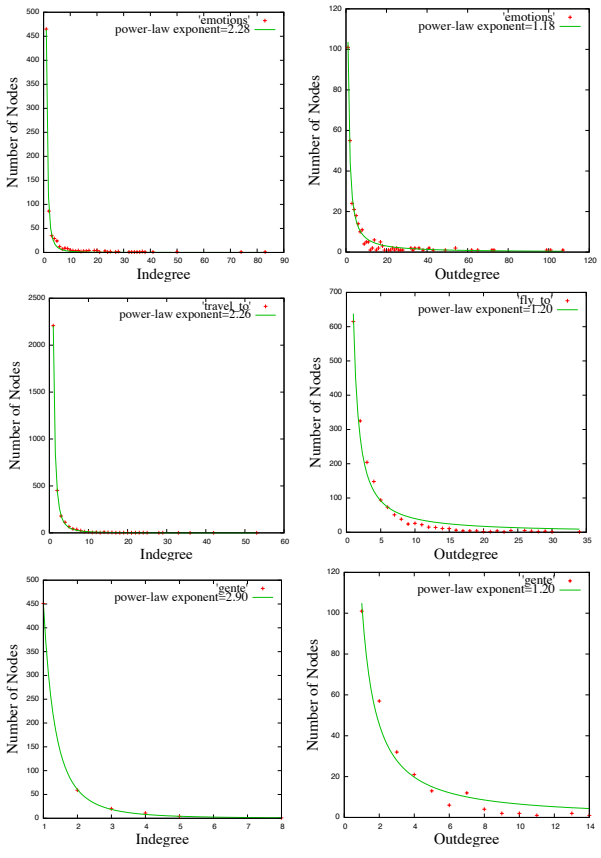

Figure 2: Degree Distributions of Semantic Networks.

4.4 Connectedness

For every network, we computed the strongly connected component (SCC) such that for all nodes (semantic terms) in the SCC, there is a path from any node to another node in the SCC considering the direction of the edges between the nodes. For each network, we found that there is only one SCC. The size of the component is shown in Table 5. Unlike WordNet and Roget's semantic networks where the SCC consists 96% of all semantic terms, in the text-mined semantic networks only 12 to 55% of the terms are in the SCC. This shows that not all nodes can reach (discover) every other node in the network. This also explains the findings of (Kozareva et al., 2008; Vyas et al., 2009) why starting with a good seed is important.

4.5 Path Lengths and Diameter

Next, we describe the properties of the shortest paths between the semantic terms in the SCC. The distance between two nodes in the SCC is measured as the length of the shortest path connecting the terms. The direction of the edges between the terms is taken into consideration. The average distance is the average value of the shortest path lengths over all pairs of nodes in the SCC. The diameter of the SCC is calculated as the maximum distance over all pairs of nodes (u, v), such that a node v is reachable from node u. Table 5 shows the average distance and the diameter of the semantic networks.

Patt.	#nodes in SCC	SCC Average Distance	SCC Diameter
P_1	364 (.33)	5.27	16
P_2	285 (.35)	4.65	13
P_3	48 (.43)	2.85	6
P_4	274 (.37)	2.94	7
P_5	1249 (.38)	5.99	17
P_6	1471 (.29)	4.82	15
P_7	2255 (.46)	3.51	11
P_8	1012 (.50)	3.87	11
P_9	289 (.33)	4.93	13
P_{10}	2342 (.55)	4.50	12
P_{11}	87 (.24)	5.00	11
P_{12}	1967 (.51)	3.20	13
P_{13}	1249 (.38)	4.75	13
P_{14}	608 (.29)	7.07	23
P_{15}	1752 (.26)	5.32	15
P_{16}	56 (.23)	4.79	12
P_{17}	69 (.12)	5.01	13

Table 5: *SCC, SCC Average Distance and SCC Diameter of the Semantic Networks.*

The diameter shows the maximum number of steps necessary to reach from any node to any other, while the average distance shows the number of steps necessary on average. Overall, all networks have very short average path lengths and small diameters that are consistent with Watt's finding for small-world networks. Therefore, the yield of harvesting seeds can be predicted within five steps explaining (Kozareva and Hovy, 2010b; Vyas et al., 2009).

We also compute for any randomly selected node in the semantic network on average how many hops (steps) are necessary to reach from one node to another. Figure 3 shows the obtained results for some of the studied semantic networks.

4.6 Clustering

The clustering coefficient (C) is another measure to study the connectivity structure of the networks (Watts and Strogatz, 1998). This measure captures the probability that the two neighbors of a randomly selected node will be neighbors. The clustering coefficient of a node u is calculated as $C_u = \frac{|e_{ij}|}{k_u(k_u-1)}$

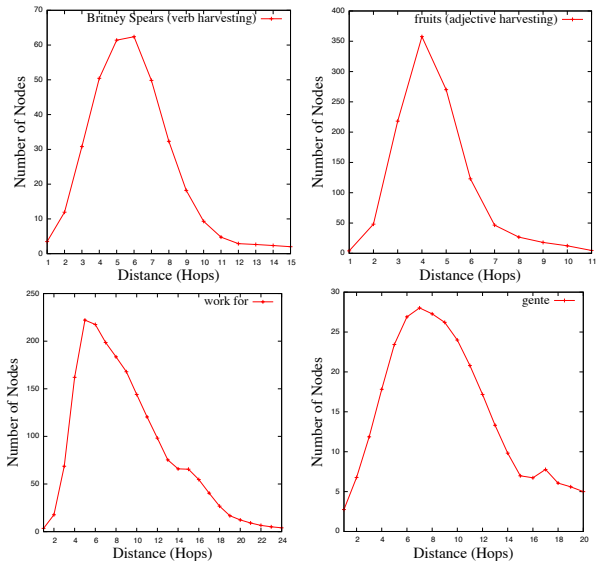

Figure 3: Hop Plot of the Semantic Networks.

Patt.	C	ClosedTriads	OpenTriads
P_1	.01	14096 (.97)	388 (.03)
P_2	.01	6487 (.97)	213 (.03)
P_3	.30	1898 (.94)	129 (.06)
P_4	.33	60734 (.94)	3944 (.06)
P_5	.10	79986 (.97)	2321 (.03)
P_6	.11	78716 (.97)	2336 (.03)

P_8	.19	21138 (.95)	10728 (.05)
P_9	.20	27830 (.95)	1354 (.05)
P_{10}	.15	712227 (.96)	62101(.04)
P_{11}	.09	3407 (.98)	63 (.02)
P_{12}	.15	734724 (.96)	32517 (.04)
P_{13}	.06	66162 (.99)	858 (.01)
P_{14}	.05	28216 (.99)	408 (.01)
P_{15}	.09	1336679 (.97)	47110 (.03)
P_{16}	.09	1525 (.98)	37 (.02)
P_{17}	.05	2222 (.99)	21 (.01)

Table 6: *Clustering Coefficient of the Semantic Networks.*

: $v_i, v_j \in N_u, e_{ij} \in E$, where k_u is the total degree of the node u and N_u is the neighborhood of u. The clustering coefficient C for the whole semantic network is the average clustering coefficient of all its nodes, C=$\frac{1}{n}\sum C_i$. The value of the clustering coefficient ranges between $[0, 1]$, where 0 indicates that the nodes do not have neighbors which are themselves connected, while 1 indicates that all nodes are connected. Table 6 shows the clustering coefficient for all text-mined semantic networks together with the number of closed and open triads[3]. The analysis suggests the presence of a strong local cluster, however there are few possibilities to form overlapping neighborhoods of nodes. The clustering coefficient of WordNet (Steyvers and Tenenbaum, 2004) is similar to those of the text-mined networks.

4.7 Joint Degree Distribution

In social networks, understanding the preferential attachment of nodes is important to identify the speed with which epidemics or gossips spread. Similarly, we are interested in understanding how the nodes of the semantic networks connect to each other. For this purpose, we examine the Joint Degree Distribution (JDD) (Li et al., 2005; Newman, 2003). JDD is approximated by the degree correlation function k_{nn} which maps the $outdegree$ and the average $indegree$ of all nodes connected to a node with that $outdegree$. High values of k_{nn} indicate that high-degree nodes tend to connect to other high-degree nodes (forming a "core" in the network), while lower values of k_{nn} suggest that the high-degree nodes tend to connect to low-degree ones. Figure 4 shows the k_{nn} for the *singer*, *whale*, *live in*, *cars*, *cantantes*, and *gente* networks. The figure plots the outdegree and the average indegree of the semantic terms in the networks on a log-log scale. We can see that for all networks the high-degree nodes tend to connect to other high-degree ones. This explains why text mining algorithms should focus their effort on high-degree nodes.

4.8 Assortivity

The property of the nodes to connect to other nodes with similar degrees can be captured through the assortivity coefficient r (Newman, 2003). The range of r is $[-1, 1]$. A positive assortivity coefficient means that the nodes tend to connect to nodes of similar degree, while negative coefficient means that nodes are likely to connect to nodes with degree very different from their own. We find that the assortivitiy coefficient of our semantic networks is positive, ranging from 0.07 to 0.20. In this respect, the semantic networks differ from the Web, which has a negative assortivity (Newman, 2003). This implies a difference in text mining and web search traversal strategies: since starting from a highly-connected seed term will tend to lead to other highly-connected terms, text mining algorithms should prefer depth-first traversal, while web search algorithms starting

[3] A triad is three nodes that are connected by either two (open triad) or three (closed triad) directed ties.

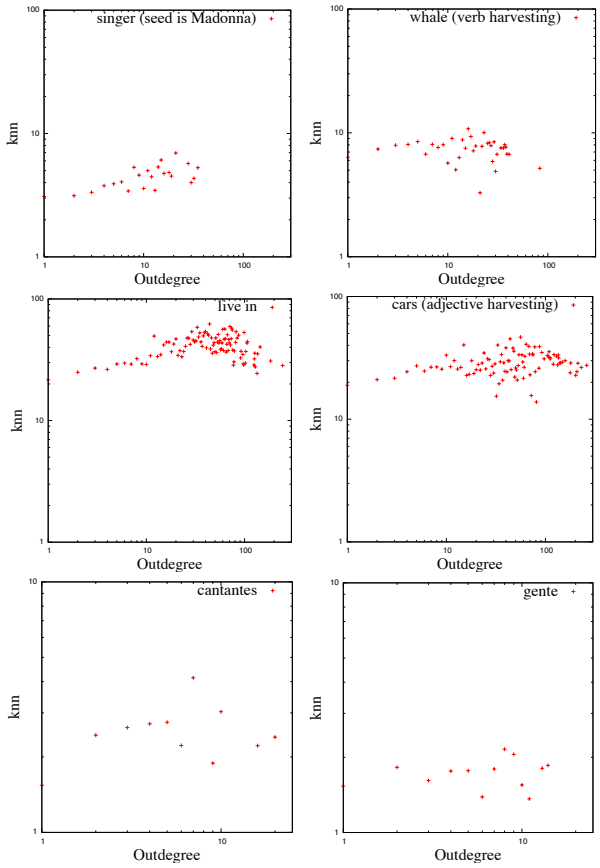

Figure 4: Joint Degree Distribution of the Semantic Networks.

from a highly-connected seed page should prefer a breadth-first strategy.

5 Discussion

The above studies show that many of the properties discovered of the network formed by the web hold also for the networks induced by semantic relations in text mining applications, for various semantic classes, semantic relations, and languages. We can therefore apply some of the research from network analysis to text mining.

The small-world phenomenon, for example, holds that any node is connected to any other node in at most six steps. Since as shown in Section 4.5 the semantic networks also exhibit this phenomenon, we can explain the observation of (Kozareva and Hovy, 2010b) that one can quite accurately predict the relative 'goodness' of a seed term (its eventual total yield and the number of steps required to obtain that) within five harvesting steps. We have shown that due to the strongly connected components in text mining networks, not all elements within the harvested graph can discover each other. This implies that harvesting algorithms have to be started with several seeds to obtain adequate Recall (Vyas et al., 2009). We have shown that centrality measures can be used successfully to rank harvested terms to guide the network traversal, and to validate the correctness of the harvested terms.

In the future, the knowledge and observations made in this study can be used to model the lexical usage of people over time and to develop new semantic search technology.

6 Conclusion

In this paper we describe the implicit 'hidden' semantic network graph structure induced over the text of the web and other sources by the semantic relations people use in sentences. We describe how term harvesting patterns whose seed terms are harvested and then applied recursively can be used to discover these semantic term networks. Although these networks differ considerably from the web in relation density, type, and network size, we show, somewhat surprisingly, that the same power-law, small-world effect, transitivity, and most other characteristics that apply to the web's hyperlinked network structure hold also for the implicit semantic term graphs—certainly for the semantic relations and languages we have studied, and most probably for almost all semantic relations and human languages.

This rather interesting observation leads us to surmise that the hyperlinks people create in the web are of essentially the same type as the semantic relations people use in normal sentences, and that they form an extension of normal language that was not needed before because people did not have the ability within the span of a single sentence to 'embed' structures larger than a clause—certainly not a whole other page's worth of information. The principal exception is the academic citation reference (lexicalized as "see"), which is not used in modern webpages. Rather, the 'lexicalization' now used is a formatting convention: the hyperlink is colored and often underlined, facilities offered by computer screens but not available to speech or easy in traditional typesetting.

Event Extraction as Dependency Parsing

David McClosky, Mihai Surdeanu, and Christopher D. Manning
Department of Computer Science
Stanford University
Stanford, CA 94305
{mcclosky,mihais,manning}@stanford.edu

Abstract

Nested event structures are a common occurrence in both open domain and domain specific extraction tasks, e.g., a "crime" event can cause a "investigation" event, which can lead to an "arrest" event. However, most current approaches address event extraction with highly local models that extract each event and argument independently. We propose a simple approach for the extraction of such structures by taking the tree of event-argument relations and using it directly as the representation in a reranking dependency parser. This provides a simple framework that captures global properties of both nested and flat event structures. We explore a rich feature space that models both the events to be parsed and context from the original supporting text. Our approach obtains competitive results in the extraction of biomedical events from the BioNLP'09 shared task with a F1 score of 53.5% in development and 48.6% in testing.

1 Introduction

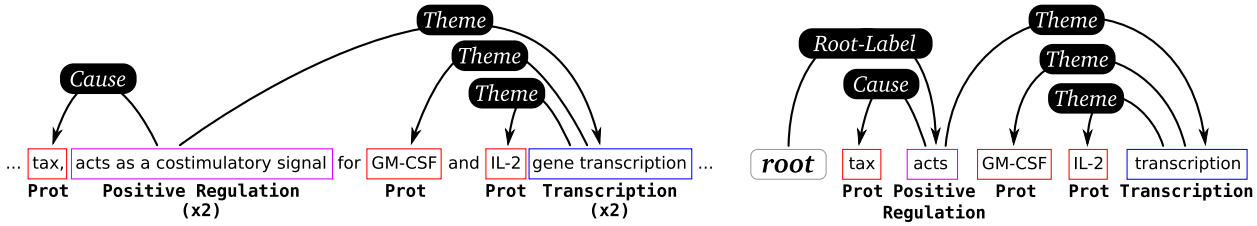
Event structures in open domain texts are frequently highly complex and nested: a "crime" event can cause an "investigation" event, which can lead to an "arrest" event (Chambers and Jurafsky, 2009). The same observation holds in specific domains. For example, the BioNLP'09 shared task (Kim et al., 2009) focuses on the extraction of nested biomolecular events, where, e.g., a REGULATION event causes a TRANSCRIPTION event (see Figure 1a for a detailed example). Despite this observation, many state-of-the-art supervised event extraction models still extract events and event arguments independently, ignoring their underlying structure (Björne et al., 2009; Miwa et al., 2010b).

In this paper, we propose a new approach for supervised event extraction where we take the tree of relations and their arguments and use it directly as the representation in a dependency parser (rather than conventional syntactic relations). Our approach is conceptually simple: we first convert the original representation of events and their arguments to dependency trees by creating dependency arcs between *event anchors* (phrases that anchor events in the supporting text) and their corresponding arguments.[1] Note that after conversion, only event anchors and entities remain. Figure 1 shows a sentence and its converted form from the biomedical domain with four events: two POSITIVE REGULATION events, anchored by the phrase "acts as a costimulatory signal," and two TRANSCRIPTION events, both anchored on "gene transcription." All events take either protein entity mentions (PROT) or other events as arguments. The latter is what allows for nested event structures. Existing dependency parsing models can be adapted to produce these semantic structures instead of syntactic dependencies. We built a global reranking parser model using multiple decoders from MSTParser (McDonald et al., 2005; McDonald et al., 2005b). The main contributions of this paper are the following:

1. We demonstrate that parsing is an attractive approach for extracting events, both nested and otherwise.

[1] While our approach only works on trees, we show how we can handle directed acyclic graphs in Section 5.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1626–1635,
Portland, Oregon, June 19-24, 2011.



(a) Original sentence with nested events

(b) After conversion to event dependencies

Figure 1: Nested events in the text fragment: "...the *HTLV-1 transactivator protein*, *tax*, **acts as a costimulatory signal** for *GM-CSF* and *IL-2* **gene transcription** ..." Throughout this paper, **bold text** indicates instances of event anchors and *italicized text* denotes entities (PROTEINs in the BioNLP'09 domain). Note that in (a) there are two copies of each type of event, which are merged to single nodes in the dependency tree (Section 3.1).

2. We propose a wide range of features for event extraction. Our analysis indicates that features which model the global event structure yield considerable performance improvements, which proves that modeling event structure jointly is beneficial.
3. We evaluate on the biomolecular event corpus from the the BioNLP'09 shared task and show that our approach obtains competitive results.

2 Related Work

The pioneering work of Miller et al. (1997) was the first, to our knowledge, to propose parsing as a framework for information extraction. They extended the syntactic annotations of the Penn Treebank corpus (Marcus et al., 1993) with entity and relation mentions specific to the MUC-7 evaluation (Chinchor et al., 1997) — e.g., EMPLOYEE OF relations that hold between person and organization named entities — and then trained a generative parsing model over this combined syntactic and semantic representation. In the same spirit, Finkel and Manning (2009) merged the syntactic annotations and the named entity annotations of the OntoNotes corpus (Hovy et al., 2006) and trained a discriminative parsing model for the joint problem of syntactic parsing and named entity recognition. However, both these works require a unified annotation of syntactic and semantic elements, which is not always feasible, and focused only on named entities and binary relations. On the other hand, our approach focuses on event structures that are nested and have an arbitrary number of arguments. We do not need a unified syntactic and semantic representation (but we can and do extract features from the underlying syntactic structure of the text).

Finkel and Manning (2009b) also proposed a parsing model for the extraction of nested named entity mentions, which, like this work, parses just the corresponding semantic annotations. In this work, we focus on more complex structures (events instead of named entities) and we explore more global features through our reranking layer.

In the biomedical domain, two recent papers proposed joint models for event extraction based on Markov logic networks (MLN) (Riedel et al., 2009; Poon and Vanderwende, 2010). Both works propose elegant frameworks where event anchors and arguments are jointly predicted for all events in the same sentence. One disadvantage of MLN models is the requirement that a human expert develop domain-specific predicates and formulas, which can be a cumbersome process because it requires thorough domain understanding. On the other hand, our approach maintains the joint modeling advantage, but our model is built over simple, domain-independent features. We also propose and analyze a richer feature space that captures more information on the global event structure in a sentence. Furthermore, since our approach is agnostic to the parsing model used, it could easily be tuned for various scenarios, e.g., models with lower inference overhead such as shift-reduce parsers.

Our work is conceptually close to the recent CoNLL shared tasks on semantic role labeling, where the predicate frames were converted to se-

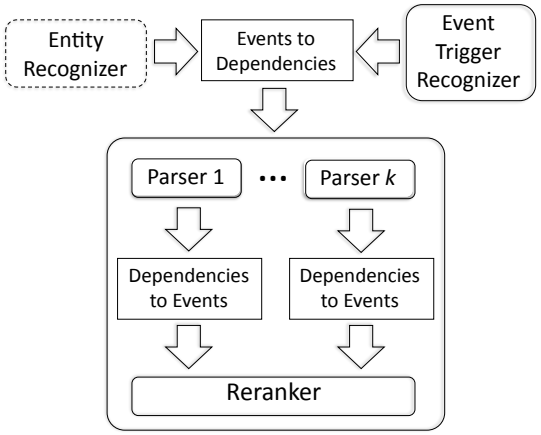


Figure 2: Overview of the approach. Rounded rectangles indicate domain-independent components; regular rectangles mark domain-specific modules; blocks in dashed lines surround components not necessary for the domain presented in this paper.

mantic dependencies between predicates and their arguments (Surdeanu et al., 2008; Hajic et al., 2009). In this representation the dependency structure is a directed acyclic graph (DAG), i.e., the same node can be an argument to multiple predicates, and there are no explicit dependencies between predicates. Due to this representation, all joint models proposed for semantic role labeling handle semantic frames independently.

3 Approach

Figure 2 summarizes our architecture. Our approach converts the original event representation to dependency trees containing both event anchors and entity mentions, and trains a battery of parsers to recognize these structures. The trees are built using event anchors predicted by a separate classifier. In this work, we do not discuss entity recognition because in the BioNLP'09 domain used for evaluation entities (PROTEINS) are given (but including entity recognition is an obvious extension of our model). Our parsers are several instances of MSTParser[2] (McDonald et al., 2005; McDonald et al., 2005b) configured with different decoders. However, our approach is agnostic to the actual parsing models used and could easily be adapted to other dependency parsers. The output from the reranking parser is converted back to the original event representation and passed to a reranker component (Collins, 2000; Charniak and Johnson, 2005), tailored to optimize the task-specific evaluation metric.

Note that although we use the biomedical event domain from the BioNLP'09 shared task to illustrate our work, the core of our approach is almost domain independent. Our only constraints are that each event mention be activated by a phrase that serves as an event anchor, and that the event-argument structures be mapped to a dependency tree. The conversion between event and dependency structures and the reranker metric are the only domain dependent components in our approach.

3.1 Converting between Event Structures and Dependencies

As in previous work, we extract event structures at sentence granularity, i.e., we ignore events which span sentences (Björne et al., 2009; Riedel et al., 2009; Poon and Vanderwende, 2010). These form approximately 5% of the events in the BioNLP'09 corpus. For each sentence, we convert the BioNLP'09 event representation to a graph (representing a labeled dependency tree) as follows. The nodes in the graph are protein entity mentions, event anchors, and a virtual ROOT node. Thus, the only words in this dependency tree are those which participate in events. We create edges in the graph in the following way. For each event anchor, we create one link to each of its arguments labeled with the slot name of the argument (for example, connecting **gene transcription** to *IL-2* with the label THEME in Figure 1b). We link the ROOT node to each entity that does not participate in an event using the ROOT-LABEL dependency label. Finally, we link the ROOT node to each top-level event anchor, (those which do not serve as arguments to other events) again using the ROOT-LABEL label. We follow the convention that the source of each dependency arc is the head while the target is the modifier.

The output of this process is a directed graph, since a phrase can easily play a role in two or more events. Furthermore, the graph may contain self-referential edges (self-loops) due to related events sharing the same anchor (example below). To guarantee that the output of this process is a tree, we must post-process the above graph with the follow-

[2] http://sourceforge.net/projects/mstparser/

ing three heuristics:

Step 1: We remove self-referential edges. An example of these can be seen in the text "the domain interacted preferentially with **underphosphorylated** *TRAF2*," there are two events anchored by the same **underphosphorylated** phrase, a NEGATIVE REGULATION and a PHOSPHORYLATION event, and the latter serves as a THEME argument for the former. Due to the shared anchor, our conversion component creates an self-referential THEME dependency. By removing these edges, 1.5% of the events in the training arguments are left without arguments, so we remove them as well.

Step 2: We break structures where one argument participates in multiple events, by keeping only the dependency to the event that appears first in text. For example, in the fragment "by enhancing its **inactivation** through **binding** to soluble *TNF-alpha receptor type II*," the protein *TNF-alpha receptor type II* is an argument in both a BINDING event (**binding**) and in a NEGATIVE REGULATION event (**inactivation**). As a consequence of this step, 4.7% of the events in training are removed.

Step 3: We unify events with the same types anchored on the same anchor phrase. For example, for the fragment "Surface **expression** of *intercellular adhesion molecule-1*, *P-selectin*, and *E-selectin*," the BioNLP'09 annotation contains three distinct GENE EXPRESSION events anchored on the same phrase (**expression**), each having one of the proteins as THEMEs. In such cases, we migrate all arguments to one of the events, and remove the empty events. 21.5% of the events in training are removed in this step (but no dependencies are lost).

Note that we do not guarantee that the resulting tree is projective. In fact, our trees are more likely to be non-projective than syntactic dependency trees of English sentences, because in our representation many nodes can be linked directly to the ROOT node. Our analysis indicates that 2.9% of the dependencies generated in the training corpus are non-projective and 7.9% of the sentences contain at least one non-projective dependency (for comparison, these numbers for the English Penn Treebank are 0.3% and 6.7%, respectively).

After parsing, we implement the inverse process, i.e., we convert the generated dependency trees to the BioNLP'09 representation. In addition to the obvious conversions, this process implements the heuristics proposed by Björne et al. (2009), which reverse step 3 above, e.g., we duplicate GENE EXPRESSION events with multiple THEME arguments. The heuristics are executed sequentially in the given order:

1. Since all non-BINDING events can have at most one THEME argument, we duplicate non-BINDING events with multiple THEME arguments by creating one separate event for each THEME.

2. Similarly, since REGULATION events accepts only one CAUSE argument, we duplicate REGULATION events with multiple CAUSE arguments, obtaining one event per CAUSE.

3. Lastly, we implement the heuristic of Björne et al. (2009) to handle the splitting of BINDING events with multiple THEME arguments. This is more complex because these events can accept one or more THEMEs. In such situations, we first group THEME arguments by the label of the first Stanford dependency (Marneffe and Manning, 2008) from the head word of the anchor to this argument. Then we create one event for each combination of THEME arguments in different groups.

3.2 Recognition of Event Anchors

For anchor detection, we used a multiclass classifier that labels each token independently.[3] Since over 92% of the anchor phrases in our evaluation domain contain a single word, we simplify the task by reducing all multi-word anchor phrases in the training corpus to their syntactic head word (e.g., "acts" for the anchor "**acts as a costimulatory signal**").

We implemented this model using a logistic regression classifier with L2 regularization over the following features:

[3] We experimented with using conditional random fields as a sequence labeler but did not see improvements in the biomedical domain. We hypothesize that the sequence tagger fails to capture potential dependencies between anchor labels – which are its main advantage over an i.i.d. classifier – because anchor words are typically far apart in text. This result is consistent with observations in previous work (Björne et al., 2009).

- **Token-level:** The form, lemma, and whether the token is present in a gazetteer of known anchor words.[4]
- **Surface context:** The above token features extracted from a context of two words around the current token. Additionally, we build token bigrams in this context window, and model them with similar features.
- **Syntactic context:** We model all syntactic dependency paths up to depth two starting from the token to be classified. These paths are built from Stanford syntactic dependencies (Marneffe and Manning, 2008). We extract token features from the first and last token in these paths. We also generate combination features by concatenating: (a) the last token in each path with the sequence of dependency labels along the corresponding path; and (b) the word to be classified, the last token in each path, and the sequence of dependency labels in that path.
- **Bag-of-word** and **entity count:** Extracted from (a) the entire sentence, and (b) a window of five words around the token to be classified.

3.3 Parsing Event Structures

Given the entities and event anchors from the previous stages in the pipeline, the parser generates labeled dependency links between them. Many dependency parsers are available and we chose MSTParser for its ability to produce non-projective and n-best parses directly. MSTParser frames parsing as a graph algorithm. To parse a sentence, MSTParser finds the tree covering all the words (nodes) in the sentence (graph) with the largest sum of edge weights, i.e., the maximum weighted spanning tree. Each labeled, directed edge in the graph represents a possible dependency between its two endpoints and has an associated score (weight). Scores for edges come from the dot product between the edge's corresponding feature vector and learned feature weights. As a result, all features for MSTParser must be *edge-factored*, i.e., functions of both endpoints and the label connecting them. McDonald et al. (2006) extends the basic model to include second-order dependencies (i.e., two adjacent sibling nodes and their parent). Both first and second-order modes include projective and non-projective decoders.

Our features for MSTParser use both the event structures themselves as well as the surrounding English sentences which include them. By mapping event anchors and entities back to the original text, we can incorporate information from the original English sentence as well its syntactic tree and corresponding Stanford dependencies. Both forms of context are valuable and complementary. MSTParser comes with a large number of features which, in our setup, operate on the event structure level (since this is the "sentence" from the parser's point of view). The majority of additional features that we introduced take advantage of the original text as context (primarily its associated Stanford dependencies). Our system includes the following first-order features:

- **Path:** Syntactic paths in the original sentence between nodes in an event dependency (as in previous work by Björne et al. (2009)). These have many variations including using Stanford dependencies ("collapsed" and "uncollapsed") or constituency trees as sources, optionally lexicalizing the path, and using words or relation names along the path. Additionally, we include the bucketed length of the paths.
- **Original sentence words:** Words from the full English sentence surrounding and between the nodes in event dependencies, and their bucketed distances. This additional context helps compensate for how our anchor detection provides only the head word of each anchor, which does not necessarily provide the full context for event disambiguation.
- **Graph:** Parents, children, and siblings of nodes in the Stanford dependencies graph along with label of the edge. This provides additional syntactic context.
- **Consistency:** Soft constraints on edges between anchors and their arguments (e.g., only regulation events can have edges labeled with CAUSE). These features fire if their constraints are violated.
- **Ontology:** Generalized types of the endpoints of edges using a given type hierarchy (e.g., POSITIVE REGULATION is a COM-

[4] These are automatically extracted from the training corpus.

PLEX EVENT[5] is an EVENT). Values of this feature are coded with the types of each of the endpoints on an edge, running over the cross-product of types for each endpoint. For instance, an edge between a BINDING event anchor and a POSITIVE REGULATION could cause this feature to fire with the values [head:EVENT, child:COMPLEX EVENT] or [head:SIMPLE EVENT, child:EVENT].[6] The latter feature can capture generalizations such as "simple event anchors cannot take other events as arguments."

Both **Consistency** and **Ontology** feature classes include domain-specific information but can be used on other domains under different constraints and type hierarchies. When using second-order dependencies, we use additional **Path** and **Ontology** features. We include the syntactic paths between sibling nodes (adjacent arguments of the same event anchor). These **Path** features are as above but differentiated as paths between sibling nodes. The second-order **Ontology** features use the type hierarchy information on both sibling nodes and their parent. For example, a POSITIVE REGULATION anchor attached to a PROTEIN and a BINDING event would produce an **Ontology** feature with the value [parent:COMPLEX EVENT, child_1:PROTEIN, child_2:SIMPLE EVENT] (among several other possible combinations).

To prune the number of features used, we employ a simple entropy-based measure. Our intuition is that good features should typically appear with only one edge label.[7] Given all edges enumerated during training and their gold labels, we obtain a distribution over edge labels (d_f) for each feature f. Given this distribution and the frequency of a feature, we can score the feature with the following:

$$score(f) = \alpha \times \log_2 \big(freq(f)\big) - H(d_f)$$

The α parameter adjusts the relative weight of the two components. The log frequency component favors more frequent features while the entropy component favors features with low entropy in their edge label distribution. Features are pruned by accepting all features with a score above a certain threshold.

3.4 Reranking Event Structures

When decoding, the parser finds the highest scoring tree which incorporates global properties of the sentence. However, its features are edge-factored and thus unable to take into account larger contexts. To incorporate arbitrary global features, we employ a two-step reranking parser. For the first step, we extend our parser to output its n-best parses instead of just its top scoring parse. In the second step, a discriminative reranker rescores each parse and reorders the n-best list. Rerankers have been successfully used in syntactic parsing (Collins, 2000; Charniak and Johnson, 2005; Huang, 2008) and semantic role labeling (Toutanova et al., 2008).

Rerankers provide additional advantages in our case due to the mismatch between the dependency structures that the parser operates on and their corresponding event structures. We convert the output from the parser to event structures (Section 3.1) before including them in the reranker. This allows the reranker to capture features over the actual event structures rather than their original dependency trees which may contain extraneous portions.[8] Furthermore, this lets the reranker optimize the actual BioNLP F1 score. The parser, on the other hand, attempts to optimize the Labeled Attachment Score (LAS) between the dependency trees and converted gold dependency trees. LAS is approximate for two reasons. First, it is much more local than the BioNLP metric.[9] Second, the converted gold dependency trees lose information that doesn't transfer to trees (specifically, that event structures are really multi-DAGs and not trees).

We adapt the maximum entropy reranker from Charniak and Johnson (2005) by creating a customized feature extractor for event structures — in all other ways, the reranker model is unchanged. We use the following types of features in the reranker:

- **Source:** Score and rank of the parse from the

[5] We define complex events are those which can accept other events are arguments. Simple events can only take PROTEINs.

[6] We omit listing the other two combinations.

[7] Labels include ROOT-LABEL, THEME, CAUSE, and NULL. We assign the NULL label to edges which aren't in the gold data.

[8] For instance, event anchors with no arguments could be proposed by the parser. These event anchors are automatically dropped by the conversion process.

[9] As an example, getting an edge label between an anchor and its argument correct is unimportant if the anchor is missing other arguments.

Decoder(s)	Unreranked			Reranked		
	R	P	F1	R	P	F1
1P	65.6	76.7	70.7	68.0	77.6	72.5
2P	67.4	77.1	71.9	67.9	77.3	72.3
1N	67.5	76.7	71.8	—	—	—
2N	68.9	77.1	72.7	—	—	—
1P, 2P, 2N	—	—	—	68.5	78.2	**73.1**

(a) Gold event anchors

Decoder(s)	Unreranked			Reranked		
	R	P	F1	R	P	F1
1P	44.7	62.2	52.0	47.8	59.6	53.1
2P	45.9	61.8	52.7	48.4	57.5	52.5
1N	46.0	61.2	52.5	—	—	—
2N	38.6	66.6	48.8	—	—	—
1P, 2P, 2N	—	—	—	48.7	59.3	**53.5**

(b) Predicted event anchors

Table 1: BioNLP recall, precision, and F1 scores of individual decoders and the best decoder combination on development data with the impact of event anchor detection and reranking. Decoder names include the features order (1 or 2) followed by the projectivity (P = projective, N = non-projective).

decoder; number of different decoders producing the parse (when using multiple decoders).

- **Event path:** Path from each node in the event tree up to the root. Unlike the **Path** features in the parser, these paths are over event structures, not the syntactic dependency graphs from the original English sentence. Variations of the **Event path** features include whether to include word forms (e.g., "binds"), types (BINDING), and/or argument slot names (THEME). We also include the path length as a feature.
- **Event frames:** Event anchors with all their arguments and argument slot names.
- **Consistency:** Similar to the parser **Consistency** features, but capable of capturing larger classes of errors (e.g., incorrect number or types of arguments). We include the number of violations from four different classes of errors.

To improve performance and robustness, features are pruned as in Charniak and Johnson (2005): selected features must distinguish a parse with the highest F1 score in a n-best list, from a parse with a suboptimal F1 score at least five times.

Rerankers can also be used to perform model combination (Toutanova et al., 2008; Zhang et al., 2009; Johnson and Ural, 2010). While we use a single parsing model, it has multiple decoders.[10] When combining multiple decoders, we concatenate their n-best lists and extract the unique parses.

4 Experimental Results

Our experiments use the BioNLP'09 shared task corpus (Kim et al., 2009) which includes 800 biomedical abstracts (7,449 sentences, 8,597 events) for training and 150 abstracts (1,450 sentences, 1,809 events) for development. The test set includes 260 abstracts, 2,447 sentences, and 3,182 events. Throughout our experiments, we report BioNLP F1 scores with approximate span and recursive event matching (as described in the shared task definition). For preprocessing, we parsed all documents using the self-trained biomedical McClosky-Charniak-Johnson reranking parser (McClosky, 2010). We bias the anchor detector to favor recall, allowing the parser and reranker to determine which event anchors will ultimately be used. When performing n-best parsing, $n = 50$. For parser feature pruning, $\alpha = 0.001$.

Table 1a shows the performance of each of the decoders when using gold event anchors. In both cases where n-best decoding is available, the reranker improves performance over the 1-best parsers. We also present the results from a reranker trained from multiple decoders which is our highest scoring model.[11] In Table 1b, we present the output for the predicted anchor scenario. In the case of the 2P decoder, the reranker does not improve performance, though the drop is minimal. This is because the reranker chose an unfortunate regularization constant during crossvalidation, most likely due to the small size of the training data. In later experiments where more

[10] We only have n-best versions of the projective decoders. For the non-projective decoders, we use their 1-best parse.

[11] Including the 1N decoder as well provided no gains, possibly because its outputs are mostly subsumed by the 2N decoder.

data is available, the reranker consistently improves accuracy (McClosky et al., 2011). As before, the reranker trained from multiple decoders outperforms unreranked models and reranked single decoders. All in all, our best model in Table 1a scores 1 F1 point higher than the best system at the BioNLP'09 shared task, and the best model in Table 1b performs similarly to the best shared task system (Björne et al., 2009), which also scores 53.5% on development.

We show the effects of each system component in Table 2. Note how our upper limit is 87.1% due to our conversion process, which enforces the tree constraint, drops events spanning sentences, and performs approximate reconstruction of BINDING events. Given that state-of-the-art systems on this task currently perform in the 50-60% range, we are not troubled by this number as it still allows for plenty of potential.[12] Björne et al. (2009) list 94.7% as the upper limit for their system. Considering this relatively large difference, we find the results in the previous table very encouraging. As in other BioNLP'09 systems, our performance drops when switching from gold to predicted anchor information. Our decrease is similar to the one seen in Björne et al. (2009).

To show the potential of reranking, we provide oracle reranker scores in Table 3. An oracle reranker picks the highest scoring parse from the available parses. We limit the n-best lists to the top k parses where $k \in \{1, 2, 10, \text{All}\}$. For single decoders, "All" uses the entire 50-best list. For multiple decoders, the n-best lists are concatenated together. The oracle score with multiple decoders and gold anchors is only 0.4% lower than our upper limit (see Table 2). This indicates that parses which could have achieved that limit were nearly always present. Improving the features in the reranker as well as the original parsers will help us move closer to the limit. With predicated anchors, the oracle score is about 13% lower but still shows significant potential.

Our final results on the test set, broken down by class, are shown in Table 4. As with other systems, complex events (e.g., REGULATION) prove harder than simple events. To get a complex event correct, one must correctly detect and parse all events in the event subtree allowing small errors to have large effects. Top systems on this task obtain F1 scores of 52.0% at the shared task evaluation (Björne et al., 2009) and 56.3% post evaluation (Miwa et al., 2010a). However, both systems are tailored to the biomedical domain (the latter uses multiple syntactic parsers), whereas our system has a design that is virtually domain independent.

[12] Additionally, improvements such as document-level parsing and DAG parsing would eliminate the need for much of the approximate and lossy portions of the conversion process.

AD	Parse	RR	Conv	R	P	F1
✓	✓		✓	45.9	61.8	52.7
✓	✓	✓	✓	48.7	59.3	53.5
G	✓		✓	68.9	77.1	72.7
G	✓	✓	✓	68.5	78.2	73.1
G	G	G	✓	81.6	93.4	87.1

Table 2: Effect of each major component to the overall performance in the development corpus. Components shown: AD — event anchor detection; Parse — best individual parsing model; RR — reranking multiple parsers; Conv — conversion between the event and dependency representations. 'G' indicates that gold data was used; '✓' indicates that the actual component was used.

		n-best parses considered			
Anchors	Decoder(s)	1	2	10	All
Gold	1P	70.7	76.6	84.0	85.7
	2P	71.8	77.5	84.8	86.2
	1P, 2P, 2N	—	—	—	86.7
Predicted	1P	52.0	60.3	69.9	72.5
	2P	52.7	60.7	70.1	72.5
	1P, 2P, 2N	—	—	—	73.4

Table 3: Oracle reranker BioNLP F1 scores for our n-best decoders and their combinations before reranking on the development corpus.

5 Discussion

We believe that the potential of our approach is higher than what the current experiments show. For example, the reranker can be used to combine not only several parsers but also multiple anchor recognizers. This passes the anchor selection decision to the reranker, which uses global information not available to the current anchor recognizer or parser. Furthermore, our approach can be adapted to parse event structures in entire documents (instead of in-

Event Class	Count	R	P	F1

Table 4: Results in the test set broken by event class; scores generated with the main official metric of approximate span and recursive event matching.

dividual sentences) by using a representation with a unique ROOT node for all event structures in a document. This representation has the advantage that it maintains cross-sentence events (which account for 5% of BioNLP'09 events), and it allows for document-level features that model discourse structure. We plan to explore these ideas in future work.

One current limitation of the proposed model is that it constrains event structures to map to trees. In the BioNLP'09 corpus this leads to the removal of almost 5% of the events, which generate DAGs instead of trees. Local event extraction models (Björne et al., 2009) do not have this limitation, because their local decisions are blind to (and hence not limited by) the global event structure. However, our approach is agnostic to the actual parsing models used, so we can easily incorporate models that can parse DAGs (Sagae and Tsujii, 2008). Additionally, we are free to incorporate any new techniques from dependency parsing. Parsing using dual-decomposition (Rush et al., 2010) seems especially promising in this area.

6 Conclusion

In this paper we proposed a simple approach for the joint extraction of event structures: we converted the representation of events and their arguments to dependency trees with arcs between event anchors and event arguments, and used a reranking parser to parse these structures. Despite the fact that our approach has very little domain-specific engineering, we obtain competitive results. Most importantly, we showed that the joint modeling of event structures is beneficial: our reranker outperforms parsing models without reranking in five out of the six configurations investigated.

Acknowledgments

The authors would like to thank Mark Johnson for helpful discussions on the reranker component and the BioNLP shared task organizers, Sampo Pyysalo and Jin-Dong Kim, for answering questions. Abstract

The automatic extraction of comparative information is an important text mining problem and an area of increasing interest. In this paper, we study how to build a Korean comparison mining system. Our work is composed of two consecutive tasks: 1) classifying comparative sentences into different types and 2) mining comparative entities and predicates. We perform various experiments to find relevant features and learning techniques. As a result, we achieve outstanding performance enough for practical use.

1 Introduction

Almost every day, people are faced with a situation that they must decide upon one thing or the other. To make better decisions, they probably attempt to compare entities that they are interesting in. These days, many web search engines are helping people look for their interesting entities. It is clear that getting information from a large amount of web data retrieved by the search engines is a much better and easier way than the traditional survey methods. However, it is also clear that directly reading each document is not a perfect solution. If people only have access to a small amount of data, they may get a biased point of view. On the other hand, investigating large amounts of data is a time-consuming job. Therefore, a *comparison mining* system, which can automatically provide a summary of comparisons between two (or more) entities from a large quantity of web documents, would be very useful in many areas such as marketing.

We divide our work into two tasks to effectively build a comparison mining system. The first task is related to a sentence classification problem and the second is related to an information extraction problem.

Task 1. Classifying comparative sentences into one non-comparative class and seven comparative classes (or types); *1) Equality, 2) Similarity, 3) Difference, 4) Greater or lesser, 5) Superlative, 6) Pseudo,* and *7) Implicit* comparisons. The purpose of this task is to efficiently perform the following task.

Task 2. Mining comparative entities and predicates taking into account the characteristics of each type. For example, from the sentence "*Stock-X is worth more than stock-Y.*" belonging to "*4) Greater or lesser*" type, we extract "*stock-X*" as a subject entity (SE), "*stock-Y*" as an object entity (OE), and "*worth*" as a comparative predicate (PR).

These tasks are not easy or simple problems as described below.

Classifying comparative sentences (Task 1): For the first task, we extract comparative sentences from text documents and then classify the extracted comparative sentences into seven

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 1636–1644,
Portland, Oregon, June 19-24, 2011.

comparative types. Our basic idea is a keyword search. Since Ha (1999a) categorized dozens of Korean comparative keywords, we easily build an initial keyword set as follows:

▪ K_{ling} = {"같 ([gat]: same)", "보다 ([bo-da]: than)", "가장 ([ga-jang]: most)", …}

In addition, we easily match each of these keywords to a particular type anchored to Ha's research, e.g., "같 ([gat]: same)" to "*1) Equality*", "보다 ([bo-da]: than)" to "*4) Greater or lesser*". However, any method that depends on just these linguistic-based keywords has obvious limitations as follows:

1) K_{ling} is insufficient to cover all of the actual comparison expressions.
2) There are many non-comparative sentences that contain some elements of K_{ling}.
3) There is no one-to-one relationship between keyword types and sentence types.

Mining comparative entities and predicates (Task 2): Our basic idea for the second task is selecting candidates first and finding answers from the candidates later. We regard each of noun words as a candidate for SE/OE, and each of adjective (or verb) words as a candidate for PR. However, this candidate detection has serious problems as follows:

4) There are many actual SEs, OEs, and PRs that consist of multiple words.
5) There are many sentences with no OE, especially among superlative sentences. It means that the ellipsis is frequently occurred in superlative sentences.

We focus on solving the above five problems. We perform various experiments to find relevant features and proper machine learning techniques. The final experimental results in 5-fold cross validation show the overall accuracy of 88.59% for the first task and the overall accuracy of 86.81% for the second task.

The remainder of the paper is organized as follows. Section 2 briefly introduces related work. Section 3 and Section 4 describe our first task and second task in detail, respectively. Section 5 reports our experimental results and finally Section 6 concludes.

2 Related Work

Linguistic researchers focus on defining the syntax and semantics of comparative constructs. Ha (1999a; 1999b) classified the structures of Korean comparative sentences into several classes and arranged comparison-bearing words from a linguistic perspective. Since he summarized the modern Korean comparative studies, his research helps us have a linguistic point of view. We also refer to Jeong (2000) and Oh (2004). Jeong classified adjective superlatives using certain measures, and Oh discussed the gradability of comparatives.

In computer engineering, we found five previous studies related to comparison mining. Jindal and Liu (2006a; 2006b) studied to mine comparative relations from English text documents. They used comparative and superlative POS tags, and some additional keywords. Their methods applied Class Sequential Rules and Label Sequential Rules. Yang and Ko (2009; 2011) studied to extract comparative sentences in Korean text documents. Li et al. (2010) studied to mine comparable entities from English comparative questions that users posted online. They focused on finding a set of comparable entities given a user's input entity.

Opinion mining is also related to our work because many comparative sentences also contain the speaker's opinion/sentiment. Lee et al. (2008) surveyed various techniques that have been developed for the key tasks of opinion mining. Kim and Hovy (2006) introduced a methodology for analyzing judgment opinion. Riloff and Wiebe (2003) presented a bootstrapping process that learns linguistically rich extraction patterns for subjective expressions.

In this study, three learning techniques are employed: the maximum entropy method (MEM) as a representative probabilistic model, the support vector machine (SVM) as a kernel model, and transformation-based learning (TBL) as a rule-based model. Berger et al. (1996) presented a Maximum Entropy Approach to natural language processing. Joachims (1998) introduced SVM for text classification. Various TBL studies have been performed. Brill (1992; 1995) first introduced TBL and presented a case study on part-of-speech

tagging. Ramshaw and Marcus (1995) applied TBL for locating chunks in tagged texts. Black and Vasilakopoulos (2002) used a modified TBL technique for Named Entity Recognition.

3 Classifying Comparative Sentences (Task 1)

We first classify the sentences into *comparatives* and *non-comparatives* by extracting only comparatives from text documents. Then we classify the comparatives into seven types.

3.1 Extracting comparative sentences from text documents

Our strategy is to first detect *Comparative Sentence candidates* (CS-candidates), and then eliminate non-comparative sentences from the candidates. As mentioned in the introduction section, we easily construct a linguistic-based keyword set, K_{ling}. However, we observe that K_{ling} is not enough to capture all the actual comparison expressions. Hence, we build a comparison lexicon as follows:

- *Comparison Lexicon* = K_{ling} U {Additional keywords that are frequently used for actual comparative expressions}

This lexicon is composed of three parts. The first part includes the elements of K_{ling} and their synonyms. The second part consists of idioms. For example, an idiom "X가 먼저 웃었다 [X-ga meon-jeo u-seot-da]" commonly means "The winner is X" while it literally means "X laughed first". The last part consists of long-distance-words sequences, e.g., "<X 는 [X-neun], 지만 [ji-man], Y 는 [Y-neun], 다 [da]>". This sequence means that the sentence is formed as < S(X) + V + but + S(Y) + V > in English (S: subject phrase; V: verb phrase; X, Y: proper nouns). We could regard a word, "지만 ([ji-man]: but)," as a single keyword. However, this word also captures numerous non-comparative sentences. Namely, the precision value can fall too much due to this word. By using long-distance-words sequences instead of single keywords, we can keep the precision value from dropping seriously low.

The comparison lexicon finally has a total of 177 elements. We call each element "CK" hereafter. Note that our lexicon does not include comparative/superlative POS tags. Unlike English, there is no Korean comparative/superlative POS tag from POS tagger commonly. Our lexicon covers 95.96% of the comparative sentences in our corpus. It means that we successfully defined a comparison lexicon for CS-candidate detection. However, the lexicon shows a relatively low precision of 68.39%. While detecting CS-candidates, the lexicon also captures many non-comparative sentences, e.g., following Ex1:

- Ex1. "내일은 주식이 오를 것 같다." ([nai-il-eun ju-sik-i o-reul-geot gat-da]: I think stock price will rise tomorrow.)

This sentence is a non-comparative sentence even though it contains a CK, "같[gat]." This CK generally means "*same*," but it often expresses "*conjecture*." Since it is an adjective in both cases, it is difficult to distinguish the difference.

To effectively filter out non-comparative sentences from CS-candidates, we use the sequences of "continuous POS tags within a radius of 3 words from each CK" as features. Each word in the sequence is replaced with its POS tag in order to reflect various expressions. However, as CKs play the most important role, they are represented as a combination of their lexicalization and POS tag, e.g., "같/pa[1]." Finally, the feature has the form of "X → y" ("X" means a sequence and "y" means a class; y_1: comparative, y_2: non-comparative). For instance, "<pv etm nbn 같/pa ef sf[2] >→ y_2" is one of the features from Ex1 sentence. Finally, we achieved an f1-score of 90.23% using SVM.

3.2 Classifying comparative sentences into seven types

As we extract comparative sentences successfully, the next step is to classify the comparatives into different types. We define seven comparative types and then employ TBL for comparative sentence classification.

We first define six broad comparative types based on modern Korean linguistics: *1) Equality, 2) Similarity, 3) Difference, 4) Greater or lesser, 5) Superlative, 6) Pseudo* comparisons. The first five types can be understood intuitively, whereas

[1] The POS tag "*pa*" means "the stem of an adjective".
[2] The labels such as "*pv*", "*etm*" are Korean POS Tags.

the sixth type needs more explanation. "*6) Pseudo*" comparison includes comparative sentences that compare two (or more) properties of one entity such as "Smartphone-X is a computer rather than a phone." This type of sentence is often classified into "*4) Greater or lesser*." However, since this paper focuses on comparisons between different entities, we separate "*6) Pseudo*" type from "*4) Greater or lesser*" type.

The seventh type is "*7) Implicit*" comparison. It is added with the goal of covering literally "implicit" comparisons. For example, the sentence "Shopping Mall X guarantees no fee full refund, but Shopping Mall Y requires refund-fee" does not directly compare two shopping malls. It implicitly gives a hint that X is more beneficial to use than Y. It can be considered as a non-comparative sentence from a linguistic point of view. However, we conclude that this kind of sentence is as important as the other explicit comparisons from an engineering point of view.

After defining the seven comparative types, we simply match each sentences to a particular type based on the CK types; e.g., a sentence which contains the word "가장 ([ga-jang]: most)" is matched to "*Superlative*" type. However, a method that uses just the CK information has a serious problem. For example, although we easily match the CK "보다 ([bo-da]: than)" to "*Greater or lesser*" without doubt, we observe that the type of CK itself does not guarantee the correct type of the sentence as we can see in the following three sentences:

- Ex2. "X 의 품질은 Y **보다** 좋지도 나쁘지도 않다." ([X-eui pum-jil-eun Y-bo-da jo-chi-do na-ppeu-ji-do an-ta]: The quality of X is neither better nor worse than that of Y.) → It can be interpreted as "The quality of X is **similar** to that of Y." (*Similarity*)
- Ex3. "X 가 Y **보다** 품질이 좋다." ([X-ga Y-bo-da pum-jil-I jo-ta]: The quality of X is better than that of Y.) → It is consistent with the CK type (*Greater or lesser*)
- Ex4. "X 는 다른 어떤 카메라**보다** 품질이 좋다." ([X-neun da-reun eo-tteon ka-me-ra-bo-da pum-jil-i jo-ta]: X is better than any other cameras in quality.) → It can be interpreted as "X is the **best** camera in quality." (*Superlative*)

If we only rely on the CK type, we should label the above three sentences as "*Greater or lesser*". However, each of these three sentences belongs to a different type. This fact addresses that many CKs could have an ambiguity problem just like the CK of "보다 ([bo-da]: than)."

To solve this ambiguity problem, we employ TBL. We first roughly annotate the type of sentences using the type of CK itself. After this initial annotating, TBL generates a set of error-driven transformation rules, and then a scoring function ranks the rules. We define our scoring function as Equation (1):

$$\boldsymbol{Score(r_i) = C_i - E_i} \quad (1)$$

Here, r_i is the *i*-th transformation rule, $\boldsymbol{C_i}$ is the number of corrected sentences after r_i is applied, and $\boldsymbol{E_i}$ is the number of the opposite case. The ranking process is executed iteratively. The iterations stop when the scoring function reaches a certain threshold. We finally set up the threshold value as 1 after tuning. This means that we use only the rules whose score is 2 or more.

4 Mining Comparative Entities and Predicates (Task 2)

This section explains how to extract comparative entities and predicates. Our strategy is to first detect *Comparative Element candidates* (CE-candidates), and then choose the answer among the candidates.

In this paper, we only present the results of two types: "*Greater or lesser*" and "*Superlative*." As we will see in the experiment section, these two types cover 65.8% of whole comparative sentences. We are still studying the other five types and plan to report their results soon.

4.1 Comparative elements

We extract three kinds of comparative elements in this paper: SE, OE and PR

- Ex5. "X 파이가 Y 파이보다 싸고 맛있다." ([X-pa-i-ga Y-pa-i-bo-da ssa-go mas-it-da]: Pie X is cheaper and more delicious than Pie Y.)
- Ex6. "대선 후보들 중 Z 가 가장 믿음직하다." ([dai-seon hu-bo-deul jung Z-ga ga-jang mit-eum-jik-ha-da]: "Z is the most trustworthy among the presidential candidates.")

In Ex5 sentence, "X 파이 (Pie X)" is a SE, "Y 파이 (Pie Y)" is an OE, and "싸고 맛있다 (cheaper and more delicious)" is a PR. In Ex6 sentence, "Z" is a SE, "대선 후보들 (the presidential candidates)" is an OE, and "믿음직하다 (trustworthy)" is a PR.

Note that comparative elements are not limited to just one word. For example, "싸고 맛있다 (cheaper and more delicious)" and "대선 후보들 (the presidential candidates)" are composed of multiple words. After investigating numerous actual comparison expressions, we conclude that SEs, OEs, and PRs should not be limited to a single word. It can miss a considerable amount of important information to restrict comparative elements to only one word. Hence, we define as follows:

- *Comparative elements (SE, OE, and PR) are composed of one or more consecutive words.*

It should also be noted that a number of superlative sentences are expressed without OE. In our corpus, the percentage of the *Superlative* sentences without any OE is close to 70%. Hence, we define as follows:

- *OEs can be omitted in the Superlative sentences.*

4.2 Detecting CE-candidates

As comparative elements are allowed to have multiple words, we need some preprocessing steps for easy detection of CE-candidates. We thus apply some simplification processes. Through the simplification processes, we represent potential SEs/OEs as one "N" and potential PRs as one "P". The following process is one of the simplification processes for making "N"

- Change each noun (or each noun compound) to a symbol "N".

And, the following two example processes are for "P".

- Change "pa (adjective)" and "pv (verb)" to a symbol "P".
- Change "P + ecc (a suffix whose meaning is "and") + P" to one "P", e.g., "cheaper and more delicious" is tagged as one "P".

In addition to the above examples, several processes are performed. We regard all the "N"s as CE-candidates for SE/OE and all the "P"s as CE-candidates for PR. It is possible that a more analytic method is used instead of this simplification task, e.g., by a syntactic parser. We leave this to our future work.

4.3 Finding final answers

We now generate features. The patterns that consist of POS tags, CKs, and "P"/"N" sequences within a radius of 4 POS tags from each "N" or "P" are considered as features.

Original sentence	"X 파이가 Y 파이보다 싸고 맛있다." (Pie X is cheaper and more delicious than Pie Y.)
After POS tagging	X 파이/nq + 가/jcs + Y 파이/nq + 보다/jca + 싸/pa + 고/ecc + 맛있/pa + 다/ef +./sf
After simplification process	X 파이/N**(SE)** + 가/jcs + Y 파이/N**(OE)** + 보다/jca + 싸고맛있다/P**(PR)** + ./sf
Patterns for SE	<**N(SE)**, jcs, N, 보다/jca,P>, …, <**N(SE)**, jcs>
Patterns for OE	<N, jcs, **N(OE)**, 보다/jca,P, sf>, …, <**N(OE)**, 보다/jca >
Patterns for PR	<N, jcs, N, 보다/jca,**P(PR)**, sf>, …, <**P(PR)**, sf>

Table 1: Feature examples for mining comparative elements

Table 1 lists some examples. Since the CKs play an important role, they are represented as a combination of their lexicalization and POS tag. After feature generation, we calculate each probability value of all CE-candidates using SVM. For example, if a sentence has three "P"s, one "P" with the highest probability value is selected as the answer PR.

5 Experimental Evaluation

5.1 Experimental Settings

The experiments are conducted on 7,384 sentences collected from the web by three trained human labelers. Firstly, two labelers annotated the corpus. A Kappa value of 0.85 showed that it was safe to say that the two labelers agreed in their judgments.

Secondly, the third labeler annotated the conflicting part of the corpus. All three labelers discussed any conflict, and finally reached an agreement. Table 2 lists the distribution of the corpus.

Comparative Types		Sentence Portion
Non-comparative:		5,001 (67.7%)
Comparative:		2,383 (32.3%)
Total (Corpus)		7,384 (100%)
Among Comparative Sentences	*1) Equality*	3.6%
	2) Similarity	7.2%
	3) Difference	4.8%
	4) Greater or lesser	54.5%
	5) Superlative	11.3%
	6) Pseudo	1.3%
	7) Implicit	17.5%
	Total (Comparative)	100%

Table 2: Distribution of the corpus

5.2 Classifying comparative sentences

Our experimental results for Task 1 showed an f1-score of 90.23% in extracting comparative sentences from text documents and an accuracy of 81.67% in classifying the comparative sentences into seven comparative types.

The integrated results showed an accuracy of 88.59%. Non-comparative sentences were regarded as an eighth comparative type in this integrated result. It means that we classify entire sentences into eight types (seven comparative types and one non-comparative type).

5.2.1 Extracting comparative sentences.

Before evaluating our proposed method for comparative sentence extraction, we conducted four experiments with all of the lexical unigrams and bigrams using MEM and SVM. Among these four cases, SVM with lexical unigrams showed the highest performance, an f1-score of 79.49%. We regard this score as our baseline performance.

Next, we did experiments using all of the continuous lexical sequences and using all of the POS tags sequences within a radius of *n* words from each CK as features (*n*=1,2,3,4,5). Among these ten cases, "the POS tags sequences within a radius of 3" showed the best performance. Besides, as SVM showed the better performance than MEM in overall experiments, we employ SVM as our proposed learning technique. Table 3 summarizes the overall results.

Systems	Precision	Recall	F1-score
baseline	87.86	72.57	79.49
comparison lexicon only	68.39	95.96	79.87
comparison lexicon & SVM (proposed)	92.24	88.31	***90.23***

Table 3: Final results in comparative sentence extraction (%)

As given above, we successfully detected CS-candidates with considerably high recall by using the comparison lexicon. We also successfully filtered the candidates with high precision while still preserving high recall by applying machine learning technique. Finally, we could achieve an outstanding performance, an f1-score of 90.23%.

5.2.2 Classifying comparative sentences into seven types.

Like the previous comparative sentence extraction task, we also conducted experiments for type classification using the same features (continuous POS tags sequences within a radius of 3 words from each CK) and the same learning technique (SVM). Here, we achieved an accuracy of 73.64%. We regard this score as our baseline performance.

Next, we tested a completely different technique, the TBL method. TBL is well-known to be relatively strong in sparse problems. We observed that the performance of type classification can be influenced by very subtle differences in many cases. Hence, we think that an error-driven approach can perform well in comparative type classification. Experimental results showed that TBL actually performed better than SVM or MEM.

In the first step, we roughly annotated the type of a sentence using the type of the CK itself. Then, we generated error-driven transformation rules from the incorrectly annotated sentences. Transformation templates we defined are given in Table 4. Numerous transformation rules were generated on the basis of the templates. For example, "Change the type of the current sentence from "*Greater or lesser*" to "*Superlative*" if this sentence holds the CK of "보다 ([bo-da]: than)",

and the second preceding word of the CK is tagged as *mm*" is a transformation rule generated by the third template.

Change the type of the current sentence from *x* to *y* if this sentence holds the CK of ***k***, and …
1. the preceding word of ***k*** is tagged ***z***.
2. the following word of ***k*** is tagged ***z***.
3. the second preceding word of ***k*** is tagged ***z***.
4. the second following word of ***k*** is tagged ***z***.
5. the preceding word of ***k*** is tagged ***z,*** and the following word of ***k*** is tagged ***w***.
6. the preceding word of ***k*** is tagged ***z,*** and the second preceding word of ***k*** is tagged ***w***.
7. the following word of ***k*** is tagged ***z,*** and the second following word of ***k*** is tagged ***w***.

Table 4: Transformation templates

For evaluation of threshold values, we performed experiments with three options as given in Table 5.

Threshold	0	1	2
Accuracy	79.99	***81.67***	80.04

Table 5: Evaluation of threshold option (%);
Threshold *n* means that the learning iterations continues while C_i-$E_i \geq n$+1

We achieved the best performance with the threshold option 1. Finally, we classified comparative sentences into seven types using TBL with an accuracy of 81.67%.

5.2.3 Integrated results of Task 1

We sum up our proposed method for Task 1 as two steps as follows;

1) The comparison lexicon detects CS-candidates in text documents, and then SVM eliminates the non-comparative sentences from the candidates. Thus, all of the sentences are divided into two classes: a comparative class and a non-comparative class.
2) TBL then classifies the sentences placed in the comparative class in the previous step into seven comparative types.

The integrated results showed an overall accuracy of 88.59% for the eight-type classification. To evaluate the effectiveness of our two-step processing, we performed one-step processing experiments using SVM and TBL. Table 6 shows a comparison of the results.

Processing		**Accuracy**
One-step processing (classifying eight types at a time)	comparison lexicon & SVM	75.64
	comparison lexicon & TBL	72.49
Two-step processing (proposed)		***88.59***

Table 6: Integrated results for Task 1 (%)

As shown above, Task 1 was successfully divided into two steps.

5.3 Mining comparative entities and predicates

For the mining task of comparative entities and predicates, we used 460 comparative sentences (*Greater or lesser*: 300, *Superlative*: 160). As previously mentioned, we allowed multiple-word comparative elements. Table 7 lists the portion of multiple-word comparative elements.

Multi-word rate	**SE**	**OE**	**PR**
Greater or lesser	30.0	31.3	8.3
Superlative	24.4	9.4 (32.6)	8.1

Table 7: Portion (%) of multiple-word comparative elements

As given above, each multiple-word portion, especially in SEs and OEs, is quite high. This fact proves that it is absolutely necessary to allow multiple-word comparative elements. Relatively lower rate of 9.4% in *Superlative*-OEs is caused by a number of omitted OEs. If sentences that do not have any OEs are excluded, the portion of multiple-words becomes 32.6% as written in parentheses.

Table 8 shows the effectiveness of simplification processes. We calculated the error rates of CE-candidate detection before and after simplification processes.

Simplification processes		SE	OE	PR
Greater or lesser	Before	34.7	39.3	10.0
	After	***4.7***	***8.0***	***1.7***
Superlative	Before	26.3	85.0 (38.9)	9.4
	After	***1.9***	***75.6 (6.3)***	***1.3***

Table 8: Error rate (%) in CE-candidate detection

Here, the first value of 34.7% means that the real SEs of 104 sentences (among total 300 *Greater or lesser* sentences) were not detected by CE-candidate detection before simplification processes. After the processes, the error rate decreased to 4.7%. The significant differences between before and after indicate that we successfully detect CE-candidates through the simplification processes. Although the *Superlative*-OEs still show the seriously high rate of 75.6%, it is also caused by a number of omitted OEs. If sentences that do not have any OEs are excluded, the error rate is only 6.3% as written in parentheses.

The final results for Task 2 are reported in Table 9. We calculated each probability of CE-candidates using MEM and SVM. Both MEM and SVM showed outstanding performance; there was no significant difference between the two machine learning methods (SVM and MEM). Hence, we only report the results of SVM. Note that many sentences do not contain any OE. To identify such sentences, if SVM tagged every "N" in a sentence as "not OE", we tagged the sentence as "no OE".

Final Results	SE	OE	PR
Greater or lesser	86.00	89.67	92.67
Superlative	84.38	71.25	90.00
Total	**85.43**	**83.26**	**91.74**

Table 9: Final results of Task 2 (Accuracy, %)

As shown above, we successfully extracted the comparative entities and predicates with outstanding performance, an overall accuracy of 86.81%.

6 Conclusions and Future Work

This paper has studied a Korean comparison mining system. Our proposed system achieved an accuracy of 88.59% for classifying comparative sentences into eight types (one non-comparative type and seven comparative types), and an accuracy of 86.81% for mining comparative entities and predicates. These results demonstrated that our proposed method could be used effectively in practical applications. Since the comparison mining is an area of increasing interest around the world, our study can contribute greatly to text mining research.

In our future work, we have the following plans. Our first plan is to complete the mining process on all the types of sentences. The second one is to conduct more experiments for obtaining better performance. The final one is about an integrated system. Since we perform Task 1 and Task 2 separately, we need to build an end-to-end system.
