Knowledge bases (KB), such as WordNet (Fellbaum, 1998), Freebase (Bollacker et al., 2008), YAGO (Suchanek et al., 2007) and DBpedia (Lehmann et al., 2015), are useful resources for many applications such as question answering (Berant et al., 2013; Yih et al., 2015; Dai et al., 2016) and information extraction (Mintz et al., 2009). However, knowledge bases suffer from incompleteness despite their formidable sizes (Socher et al., 2013; West et al., 2014), leading to a number of studies on automatic knowledge base completion (KBC) (Nickel et al., 2015) or link prediction.

The fundamental motivation behind these studies is that there exist some statistical regularities under the intertwined facts stored in the multi-relational knowledge base. By discovering generalizable regularities in known facts, missing ones may be recovered in a faithful way. Due to its excellent generalization capability, distributed representations, a.k.a. embeddings, have been popularized to address the KBC task (Nickel et al., 2011; Bordes et al., 2011, 2014, 2013; Socher et al., 2013; Wang et al., 2014; Guu et al., 2015; Nguyen et al., 2016b).

As a seminal work, Bordes et al. (2013) proposes the TransE, which models the statistical regularities with linear translations between entity embeddings operated by a relation embedding. Implicitly, TransE assumes both entity embeddings and relation embeddings dwell in the same vector space, posing an unnecessarily strong prior. To relax this requirement, a variety of models first project the entity embeddings to a relation-dependent space (Bordes et al., 2014; Ji et al., 2015; Lin et al., 2015b; Nguyen et al., 2016b), and then model the translation property in the projected space. Typically, these relation-dependent spaces are characterized by the projection matrices unique to each relation. As a benefit, different aspects of the same entity can be temporarily emphasized or depressed as an effect of the projection. For instance, STransE (Nguyen et al., 2016b) utilizes two projection matrices per relation, one for the head entity and the other for the tail entity.

Despite the superior performance of STransE compared to TransE, it is more prone to the data sparsity problem. Concretely, since the projection spaces are unique to each relation, projection matrices associated with rare relations can only be exposed to very few facts during training, resulting in poor generalization. For common relations, a similar issue exists. Without any restrictions on the number of projection matrices, logically related or conceptually similar relations may have distinct projection spaces, hindering the discovery, sharing, and generalization of statistical regularities.

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 950–962
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1088

Previously, a line of research makes use of external information such as textual relations from web-scale corpus or node features (Toutanova et al., 2015; Toutanova and Chen, 2015; Nguyen et al., 2016a), alleviating the sparsity problem. In parallel, recent work has proposed to model regularities beyond local facts by considering multi-relation paths (García-Durán et al., 2015; Lin et al., 2015a; Shen et al., 2016). Since the number of paths grows exponentially with its length, as a side effect, path-based models enjoy much more training cases, suffering less from the problem.

In this paper, we propose an interpretable knowledge transfer model (ITransF), which encourages the sharing of statistic regularities between the projection matrices of relations and alleviates the data sparsity problem. At the core of ITransF is a sparse attention mechanism, which learns to compose shared concept matrices into relation-specific projection matrices, leading to a better generalization property. Without any external resources, ITransF improves mean rank and Hits@10 on two benchmark datasets, over all previous approaches of the same kind. In addition, the parameter sharing is clearly indicated by the learned sparse attention vectors, enabling us to interpret how knowledge transfer is carried out. To induce the desired sparsity during optimization, we further introduce a block iterative optimization algorithm.

In summary, the contributions of this work are: (i) proposing a novel knowledge embedding model which enables knowledge transfer by learning to discover shared regularities; (ii) introducing a learning algorithm to directly optimize a sparse representation from which the knowledge transferring procedure is interpretable; (iii) showing the effectiveness of our model by outperforming baselines on two benchmark datasets for knowledge base completion task.

2 Notation and Previous Models

Let E denote the set of entities and R denote the set of relations. In knowledge base completion, given a training set P of triples (h, r, t) where $h, t \in E$ are the head and tail entities having a relation $r \in R$, e.g., (*Steve Jobs*, `FounderOf`, *Apple*), we want to predict missing facts such as (*Steve Jobs*, `Profession`, *Businessperson*).

Most of the embedding models for knowledge base completion define an energy function $f_r(h, t)$ according to the fact's plausibility (Bordes et al., 2011, 2014, 2013; Socher et al., 2013; Wang et al., 2014; Yang et al., 2015; Guu et al., 2015; Nguyen et al., 2016b). The models are learned to minimize energy $f_r(h, t)$ of a plausible triple (h, r, t) and to maximize energy $f_r(h', t')$ of an implausible triple (h', r, t').

Motivated by the linear translation phenomenon observed in well trained word embeddings (Mikolov et al., 2013), TransE (Bordes et al., 2013) represents the head entity h, the relation r and the tail entity t with vectors $\mathbf{h}, \mathbf{r}$ and $\mathbf{t} \in \mathbb{R}^n$ respectively, which were trained so that $\mathbf{h} + \mathbf{r} \approx \mathbf{t}$. They define the energy function as

$$f_r(h, t) = \|\mathbf{h} + \mathbf{r} - \mathbf{t}\|_\ell$$

where $\ell = 1$ or 2, which means either the ℓ_1 or the ℓ_2 norm of the vector $\mathbf{h} + \mathbf{r} - \mathbf{t}$ will be used depending on the performance on the validation set.

To better model relation-specific aspects of the same entity, TransR (Lin et al., 2015b) uses projection matrices and projects the head entity and the tail entity to a relation-dependent space. STransE (Nguyen et al., 2016b) extends TransR by employing different matrices for mapping the head and the tail entity. The energy function is

$$f_r(h, t) = \|\mathbf{W}_{r,1}\mathbf{h} + \mathbf{r} - \mathbf{W}_{r,2}\mathbf{t}\|_\ell$$

However, not all relations have abundant data to estimate the relation specific matrices as most of the training samples are associated with only a few relations, leading to the data sparsity problem for rare relations.

3 Interpretable Knowledge Transfer

3.1 Model

As discussed above, a fundamental weakness in TransR and STransE is that they equip each relation with a set of unique projection matrices, which not only introduces more parameters but also hinders knowledge sharing. Intuitively, many relations share some concepts with each other, although they are stored as independent symbols in KB. For example, the relation "(somebody) won award for (some work)" and "(somebody) was nominated for (some work)" both describe a person's high-quality work which wins an award or a nomination respectively. This phenomenon suggests that one relation actually represents a collection of real-world concepts, and one concept

can be shared by several relations. Inspired by the existence of such lower-level concepts, instead of defining a unique set of projection matrices for every relation, we can alternatively define a small set of concept projection matrices and then compose them into customized projection matrices. Effectively, the relation-dependent translation space is then reduced to the smaller concept spaces.

However, in general, we do not have prior knowledge about what concepts exist out there and how they are composed to form relations. Therefore, in ITransF, we propose to learn this information simultaneously from data, together with all knowledge embeddings. Following this idea, we first present the model details, then discuss the optimization techniques for training.

Energy function Specifically, we stack all the concept projection matrices to a 3-dimensional tensor $\mathbf{D} \in \mathbb{R}^{m \times n \times n}$, where m is the pre-specified number of concept projection matrices and n is the dimensionality of entity embeddings and relation embeddings. We let each relation select the most useful projection matrices from the tensor, where the selection is represented by an attention vector. The energy function of ITransF is defined as:

$$f_r(h,t) = \|\boldsymbol{\alpha}_r^H \cdot \mathbf{D} \cdot \mathbf{h} + \mathbf{r} - \boldsymbol{\alpha}_r^T \cdot \mathbf{D} \cdot \mathbf{t}\|_\ell \quad (1)$$

where $\boldsymbol{\alpha}_r^H, \boldsymbol{\alpha}_r^T \in [0,1]^m$, satisfying $\sum_i \boldsymbol{\alpha}_{r,i}^H = \sum_i \boldsymbol{\alpha}_{r,i}^T = 1$, are normalized attention vectors used to compose all concept projection matrices in $\mathbf{D}$ by a convex combination. It is obvious that STransE can be expressed as a special case of our model when we use $m = 2|R|$ concept matrices and set attention vectors to disjoint one-hot vectors. Hence our model space is a generalization of STransE. Note that we can safely use fewer concept matrices in ITransF and obtain better performance (see section 4.3), though STransE always requires $2|R|$ projection matrices.

We follow previous work to minimize the following hinge loss function:

$$\mathcal{L} = \sum_{\substack{(h,r,t)\sim P,\\ (h',r,t')\sim N}} \left[\gamma + f_r(h,t) - f_r(h',t')\right]_+ \quad (2)$$

where P is the training set consisting of correct triples, N is the distribution of corrupted triples defined in section 3.3, and $[\cdot]_+ = \max(\cdot, 0)$. Note that we have omitted the dependence of N on (h,r,t) to avoid clutter. We normalize the entity vectors $\mathbf{h}, \mathbf{t}$, and the projected entity vectors $\boldsymbol{\alpha}_r^H \cdot \mathbf{D} \cdot \mathbf{h}$ and $\boldsymbol{\alpha}_r^T \cdot \mathbf{D} \cdot \mathbf{t}$ to have unit length after each update, which is an effective regularization method that benefits all models.

Sparse attention vectors In Eq. (1), we have defined $\boldsymbol{\alpha}_r^H, \boldsymbol{\alpha}_r^T$ to be some normalized vectors used for composition. With a dense attention vector, it is computationally expensive to perform the convex combination of m matrices in each iteration. Moreover, a relation usually does not consist of all existing concepts in practice. Furthermore, when the attention vectors are sparse, it is often easier to interpret their behaviors and understand how concepts are shared by different relations.

Motivated by these potential benefits, we further hope to learn sparse attention vectors in ITransF. However, directly posing ℓ_1 regularization (Tibshirani, 1996) on the attention vectors fails to produce sparse representations in our preliminary experiment, which motivates us to enforce ℓ_0 constraints on $\boldsymbol{\alpha}_r^T, \boldsymbol{\alpha}_r^H$.

In order to satisfy both the normalization condition and the ℓ_0 constraints, we reparameterize the attention vectors in the following way:

$$\boldsymbol{\alpha}_r^H = \mathrm{SparseSoftmax}(\mathbf{v}_r^H, \mathbf{I}_r^H)$$
$$\boldsymbol{\alpha}_r^T = \mathrm{SparseSoftmax}(\mathbf{v}_r^T, \mathbf{I}_r^T)$$

where $\mathbf{v}_r^H, \mathbf{v}_r^T \in \mathbb{R}^m$ are the pre-softmax scores, $\mathbf{I}_r^H, \mathbf{I}_r^T \in \{0,1\}^m$ are the sparse assignment vectors, indicating the non-zero entries of attention vectors, and the $\mathrm{SparseSoftmax}$ is defined as

$$\mathrm{SparseSoftmax}(\mathbf{v}, \mathbf{I})_i = \frac{\exp(\mathbf{v}_i/\tau)\mathbf{I}_i}{\sum_j \exp(\mathbf{v}_j/\tau)\mathbf{I}_j}$$

with τ being the temperature of Softmax.

With this reparameterization, $\mathbf{v}_r^H, \mathbf{v}_r^T$ and $\mathbf{I}_r^H, \mathbf{I}_r^T$ replace $\boldsymbol{\alpha}_r^T, \boldsymbol{\alpha}_r^H$ to become the real parameters of the model. Also, note that it is equivalent to pose the ℓ_0 constraints on $\mathbf{I}_r^H, \mathbf{I}_r^T$ instead of $\boldsymbol{\alpha}_r^T, \boldsymbol{\alpha}_r^H$. Putting these modifications together, we can rewrite the optimization problem as

$$\begin{aligned} &\text{minimize} && \mathcal{L} \\ &\text{subject to} && \|\mathbf{I}_r^H\|_0 \le k, \|\mathbf{I}_r^T\|_0 \le k \end{aligned} \quad (3)$$

where $\mathcal{L}$ is the loss function defined in Eq. (2).

3.2 Block Iterative Optimization

Though sparseness is favorable in practice, it is generally NP-hard to find the optimal solution under ℓ_0 constraints. Thus, we resort to an approximated algorithm in this work.

For convenience, we refer to the parameters with and without the sparse constraints as the *sparse* partition and the *dense* partition, respectively. Based on this notion, the high-level idea of the approximated algorithm is to iteratively optimize one of the two partitions while holding the other one fixed. Since all parameters in the dense partition, including the embeddings, the projection matrices, and the pre-softmax scores, are fully differentiable with the sparse partition fixed, we can simply utilize SGD to optimize the dense partition. Then, the core difficulty lies in the step of optimizing the sparse partition (i.e. the sparse assignment vectors), during which we want the following two properties to hold

1. the sparsity required by the ℓ_0 constaint is maintained, and
2. the cost define by Eq. (2) is decreased.

Satisfying the two criterion seems to highly resemble the original problem defined in Eq. (3). However, the dramatic difference here is that with parameters in the dense partition regarded as constant, the cost function is decoupled w.r.t. each relation r. In other words, the optimal choice of $\mathbf{I}_r^H, \mathbf{I}_r^T$ is independent of $\mathbf{I}_{r'}^H, \mathbf{I}_{r'}^T$ for any $r' \neq r$. Therefore, we only need to consider the optimization for a single relation r, which is essentially an assignment problem. Note that, however, $\mathbf{I}_r^H$ and $\mathbf{I}_r^T$ are still coupled, without which we basically reach the situation in a backpack problem. In principle, one can explore combinatorial optimization techniques to optimize $\mathbf{I}_{r'}^H, \mathbf{I}_{r'}^T$ jointly, which usually involve some iterative procedure. To avoid adding another inner loop to our algorithm, we turn to a simple but fast approximation method based on the following single-matrix cost.

Specifically, for each relation r, we consider the induced cost $\mathcal{L}_{r,i}^H$ where only a single projection matrix i is used for the head entity:

$$\mathcal{L}_{r,i}^H = \sum_{\substack{(h,r,t)\sim P_r,\\ (h',r,t')\sim N_r}} \left[\gamma + f_{r,i}^H(h,t) - f_{r,i}^H(h',t')\right]_+$$

where $f_{r,i}^H(h,t) = \|\mathbf{D}_i \cdot \mathbf{h} + \mathbf{r} - \boldsymbol{\alpha}_r^T \cdot \mathbf{D} \cdot \mathbf{t}\|$ is the corresponding energy function, and the subscript in P_r and N_r denotes the subsets with relation r. Intuitively, $\mathcal{L}_{r,i}^H$ measures, given the current tail attention vector $\boldsymbol{\alpha}_r^T$, if only one project matrix could be chosen for the head entity, how implausible D_i would be. Hence, $i^* = \arg\min_i \mathcal{L}_{r,i}^H$ gives us the best single projection matrix on the head side given $\boldsymbol{\alpha}_r^T$.

Now, in order to choose the best k matrices, we basically ignore the interaction among projection matrices, and update $\mathbf{I}_r^H$ in the following way:

$$\mathbf{I}_{r,i}^H \leftarrow \begin{cases} 1, & i \in \text{argpartition}_i(\mathcal{L}_{r,i}^H, k) \\ 0, & \text{otherwise} \end{cases}$$

where the function $\text{argpartition}_i(x_i, k)$ produces the index set of the lowest-k values of x_i.

Analogously, we can define the single-matrix cost $\mathcal{L}_{r,i}^T$ and the energy function $f_{r,i}^T(h,t)$ on the tail side in a symmetric way. Then, the update rule for $\mathbf{I}_r^H$ follows the same derivation. Admittedly, the approximation described here is relatively crude. But as we will show in section 4, the proposed algorithm yields good performance empirically. We leave the further improvement of the optimization method as future work.

3.3 Corrupted Sample Generating Method

Recall that we need to sample a negative triple (h', r, t') to compute hinge loss shown in Eq. 2, given a positive triple $(h, r, t) \in P$. The distribution of negative triple is denoted by $N(h, r, t)$. Previous work (Bordes et al., 2013; Lin et al., 2015b; Yang et al., 2015; Nguyen et al., 2016b) generally constructs a set of corrupted triples by replacing the head entity or tail entity with a random entity uniformly sampled from the KB.

However, uniformly sampling corrupted entities may not be optimal. Often, the head and tail entities associated a relation can only belong to a specific domain. When the corrupted entity comes from other domains, it is very easy for the model to induce a large energy gap between true triple and corrupted one. As the energy gap exceeds γ, there will be no training signal from this corrupted triple. In comparison, if the corrupted entity comes from the same domain, the task becomes harder for the model, leading to more consistent training signal.

Motivated by this observation, we propose to sample corrupted head or tail from entities in the same domain with a probability p_r and from the whole entity set with probability $1 - p_r$. The choice of relation-dependent probability p_r is specified in Appendix A.1. In the rest of the paper, we refer to the new proposed sampling method as "domain sampling".

4 Experiments

4.1 Setup

To evaluate link prediction, we conduct experiments on the WN18 (WordNet) and FB15k (Freebase) introduced by Bordes et al. (2013) and use the same training/validation/test split as in (Bordes et al., 2013). The information of the two datasets is given in Table 1.

Dataset	#E	#R	#Train	#Valid	#Test
WN18	40,943	18	141,442	5,000	5,000
FB15k	14,951	1,345	483,142	50,000	59,071

Table 1: Statistics of FB15k and WN18 used in experiments. #E, #R denote the number of entities and relation types respectively. #Train, #Valid and #Test are the numbers of triples in the training, validation and test sets respectively.

In knowledge base completion task, we evaluate model's performance of predicting the head entity or the tail entity given the relation and the other entity. For example, to predict head given relation r and tail t in triple (h, r, t), we compute the energy function $f_r(h', t)$ for each entity h' in the knowledge base and rank all the entities according to the energy. We follow Bordes et al. (2013) to report the *filter* results, i.e., removing all other correct candidates h' in ranking. The rank of the correct entity is then obtained and we report the mean rank (mean of the predicted ranks) and Hits@10 (top 10 accuracy). Lower mean rank or higher Hits@10 mean better performance.

4.2 Implementation Details

We initialize the projection matrices with identity matrices added with a small noise sampled from normal distribution $\mathcal{N}(0,\, 0.005^2)$. The entity and relation vectors of ITransF are initialized by TransE (Bordes et al., 2013), following Lin et al. (2015b); Ji et al. (2015); García-Durán et al. (2016, 2015); Lin et al. (2015a). We ran mini-batch SGD until convergence. We employ the "*Bernoulli*" sampling method to generate incorrect triples as used in Wang et al. (2014), Lin et al. (2015b), He et al. (2015), Ji et al. (2015) and Lin et al. (2015a).

STransE (Nguyen et al., 2016b) is the most similar knowledge embedding model to ours except that they use distinct projection matrices for each relation. We use the same hyperparameters as used in STransE and no significant improvement is observed when we alter hyperparameters. We set the margin γ to 5 and dimension of embedding n to 50 for WN18, and $\gamma = 1, n = 100$ for FB15k. We set the batch size to 20 for WN18 and 1000 for FB15k. The learning rate is 0.01 on WN18 and 0.1 on FB15k. We use 30 matrices on WN18 and 300 matrices on FB15k. All the models are implemented with Theano (Bergstra et al., 2010). The Softmax temperature is set to $1/4$.

4.3 Results & Analysis

The overall link prediction results[1] are reported in Table 2. Our model consistently outperforms previous models without external information on both the metrics of WN18 and FB15k. On WN18, we even achieve a much better mean rank with comparable Hits@10 than current state-of-the-art model IRN employing external information.

We can see that path information is very helpful on FB15k and models taking advantage of path information outperform intrinsic models by a significant margin. Indeed, a lot of facts are easier to recover with the help of multi-step inference. For example, if we know Barack Obama is born in Honolulu, a city in the United States, then we easily know the nationality of Obama is the United States. An straightforward way of extending our proposed model to k-step path $P = \{r_i\}_{i=1}^{k}$ is to define a path energy function $\|\boldsymbol{\alpha}_P^H \cdot \mathbf{D} \cdot \mathbf{h} + \sum_{r_i \in P} \mathbf{r}_i - \boldsymbol{\alpha}_P^T \cdot \mathbf{D} \cdot \mathbf{t}\|_\ell$, $\boldsymbol{\alpha}_P^H$ is a concept association related to the path. We plan to extend our model to multi-step path in the future.

To provide a detailed understanding why the proposed model achieves better performance, we present some further analysis in the sequel.

Performance on Rare Relations In the proposed ITransF, we design an attention mechanism to encourage knowledge sharing across different relations. Naturally, facts associated with rare relations should benefit most from such sharing, boosting the overall performance. To verify this hypothesis, we investigate our model's performance on relations with different frequency.

The overall distribution of relation frequencies resembles that of word frequencies, subject to the zipf's law. Since the frequencies of relations approximately follow a power distribution, their log

[1]Note that although IRN (Shen et al., 2016) does not explicitly exploit path information, it performs multi-step inference through the multiple usages of external memory. When IRN is allowed to access memory once for each prediction, its Hits@10 is 80.7, similar to models without path information.

Table 2: Link prediction results on two datasets. Higher Hits@10 or lower Mean Rank indicates better performance. Following Nguyen et al. (2016b) and Shen et al. (2016), we divide the models into two groups. The first group contains intrinsic models without using extra information. The second group make use of additional information. Results in the brackets are another set of results STransE reported.

frequencies are linear. The statistics of relations on FB15k and WN18 are shown in Figure 1. We can clearly see that the distributions exhibit long tails, just like the Zipf's law for word frequency.

In order to study the performance of relations with different frequencies, we sort all relations by their frequency in the training set, and split them into 3 buckets evenly so that each bucket has a similar interval length of log frequency.

Within each bucket, we compare our model with STransE, as shown in Figure 2.[2] As we can see, on WN18, ITransF outperforms STransE by a significant margin on rare relations. In particular, in the last bin (rarest relations), the average Hits@10 increases from 55.2 to 93.8, showing the great benefits of transferring statistical strength from common relations to rare ones. The comparison on each relation is shown in Appendix A.2. On FB15k, we can also observe a similar pattern, although the degree of improvement is less significant. We conjecture the difference roots in the fact that many rare relations on FB15k have disjoint domains, knowledge transfer through common concepts is harder.

Interpretability In addition to the quantitative evidence supporting the effectiveness of knowledge sharing, we provide some intuitive examples to show how knowledge is shared in our model. As we mentioned earlier, the sparse attention vectors fully capture the association between relations and concepts and hence the knowledge transfer among relations. Thus, we visualize the attention vectors for several relations on both WN18 and FB15K in Figure 3.

For WN18, the words "hyponym" and "hypernym" refer to words with more specific or general meaning respectively. For example, PhD is a hyponym of student and student is a hypernym of PhD. As we can see, concepts associated with the head entities in one relation are also associated with the tail entities in its reverse relation. Further, "instance_hypernym" is a special hypernym with the head entity being an instance, and the tail entity being an abstract notion. A typical example is (*New York*, `instance_hypernym`, *city*). This connection has also been discovered by our model, indicated by the fact that "instance_hypernym(T)" and "hypernym(T)" share a common concept matrix. Finally, for symmetric relations like "similar_to", we see the head attention is identical to the tail attention, which well matches our intuition.

On FB15k, we also see the sharing between reverse relations, as in "(somebody) won_award_for (some work)" and "(some work) award_winning_work (somebody)". What's more, although relation "won_award_for" and "was_nominated_for" share the same concepts,

[2]Domain sampling is not employed.

Figure 2: Hits@10 on relations with different amount of data. We give each relation the equal weight and report the average Hits@10 of each relation in a bin instead of reporting the average Hits@10 of each sample in a bin. Bins with smaller index corresponding to high-frequency relations.

their attention distributions are different, suggesting distinct emphasis. Finally, symmetric relations like spouse behave similarly as mentioned before.

Model Compression A byproduct of parameter sharing mechanism employed by ITransF is a much more compact model with equal performance. Figure 5 plots the average performance of ITransF against the number of projection matrices m, together with two baseline models. On FB15k, when we reduce the number of matrices from 2200 to 30 ($\sim$ 90$\times$ compression), our model performance decreases by only 0.09% on Hits@10, still outperforming STransE. Similarly, on WN18, ITransF continues to achieve the best performance when we reduce the number of concept project matrices to 18.

5 Analysis on Sparseness

Sparseness is desirable since it contribute to interpretability and computational efficiency of our model. We investigate whether enforcing sparseness would deteriorate the model performance and compare our method with another sparse encoding methods in this section.

Dense Attention w/o ℓ_1 regularization Although ℓ_0 constrained model usually enjoys many practical advantages, it may deteriorate the model performance when applied improperly. Here, we show that our model employing sparse attention can achieve similar results with dense attention with a significantly less computational burden. We also compare dense attention with ℓ_1 regularization. We set the ℓ_1 coefficient to 0.001 in our experiments and does not apply Softmax since the ℓ_1 of a vector after Softmax is always 1. We compare models in a setting where the computation time of

Figure 5: Performance with different number of projection matrices. Note that the X-axis denoting the number of matrices is not linearly scaled.

dense attention model is acceptable[3]. We use 22 weight matrices on WN18 and 15 weight matrices on FB15k and train both the models for 2000 epochs.

The results are reported in Table 3. Generally, ITransF with sparse attention has slightly better or comparable performance comparing to dense attention. Further, we show the attention vectors of model with ℓ_1 regularized dense attention in Figure 4. We see that ℓ_1 regularization does not produce a sparse attention, especially on FB15k.

Nonnegative Sparse Encoding In the proposed model, we induce the sparsity by a carefully designed iterative optimization procedure. Apart from this approach, one may utilize sparse encoding techniques to obtain sparseness based on the pretrained projection matrices from STransE. Concretely, stacking $|2R|$ pretrained projection

[3]With 300 projection matrices, it takes $1h1m$ to run one epoch for a model with dense attention.

Method	WN18			FB15k		
	MR	H10	Time	MR	H10	Time
Dense	**199**	94.0	4m34s	69	79.4	4m30s
Dense + ℓ_1	228	**94.2**	4m25s	131	78.9	5m47s
Sparse	207	94.1	**2m32s**	**67**	**79.6**	**1m52s**

Table 3: Performance of model with dense attention vectors or sparse attention vectors. MR, H10 and Time denotes mean rank, Hits@10 and training time per epoch respectively

matrices into a 3-dimensional tensor $X \in \mathbb{R}^{2|R|\times n\times n}$, similar sparsity can be induced by solving an ℓ_1-regularized tensor completion problem $\min_{\mathbf{A},\mathbf{D}} ||\mathbf{X} - \mathbf{DA}||_2^2 + \lambda\|\mathbf{A}\|_{\ell_1}$. Basically, $\mathbf{A}$ plays the same role as the attention vectors in our model. For more details, we refer readers to (Faruqui et al., 2015).

For completeness, we compare our model with the aforementioned approach[4]. The comparison is summarized in table 4. On both benchmarks, ITransF achieves significant improvement against sparse encoding on pretrained model. This performance gap should be expected since the objective function of sparse encoding methods is to minimize the reconstruction loss rather than optimize the criterion for link prediction.

Method	WN18		FB15k	
	MR	H10	MR	H10
Sparse Encoding	211	86.6	66	79.1
ITransF	**205**	**94.2**	**65**	**81.0**

6 Related Work

In KBC, CTransR (Lin et al., 2015b) enables relation embedding sharing across similar relations, but they cluster relations before training rather than learning it in a principled way. Further, they do not solve the data sparsity problem because there is no sharing of projection matrices which have a lot more parameters. Learning the association between semantic relations has been used in related problems such as relational similarity measurement (Turney, 2012) and relation adaptation (Bollegala et al., 2015).

Data sparsity is a common problem in many fields. Transfer learning (Pan and Yang, 2010) has been shown to be promising to transfer knowledge and statistical strengths across similar models or languages. For example, Bharadwaj et al. (2016) transfers models on resource-rich languages to low resource languages by parameter sharing through common phonological features in name entity recognition. Zoph et al. (2016) initialize from models trained by resource-rich languages to translate low-resource languages.

Several works on obtaining a sparse attention (Martins and Astudillo, 2016; Makhzani and Frey, 2014; Shazeer et al., 2017) share a similar idea of sorting the values before softmax and only keeping the K largest values. However, the sorting operation in these works is not GPU-friendly.

The block iterative optimization algorithm in our work is inspired by LightRNN (Li et al., 2016). They allocate every word in the vocabulary in a table. A word is represented by a row vector and a column vector depending on its position in the table. They iteratively optimize embeddings and allocation of words in tables.

7 Conclusion and Future Work

In summary, we propose a knowledge embedding model which can discover shared hidden concepts, and design a learning algorithm to induce the interpretable sparse representation. Empirically, we show our model can improve the performance on two benchmark datasets without external resources, over all previous models of the same kind.

In the future, we plan to enable ITransF to perform multi-step inference, and extend the sharing mechanism to entity and relation embeddings, further enhancing the statistical binding across parameters. In addition, our framework can also be applied to multi-task learning, promoting a finer sharing among different tasks.

A Appendix

A.1 Domain Sampling Probability

In this section, we define the probability p_r to generate a negative sample from the same domain mentioned in Section 3.3. The probability cannot be too high to avoid generating negative samples that are actually correct, since there are generally a lot of facts missing in KBs.

Specifically, let $\mathrm{M}_r^H = \{h \mid \exists t(h,r,t) \in P\}$ and $\mathrm{M}_r^T = \{t \mid \exists h(h,r,t) \in P\}$ denote the head or tail domain of relation r. Suppose $N_r = \{(h,r,t) \in P\}$ is the induced set of edges with relation r. We define the probability p_r as

$$p_r = min(\frac{\lambda|\mathrm{M}_r^T||\mathrm{M}_r^H|}{|N_r|}, 0.5) \tag{4}$$

Our motivation of such a formulation is as follows: Suppose O_r is the set that contains all truthful fact triples on relation r, i.e., all triples in training set and all other missing correct triples. If we assume all fact triples within the domain has uniform probability of being true, the probability of a random triple being correct is $Pr((h,r,t) \in O_r \mid h \in \mathrm{M}_r^H, t \in \mathrm{M}_r^T) = \frac{|O_r|}{|\mathrm{M}_r^H||\mathrm{M}_r^T|}$

Assume that all facts are missing with a probability λ, then $|N_r| = \lambda|O_r|$ and the above probability can be approximated by $\frac{|N_r|}{\lambda|\mathrm{M}_r^H||\mathrm{M}_r^T|}$. We want the probability of generating a negative sample from the domain to be inversely proportional to the probability of the sample being true, so we define the probability as Eq. 4. The results in section 4 are obtained with λ set to 0.001.

We compare how different value of λ would influence our model's performance in Table. 5. With large λ and higher domain sampling probability, our model's Hits@10 increases while mean rank also increases. The rise of mean rank is due to higher probability of generating a valid triple as a negative sample causing the energy of a valid triple to increase, which leads to a higher overall rank of a correct entity. However, the reasoning capability is boosted with higher Hits@10 as shown in the table.

A.2 Performance on individual relations of WN18

We plot the performance of ITransF and STransE on each relation. We see that the improvement is greater on rare relations.

Method	WN18		FB15k	
	MR	H10	MR	H10
$\lambda = 0.0003$	**217**	95.0	**68**	80.4
$\lambda = 0.001$	223	**95.2**	73	80.6
$\lambda = 0.003$	239	**95.2**	82	**80.9**

Table 5: Different λ's effect on our model performance. The compared models are trained for 2000 epochs

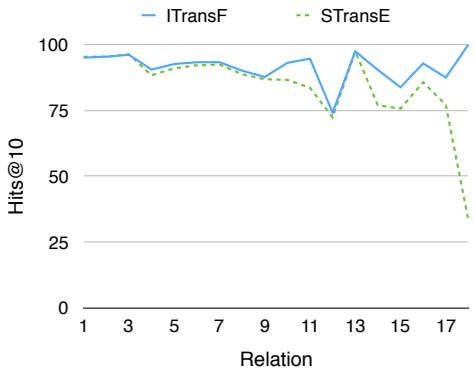

Figure 6: Hits@10 on each relation in WN18. The relations are sorted according to their frequency.

Learning a Neural Semantic Parser from User Feedback

Abstract

We present an approach to rapidly and easily build natural language interfaces to databases for new domains, whose performance improves over time based on user feedback, and requires minimal intervention. To achieve this, we adapt neural sequence models to map utterances directly to SQL with its full expressivity, bypassing any intermediate meaning representations. These models are immediately deployed online to solicit feedback from real users to flag incorrect queries. Finally, the popularity of SQL facilitates gathering annotations for incorrect predictions using the crowd, which is directly used to improve our models. This complete feedback loop, without intermediate representations or database specific engineering, opens up new ways of building high quality semantic parsers. Experiments suggest that this approach can be deployed quickly for any new target domain, as we show by learning a semantic parser for an online academic database from scratch.

1 Introduction

Existing semantic parsing approaches for building natural language interfaces to databases (NLIDBs) either use special-purpose intermediate meaning representations that lack the full expressivity of database query languages or require extensive feature engineering, making it difficult to deploy them in new domains. We present a robust approach to quickly and easily learn and deploy semantic parsers from scratch, whose performance improves over time based on user feedback, and requires very little expert intervention.

  AND a2.city_code = c2.city_code
  AND c2.city_name = 'toronto';
```

Figure 1: Utterances with corresponding SQL queries to answer them for two domains, an academic database and a flight reservation database.

To learn these semantic parsers, we (1) adapt neural sequence models to map utterances directly to SQL thereby bypassing intermediate representations and taking full advantage of SQL's querying capabilities, (2) immediately deploy the model online to solicit questions and user feedback on results to reduce SQL annotation efforts, and (3) use crowd workers from skilled markets to provide SQL annotations that can directly be used for model improvement, in addition to being easier and cheaper to obtain than logical meaning representations. We demonstrate the effectiveness of the complete approach by successfully learning a semantic parser for an academic domain by simply deploying it online for three days.

This type of interactive learning is related to a number of recent ideas in semantic parsing, in-

[◇]Work done partly during an internship at the Allen Institute for Artificial Intelligence.

cluding batch learning of models that directly produce programs (e.g., regular expressions (Locascio et al., 2016)), learning from paraphrases (often gathered through crowdsourcing (Wang et al., 2015)), data augmentation (e.g. based on manually engineered semantic grammars (Jia and Liang, 2016)) and learning through direct interaction with users (e.g., where a single user teaches the model new concepts (Wang et al., 2016)). However, there are unique advantages to our approach, including showing (1) that non-linguists can write SQL to encode complex, compositional computations (see Fig 1 for an example), (2) that external paraphrase resources and the structure of facts from the target database itself can be used for effective data augmentation, and (3) that actual database users can effectively drive the overall learning by simply providing feedback about what the model is currently getting correct.

Our experiments measure the performance of these learning advances, both in batch on existing datasets and through a simple online experiment for the full interactive setting. For the batch evaluation, we use sentences from the benchmark GeoQuery and ATIS domains, converted to contain SQL meaning representations. Our neural learning with data augmentation achieves reasonably high accuracies, despite the extra complexities of mapping directly to SQL. We also perform simulated interactive learning on this data, showing that with perfect user feedback our full approach could learn high quality parsers with only 55% of the data. Finally, we do a small scale online experiment for a new domain, academic paper metadata search, demonstrating that actual users can provide useful feedback and our full approach is an effective method for learning a high quality parser that continues to improve over time as it is used.

2 Related Work

Although diverse meaning representation languages have been used with semantic parsers – such as regular expressions (Kushman and Barzilay, 2013; Locascio et al., 2016), Abstract Meaning Representations (AMR) (Artzi et al., 2015; Misra and Artzi, 2016), and systems of equations (Kushman et al., 2014; Roy et al., 2016) – parsers for querying databases have typically used either logic programs (Zelle and Mooney, 1996), lambda calculus (Zettlemoyer and Collins, 2005), or λ-DCS (Liang et al., 2013) as the meaning representation language. All three of these languages are modeled after natural language to simplify parsing. However, none of them is used to query databases outside of the semantic parsing literature; therefore, they are understood by few people and not supported by standard database implementations. In contrast, we parse directly to SQL, which is a popular database query language with wide usage and support. Learning parsers directly from SQL queries has the added benefit that we can potentially hire programmers on skilled-labor crowd markets to provide labeled examples, such as UpWork[1], which we demonstrate in this work.

A few systems have been developed to directly generate SQL queries from natural language (Popescu et al., 2003; Giordani and Moschitti, 2012; Poon, 2013). However, all of these systems make strong assumptions on the structure of queries: they use manually engineered rules that can only generate a subset of SQL, require lexical matches between question tokens and table/column names, or require questions to have a certain syntactic structure. In contrast, our approach can generate arbitrary SQL queries, only uses lexical matching for entity names, and does not depend on syntactic parsing.

We use a neural sequence-to-sequence model to directly generate SQL queries from natural language questions. This approach builds on recent work demonstrating that such models are effective for tasks such as machine translation (Bahdanau et al., 2015) and natural language generation (Kiddon et al., 2016). Recently, neural models have been successfully applied to semantic parsing with simpler meaning representation languages (Dong and Lapata, 2016; Jia and Liang, 2016) and short regular expressions (Locascio et al., 2016). Our work extends these results to the task of SQL generation. Finally, Ling et al. (2016) generate Java/Python code for trading cards given a natural language description; however, this system suffers from low overall accuracy.

A final direction of related work studies methods for reducing the annotation effort required to train a semantic parser. Semantic parsers have been trained from various kinds of annotations, including labeled queries (Zelle and Mooney, 1996; Wong and Mooney, 2007; Zettlemoyer and Collins, 2005), question/answer pairs (Liang et al., 2013; Kwiatkowski et al., 2013; Berant et al.,

[1] http://www.upwork.com

2013), distant supervision (Krishnamurthy and Mitchell, 2012; Choi et al., 2015), and binary correct/incorrect feedback signals (Clarke et al., 2010; Artzi and Zettlemoyer, 2013). Each of these schemes presents a particular trade-off between annotation effort and parser accuracy; however, recent work has suggested that labeled queries are the most effective (Yih et al., 2016). Our approach trains on fully labeled SQL queries to maximize accuracy, but uses binary feedback from users to reduce the number of queries that need to be labeled. Annotation effort can also be reduced by using crowd workers to paraphrase automatically generated questions (Wang et al., 2015); however, this approach may not generate the questions that users actually want to ask the database – an experiment in this paper demonstrated that 48% of users' questions in a calendar domain could not be generated.

3 Feedback-based Learning

Our feedback-based learning approach can be used to quickly deploy semantic parsers to create NLIDBs for any new domain. It is a simple interactive learning algorithm that deploys a preliminary semantic parser, then iteratively improves this parser using user feedback and selective query annotation. A key requirement of this algorithm is the ability to cheaply and efficiently annotate queries for chosen user utterances. We address this requirement by developing a model that directly outputs SQL queries (Section 4), which can also be produced by crowd workers.

Our algorithm alternates between stages of training the model and making predictions to gather user feedback, with the goal of improving performance in each successive stage. The procedure is described in Algorithm 1. Our neural model $\mathscr{N}$ is initially trained on synthetic data T generated by domain-independent schema templates (see Section 4), and is then ready to answer new user questions, n. The results $\mathscr{R}$ of executing the predicted SQL query q are presented to the user who provides a binary correct/incorrect feedback signal. If the user marks the result correct, the pair (n, q) is added to the training set. If the user marks the result incorrect, the algorithm asks a crowd worker to annotate the utterance with the correct query, $\hat{q}$, and adds $(n, \hat{q})$ to the training set. This procedure can be repeated indefinitely, ideally increasing parser accuracy and requesting fewer annotations in each successive stage.

```
Procedure LEARN(schema)
    T ← initial_data(schema)
    while true do
        𝒯 ← T ∪ paraphrase(T)
        𝒩 ← train_model(𝒯)
        for n ∈ new utterances do
            q ← predict(𝒩, n)
            ℛ ← execute(q)
            f ← feedback(ℛ)
            if f = correct then
                T ← T ∪ (n, q)
            else if f = wrong then
                q̂ ← annotate(n)
                T ← T ∪ (n, q̂)
            end
        end
    end
end
```

Algorithm 1: Feedback-based learning.

4 Semantic Parsing to SQL

We use a neural sequence-to-sequence model for mapping natural language questions directly to SQL queries and this allows us to scale our feedback-based learning approach, by easily crowdsourcing labels when necessary. We further present two data augmentation techniques which use content from the database schema and external paraphrase resources.

4.1 Model

We use an encoder-decoder model with global attention, similar to Luong et al. (2015), where the anonymized utterance (see Section 4.2) is encoded using a bidirectional LSTM network, then decoded to directly predict SQL query tokens. Fixed pre-trained word embeddings from word2vec (Mikolov et al., 2013) are concatenated to the embeddings that are learned for source tokens from the training data. The decoder predicts a conditional probability distribution over possible values for the next SQL token given the previous tokens using a combination of the previous SQL token embedding, attention over the hidden states of the encoder network, and an attention signal from the previous time step.

Formally, if $\mathbf{q_i}$ represents an embedding for the

i^{th} SQL token q_i, the decoder distribution is

$$p(q_i|q_1, \ldots, q_{i-1}) \propto \exp\left(\mathbf{W} \tanh(\hat{\mathbf{W}}[\mathbf{h_i} : \mathbf{c_i}])\right)$$

where $\mathbf{h_i}$ represents the hidden state output of the decoder LSTM at the i^{th} timestep, $\mathbf{c_i}$ represents the context vector generated using an attention weighted sum of encoder hidden states based on $\mathbf{h_i}$, and, $\mathbf{W}$ and $\hat{\mathbf{W}}$ are linear transformations. If $\mathbf{s_j}$ is the hidden representation generated by the encoder for the j^{th} word in the utterance (k words long), then the context vectors are defined to be:

$$\mathbf{c_i} = \sum_{j=1}^{k} \alpha_{i,j} \cdot \mathbf{s_j}$$

The attention weights $\alpha_{i,j}$ are computed using an inner product between the decoder hidden state for the current timestep $\mathbf{h_i}$, and the hidden representation of the j^{th} source token $\mathbf{s_j}$:

$$\alpha_{i,j} = \frac{\exp(\mathbf{h_i}^{\mathrm{T}} \mathbf{F} \mathbf{s_j})}{\sum_{j=1}^{k} \exp(\mathbf{h_i}^{\mathrm{T}} \mathbf{F} \mathbf{s_j})}$$

where $\mathbf{F}$ is a linear transformation. The decoder LSTM cell f computes the next hidden state $\mathbf{h_i}$, and cell state, $\mathbf{m_i}$, based on the previous hidden and cell states, $\mathbf{h_{i-1}}, \mathbf{m_{i-1}}$, the embeddings of the previous SQL token $\mathbf{q_{i-1}}$ and the context vector of the previous timestep, $\mathbf{c_{i-1}}$

$$\mathbf{h_i}, \mathbf{m_i} = f(\mathbf{h_{i-1}}, \mathbf{m_{i-1}}, \mathbf{q_{i-1}}, \mathbf{c_{i-1}})$$

We apply dropout on non-recurrent connections for regularization, as suggested by Pham et al. (2014). Beam search is used for decoding the SQL queries after learning.

4.2 Entity Anonymization

We handle entities in the utterances and SQL by replacing them with their types, using incremental numbering to model multiple entities of the same type (e.g., `CITY_NAME_1`). During training, when the SQL is available, we infer the type from the associated column name; for example, Boston is a city in `city.city_name = 'Boston'`. To recognize entities in the utterances at test time, we build a search engine on all entities from the target database. For every span of words (starting with a high span size and progressively reducing it), we query the search engine using a TF-IDF scheme to retrieve the entity that most closely matches the span, then replace the span with the entity's type. We store these mappings and apply them to the generated SQL to fill in the entity names. TF-IDF matching allows some flexibility in matching entity names in utterances, for example, a user could say *Donald Knuth* instead of *Donald E. Knuth*.

4.3 Data Augmentation

We present two data augmentation strategies that either (1) provide the initial training data to start the interactive learning, before more labeled examples become available, or (2) use external paraphrase resources to improve generalization.

Schema Templates To bootstrap the model to answer simple questions initially, we defined 22 language/SQL templates that are schema-agnostic, so they can be applied to any database. These templates contain slots whose values are populated given a database schema. An example template is shown in Figure 2a. The `<ENT>` types represent tables in the database schema, `<ENT>.<COL>` represents a column in the particular table and `<ENT>.<COL>.<TYPE>` represents the type associated with the particular column. A template is instantiated by first choosing the entities and attributes. Next, join conditions, i.e., `JOIN_FROM` and `JOIN_WHERE` clauses, are generated from the tables on the shortest path between the chosen tables in the database schema graph, which connects tables (graph nodes) using foreign key constraints. Figure 2b shows an instantiation of a template using the path author - writes - paper - paperdataset - dataset. SQL queries generated in this manner are guaranteed to be executable on the target database. On the language side, an English name of each entity is plugged into the template to generate an utterance for the query.

Paraphrasing The second data augmentation strategy uses the Paraphrase Database (PPDB) (Ganitkevitch et al., 2013) to automatically generate paraphrases of training utterances. Such methods have been recently used to improve performance for parsing to logical forms (Chen et al., 2016). PPDB contains over 220 million paraphrase pairs divided into 6 sets (small to XXXL) based on precision of the paraphrases. We use the one-one and one-many paraphrases from the large version of PPDB. To paraphrase a training utterance, we pick a random word in the utterance that is not a stop word or entity and replace it with a random paraphrase. We perform paraphrase expansion on all examples labeled during learning, as well as the initial seed examples from schema templates.

```
Get all <ENT1>.<NAME> having
<ENT2>.<COL1>.<NAME> as <ENT2>.<COL1>.<TYPE>

SELECT <ENT1>.<DEF> FROM JOIN_FROM(<ENT1>, <ENT2>)
WHERE JOIN_WHERE(<ENT1>, <ENT2>) AND
 <ENT2>.<COL1> = <ENT2>.<COL1>.<TYPE>
```

(a) Schema template

```
Get all author having dataset  as DATASET_TYPE

SELECT author.authorId
FROM author , writes , paper , paperDataset , dataset
WHERE author.authorId = writes.authorId
 AND writes.paperId = paper.paperId
 AND paper.paperId = paperDataset.paperId
 AND paperDataset.datasetId = dataset.datasetId
 AND dataset.datasetName = DATASET_TYPE
```

(b) Generated utterance-SQL pair

5 Benchmark Experiments

Our first set of experiments demonstrates that our semantic parsing model has comparable accuracy to previous work, despite the increased difficulty of directly producing SQL. We demonstrate this result by running our model on two benchmark datasets for semantic parsing, GEO880 and ATIS.

5.1 Data sets

GEO880 is a collection of 880 utterances issued to a database of US geographical facts (Geobase), originally in Prolog format. Popescu et al. (2003) created a relational database schema for Geobase together with SQL queries for a subset of 700 utterances. To compare against prior work on the full corpus, we annotated the remaining utterances and used the standard 600/280 training/test split (Zettlemoyer and Collins, 2005).

ATIS is a collection of 5,418 utterances to a flight booking system, accompanied by a relational database and SQL queries to answer the questions. We use 4,473 utterances for training, 497 for development and 448 for test, following Kwiatkowski et al. (2011). The original SQL queries were very inefficient to execute due to the use of `IN` clauses, so we converted them to joins (Ramakrishnan and Gehrke, 2003) while verifying that the output of the queries was unchanged.

Table 1 shows characteristics of both data sets. GEO880 has shorter queries but is more compositional: almost 40% of the SQL queries have at least one nested subquery. ATIS has the longest utterances and queries, with an average utterance length of 11 words and an average SQL query length of 67 tokens. They also operate on approximately 6 tables per query on average. We will release our processed versions of both datasets.

	Geo880	ATIS	SCHOLAR
Avg. NL length	7.56	10.97	6.69
NL vocab size	151	808	303
Avg. SQL length	16.06	67.01	28.85
SQL vocab size	89	605	163
% Subqueries > 1	39.8	12.42	2.58
# Tables	1.19	5.88	3.33

Table 1: Utterance and SQL query statistics for each dataset. Vocabulary sizes are counted after entity anonymization.

5.2 Experimental Methodology

We follow a standard train/dev/test methodology for our experiments. The training set is augmented using schema templates and 3 paraphrases per training example, as described in Section 4. Utterances were anonymized by replacing them with their corresponding types and all words that occur only once were replaced by UNK symbols. The development set is used for hyperparameter tuning and early stopping. For GEO880, we use cross validation on the training set to tune hyperparameters. We used a minibatch size of 100 and used Adam (Kingma and Ba, 2015) with a learning rate of 0.001 for 70 epochs for all our experiments. We used a beam size of 5 for decoding. We report test set accuracy of our SQL query predictions by executing them on the target database and comparing the result with the true result.

5.3 Results

Tables 2 and 3 show test accuracies based on denotations for our model on GEO880 and ATIS respectively, compared with previous work.[2] To our knowledge, this is the first result on directly parsing to SQL to achieve comparable performance to prior work without using any database-specific feature engineering. Popescu et al. (2003) and Giordani and Moschitti (2012) also directly produce SQL queries but on a subset of 700 examples from GEO880. The former only works on semantically tractable utterances where words can be un-

[2]Note that 2.8% of GEO880 and 5% ATIS gold test set SQL queries (before any processing) produced empty results.

System	Acc.

ambiguously mapped to schema elements, while the latter uses a reranking approach that also limits the complexity of SQL queries that can be handled. GUSP (Poon, 2013) creates an intermediate representation that is then deterministically converted to SQL to obtain an accuracy of 74.8% on ATIS, which is boosted to 83.5% using manually introduced disambiguation rules. However, it requires a lot of SQL specific engineering (for example, special nodes for argmax) and is hard to extend to more complex SQL queries.

On both datasets, our SQL model achieves reasonably high accuracies approaching that of the best non-SQL results. Most relevant to this work are the neural sequence based approaches of Dong and Lapata (2016) and Jia and Liang (2016). We note that Jia and Liang (2016) use a data recombination technique that boosts accuracy from 85.0 on GEO880 and 76.3 on ATIS; this technique is also compatible with our model and we hope to experiment with this in future work. Our results demonstrate that these models are powerful enough to directly produce SQL queries. Thus, our methods enable us to utilize the full expressivity of the SQL language without any extensions that certain logical representations require to answer more complex queries. More importantly, it can be immediately deployed for users in new domains, with a large programming community available for annotation, and thus, fits effectively into a framework for interactive learning.

System	GEO880	ATIS
Ours	84.8	86.2
- paraphrases	81.8	84.3
- templates	84.7	85.7

Table 4: Addition of paraphrases to the training set helps performance, but template based data augmentation does not significantly help in the fully supervised setting. Accuracies are reported on the standard dev set for ATIS and on the training set, using cross-validation, for Geo880.

We perform ablation studies on the development sets (see Table 4) and find that paraphrasing using PPDB consistently helps boost performance. However, unlike in the interactive experiments (Section 6), data augmentation using schema templates does not improve performance in the fully supervised setting.

6 Interactive Learning Experiments

In this section, we learn a semantic parser for an academic domain from scratch by deploying an online system using our interactive learning algorithm (Section 3). After three train-deploy cycles, the system correctly answered 63.51% of user's questions. To our knowledge, this is the first effort to learn a semantic parser using a live system, and is enabled by our models that can directly parse language to SQL without manual intervention.

6.1 User Interface

We developed a web interface for accepting natural language questions to an academic database from users, using our model to generate a SQL query, and displaying the results after execution. Several example utterances are also displayed to help users understand the domain. Together with the results of the generated SQL query, users are prompted to provide feedback which is used for

interactive learning. Screenshots of our interface are included in our Supplementary Materials.

Collecting accurate user feedback on predicted queries is a key challenge in the interactive learning setting for two reasons. First, the system's results can be incorrect due to poor entity identification or incompleteness in the database, neither of which are under the semantic parser's control. Second, it can be difficult for users to determine if the presented results are in fact correct. This determination is especially challenging if the system responds with the correct type of result, for example, if the user requests "papers at ACL 2016" and the system responds with all ACL papers.

We address this challenge by providing users with two assists for understanding the system's behavior, and allowing users to provide more granular feedback than simply correct/incorrect. The first assist is **type highlighting**, which highlights entities identified in the utterance, for example, "paper by *Michael I. Jordan (AUTHOR)* in *ICRA (VENUE)* in *2016 (YEAR)*." This assist is especially helpful because the academic database contains noisy keyword and dataset tables that were automatically extracted from the papers. The second assist is **utterance paraphrasing**, which shows the user another utterance that maps to the same SQL query. For example, for the above query, the system may show "what papers does *Michael I. Jordan (AUTHOR)* have in *ICRA (VENUE)* in *2016 (YEAR)*." This assist only appears if a matching query (after entity anonymization) exists in the model's training set.

Using these assists and the predicted results, users are asked to select from five feedback options: *Correct*, *Wrong Types*, *Incomplete Result*, *Wrong Result* and *Can't Tell*. The *Correct* and *Wrong Result* options represent scenarios when the user is satisfied with the result, or the result is identifiably wrong, respectively. *Wrong Types* indicates incorrect entity identification, which can be determined from type highlighting. *Incomplete Result* indicates that the query is correct but the result is not; this outcome can occur because the database is incomplete. *Can't Tell* indicates that the user is unsure about the feedback to provide.

6.2 Three-Stage Online Experiment

In this experiment, using our developed user interface, we use Algorithm 1 to learn a semantic parser from scratch. The experiment had three stages; in each stage, we recruited 10 new users (computer science graduate students) and asked them to issue at least 10 utterances each to the system and to provide feedback on the results. We considered results marked as either *Correct* or *Incomplete Result* as correct queries for learning. The remaining incorrect utterances were sent to a crowd worker for annotation and were used to retrain the system for the next stage. The crowd worker had prior experience in writing SQL queries and was hired from Upwork after completing a short SQL test. The worker was also given access to the database to be able to execute the queries and ensure that they are correct. For the first stage, the system was trained using 640 examples generated using templates, that were augmented to 1746 examples using paraphrasing (see Section 4.3). The complexity of the utterances issued in each of the three phases were comparable, in that, the average length of the correct SQL query for the utterances, and the number of tables required to be queried, were similar.

Table 5 shows the percent of utterances judged by users as either *Correct* or *Incomplete Result* in each stage. In the first stage, we do not have any labeled examples, and the model is trained using only synthetically generated data from schema templates and paraphrases (see Section 4.3). Despite the lack of real examples, the system correctly answers 25% of questions. The system's accuracy increases and annotation effort decreases in each successive stage as additional utterances are contributed and incorrect utterances are labeled. This result demonstrates that we can successfully build semantic parsers for new domains by using neural models to generate SQL with crowdsourced annotations driven by user feedback.

We analyzed the feedback signals provided by the users in the final stage of the experiment to measure the quality of feedback. We found that 22.3% of the generated queries did not execute (and hence were incorrect). 6.1% of correctly generated queries were marked wrong by users (see Table 6). This erroneous feedback results in redundant annotation of already correct examples. The main cause of this erroneous feedback was incomplete data for aggregation queries, where users chose *Wrong* instead of *Incomplete*. 6.3% of incorrect queries were erroneously deemed correct by users. It is important that this fraction be low, as these queries become incorrectly-labeled exam-

	Stage 1	Stage 2	Stage 3
Accuracy (%)	25	53.7	63.5

Table 5: Percentage of utterances marked as *Correct* or *Incomplete* by users, in each stage of our online experiment.

	Feedback Error Rate (%)
Correct SQL	6.1
Incorrect SQL	6.3

Table 6: Error rates of user feedback when the SQL is correct and incorrect. The *Correct* and *Incomplete results* options are erroneous if the SQL query is correct, and vice versa for incorrect queries.

ples in the training set that may contribute to the deterioration of model accuracy over time. This quality of feedback is already sufficient for our neural models to improve with usage, and creating better interfaces to make feedback more accurate is an important task for future work.

6.3 SCHOLAR dataset

We release a new semantic parsing dataset for academic database search using the utterances gathered in the user study. We augment these labeled utterances with additional utterances labeled by crowd workers. (Note that these additional utterances were not used in the online experiment). The final dataset comprises 816 natural language utterances labeled with SQL, divided into a 600/216 train/test split. We also provide a database on which to execute these queries containing academic papers with their authors, citations, journals, keywords and datasets used. Table 1 shows statistics of this dataset. Our parser achieves an accuracy of 67% on this train/test split in the fully supervised setting. In comparison, a nearest neighbor strategy that uses the cosine similarity metric using a TF-IDF representation for the utterances yields an accuracy of 52.75%.

We found that 15% of the predicted queries did not execute, predominantly owing to (1) accessing table columns without joining with those tables, and (2) generating incorrect types that could not be deanonymized using the utterance. The main types of errors in the remaining well-formed queries that produced incorrect results were (1) portions of the utterance (such as 'top' and 'cited by both') were ignored, and (2) some types from the utterance were not transferred to the SQL query.

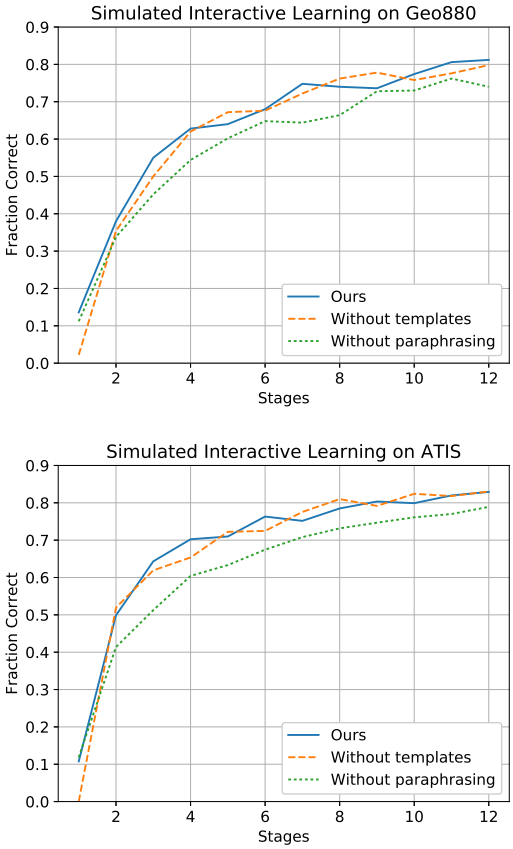

Figure 3: Accuracy as a function of batch number in simulated interactive learning experiments on Geo880 (top) and ATIS (bottom).

6.4 Simulated Interactive Experiments

We conducted additional simulated interactive learning experiments using GEO880 and ATIS to better understand the behavior of our train-deploy feedback loop, the effects of our data augmentation approaches, and the annotation effort required. We randomly divide each training set into K batches and present these batches sequentially to our interactive learning algorithm. Correctness feedback is provided by comparing the result of the predicted query to the gold query, i.e., we assume that users are able to perfectly distinguish correct results from incorrect ones.

Figure 3 shows accuracies on GEO880 and ATIS respectively of each batch when the model is trained on all previous batches. As in the live experiment, accuracy improves with successive batches. Data augmentation using templates helps in the initial stages of GEO880, but its advantage

Batch Size	150	100	50
% Wrong	70.2	60.4	54.3

Table 7: Percentage of examples that required annotation (i.e., where the model initially made an incorrect prediction) on GEO880 vs. batch size.

is reduced as more labeled data is obtained. Templates did not improve accuracy on ATIS, possibly because most ATIS queries involve two entities, i.e., a source city and a destination city, whereas our templates only generate questions with a single entity type. Nevertheless, templates are important in a live system to motivate users to interact with it in early stages. As observed before, paraphrasing improves performance at all stages.

Table 7 shows the percent of examples that require annotation using various batch sizes for GEO880. Smaller batch sizes reduce annotation effort, with a batch size of 50 requiring only 54.3% of the examples to be annotated. This result demonstrates that more frequent deployments of improved models leads to fewer mistakes.

7 Conclusion

We describe an approach to rapidly train a semantic parser as a NLIDB that iteratively improves parser accuracy over time while requiring minimal intervention. Our approach uses an attention-based neural sequence-to-sequence model, with data augmentation from the target database and paraphrasing, to parse utterances to SQL. This model is deployed in an online system, where user feedback on its predictions is used to select utterances to send for crowd worker annotation.

We find that the semantic parsing model is comparable in performance to previous systems that either map from utterances to logical forms, or generate SQL, on two benchmark datasets, GEO880 and ATIS. We further demonstrate the effectiveness of our online system by learning a semantic parser from scratch for an academic domain. A key advantage of our approach is that it is not language-specific, and can easily be ported to other commonly used query languages, such as SPARQL or ElasticSearch. Finally, we also release a new dataset of utterances and SQL queries for an academic domain.

Acknowledgments

The research was supported in part by DARPA, under the DEFT program through the AFRL (FA8750-13-2-0019), the ARO (W911NF-16-1-0121), the NSF (IIS-1252835, IIS-1562364, IIS-1546083, IIS-1651489, CNS-1563788), the DOE (DE-SC0016260), an Allen Distinguished Investigator Award, and gifts from NVIDIA, Adobe, and Google. Abstract

We present a joint modeling approach to identify salient discussion points in spoken meetings as well as to label the discourse relations between speaker turns. A variation of our model is also discussed when discourse relations are treated as latent variables. Experimental results on two popular meeting corpora show that our joint model can outperform state-of-the-art approaches for both phrase-based content selection and discourse relation prediction tasks. We also evaluate our model on predicting the consistency among team members' understanding of their group decisions. Classifiers trained with features constructed from our model achieve significant better predictive performance than the state-of-the-art.

1 Introduction

Goal-oriented dialogues, such as meetings, negotiations, or customer service transcripts, play an important role in our daily life. Automatically extracting the critical points and important outcomes from dialogues would facilitate generating summaries for complicated conversations, understanding the decision-making process of meetings, or analyzing the effectiveness of collaborations.

We are interested in a specific type of dialogues — spoken meetings, which is a common way for collaboration and idea sharing. Previous work (Kirschner et al., 2012) has shown that discourse structure can be used to capture the main discussion points and arguments put forward during problem-solving and decision-making processes in meetings. Indeed, content of different speaker turns do not occur in isolation, and should be interpreted within the context of discourse. Meanwhile, content can also reflect the purpose of speaker turns, thus facilitate with discourse relation understanding. Take the meeting snippet from

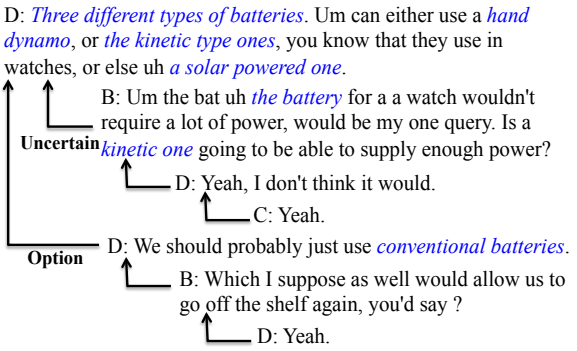

Figure 1: A sample clip from AMI meeting corpus. B, C, and D denotes different speakers. Here we highlight salient phrases (in *italics*) that are relevant to the major topic discussed, i.e., "which type of battery to use for the remote control". Arrows indicate discourse structure between speaker turns. We also show some of the discourse relations for illustration.

AMI corpus (Carletta et al., 2006) in Figure 1 as an example. This discussion is annotated with discourse structure based on the Twente Argumentation Schema (TAS) by Rienks et al. (2005), which focuses on argumentative discourse information. As can be seen, meeting participants evaluate different options by showing doubt (UNCERTAIN), bringing up alternative solution (OPTION), or giving feedback. The discourse information helps with the identification of the key discussion point, i.e., "which type of battery to use", by revealing the discussion flow.

To date, most efforts to leverage discourse information to detect salient content from dialogues have focused on encoding gold-standard discourse relations as features for use in classifier training (Murray et al., 2006; Galley, 2006; McKeown et al., 2007; Bui et al., 2009). However, automatic discourse parsing in dialogues is still a challenging problem (Perret et al., 2016). Moreover, acquiring human annotation on discourse relations is a time-consuming and expensive process, and does not

Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1090

scale for large datasets.

In this paper, we propose *a joint modeling approach to select salient phrases reflecting key discussion points as well as label the discourse relations between speaker turns in spoken meetings*. We hypothesize that leveraging the interaction between content and discourse has the potential to yield better prediction performance on both *phrase-based content selection* and *discourse relation prediction*. Specifically, we utilize argumentative discourse relations as defined in Twente Argument Schema (TAS) (Rienks et al., 2005), where discussions are organized into tree structures with discourse relations labeled between nodes (as shown in Figure 1). Algorithms for joint learning and joint inference are proposed for our model. We also present a variation of our model to treat discourse relations as latent variables when true labels are not available for learning. We envision that the extracted salient phrases by our model can be used as input to abstractive meeting summarization systems (Wang and Cardie, 2013; Mehdad et al., 2014). Combined with the predicted discourse structure, a visualization tool can be exploited to display conversation flow to support intelligent meeting assistant systems.

To the best of our knowledge, our work is the first to jointly model content and discourse relations in meetings. We test our model with two meeting corpora — the AMI corpus (Carletta et al., 2006) and the ICSI corpus (Janin et al., 2003). Experimental results show that our model yields an accuracy of 63.2 on phrase selection, which is significantly better than a classifier based on Support Vector Machines (SVM). Our discourse prediction component also obtains better accuracy than a state-of-the-art neural network-based approach (59.2 vs. 54.2). Moreover, our model trained with latent discourse outperforms SVMs on both AMI and ICSI corpora for phrase selection. We further evaluate the usage of selected phrases as extractive meeting summaries. Results evaluated by ROUGE (Lin and Hovy, 2003) demonstrate that our system summaries obtain a ROUGE-SU4 F1 score of 21.3 on AMI corpus, which outperforms non-trivial extractive summarization baselines and a keyword selection algorithm proposed in Liu et al. (2009).

Moreover, since both content and discourse structure are critical for building shared understanding among participants (Mulder et al., 2002; Mercer, 2004), we further investigate whether our learned model can be utilized to predict the consistency among team members' understanding of their group decisions. This task is first defined as *consistency of understanding* (COU) prediction by Kim and Shah (2016), who have labeled a portion of AMI discussions with consistency or inconsistency labels. We construct features from our model predictions to capture different discourse patterns and word entrainment scores for discussion with different COU level. Results on AMI discussions show that SVM classifiers trained with our features significantly outperform the state-of-the-art results (Kim and Shah, 2016) (F1: 63.1 vs. 50.5) and non-trivial baselines.

The rest of the paper is structured as follows: we first summarize related work in Section 2. The joint model is presented in Section 3. Datasets and experimental setup are described in Section 4, which is followed by experimental results (Section 5). We then study the usage of our model for predicting consistency of understanding in groups in Section 6. We finally conclude in Section 7.

2 Related Work

Our model is inspired by research work that leverages discourse structure for identifying salient content in conversations, which is still largely reliant on features derived from gold-standard discourse labels (McKeown et al., 2007; Murray et al., 2010; Bokaei et al., 2016). For instance, adjacency pairs, which are paired utterances with question-answer or offer-accept relations, are found to frequently appear in meeting summaries together and thus are utilized to extract summary-worthy utterances by Galley (2006). There is much less work that jointly predicts the importance of content along with the discourse structure in dialogus. Oya and Carenini (2014) employs Dynamic Conditional Random Field to recognize sentences in email threads for use in summary as well as their dialogue acts. Only local discourse structures from adjacent utterances are considered. Our model is built on tree structures, which captures more global information.

Our work is also in line with keyphrase identification or phrase-based summarization for conversations. Due to the noisy nature of dialogues, recent work focuses on identifying summary-worthy phrases from meetings (Fernández et al., 2008; Riedhammer et al., 2010) or email threads (Loza

et al., 2014). For instance, Wang and Cardie (2012) treat the problem as an information extraction task, where summary-worthy content represented as indicator and argument pairs is identified by an unsupervised latent variable model. Our work also targets at detecting salient phrases from meetings, but focuses on the joint modeling of critical discussion points and discourse relations held between them.

For the area of discourse analysis in dialogues, a significant amount of work has been done in predicting local discourse structures, such as recognizing dialogue acts or social acts of adjacent utterances from phone conversations (Stolcke et al., 2000; Kalchbrenner and Blunsom, 2013; Ji et al., 2016), spoken meetings (Dielmann and Renals, 2008), or emails (Cohen et al., 2004). Although discourse information from non-adjacent turns has been studied in the context of online discussion forums (Ghosh et al., 2014) and meetings (Hakkani-Tur, 2009), none of them models the effect of discourse structure on content selection, which is a gap that this work fills in.

3 The Joint Model of Content and Discourse Relations

In this section, we first present our joint model in Section 3.1. The algorithms for learning and inference are described in Sections 3.2 and 3.3, followed by feature description (Section 3.4).

3.1 Model Description

Our proposed model learns to jointly perform phrase-based content selection and discourse relation prediction by making use of the interaction between the two sources of information. Assume that a meeting discussion is denoted as $\mathbf{x}$, where $\mathbf{x}$ consists of a sequence of discourse units $\mathbf{x} = \{x_1, x_2, \cdots, x_n\}$. Each discourse unit can be a complete speaker turn or a part of it. As demonstrated in Figure 1, a tree-structured discourse diagram is constructed for each discussion with each discourse unit x_i as a node of the tree. In this work, we consider the argumentative discourse structure by Twente Argument Schema (TAS) (Rienks et al., 2005). For each node x_i, it is attached to another node $x_{i'}$ ($i' < i$) in the discussion, and a discourse relation d_i is hold on the link $\langle x_i, x_{i'} \rangle$ (d_i is empty if x_i is the root). Let $\mathbf{t}$ denote the set of links $\langle x_i, x_{i'} \rangle$ in $\mathbf{x}$. Following previous work on discourse analysis in meetings (Rienks et al., 2005; Hakkani-Tur, 2009), we assume that the attachment structure between discourse units are given during both training and testing.

A set of candidate phrases are extracted from each discourse unit x_i, from which salient phrases that contain gist information will be identified. We obtain constituent and dependency parses for utterances using Stanford parser (Klein and Manning, 2003). We restrict eligible candidate to be a noun phrase (NP), verb phrase (VP), prepositional phrase (PP), or adjective phrase (ADJP) with at most 5 words, and its head word cannot be a stop word.[1] If a candidate is a parent of another candidate in the constituent parse tree, we will only keep the parent. We further merge a verb and a candidate noun phrase into one candidate if the later is the direct object or subject of the verb. For example, from utterance "let's use a rubber case as well as rubber buttons", we can identify candidates "use a rubber case" and "rubber buttons". For x_i, the set of candidate phrases are denoted as $c_i = \{c_{i,1}, c_{i,2}, \cdots, c_{i,m_i}\}$, where m_i is the number of candidates. $c_{i,j}$ takes a value of 1 if the corresponding candidate is selected as salient phrase; otherwise, $c_{i,j}$ is equal to 0. All candidate phrases in discussion $\mathbf{x}$ are represented as $\mathbf{c}$.

We then define a log-linear model with feature parameters $\mathbf{w}$ for the candidate phrases $\mathbf{c}$ and discourse relations $\mathbf{d}$ in $\mathbf{x}$ as:

$$
\begin{aligned}
p(\mathbf{c}, \mathbf{d} | \mathbf{x}, \mathbf{w}) &\propto \exp[\mathbf{w} \cdot \Phi(\mathbf{c}, \mathbf{d}, \mathbf{x})] \\
&\propto \exp[\mathbf{w} \cdot \sum_{i=1, <x_i, x_{i'}> \in \mathbf{t}}^{n} \phi(c_i, d_i, d_{i'}, \mathbf{x})] \\
&\propto \exp[\sum_{i=1, <x_i, x_{i'}> \in \mathbf{t}}^{n} (\mathbf{w_c} \cdot \sum_{j=1}^{m_i} \phi_c(c_{i,j}, \mathbf{x}) \\
&+ \mathbf{w_d} \cdot \phi_d(d_i, d_{i'}, \mathbf{x}) + \mathbf{w_{cd}} \cdot \sum_{j=1}^{m_i} \phi_{cd}(c_{i,j}, d_i, \mathbf{x}))]
\end{aligned}
\tag{1}
$$

Here $\Phi(\cdot)$ and $\phi(\cdot)$ denote feature vectors. We utilize three types of feature functions: (1) content-only features $\phi_c(\cdot)$, which capture the importance of phrases, (2) discourse-only features $\phi_d(\cdot)$, which characterize the (potentially higher-order) discourse relations, and (3) joint features of content and discourse $\phi_{cd}(\cdot)$, which model the interaction between the two. $\mathbf{w_c}$, $\mathbf{w_d}$, and $\mathbf{w_{cd}}$ are

[1] Other methods for mining candidate phrases, such as frequency-based method (Liu et al., 2015), will be studied for future work.

corresponding feature parameters. Detailed feature descriptions can be found in Section 3.4.

Discourse Relations as Latent Variables. As we mentioned in the introduction, acquiring labeled training data for discourse relations is a time-consuming process since it would require human annotators to inspect the full discussions. Therefore, we further propose a variation of our model where it treats the discourse relations as latent variables, so that $p(\mathbf{c}|\mathbf{x},\mathbf{w}) = \sum_{\mathbf{d}} p(\mathbf{c},\mathbf{d}|\mathbf{x},\mathbf{w})$. Its learning algorithm is slightly different as described in the next section.

3.2 Joint Learning for Parameter Estimation

For learning the model parameters $\mathbf{w}$, we employ an algorithm based on SampleRank (Rohanimanesh et al., 2011), which is a stochastic structure learning method. In general, the learning algorithm constructs a sequence of configurations for sample labels as a Markov chain Monte Carlo (MCMC) chain based on a task-specific loss function, where stochastic gradients are distributed across the chain.

The full learning procedure is described in Algorithm 1. To start with, the feature weights $\mathbf{w}$ is initialized with each value randomly drawn from $[-1, 1]$. Multiple epochs are run through all samples. For each sample, we randomly initialize the assignment of candidate phrases labels $\mathbf{c}$ and discourse relations $\mathbf{d}$. Then an MCMC chain is constructed with a series of configurations $\sigma = (\mathbf{c}, \mathbf{d})$: at each step, it first samples a discourse structure $\mathbf{d}$ based on the proposal distribution $q(\mathbf{d}'|\mathbf{d},\mathbf{x})$, and then samples phrase labels conditional on the new discourse relations and previous phrase labels based on $q(\mathbf{c}'|\mathbf{c},\mathbf{d}',\mathbf{x})$. Local search is used for both proposal distributions.[2] The new configuration is accepted if it improves on the score by $\omega(\sigma')$. The parameters $\mathbf{w}$ are updated accordingly.

For the scorer ω, we use a weighted combination of F1 scores of phrase selection ($F1_c$) and discourse relation prediction ($F1_d$): $\omega(\sigma) = \alpha \cdot F1_c + (1-\alpha) \cdot F1_d$. We fix α to 0.1.

When discourse relations are treated as latent, we initialize discourse relations for each sample with a label in $\{1, 2, \ldots, K\}$ if there are K relations indicated, and we only use $F1_c$ as the scorer.

[2]For future work, we can explore other proposal distributions that utilize the conditional distribution of salient phrases given sampled discourse relations.

Input : $\mathbf{X} = \{\mathbf{x}\}$: discussions in the training set,
η: learning rate, ϵ: number of epochs,
δ: number of sampling rounds,
$\omega(\cdot)$: scoring function, $\Phi(\cdot)$: feature functions
Output: feature weights $\frac{1}{|\mathcal{W}|}\sum_{\mathbf{w}\in\mathcal{W}} \mathbf{w}$

Initialize $\mathbf{w}$;
$\mathcal{W} \leftarrow \{\mathbf{w}\}$;
for $e = 1$ *to* ϵ **do**
  for $\mathbf{x}$ *in* $\mathbf{X}$ **do**
    // Initialize configuration for $\mathbf{x}$
    Initialize $\mathbf{c}$ and $\mathbf{d}$;

      // New configuration via local search
      $\mathbf{d}' \sim q_d(\cdot|\mathbf{x},\mathbf{d})$;
      $\mathbf{c}' \sim q_d(\cdot|\mathbf{x},\mathbf{c},\mathbf{d}')$;
      $\sigma' = (\mathbf{c}', \mathbf{d}')$;
      $\sigma^+ = \arg\max_{\tilde{\sigma}\in\{\sigma,\sigma'\}} \omega(\tilde{\sigma})$;
      $\sigma^- = \arg\min_{\tilde{\sigma}\in\{\sigma,\sigma'\}} \omega(\tilde{\sigma})$;
      $\hat{\nabla} = \Phi(\sigma^+) - \Phi(\sigma^-)$;
      $\Delta\omega = \omega(\sigma^+) - \omega(\sigma^-)$;
      // Update parameters
      if $\mathbf{w}\cdot\hat{\nabla} < \Delta\omega$ & $\Delta\omega \neq 0$ **then**
        $\mathbf{w} \leftarrow \mathbf{w} + \eta \cdot \hat{\nabla}$;
        Add $\mathbf{w}$ in $\mathcal{W}$;
      end
      // Accept or reject new configuration
      if $\sigma^+ == \sigma'$ **then**
        $\sigma = \sigma'$
      end
    end
  end
end

Algorithm 1: SampleRank-based joint learning.

3.3 Joint Inference for Prediction

Given a new sample $\mathbf{x}$ and learned parameters $\mathbf{w}$, we predict phrase labels and discourse relations as $\arg\max_{\mathbf{c},\mathbf{d}} p(\mathbf{c},\mathbf{d}|\mathbf{x},\mathbf{w})$.

Dynamic programming can be employed to carry out joint inference, however, it would be time-consuming since our objective function has a large search space for both content and discourse labels. Hence we propose an alternating optimizing algorithm to search for $\mathbf{c}$ and $\mathbf{d}$ iteratively. Concretely, for each iteration, we first optimize on $\mathbf{d}$ by maximizing $\sum_{i=1,<x_i,x_i'>\in\mathbf{t}}^{n}(\mathbf{w_d}\cdot\phi_d(d_i,d_{i'},\mathbf{x}) + \mathbf{w_{cd}}\cdot\sum_{j=1}^{m_i}\phi_{cd}(c_{i,j},d_i,\mathbf{x}))$. Message-passing (Smith and Eisner, 2008) is used to find the best $\mathbf{d}$.

In the second step, we search for $\mathbf{c}$ that maximizes $\sum_{i=1,<x_i,x_i'>\in\mathbf{t}}^{n}(\mathbf{w_c}\cdot\sum_{j=1}^{m_i}\phi_c(c_{i,j},\mathbf{x}) + \mathbf{w_{cd}}\cdot\sum_{j=1}^{m_i}\phi_{cd}(c_{i,j},d_i,\mathbf{x}))$. We believe that candidate phrases based on the same concepts should have the same predicted label. Therefore, candidates of the same phrase type and sharing the same head word are grouped into one cluster. We then cast our task as an integer linear programming

problem.[3] We optimize our objective function under constraints: (1) $c_{i,j} = c_{i',j'}$ if $c_{i,j}$ and $c_{i',j'}$ are in the same cluster, and (2) $c_{i,j} \in \{0, 1\}, \forall i, j$.

The inference process is the same for models trained with latent discourse relations.

3.4 Features

We use features that characterize content, discourse relations, and the combination of both.

Content Features. For modeling the salience of content, we calculate the minimum, maximum, and average of `TF-IDF` scores of words and `number of content words` in each phrase based on the intuition that important phrases tend to have more content words with high TF-IDF scores (Fernández et al., 2008). We also consider whether the head word of the phrase has been `mentioned in preceding turn`, which implies the focus of a discussion. The `size of the cluster` each phrase belongs to is also included. `Number of POS tags` and `phrase types` are counted to characterize the syntactic structure. Previous work (Wang and Cardie, 2012) has found that a discussion usually ends with decision-relevant information. We thus identify the `absolute and relative positions` of the turn containing the candidate phrase in the discussion. Finally, we record whether the candidate phrase is `uttered by the main speaker`, who speakers the most words in the discussion.

Discourse Features. For each discourse unit, we collect the `dialogue act types` of the current unit and its parent node in discourse tree, whether there is any `adjacency pair` held between the two nodes (Hakkani-Tur, 2009), and the `Jaccard similarity` between them. We record whether two turns are `uttered by the same speaker`, for example, ELABORATION is commonly observed between the turns from the same participant. We also calculate the `number of candidate phrases` based on the observation that OPTION and SPECIALIZATION tend to contain more informative words than POSITIVE feedback. Length of the discourse unit is also relevant. Therefore, we compute the `time span` and `number of words`. To incorporate global structure features, we encode the `depth of the node` in the discourse tree and the `number of its siblings`. Finally, we include an `order-2 discourse relation` feature that encodes the relation between current discourse unit and its parent, and the relation between the parent and its grandparent if it exists.

Joint Features. For modeling the interaction between content and discourse, the discourse relation is added to each content feature to compose a joint feature. For example, if candidate c in discussion x has a content feature $\phi_{[avg-TFIDF]}(c, \mathbf{x})$ with a value of 0.5, and its discourse relation d is POSITIVE, then the joint feature takes the form of $\phi_{[avg-TFIDF,Positive]}(c, d, \mathbf{x}) = 0.5$.

4 Datasets and Experimental Setup

Meeting Corpora. We evaluate our joint model on two meeting corpora with rich annotations: the AMI meeting corpus (Carletta et al., 2006) and the ICSI meeting corpus (Janin et al., 2003). AMI corpus consists of 139 scenario-driven meetings, and ICSI corpus contains 75 naturally occurring meetings. Both of the corpora are annotated with dialogue acts, adjacency pairs, and topic segmentation. We treat each topic segment as one discussion, and remove discussions with less than 10 turns or labeled as "opening" and "chitchat". 694 discussions from AMI and 1139 discussions from ICSI are extracted, and these two datasets are henceforth referred as AMI-FULL and ICSI-FULL.

Acquiring Gold-Standard Labels. Both corpora contain human constructed abstractive summaries and extractive summaries on meeting level. Short abstracts, usually in one sentence, are constructed by meeting participants — *participant summaries*, and external annotators — *abstractive summaries*. Dialogue acts that contribute to important output of the meeting, e.g. decisions, are identified and used as extractive summaries, and some of them are also linked to the corresponding abstracts.

Since the corpora do not contain phrase-level importance annotation, we induce gold-standard labels for candidate phrases based on the following rule. A candidate phrase is considered as a positive sample if its head word is contained in any abstractive summary or participant summary. On average, 71.9 candidate phrases are identified per discussion for AMI-FULL with 31.3% labeled as positive, and 73.4 for ICSI-FULL with 24.0% of them as positive samples.

Furthermore, a subset of discussions in AMI-

[3] We use lpsolve: `http://lpsolve.sourceforge.net/5.5/`.

FULL are annotated with discourse structure and relations based on Twente Argumentation Schema (TAS) by Rienks et al. (2005)[4]. A tree-structured argument diagram (as shown in Figure 1) is created for each discussion or a part of the discussion. The nodes of the tree contain partial or complete speaker turns, and discourse relation types are labeled on the links between the nodes. In total, we have 129 discussions annotated with discourse labels. This dataset is called AMI-SUB hereafter.

Experimental Setup. 5-fold cross validation is used for all experiments. All real-valued features are uniformly normalized to [0,1]. For the joint learning algorithm, we use 10 epochs and carry out 50 sampling for MCMC for each training sample. The learning rate is set to 0.01. We run the learning algorithm for 20 times, and use the average of the learned weights as the final parameter values. For models trained with latent discourse relations, we fix the number of relations to 9.

Baselines and Comparisons. For both phrase-based content selection and discourse relation prediction tasks, we consider a baseline that always predicts the majority label (Majority). Previous work has shown that Support Vector Machines (SVMs)-based classifiers achieve state-of-the-art performance for keyphrase selection in meetings (Fernández et al., 2008; Wang and Cardie, 2013) and discourse parsing for formal text (Hernault et al., 2010). Therefore, we compare with linear SVM-based classifiers, trained with the same feature set of content features or discourse features. We fix the trade-off parameter to 1.0 for all SVM-based experiments. For discourse relation prediction, we use one-vs-rest strategy to build multiple binary classifiers.[5] We also compare with a state-of-the-art discourse parser (Ji et al., 2016), which employs neural language model to predict discourse relations.

5 Experimental Results

5.1 Phrase Selection and Discourse Labeling

Here we present the experimental results on phrase-based content selection and discourse relation prediction. We experiment with two variations of our joint model: one is trained on gold-standard discourse relations, the other is trained by treating discourse relations as latent models as described in Section 3.1. Remember that we have gold-standard argument diagrams on the AMI-SUB dataset, we can thus conduct experiments by assuming the *True Attachment Structure* is given for latent versions. When argument diagrams are not available, we build a tree among the turns in each discussion as follows. Two turns are attached if there is any adjacency pair between them. If one turn is attached to more than one previous turns, the closest one is considered. For the rest of the turns, they are attached to the preceding turn. This construction is applied on AMI-FULL and ICSI-FULL.

We also investigate whether joint learning and joint inference can produce better prediction per-

formance. We consider joint learning with separate inference, where only content features or discourse features are used for prediction (Separate-Inference). We further study learning separate classifiers for content selection and discourse relations without joint features (Separate-Learn).

We first show the phrase selection and discourse relation prediction results on AMI-SUB in Tables 1 and 2. As shown in Table 1, our models, trained with gold-standard discourse relations or latent ones with true attachment structure, yield significant better accuracy and F1 scores than SVM-based classifiers trained with the same feature sets for phrase selection (paired t-test, $p < 0.05$). Our joint learning model with separate inference also outperforms neural network-based discourse parsing model (Ji et al., 2016) in Table 2.

Moreover, Tables 1 and 2 demonstrate that joint learning usually produces superior performance for both tasks than separate learning. Combined with joint inference, our model obtains the best accuracy and F1 on phrase selection. This indicates that leveraging the interplay between content and discourse boost the prediction performance. Similar results are achieved on AMI-FULL and ICSI-FULL in Table 3, where latent discourse relations without true attachment structure are employed for training.

5.2 Phrase-Based Extractive Summarization

We further evaluate whether the prediction of the content selection component can be used for summarizing the key points on discussion level. For each discussion, salient phrases identified by our model are concatenated in sequence for use as the summary. We consider two types of gold-standard summaries. One is utterance-level extractive summary, which consists of human labeled summary-worthy utterances. The other is abstractive summary, where we collect human abstract with at least one link from summary-worthy utterances.

Extractive Summaries as Gold-Standard

Our Model-latent	85.9	11.4	**20.0**	12.4∗	3.3	**6.1**∗	3.5∗

Table 4: ROUGE scores for phrase-based extractive summarization evaluated against human-constructed utterance-level extractive summaries and abstractive summaries. Our models that statistically significantly outperform SVM and Liu et al. (2009) are highlighted with ∗ ($p < 0.05$, paired t-test). Best ROUGE score for each column is in **bold**.

We calculate scores based on ROUGE (Lin and Hovy, 2003), which is a popular tool for evaluating text summarization (Gillick et al., 2009; Liu and Liu, 2010). ROUGE-1 (unigrams) and ROUGE-SU4 (skip-bigrams with at most 4 words in between) are used. Following previous work on meeting summarization (Riedhammer et al., 2010; Wang and Cardie, 2013), we consider two dialogue act-level summarization baselines: (1) LONGEST DA in each discussion is selected as the summary, and (2) CENTROID DA, the one with the highest TF-IDF similarity with all DAs in the discussion. We also compare with an unsupervised keyword extraction approach by Liu et al. (2009), where word importance is estimated by its TF-IDF score, POS tag, and the salience of its corresponding sentence. With the same candidate phrases as in our model, we extend Liu et al. (2009) by scoring each phrase based on its average score of the words. Top phrases, with the same number of phrases output by our model, are included into the summaries. Finally, we compare with summaries consisting of salient phrases predicted by an SVM classifier trained with our content features.

From the results in Table 4, we can see that phrase-based extractive summarization methods can yield better ROUGE scores for recall and F1 than baselines that extract the whole sentences. Meanwhile, our system significantly out-

Meeting Clip:
D: can we uh power a light in this? can we get a strong enough battery to power a light?
A: um i think we could because the lcd panel requires power, and the lcd is a form of a light so that. . .
D: . . .it's gonna have to have something high-tech about it and that's gonna take battery power. . .
D: illuminate the buttons. yeah it glows.
D: well m i'm thinking along the lines of you're you're in the dark watching a dvd and you um you find the thing in the dark and you go like this . . . oh where's the volume button in the dark, and uh y you just touch it . . . and it lights up or something.

Abstract by Human:
What sort of battery to use. The industrial designer presented options for materials, components, and batteries and discussed the restrictions involved in using certain materials.

Longest DA:
well m i'm thinking along the lines of you're you're in the dark watching a dvd and you um you find the thing in the dark and you go like this.
Centroid DA:
can we uh power a light in this?
Our Method:
- power a light, a strong enough battery,
- requires power, a form,
- a really good battery, battery power,
- illuminate the buttons, glows,
- watching a dvd, the volume button, lights up or something

Figure 2: Sample summaries output by different systems for a meeting clip from AMI corpus (less relevant utterances in between are removed). Salient phrases by our system output are displayed for each turn of the clip, with duplicated phrases removed for brevity.

performs the SVM-based classifiers when evaluated on ROUGE recall and F1, while achieving comparable precision. Compared to Liu et al. (2009), our system also yields better results on all metrics.

Sample summaries by our model along with two baselines are displayed in Figure 2. Utterance-level extract-based baselines unavoidably contain disfluency and unnecessary details. Our phrase-based extractive summary is able to capture the key points from both the argumentation process and important outcomes of the conversation. This implies that our model output can be used as input for an abstractive summarization system. It can also facilitate the visualization of decision-making processes.

5.3 Further Analysis and Discussions

Features Analysis. We first discuss salient features with top weights learned by our joint model. For content features, main speaker tends to utter more salient content. Higher TF-IDF scores also indicate important phrases. If a phrase is mentioned in previous turn and repeated in the current turn, it is likely to be a key point. For discourse features, structure features matter the most. For instance, jointly modeling the discourse relation of the parent node along with the current node can lead to better inference. An example is that giving more details on the proposal (ELABORATION) tends to lead to POSITIVE feedback. Moreover, REQUEST usually appears close to the root of the argument diagram tree, while POSITIVE feedback is usually observed on leaves. Adjacency pairs also play an important role for discourse prediction. For joint features, features that composite "phrase mentioned in previous turn" and relation POSITIVE feedback or REQUEST yield higher weight, which are indicators for both key phrases and discourse relations. We also find that main speaker information composite with ELABORATION and UNCERTAIN are associated with high weights.

Error Analysis and Potential Directions. Taking a closer look at our prediction results, one major source of incorrect prediction for phrase selection is based on the fact that similar concepts might be expressed in different ways, and our model predicts inconsistently for different variations. For example, participants use both "thick" and "two centimeters" to talk about the desired shape of a remote control. However, our model does not group them into the same cluster and later makes different predictions. For future work, semantic similarity with context information can be leveraged to produce better clustering results. Furthermore, identifying discourse relations in dialogues is still a challenging task. For instance, "I wouldn't choose a plastic case" should be labeled as OPTION EXCLUSION, if the previous turns talk about different options. Otherwise, it can be labeled as NEGATIVE. Therefore, models that better handle semantics and context need to be considered.

6 Predicting Consistency of Understanding

As discussed in previous work (Mulder et al., 2002; Mercer, 2004), both content and discourse structure are critical for building shared understanding among discussants. In this section, we test whether our joint model can be utilized to predict the consistency among team members' under-

standing of their group decisions, which is defined as consistency of understanding (COU) in Kim and Shah (2016).

Kim and Shah (2016) establish gold-standard COU labels on a portion of AMI discussions, by comparing participant summaries to determine whether participants report the same decisions. If all decision points are consistent, the associated topic discussion is labeled as *consistent*; otherwise, the discussion is identified as *inconsistent*. Their annotation covers the AMI-SUB dataset. Therefore, we run the prediction experiments on AMI-SUB by using the same annotation. Out of total 129 discussions in AMI-SUB, 86 discussions are labeled as consistent and 43 are inconsistent.

We construct three types of features by using our model's predicted labels. Firstly, we learn two versions of our model based on the "consistent" discussions and the "inconsistent" ones in the training set, with learned parameters $\mathbf{w_{con}}$ and $\mathbf{w_{incon}}$. For a discussion in the test set, these two models output two probabilities $p_{con} = \max_{\mathbf{c},\mathbf{d}} P(\mathbf{c}, \mathbf{d}|\mathbf{x}, \mathbf{w_{con}})$ and $p_{incon} = \max_{\mathbf{c},\mathbf{d}} P(\mathbf{c}, \mathbf{d}|\mathbf{x}, \mathbf{w_{incon}})$. We use $p_{con} - p_{incon}$ as a feature.

Furthermore, we consider discourse relations of length one and two from the discourse structure tree. Intuitively, some discourse relations, e.g., ELABORATION followed by multiple POSITIVE feedback, imply consistent understanding.

The third feature is based on word entrainment, which has been shown to correlate with task success for groups (Nenkova et al., 2008). Using the formula in Nenkova et al. (2008), we compute the average word entrainment between the main speaker who utters the most words and all the other participants. The content words in the salient phrases predicted by our model is considered for entrainment computation.

Results. Leave-one-out is used for experiments. For training, our features are constructed from gold-standard phrase and discourse labels. Predicted labels by our model is used for constructing features during testing. SVM-based classifier is used for experimenting with different sets of features output by our model. A majority class baseline is constructed as well. We also consider an SVM classifier trained with ngram features (unigrams and bigrams). Finally, we compare with the state-of-the-art method in Kim and Shah (2016), where discourse-relevant features and head gesture features are utilized in Hidden Markov Models to predict the consistency label.

	Acc	F1
Comparisons		
Baseline (Majority)	66.7	40.0
Ngrams (SVM)	51.2	50.6
Kim and Shah (2016)	60.5	50.5
Features from Our Model		
Consistency Probability (Prob)	52.7	52.1
Discourse Relation (Disc)	63.6	57.1∗
Word Entrainment (Ent)	60.5∗	57.1∗
Prob + Disc+ Ent	**68.2**∗	**63.1**∗
Oracles		
Discourse Relation	69.8	62.7
Word Entrainment	61.2	57.8

Table 5: Consistency of Understanding (COU) prediction results on AMI-SUB. Results that statistically significantly outperform ngrams-based baseline and Kim and Shah (2016) are highlighted with $*$ ($p < 0.05$, paired t-test). For reference, we also show the prediction performance based on gold-standard discourse relations and phrase selection labels.

The results are displayed in Table 5. All SVMs trained with our features surpass the ngrams-based baseline. Especially, the discourse features, word entrainment feature, and the combination of the three, all significantly outperform the state-of-the-art system by Kim and Shah (2016).[6]

7 Conclusion

We presented a joint model for performing phrase-level content selection and discourse relation prediction in spoken meetings. Experimental results on AMI and ICSI meeting corpora showed that our model can outperform state-of-the-art methods for both tasks. Further evaluation on the task of predicting consistency-of-understanding in meetings demonstrated that classifiers trained with features constructed from our model output produced superior performance compared to the state-of-the-art model. This provides an evidence of our model being successfully applied in other prediction tasks in spoken meetings.

Abstract

We propose a novel factor graph model for argument mining, designed for settings in which the argumentative relations in a document do not necessarily form a tree structure. (This is the case in over 20% of the web comments dataset we release.) Our model jointly learns elementary unit type classification and argumentative relation prediction. Moreover, our model supports SVM and RNN parametrizations, can enforce structure constraints (e.g., transitivity), and can express dependencies between adjacent relations and propositions. Our approaches outperform unstructured baselines in both web comments and argumentative essay datasets.

1 Introduction

Argument mining consists of the automatic identification of argumentative structures in documents, a valuable task with applications in policy making, summarization, and education, among others. The argument mining task includes the tightly-knit subproblems of classifying propositions into elementary unit types and detecting argumentative relations between the elementary units. The desired output is a document argumentation graph structure, such as the one in Figure 1, where propositions are denoted by letter subscripts, and the associated argumentation graph shows their types and support relations between them.

Most annotation and prediction efforts in argument mining have focused on tree or forest structures (Peldszus and Stede, 2015; Stab and Gurevych, 2016), constraining argument structures to form one or more trees. This makes the problem computationally easier by enabling the use of maximum spanning tree–style parsing approaches. However, argumentation *in the wild* can be less well-formed. The argument put forth in Figure 1, for instance, consists of two components: a simple tree structure and a more complex graph structure (c jointly supports b and d). In this work, we design a flexible and highly expressive structured prediction model for argument mining, jointly learning to classify elementary units (henceforth *propositions*) and to identify the argumentative relations between them (henceforth *links*). By formulating argument mining as inference in a factor graph (Kschischang et al., 2001), our model (described in Section 4) can account for correlations between the two tasks, can consider second order link structures (e.g., in Figure 1, $c \rightarrow b \rightarrow a$), and can impose arbitrary constraints (e.g., transitivity).

To parametrize our models, we evaluate two alternative directions: linear structured SVMs

[Calling a debtor at work is counter-intuitive;]$_a$ [if collectors are continuously calling someone at work, other employees may report it to the debtor's supervisor.]$_b$ [Most companies have established rules about receiving or making personal calls during working hours.]$_c$ [If a collector or creditor calls a debtor on his/her cell phone and is informed that the debtor is at work, the call should be terminated.]$_d$ [No calls to employers should be allowed,]$_e$ [as this jeopardizes the debtor's job.]$_f$

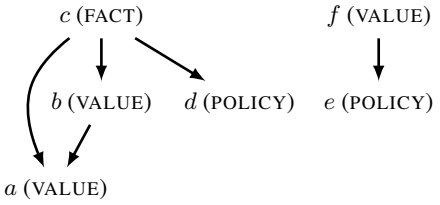

Figure 1: Example annotated CDCP comment.[1]

[1] We describe proposition types (FACT, etc.) in Section 3.

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 985–995

(Tsochantaridis et al., 2005), and recurrent neural networks with structured loss, extending (Kiperwasser and Goldberg, 2016). Interestingly, RNNs perform poorly when trained with classification losses, but become competitive with the feature-engineered structured SVMs when trained within our proposed structured learning model.

We evaluate our approach on two argument mining datasets. Firstly, on our new *Cornell eRulemaking Corpus – CDCP*,[2] consisting of argument annotations on comments from an eRulemaking discussion forum, where links don't always form trees (Figure 1 shows an abridged example comment, and Section 3 describes the dataset in more detail). Secondly, on the UKP argumentative essays v2 (henceforth UKP), where argument graphs are annotated strictly as multiple trees (Stab and Gurevych, 2016). In both cases, the results presented in Section 5 confirm that our models outperform unstructured baselines. On UKP, we improve link prediction over the best reported result in (Stab and Gurevych, 2016), which is based on integer linear programming postprocessing. For insight into the strengths and weaknesses of the proposed models, as well as into the differences between SVM and RNN parameterizations, we perform an error analysis in Section 5.1. To support argument mining research, we also release our Python implementation, `Marseille`.[3]

2 Related work

Our factor graph formulation draws from ideas previously used independently in parsing and argument mining. In particular, maximum spanning tree (MST) methods for arc-factored dependency parsing have been successfully used by McDonald et al. (2005) and applied to argument mining with mixed results by Peldszus and Stede (2015). As they are not designed for the task, MST parsers cannot directly handle proposition classification or model the correlation between proposition and link prediction—a limitation our model addresses. Using RNN features in an MST parser with a structured loss was proposed by Kiperwasser and Goldberg (2016); their model can be seen as a particular case of our factor graph approach, limited to link prediction with a tree structure constraint. Our models support multi-task learning for proposition classification, parameterizing adjacent links with higher-order structures (e.g., $c \rightarrow b \rightarrow a$) and enforcing arbitrary constraints on the link structure, not limited to trees. Such higher-order structures and logic constraints have been successfully used for dependency and semantic parsing by Martins et al. (2013) and Martins and Almeida (2014); to our knowledge we are the first to apply them to argument mining, as well as the first to parametrize them with neural networks. Stab and Gurevych (2016) used an integer linear program to combine the output of independent proposition and link classifiers using a hand-crafted scoring formula, an approach similar to our baseline. Our factor graph method can combine the two tasks in a more principled way, as it fully learns the correlation between the two tasks without relying on hand-crafted scoring, and therefore can readily be applied to other argumentation datasets. Furthermore, our model can enforce the tree structure constraint, required on the UKP dataset, using MST cycle constraints used by Stab and Gurevych (2016), thanks to the AD^3 inference algorithm (Martins et al., 2015).

Sequence tagging has been applied to the related structured tasks of proposition identification and classification (Stab and Gurevych, 2016; Habernal and Gurevych, 2016; Park et al., 2015b); integrating such models is an important next step. Meanwhile, a new direction in argument mining explores *pointer networks* (Potash et al., 2016); a promising method, currently lacking support for tree structures and domain-specific constraints.

3 Data

We release a new argument mining dataset consisting of user comments about rule proposals regarding Consumer Debt Collection Practices (CDCP) by the Consumer Financial Protection Bureau collected from an eRulemaking website, `http://regulationroom.org`.

Argumentation structures found in web discussion forums, such as the eRulemaking one we use, can be more free-form than the ones encountered in controlled, elicited writing such as (Peldszus and Stede, 2015). For this reason, we adopt the model proposed by Park et al. (2015a), which does not constrain links to form tree structures, but unrestricted directed graphs. Indeed, over 20% of the comments in our dataset exhibit local structures that would not be allowable in a tree. Possible link types are *reason* and *evidence*, and propo-

[2] Dataset available at `http://joonsuk.org`.

[3] Available at `https://github.com/vene/marseille`.

sition types are split into five fine-grained categories: POLICY and VALUE contain subjective judgements/interpretations, where only the former specifies a specific course of action to be taken. On the other hand, TESTIMONY and FACT do not contain subjective expressions, the former being about personal experience, or "anecdotal." Lastly, REFERENCE covers URLs and citations, which are used to point to objective evidence in an online setting.

In comparison, the UKP dataset (Stab and Gurevych, 2016) only makes the syntactic distinction between CLAIM, MAJOR CLAIM, and PREMISE types, but it also includes *attack* links. The permissible link structure is stricter in UKP, with links constrained in annotation to form one or more disjoint directed trees within each paragraph. Also, since web arguments are not necessarily fully developed, our dataset has many argumentative propositions that are not in any argumentation relations. In fact, it isn't unusual for comments to have no argumentative links at all: 28% of CDCP comments have no links, unlike UKP, where all essays have complete argument structures. Such comments with no links make the problem harder, emphasizing the importance of capturing the *lack* of argumentative support, not only its presence.

3.1 Annotation results

Each user comment was annotated by two annotators, who independently annotated the boundaries and types of propositions, as well as the links among them.[4] To produce the final corpus, a third annotator manually resolved the conflicts,[5] and two automatic preprocessing steps were applied: we take the link transitive closure, and we remove a small number of nested propositions.[6] The resulting dataset contains 731 comments, consisting of about 3800 sentences (≈4700 propositions) and 88k words. Out of the 43k possible pairs of propositions, links are present between only 1300 (roughly 3%). In comparison, UKP has fewer documents (402), but they are longer, with a total of 7100 sentences (6100 propositions) and 147k words. Since UKP links only occur within the same paragraph and propositions not connected to the argument are removed in a preprocessing step, link prediction is less imbalanced in UKP, with 3800 pairs of propositions being linked out of a total of 22k (17%). We reserve a test set of 150 documents (973 propositions, 272 links) from CDCP, and use the provided 80-document test split from UKP (1266 propositions, 809 links).

[4]The annotators used the GATE annotation tool (Cunningham et al., 2011).

[5]Inter-annotator agreement is measured with Krippendorff's α (Krippendorff, 1980) with respect to elementary unit type (α=64.8%) and links (α=44.1%). A separate paper describing the dataset is under preparation.

[6]When two propositions overlap, we keep the one that results in losing the fewest links. For generality, we release the dataset without this preprocessing, and include code to reproduce it; we believe that handling nested argumentative units is an important direction for further research.

4 Structured learning for argument mining

4.1 Preliminaries

Binary and multi-class classification have been applied with some success to proposition and link prediction separately, but we seek a way to jointly learn the argument mining problem at the *document* level, to better model contextual dependencies and constraints. We therefore turn to *structured learning*, a framework that provides the desired level of expressivity.

In general, learning from a dataset of documents $x_i \in \mathcal{X}$ and their associated labels $y_i \in \mathcal{Y}$ involves seeking model parameters $\boldsymbol{w}$ that can "pick out" the best label under a scoring function f:

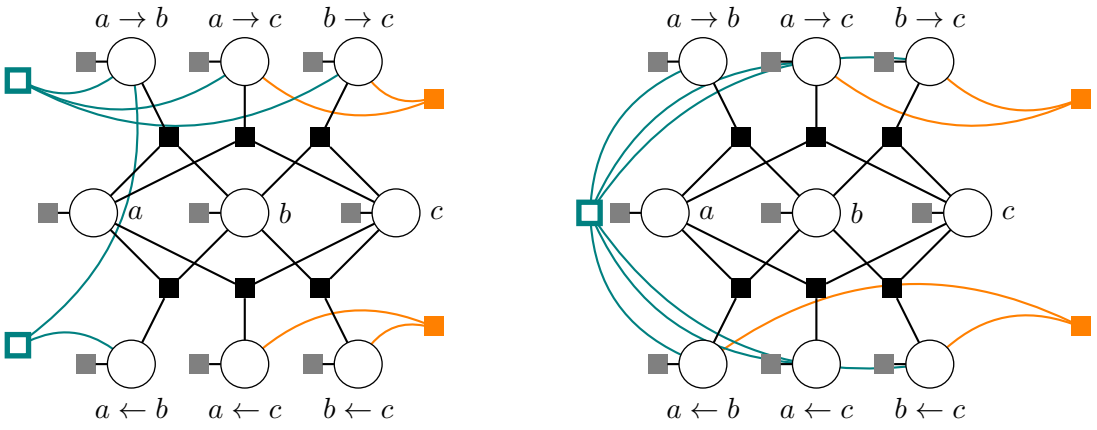
$$\hat{y} := \arg\max_{y \in \mathcal{Y}} f(x, y; \boldsymbol{w}). \quad (1)$$

Unlike classification or regression, where $\mathcal{X}$ is usually a feature space $\mathbb{R}^d$ and $\mathcal{Y} \subseteq \mathbb{R}$ (e.g., we predict an integer class index or a probability), in structured learning, more complex inputs and outputs are allowed. This makes the $\arg\max$ in Equation 1 impossible to evaluate by enumeration, so it is desirable to find models that decompose over smaller units and dependencies between them; for instance, as *factor graphs*. In this section, we give a factor graph description of our proposed structured model for argument mining.

4.2 Model description

An input document is a string of words with proposition offsets delimited. We denote the propositions in a document by $\{a, b, c, ...\}$ and the possible directed link between a and b as $a \to b$. The argument structure we seek to predict consists of the type of each proposition $y_a \in \mathcal{P}$ and a binary label for each link $y_{a \to b} \in \mathcal{R} = \{\texttt{on}, \texttt{off}\}$.[7]

[7]For simplicity and comparability, we follow Stab and Gurevych (2016) in using binary link labels even if links could be of different types. This can be addressed in our model by incorporating "labeled link" factors.



(a) CDCP (b) UKP

Figure 2: Factor graphs for a document with three propositions (a, b, c) and the six possible edges between them, and some of the factors used, illustrating differences and similarities between our models for the two datasets. Unary factors are light gray; compatibility factors are black. Factors not part of the basic model have curved edges: higher-order factors are orange and on the right; link structure factors are hollow, as that they don't have any parameters. Strict constraint factors are omitted for simplicity.

The possible proposition types $\mathcal{P}$ differ for the two datasets; such differences are documented in Table 1. As we describe the variables and factors constituting a document's factor graph, we shall refer to Figure 2 for illustration.

Unary potentials. Each proposition a and each link $a \to b$ has a corresponding random variable in the factor graph (the circles in Figure 2). To encode the model's belief in each possible value for these variables, we parametrize the *unary factors* (gray boxes in Figure 2) with unary potentials: $\boldsymbol{\phi}(a) \in \mathbb{R}^{|\mathcal{P}|}$ is a score of y_a for each possible proposition type. Similarly, link unary potentials $\boldsymbol{\phi}(a \to b) \in \mathbb{R}^{|\mathcal{R}|}$ are scores for $y_{a \to b}$ being `on`/`off`. Without any other factors, this would amount to independent classifiers for each task.

Compatibility factors. For every possible link $a \to b$, the variables $(a, b, a \to b)$ are bound by a dense factor scoring their joint assignment (the black boxes in Figure 2). Such a factor could automatically learn to encourage links from compatible types (e.g., from TESTIMONY to POLICY) or discourage links between less compatible ones (e.g., from FACT to TESTIMONY). In the simplest form, this factor would be parametrized as a tensor $\boldsymbol{\mathcal{T}} \in \mathbb{R}^{|\mathcal{P}| \times |\mathcal{P}| \times |\mathcal{R}|}$, with t_{ijk} retaining the score of a source proposition of type i to be (k = `on`) or not to be (k = `off`) in a link with a proposition of type j. For more flexibility, we parametrize this factor with **compatibility features** depending only on simple structure: $\boldsymbol{t}_{ijk}$ becomes a vector, and the score of configuration (i, j, k) is given by $\boldsymbol{v}_{ab}^{\top} \boldsymbol{t}_{ijk}$ where $\boldsymbol{v}_{ab}$ consists of three binary features:

- **bias:** a constant value of 1, allowing $\boldsymbol{\mathcal{T}}$ to learn a base score for a label configuration (i, j, k), as in the simple form above,
- **adjacency:** when there are no other propositions between the source and the target,
- **order:** when the source precedes the target.

Second order factors. Local argumentation graph structures such as $a \to b \to c$ might be modeled better together rather than through separate link factors for $a \to b$ and $b \to c$. As in higher-order structured models for semantic and dependency parsing (Martins et al., 2013; Martins and Almeida, 2014), we implement three types of second order factors: **grandparent** $(a \to b \to c)$, **sibling** $(a \leftarrow b \to c)$, and **co-parent** $(a \to b \leftarrow c)$. Not all of these types of factors make sense on all datasets: as sibling structures cannot exist in directed trees, we don't use sibling factors on UKP. On CDCP, by transitivity, every grandparent structure implies a corresponding sibling, so it is sufficient to parametrize siblings. This difference between datasets is emphasized in Figure 2, where one example of each type of factor is pictured on the right side of the graphs (orange boxes with curved edges): on CDCP we illustrate a co-parent factor (top right) and a sibling factor (bot-

tom right), while on UKP we show a co-parent factor (top right) and a grandparent factor (bottom right). We call these factors *second order* because they involve two link variables, scoring the joint assignment of both links being on.

Valid link structure. The global structure of argument links can be further constrained using domain knowledge. We implement this using constraint factors; these have no parameters and are denoted by empty boxes in Figure 2. In general, well-formed arguments should be cycle-free. In the UKP dataset, links form a directed forest and can never cross paragraphs. This particular constraint can be expressed as a series of *tree factors*,[8] one for each paragraph (the factor connected to all link variables in Figure 2). In CDCP, links do not form a tree, but we use logic constraints to enforce transitivity (top left factor in Figure 2) and to prevent symmetry (bottom left); the logic formulas implemented by these factors are described in Table 1. Together, the two constraints have the desirable side effect of preventing cycles.

Strict constraints. We may include further domain-specific constraints into the model, to express certain disallowed configurations. For instance, proposition types that appear in CDCP data can be ordered by the level of objectivity (Park et al., 2015a), as shown in Table 1. In a well-formed argument, we would want to see links from more objective to equally or less objective propositions: it's fine to provide FACT as reason for VALUE, but not the other way around. While the training data sometimes violates this constraint, enforcing it might provide a useful inductive bias.

Inference. The $\arg\max$ in Equation 1 is a MAP over a factor graph with cycles and many overlapping factors, including logic factors. While exact inference methods are generally unavailable, our setting is perfectly suited for the Alternating Directions Dual Decomposition (AD^3) algorithm: approximate inference on expressive factor graphs with overlapping factors, logic constraints, and generic factors (e.g., directed tree factors) defined through maximization oracles (Martins et al., 2015). When AD^3 returns an integral solution, it is globally optimal, but when solutions are fractional, several options are available. At test time, for analysis, we retrieve exact solutions using the branch-and-bound method. At training time, however, fractional solutions can be used *as-is*; this makes better use of each iteration and actually increases the ratio of integral solutions in future iterations, as well as at test time, as proven by Meshi et al. (2016). We also find that after around 15 training iterations with fractional solutions, over 99% of inference calls are integral.

Learning. We train the models by minimizing the structured hinge loss (Taskar et al., 2004):

$$\sum_{(x,y)\in\mathcal{D}} \max_{y'\in\mathcal{Y}} (f(x,y';\boldsymbol{w}) + \rho(y,y')) - f(x,y;\boldsymbol{w}) \tag{2}$$

where ρ is a configurable misclassification cost. The $\max$ in Equation 2 is not the same as the one used for prediction, in Equation 1. However, when the cost function ρ decomposes over the variables, cost-augmented inference amounts to regular inference after augmenting the potentials accordingly. We use a weighted Hamming cost:

$$\rho(y,\hat{y}) := \sum_v \rho(y_v)\mathbb{I}[y_v = \hat{y}_v]$$

where v is summed over all variables in a document $\{a\} \cup \{a \to b\}$, and $\rho(y_v)$ is a misclassification cost. We assign uniform costs ρ to 1 for all mistakes except false-negative links, where we use higher cost proportional to the class imbalance in the training split, effectively giving more weight to positive links during training.

4.3 Argument structure SVM

One option for parameterizing the potentials of the unary and higher-order factors is with *linear models*, using proposition, link, and higher-order features. This gives birth to a linear structured SVM (Tsochantaridis et al., 2005), which, when using l_2 regularization, can be trained efficiently in the dual using the online block-coordinate Frank-Wolfe algorithm of Lacoste-Julien et al. (2013), as implemented in the `pystruct` library (Müller and Behnke, 2014). This algorithm is more convenient than subgradient methods, as it does not require tuning a learning rate parameter.

Features. For unary proposition and link features, we faithfully follow Stab and Gurevych (2016, Tables 9 and 10): proposition features are

[8] A tree factor regards each bound variable as an edge in a graph and assigns $-\infty$ scores to configurations that are not valid trees. For inference, we can use maximum spanning arborescence algorithms such as Chu-Liu/Edmonds.

Model part	CDCP dataset	UKP dataset
proposition types	REFERENCE $\succ$ TESTIMONY $\succ$ FACT $\succ$ VALUE $\succ$ POLICY	CLAIM, MAJOR CLAIM, PREMISE
links	all possible	within each paragraph
2nd order factors	siblings, co-parents	grandparents, co-parents
link structure	transitive acyclic: • $a \to b \;\&\; b \to c \implies a \to c$ • ATMOSTONE$(a \to b, b \to a)$	directed forest: • TREEFACTOR over each paragraph • zero-potential "root" links $a \to *$
strict constraints	link source must be as least as objective as the target: $a \to b \implies a \succeq b$	link source must be premise: $a \to b \implies a =$ PREMISE

Table 1: Instantiation of model design choices for each dataset.

lexical (unigrams and dependency tuples), structural (token statistics and proposition location), indicators (from hand-crafted lexicons), contextual, syntactic (subclauses, depth, tense, modal, and POS), probability, discourse (Lin et al., 2014), and average GloVe embeddings (Pennington et al., 2014). Link features are lexical (unigrams), syntactic (POS and productions), structural (token statistics, proposition statistics and location features), hand-crafted indicators, discourse triples, PMI, and shared noun counts.

Our proposed higher-order factors for grandparent, co-parent, and sibling structures require features extracted from a proposition triplet a, b, c. In dependency and semantic parsing, higher-order factors capture relationships between words, so sparse indicator features can be efficiently used. In our case, since propositions consist of many words, BOW features may be too noisy and too dense; so for simplicity we again take a cue from the link-specific features used by Stab and Gurevych (2016). Our higher-order factor features are: same sentence indicators (for all 3 and for each pair), proposition order (one for each of the 6 possible orderings), Jaccard similarity (between all 3 and between each pair), presence of any shared nouns (between all 3 and between each pair), and shared noun ratios: nouns shared by all 3 divided by total nouns in each proposition and each pair, and shared nouns between each pair with respect to each proposition. Up to vocabulary size difference, our total feature dimensionality is approximately 7000 for propositions and 2100 for links. The number of second order features is 35.

Hyperparameters. We pick the SVM regularization parameter $C \in \{0.001, 0.003, 0.01, 0.03, 0.1, 0.3\}$ by k-fold cross validation at document level, optimizing for the average between link and proposition F_1 scores.

4.4 Argument structure RNN

Neural network methods have proven effective for natural language problems even with minimal-to-no feature engineering. Inspired by the use of LSTMs (Hochreiter and Schmidhuber, 1997) for MST dependency parsing by Kiperwasser and Goldberg (2016), we parametrize the potentials in our factor graph with an LSTM-based neural network,[9] replacing MST inference with the more general AD^3 algorithm, and using relaxed solutions for training when inference is inexact.

We extract embeddings of all words with a corpus frequency > 1, initialized with GloVe word vectors. We use a deep bidirectional LSTM to encode contextual information, representing a proposition a as the average of the LSTM outputs of its words, henceforth denoted $\overleftrightarrow{\boldsymbol{a}}$.

Proposition potentials. We apply a multi-layer perceptron (MLP) with rectified linear activations to each proposition, with all layer dimensions equal except the final output layer, which has size $|\mathcal{P}|$ and is not passed through any nonlinearities.

Link potentials. To score a dependency $a \to b$, Kiperwasser and Goldberg (2016) pass the concatenation $[\overleftrightarrow{\boldsymbol{a}}; \overleftrightarrow{\boldsymbol{b}}]$ through an MLP. After trying this, we found slightly better performance by first passing *each* proposition through a slot-specific dense layer $\left(\overline{\boldsymbol{a}} := \sigma_{\text{src}}(\overleftrightarrow{\boldsymbol{a}}), \overline{\boldsymbol{b}} := \sigma_{\text{trg}}(\overleftrightarrow{\boldsymbol{b}})\right)$ followed by a *bilinear* transformation:

$$\phi_{\text{on}}(a \to b) := \overline{\boldsymbol{a}}^{\top} \boldsymbol{W} \overline{\boldsymbol{b}} + \boldsymbol{w}_{\text{src}}^{\top} \overline{\boldsymbol{a}} + \boldsymbol{w}_{\text{trg}}^{\top} \overline{\boldsymbol{b}} + w_0^{(\text{on})}.$$

Since the bilinear expression returns a scalar, but the link potentials must have a value for both the `on` and `off` states, we set the full potential to $\boldsymbol{\phi}(a \to b) := [\phi_{\text{on}}(a \to b), w_0^{(\text{off})}]$ where $w_0^{(\text{off})}$ is a learned scalar bias. We initialize $\boldsymbol{W}$ to the diagonal identity matrix.

[9] We use the `dynet` library (Neubig et al., 2017).

Second order potentials. Grandparent potentials $\phi(a \to b \to c)$ score two adjacent directed edges, in other words three propositions. We again first pass each proposition representation through a slot-specific dense layer. We implement a multilinear scorer analogously to the link potentials:

$$\phi(a \to b \to c) := \sum_{i,j,k} \overline{\boldsymbol{a}}_i \overline{\boldsymbol{b}}_j \overline{\boldsymbol{c}}_k w_{ijk}$$

where $\mathcal{W} = (w)_{ijk}$ is a third-order cube tensor. To reduce the large numbers of parameters, we implicitly represent $\mathcal{W}$ as a rank r tensor: $w_{ijk} = \sum_{s=1}^{r} u_{is}^{(1)} u_{js}^{(2)} u_{ks}^{(3)}$. Notably, this model captures only third-order interactions between the representation of the three propositions. To capture first-order "bias" terms, we could include slot-specific linear terms, e.g., $\boldsymbol{w}_a^\top \overline{\boldsymbol{a}}$; but to further capture quadratic *backoff* effects (for instance, if two propositions carry a strong signal of being siblings regardless of their parent), we would require quadratically many parameters. Instead of explicit lower-order terms, we propose *augmenting* $\overline{\boldsymbol{a}}, \overline{\boldsymbol{b}}$, and $\overline{\boldsymbol{c}}$ with a constant feature of 1, which has approximately the same effect, while benefiting from the parameter sharing in the low-rank factorization; an effect described by Blondel et al. (2016). Siblings and co-parents factors are similarly parametrized with their own tensors.

Hyperparameters. We perform grid search using k-fold document-level cross-validation, tuning the dropout probability in the dense MLP layers over $\{0.05, 0.1, 0.15, 0.2, 0.25\}$ and the optimal number of passes over the training data over $\{10, 25, 50, 75, 100\}$. We use 2 layers for the LSTM and the proposition classifier, 128 hidden units in all layers, and a multilinear decomposition with rank $r = 16$, after preliminary CV runs.

4.5 Baseline models

We compare our proposed models to equivalent independent unary classifiers. The unary-only version of a structured SVM is an l_2-regularized linear SVM.[10] For the RNN, we compute unary potentials in the same way as in the structured model, but apply independent hinge losses at each variable, instead of the global structured hinge loss. Since the RNN weights are shared, this is a form of multi-task learning. The baseline predictions can be interpreted as unary potentials, therefore we can simply round their output to the highest scoring labels, or we can, alternatively, perform test-time inference, imposing the desired structure.

5 Results

We evaluate our proposed models on both datasets. For model selection and development we used k-fold cross-validation at document level: on CDCP we set $k = 3$ to avoid small validation folds, while on UKP we follow Stab and Gurevych (2016) setting $k = 5$. We compare our proposed structured learning systems (the linear structured SVM and the structured RNN) to the corresponding baseline versions. We organize our experiments in three incremental variants of our factor graph: *basic*, *full*, and *strict*, each with the following components:[11]

component	basic	full	strict	(baseline)
unaries	✓	✓	✓	✓
compat. factors	✓	✓	✓	
compat. features		✓	✓	
higher-order		✓	✓	
link structure		✓	✓	✓
strict constraints			✓	✓

Following Stab and Gurevych (2016), we compute F_1 scores at proposition and link level, and also report their average as a summary of overall performance.[12] The results of a single prediction run on the test set are displayed in Table 2. The overall trend is that training using a structured objective is better than the baseline models, even when structured inference is applied on the baseline predictions. On UKP, for link prediction, the linear baseline can reach good performance when using inference, similar to the approach of Stab and Gurevych (2016), but the improvement in proposition prediction leads to higher overall F_1 for the structured models. Meanwhile, on the more difficult CDCP setting, performing inference on the baseline output is not competitive. While feature engineering still outperforms our RNN model, we find that RNNs shine on proposition classification, especially on UKP, and that structured training can make them competitive, reducing their observed lag on link prediction (Katiyar and Cardie, 2016), possibly through mitigating class imbalance.

[10] We train our SVM using SAGA (Defazio et al., 2014) in `lightning` (Blondel and Pedregosa, 2016).

[11] Components are described in Section 4. The baselines *with inference* support only unaries and factors with no parameters, as indicated in the last column.

[12] For link F_1 scores, however, we find it more intuitive to only consider retrieval of positive links rather than macro-averaged two-class scores.

Table 2: Test set F_1 scores for link and proposition classification, as well as their average, on the two datasets. The number of test instances is shown in parentheses; best scores on overall tasks are in bold.

5.1 Discussion and analysis

Contribution of compatibility features. The compatibility factor in our model can be visualized as conditional odds ratios given the source and target proposition types. Since there are only four possible configurations of the compatibility features, we can plot all cases in Figure 3, alongside the basic model. Not using compatibility features, the basic model can only learn whether certain configurations are more likely than others (e.g. a REFERENCE supporting another REFERENCE is unlikely, while a REFERENCE supporting a FACT is more likely; essentially a soft version of our domain-specific strict constraints. The full model with compatibility features is finer grained, capturing, for example, that links from REFERENCE to FACT are more likely when the reference comes *after*, or that links from VALUE to POLICY are extremely likely only when the two are adjacent.

Proposition errors. The confusion matrices in Figure 4 reveal that the most common confusion is misclassifying FACT as VALUE. The strongest difference between the various models tested is that the RNN-based models make this error less often. For instance, in the proposition:

> And the single most frequently used excuse of any debtor is "I didn't receive the letter/invoice/statement"

the pronouns in the nested quote may be mistaken for subjectivity, leading to the structured SVMs predictions of VALUE or TESTIMONY, while the basic structured RNN correctly classifies it as FACT.

Link errors. While structured inference certainly helps baselines by preventing invalid structures such as cycles, it still depends on local decisions, losing to fully structured training in cases where joint proposition and link decisions are needed. For instance, in the following conclusion of an UKP essay, the annotators found no links:

> In short, [the individual should finance his or her education]$_a$ because [it is a personal choice.]$_b$ Otherwise, [it would cause too much cost from taxpayers and the government.]$_c$

Indeed, no reasons are provided, but baseline are misled by the connectives: the SVM baseline outputs that b and c are PREMISES supporting the CLAIM a. The full structured SVM combines the two tasks and correctly recognizes the link structure.

Linear SVMs are still a very good baseline, but they tend to overgenerate links due to class imbalance, even if we use class weights during training. Surprisingly, RNNs are at the opposite end, being extremely conservative, and getting the highest precision among the models. On CDCP, where the number of true links is 272, the linear baseline with strict inference predicts 796 links with a precision of only 16%, while the strict structured RNN only predicts 52 links, with 33% precision; the example in Figure 5 illustrates this. In terms of higher-order structures, we find that using higher-order factors increases precision, at a cost in recall.

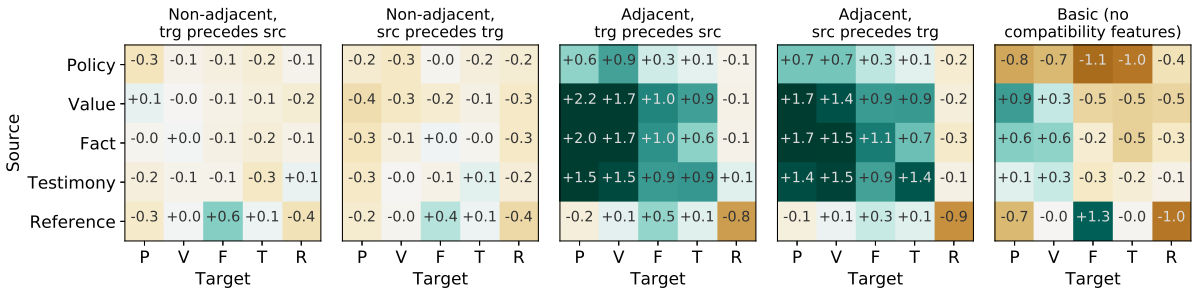

Figure 3: Learned conditional log-odds $\log \frac{p(\texttt{on}|\cdot)}{p(\texttt{off}|\cdot)}$, given the source and target proposition types and compatibility feature settings. First four figures correspond to the four possible settings of the compatibility features in the full structured SVM model. For comparison, the rightmost figure shows the same parameters in the basic structured SVM model, which does not use compatibility features.

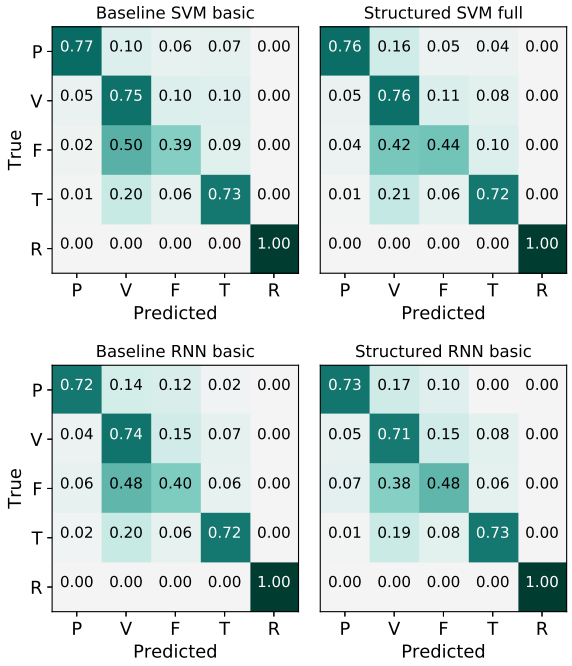

Figure 4: Normalized confusion matrices for proposition type classification.

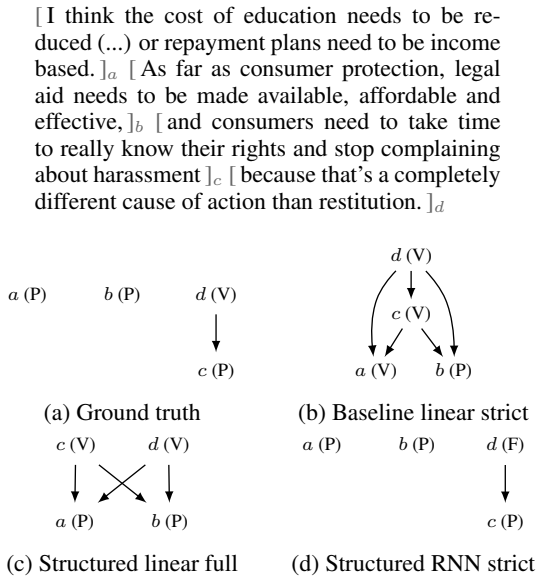

Figure 5: Predictions on a CDCP comment where the structured RNN outperforms the other models.

This is most beneficial for the 856 co-parent structures in the UKP test set: the full structured SVM has 53% F_1, while the basic structured SVM and the basic baseline get 47% and 45% respectively. On CDCP, while higher-order factors help, performance on siblings and co-parents is below 10% F_1 score. This is likely due to link sparsity and suggests plenty of room for further development.

6 Conclusions and future work

We introduce an argumentation parsing model based on AD^3 relaxed inference in expressive factor graphs, experimenting with both linear structured SVMs and structured RNNs, parametrized with higher-order factors and link structure constraints. We demonstrate our model on a new argumentation mining dataset with more permissive argument structure annotation. Our model also achieves state-of-the-art link prediction performance on the UKP essays dataset.

Future work. Stab and Gurevych (2016) found polynomial kernels useful for modeling feature interactions, but kernel structured SVMs scale poorly, we intend to investigate alternate ways to capture feature interactions. While we focus on monological argumentation, our model could be extended to dialogs, for which argumentation theory thoroughly motivates non-tree structures (Afantenos and Asher, 2014).

Neural Discourse Structure for Text Categorization

Yangfeng Ji and **Noah A. Smith**

Abstract

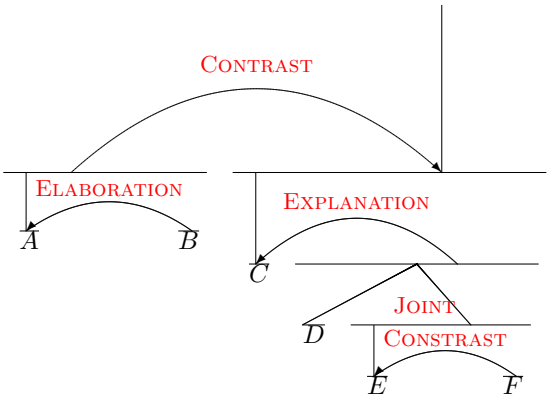
We show that discourse structure, as defined by Rhetorical Structure Theory and provided by an existing discourse parser, benefits text categorization. Our approach uses a recursive neural network and a newly proposed attention mechanism to compute a representation of the text that focuses on salient content, from the perspective of both RST and the task. Experiments consider variants of the approach and illustrate its strengths and weaknesses.

1 Introduction

Advances in text categorization have the potential to improve systems for analyzing sentiment, inferring authorship or author attributes, making predictions, and many more. Several past researchers have noticed that methods that reason about the relative salience or importance of passages within a text can lead to improvements (Ko et al., 2004). Latent variables (Yessenalina et al., 2010), structured-sparse regularizers (Yogatama and Smith, 2014), and neural attention models (Yang et al., 2016) have all been explored.

Discourse structure, which represents the organization of a text as a tree (for an example, see Figure 1), might provide cues for the importance of different parts of a text. Some promising results on sentiment classification tasks support this idea: Bhatia et al. (2015) and Hogenboom et al. (2015) applied hand-crafted weighting schemes to the sentences in a document, based on its discourse structure, and showed benefit to sentiment polarity classification.

In this paper, we investigate the value of discourse structure for text categorization more broadly, considering five tasks, through the use of a recursive neural network built on an automatically-derived document parse from a top-performing, open-source discourse parser, DPLP (Ji and Eisenstein, 2014). Our models learn to weight the importance of a document's sentences, based on their positions and relations in the discourse tree. We introduce a new, unnormalized attention mechanism to this end.



[Although the food was amazing]^{A} [and I was in love with the spicy pork burrito,]^{B} [the service was really awful.]^{C} [We watched our waiter serve himself many drinks.]^{D} [He kept running into the bathroom]^{E} [instead of grabbing our bill.]^{F}

Figure 1: A manually constructed example of the RST (Mann and Thompson, 1988) discourse structure on a text.

Experimental results show that variants of our model outperform prior work on four out of five tasks considered. Our method unsurprisingly underperforms on the fifth task, making predictions about legislative bills—a genre in which discourse conventions are quite different from those in the discourse parser's training data. Further experiments show the effect of discourse parse quality on text categorization performance, suggesting that future improvements to discourse parsing will pay off for text categorization, and validate our new attention mechanism.

Our implementation is available at https://github.com/jiyfeng/disco4textcat.

2 Background: Rhetorical Structure Theory

Rhetorical Structure Theory (RST; Mann and Thompson, 1988) is a theory of discourse that has enjoyed popularity in NLP. RST posits that a document can be represented by a tree whose leaves are elementary discourse units (EDUs, typically clauses or sentences). Internal nodes in the tree correspond to spans of sentences that are connected via discourse relations such as CONTRAST and ELABORATION. In most cases, a discourse relation links adjacent spans denoted "nucleus" and "satellite," with the former more essential to the writer's purpose than the latter.[1]

An example of a manually constructed RST parse for a restaurant review is shown in Figure 1. The six EDUs are indexed from A to F; the discourse tree organizes them hierarchically into increasingly larger spans, with the last CONTRAST relation resulting in a span that covers the whole review. Within each relation, the RST tree indicates the nucleus pointed by an arrow from its satellite (e.g., in the ELABORATION relation, A is the nucleus and B is the satellite).

The information embedded in RST trees has motivated many applications in NLP research, including document summarization (Marcu, 1999), argumentation mining (Azar, 1999), and sentiment analysis (Bhatia et al., 2015). In most applications, RST trees are built by automatic discourse parsing, due to the expensive cost of manual annotation. In this work, we use a state-of-the-art open-source RST-style discourse parser, DPLP (Ji and Eisenstein, 2014).[2]

We follow recent work that suggests transforming the RST tree into a dependency structure (Yoshida et al., 2014).[3] Figure 2(a) shows the corresponding dependency structure of the RST tree in Figure 1. It is clear that C is the root of the tree, and in fact this clause summarizes the review and suffices to categorize it as negative. This dependency representation of the RST tree offers a form of inductive bias for our neural model, helping it to discern the most salient parts of a text in order to assign it a label.

[1] There are also a few exceptions in which a relation can be realized with multiple nuclei.

[2] https://github.com/jiyfeng/DPLP

[3] The transformation is trivial and deterministic given the nucleus-satellite mapping for each relation. The procedure is analogous to the transformation of a headed phrase-structure parse in syntax into a dependency tree (e.g., Yamada and Matsumoto, 2003).

3 Model

Our model is a recursive neural network built on a discourse dependency tree. It includes a distributed representation computed for each EDU, and a composition function that combines EDUs and partial trees into larger trees. At the top of the tree, the representation of the complete document is used to make a categorization decision. Our approach is analogous to (and inspired by) the use of recursive neural networks on *syntactic* dependency trees, with word embeddings at the leaves (Socher et al., 2014).

3.1 Representation of Sentences

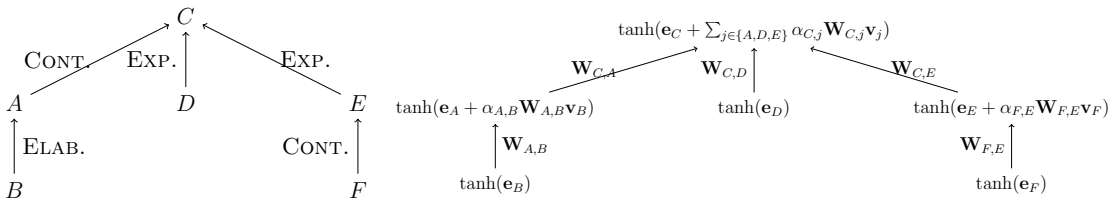
Let $\mathbf{e}$ be the distributed representation of an EDU. We use a bidirectional LSTM on the words' embeddings within each EDU (details of word embeddings are given in section 4), concatenating the last hidden state vector from the forward LSTM ($\overrightarrow{\mathbf{e}}$) with that of the backward LSTM ($\overleftarrow{\mathbf{e}}$) to get $\mathbf{e}$.

There is extensive recent work on architectures for embedding representations of sentences and other short pieces of text, including, for example, (bi)recursive neural networks (Paulus et al., 2014) and convolutional neural networks (Kalchbrenner et al., 2014). Future work might consider alternatives; we chose the bidirectional LSTM due to its effectiveness in many settings.

3.2 Full Recursive Model

Given the discourse dependency tree for an input text, our recursive model builds a vector representation through composition at each arc in the tree. Let $\mathbf{v}_i$ denote the vector representation of EDU i and its descendants. For the base case where EDU i is a leaf in the tree, we let $\mathbf{v}_i = \tanh(\mathbf{e}_i)$, which is the elementwise hyperbolic tangent function.

For an internal node i, the composition function considers a parent and all of its children, whose indices are denoted by $children(i)$. In defining this composition function, we seek for (i.) the contribution of the parent node $\mathbf{e}_i$ to be central; and (ii.) the contribution of each child node $\mathbf{e}_j$ be determined by its content as well as the discourse relation it holds with the parent. We therefore define



(a) dependency structure (b) recursive neural network structure

Figure 2: The dependency discourse tree derived from the example RST tree in Figure 1 (a) and the corresponding recursive neural network model on the tree (b).

$$\mathbf{v}_i = \tanh\left(\mathbf{e}_i + \sum_{j\in children(i)} \alpha_{i,j}\mathbf{W}_{r_{i,j}}\mathbf{v}_j\right), \quad (1)$$

where $\mathbf{W}_{r_{i,j}}$ is a relation-specific composition matrix indexed by the relation between i and j, $r_{i,j}$.

$\alpha_{i,j}$ is an "attention" weight, defined as

$$\alpha_{i,j} = \sigma\left(\mathbf{e}_i^\top \mathbf{W}_\alpha \mathbf{v}_j\right), \quad (2)$$

where σ is the elementwise sigmoid and $\mathbf{W}_\alpha$ contains attention parameters (these are relation-independent). Our attention mechanism differs from prior work (Bahdanau et al., 2015), in which attention weights are normalized to sum to one across competing candidates for attention. Here, $\alpha_{i,j}$ does not depend on node i's other children. This is motivated by RST, in which the presence of a node does not signify lesser importance to its siblings. Consider, for example, EDU D and text span E-F in Figure 1, which in parallel provide EXPLANATION for EDU C. This scenario differs from machine translation, where attention is used to implicitly and softly align output-language words to relatively few input-language words. It also differs from attention in composition functions used in syntactic parsing (Kuncoro et al., 2017), where attention can mimic head rules that follow from an endocentricity hypothesis of syntactic phrase representation.

Our recursive composition function, through the attention mechanism and the relation-specific weight matrices, is designed to learn how to differently weight EDUs for the categorization task. This idea of using a weighting scheme along with discourse structure is explored in prior works (Bhatia et al., 2015; Hogenboom et al., 2015), although they are manually designed, rather than learned from training data.

Once we have $\mathbf{v}_{root}$ of a text, the prediction of its category is given by softmax $(\mathbf{W}_o\mathbf{v}_{root} + \mathbf{b})$.

We refer to this model as the FULL model, since it makes use of the entire discourse dependency tree.

3.3 Unlabeled Model

The FULL model based on Equation 1 uses a dependency discourse tree with relations. Because alternate discourse relation labels have been proposed (e.g., Prasad et al., 2008), we seek to measure the effect of these labels. We therefore consider an UNLABELED model based only on the tree structure, without the relations:

$$\mathbf{v}_i = \tanh\left(\mathbf{e}_i + \sum_{j\in children(i)} \alpha_{i,j}\mathbf{v}_j\right). \quad (3)$$

Here, only attention weights are used to compose the children nodes' representations, significantly reducing the number of model parameters.

This UNLABELED model is similar to the depth weighting scheme introduced by Bhatia et al. (2015), which also uses an unlabeled discourse dependency tree, but our attention weights are computed by a function whose parameters are learned. This approach sits squarely between Bhatia et al. (2015) and the flat document structure used by Yang et al. (2016); the UNLABELED model still uses discourse to bias the model toward some content (that which is closer to the tree's root).

3.4 Simpler Variants

We consider two additional baselines that are even simpler. The first, ROOT, uses the discourse dependency structure only to select the root EDU, which is used to represent the entire text: $\mathbf{v}_{root} = \mathbf{e}_{root}$. No composition function is needed. This model variant is motivated by work on document summarization (Yoshida et al., 2014), where the

most central EDU is used to represent the whole text.

The second variant, ADDITIVE, uses all the EDUs with a simple composition function, and does not depend on discourse structure at all: $\mathbf{v}_{root} = \frac{1}{N}\sum_{i=1}^{N}\mathbf{e}_i$, where N is the total number of EDUs. This serves as a baseline to test the benefits of discourse, controlling for other design decisions and implementation choices. Although sentence representations $\mathbf{e}_i$ are built in a different way from the work of Yang et al. (2016), this model is quite similar to their HN-AVE model on building document representations.

4 Implementation Details

The parameters of all components of our model (top-level classification, composition, and EDU representation) are learned end-to-end using standard methods. We implement our learning procedure with the `DyNet` package (Neubig et al., 2017).

Preprocessing. For all datasets, we use the same preprocessing steps, mostly following recent work on language modeling (e.g., Mikolov et al., 2010). We lowercased all the tokens and removed tokens that contain only punctuation symbols. We replaced numbers in the documents with a special number token. Low-frequency word types were replaced by UNK; we reduce the vocabulary for each dataset until approximately 5% of tokens are mapped to UNK. The vocabulary sizes after preprocessing are also shown in Table 1.

Discourse parsing. Our model requires the discourse structure for each document. We used DPLP, the RST parser from Ji and Eisenstein (2014), which is one of the best discourse parsers on the RST discourse treebank benchmark (Carlson et al., 2001). It employs a greedy decoding algorithm for parsing, producing 2,000 parses per minute on average on a single CPU. DPLP provides discourse segmentation, breaking a text into EDUs, typically clauses or sentences, based on syntactic parses provided by Stanford CoreNLP. RST trees are converted to dependencies following the method of Yoshida et al. (2014). DPLP as distributed is trained on 347 *Wall Street Journal* articles from the Penn Treebank (Marcus et al., 1993).

Word embeddings. In cases where there are 10,000 or fewer training examples, we used pretrained GloVe word embeddings (Pennington et al., 2014), following previous work on neural discourse processing (Ji and Eisenstein, 2015). For larger datasets, we randomly initialized word embeddings and trained them alongside other model parameters.

Learning and hyperparameters. Online learning was performed with the optimization method and initial learning rate as hyperparameters. To avoid the exploding gradient problem, we used the norm clipping trick with a threshold of $\tau = 5.0$. In addition, dropout rate 0.3 was used on both input and hidden layers to avoid overfitting. We performed grid search over the word vector representation dimensionality, the LSTM hidden state dimensionality (both $\{32, 48, 64, 128, 256\}$), the initial learning rate ($\{0.1, 0.01, 0.001\}$), and the update method (SGD and Adam, Kingma and Ba, 2015). For each corpus, the highest-accuracy combination of these hyperparameters is selected using development data or ten-fold cross validation, which will be specified in section 5.

5 Datasets

We selected five datasets of different sizes and corresponding to varying categorization tasks. Some information about these datasets is summarized in Table 1.

Sentiment analysis on Yelp reviews. Originally from the Yelp Dataset Challenge in 2015, this dataset contains 1.5 million examples. We used the preprocessed dataset from Zhang et al. (2015), which has 650,000 training and 50,000 test examples. The task is to predict an ordinal rating (1–5) from the text of the review. To select the best combination of hyperparameters, we randomly sampled 10% training examples as the development data. We compared with hierarchical attention networks (Yang et al., 2016), which use the normalized attention mechanism on both word and sentence layers with a flat document structure, and provide the state-of-the-art result on this corpus.

Framing dimensions in news articles. The Media Frames Corpus (MFC; Card et al., 2015) includes around 4,200 news articles about immigration from 13 U.S. newspapers over the years 1980–2012. The annotations of these articles are in terms of a set of 15 general-purpose labels, such as ECONOMICS and MORALITY, designed to categorize the emphasis framing applied to the

Dataset	Task	Classes	Number of docs.				Vocab. size
			Total	Training	Development	Test	
Yelp	Sentiment	5	700K	650K	–	50K	10K
MFC	Frames	15	4.2K	–	–	–	7.5K
Debates	Vote	2	1.6K	1,135	105	403	5K
Movies	Sentiment	2	2.0K	–	–	–	5K
Bills	Survival	2	52K	46K	–	6K	10K

Table 1: Information about the five datasets used in our experiments. To compare with prior work, we use different experimental settings. For Yelp and Bill corpora, we use 10% of the training examples as development data. For MFC and Movies corpora, we use 10-fold cross validation and report averages across all folds.

immigration issue within the articles. We focused on predicting the single *primary* frame of each article. The state-of-the-art result on this corpus is from Card et al. (2016), where they used logistic regression together with unigrams, bigrams and Bamman-style personas (Bamman et al., 2014) as features. The best feature combination in their model alongside other hyperparameters was identified by a Bayesian optimization method (Bergstra et al., 2015). To select hyperparameters, we used a small set of examples from the corpus as a development set. Then, we report average accuracy across 10-fold cross validation as in (Card et al., 2016).

Congressional floor debates. The corpus was originally collected by Thomas et al. (2006), and the data split we used was constructed by Yessenalina et al. (2010). The goal is to predict the vote ("yea" or "nay") for the speaker of each speech segment. The most recent work on this corpus is from Yogatama and Smith (2014), which proposed structured regularization methods based on linguistic components, e.g., sentences, topics, and syntactic parses. Each regularization method induces a linguistic bias to improve text classification accuracy, where the best result we repeated here is from the model with sentence regularizers.

Movie reviews. This classic movie review corpus was constructed by Pang and Lee (2004) and includes 1,000 positive and 1,000 negative reviews. On this corpus, we used the standard ten-fold data split for cross validation and reported the average accuracy across folds. We compared with the work from both Bhatia et al. (2015) and Hogenboom et al. (2015), which are two recent works on discourse for sentiment analysis. Bhatia et al. (2015) used a hand-crafted weighting scheme to bias the bag-of-word representations on sentences. Hogenboom et al. (2015) also considered manually-designed weighting schemes and a lexicon-based model as classifier, achieving performance inferior to fully-supervised methods like Bhatia et al. (2015) and ours.

Congressional bill corpus. This corpus, collected by Yano et al. (2012), includes 51,762 legislative bills from the 103rd to 111th U.S. Congresses. The task is to predict whether a bill will survive based on its content. We randomly sampled 10% training examples as development data to search for the best hyperparameters. To our knowledge, the best published results are due to Yogatama and Smith (2014), which is the same baseline as for the congressional floor debates corpus.

6 Experiments

We evaluated all variants of our model on the five datasets presented in section 5, comparing in each case to the published state of the art as well as the most relevant works.

Results. See Table 2. On four out of five datasets, our UNLABELED model (line 8) outperforms past methods. In the case of the very large Yelp dataset, our FULL model (line 9) gives even stronger performance, but not elsewhere, suggesting that it is overparameterized for the smaller datasets. Indeed, on the MFC and Movies tasks, the discourse-ignorant ADDITIVE outperforms the FULL model. On these datasets, the selected FULL model had nearly 20 times as many parameters as the UNLABELED model, which in turn had twice as many parameters as the ADDITIVE.

Method	Yelp	MFC	Debates	Movies	Bills
Prior work					
1. Yang et al. (2016)	71.0	—	—	—	—
2. Card et al. (2016)	—	56.8	—	—	—
3. Yogatama and Smith (2014)	—	—	74.0	—	88.5
4. Bhatia et al. (2015)	—	—	—	82.9	—
5. Hogenboom et al. (2015)	—	—	—	71.9	—
Variants of our model					
6. ADDITIVE	68.5	**57.6**	69.0	82.7	80.1
7. ROOT	54.3	51.2	60.3	68.7	70.5
8. UNLABELED	**71.3**	**58.4**	**75.7**	**83.1**	78.4
9. FULL	**71.8**	56.3	**74.2**	79.5	77.0

Table 2: Test-set accuracy across five datasets. Results from prior work are reprinted from the corresponding publications. Boldface marks performance stronger than the previous state of the art.

This finding demonstrates the benefit of explicit discourse structure—even the output from an imperfect parser—for text categorization in some genres. This benefit is supported by both UNLABELED and FULL, since both of them use discourse structures of texts. The advantage of using discourse information varies on different genres and different corpus sizes. Even though the discourse parser is trained on news text, it still offers benefit to restaurant and movie reviews and to the genre of congressional debates. Even for news text, if the training dataset is small (e.g., MFC), a lighter-weight variant of discourse (UNLABELED) is preferred.

Legislative bills, which have technical legal content and highly specialized conventions (see the supplementary material for an example), are arguably the most distant genre from news among those we considered. On that task, we see discourse working against accuracy. Note that the corpus of bills is more than ten times larger than three cases where our UNLABELED model outperformed past methods, suggesting that the drop in performance is not due to lack of data.

It is also important to notice that the ROOT model performs quite poorly in all cases. This implies that discourse structure is not simply helping by finding a single EDU upon which to make the categorization decision.

Qualitative analysis. Figure 3 shows some example texts from the Yelp Review corpus with their discourse structures produced by DPLP, where the weights were generated with the FULL model. Figures 3(a) and 3(b) are two successful examples of the FULL model. Figure 3(a) shows a simple case with respect to the discourse structure. Figure 3(b) is slightly different—the text in this example may have more than one reasonable discourse structure, e.g., $2D$ could be a child of $2C$ instead of $2A$. In both cases, discourse structures help the FULL model bias to the important sentences.

Figure 3(c), on the other hand, presents a negative example, where DPLP failed to identify the most salient sentence $3F$. In addition, the weights produced by the FULL model do not make much sense, which we suspect the model was confused by the structure. Figure 3(c) also presents a manually-constructed discourse structure on the same text for reference. A more accurate prediction is expected if we use this manually-constructed discourse structure, because it has the appropriate dependency between sentences. In addition, the annotated discourse relations are able to select the right relation-specific composition matrices in FULL model, which are consistent with the training examples.

Effect of parsing performance. A natural question is whether further improvements to RST discourse parsing would lead to even greater gains in text categorization. While advances in discourse parsing are beyond the scope of this paper, we can gain some insight by exploring degradation to the DPLP parser. An easy way to do this is to train it on subsets of the RST discourse treebank. We repeated the conditions described above for our FULL model, training DPLP on 25%, 50%, and 75% of the training set (randomly selected in

[We use to visit this pub 10 years ago because they had a nice english waitress and excellent fish and chips for the price.]^{3A} [However we went back a few weeks ago and were disappointed.]^{3B} [The price of the fish and chip dinner went up and they cut the portion in half.]^{3C} [No one assisted us in putting two tables together we had to do it ourselves.]^{3D} [Two guests wanted a good English hot tea and they didn't brew it in advance.]^{3E} [So we've decided there are newer and better places to eat fish and chips especially up in north phoenix.]^{3F}

(c) true label: 1, predicted label: 3

Figure 3: Some example texts (with light revision for readability) from the Yelp Review corpus and their corresponding dependency discourse parses from DPLP (Ji and Eisenstein, 2014). The numbers on dependency edges are attention weights produced by the Full model.

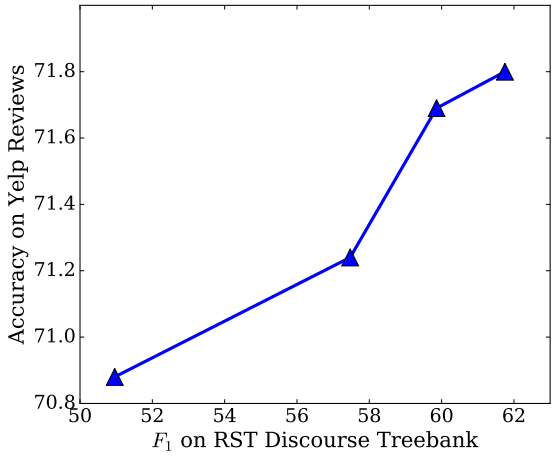

Figure 4: Varying the amount of training data for the discourse parser, we can see how parsing F_1 performance affects accuracy on the Yelp review task.

each case) before re-parsing the data for the sentiment analysis task. We did not repeat the hyperparameter search. In Figure 4, we plot accuracy of the classifier (y-axis) against the F_1 performance of the discourse parser (x-axis). Unsurprisingly, lower parsing performance implies lower classification accuracy. Notably, if the RST discourse treebank were reduced to 25% of its size, our method would underperform the discourse-ignorant model of Yang et al. (2016). While we cannot extrapolate with certainty, these findings suggest that further improvements to discourse parsing, through larger annotated datasets or improved models, could lead to greater gains.

Attention mechanism. In section 3, we contrasted our new attention mechanism (Equation 2), which is inspired by RST's lack of "competition" for salience among satellites, with the attention mechanism used in machine translation (Bahdanau et al., 2015). We consider here a variant of our model with normalized attention:

$$\boldsymbol{\alpha}'_i = \text{softmax}\left(\begin{bmatrix} \vdots \\ \mathbf{v}_j^\top \\ \vdots \end{bmatrix}_{j \in children(i)} \mathbf{W}_\alpha \cdot \mathbf{e}_i\right). \quad (4)$$

The result here is a vector $\boldsymbol{\alpha}'_i$, with one element for each child node $j \in children(i)$, and which sums to one.

On Yelp dateset, this variant of the FULL model achieves 70.3% accuracy (1.5% absolute behind our FULL model), giving empirical support to our theoretically-motivated design decision not to normalize attention. Of course, further architecture improvements may yet be possible.

Discussion. Our findings in this work show the benefit of using discourse structure for text categorization. Although discourse structure strongly improves the performance on most of corpora in our experiments, its benefit is limited particularly by two factors: (1) the state-of-the-art performance on RST discourse parsing; and (2) domain mismatch between the training corpus for a discourse parser and the domain where the discourse parser is used. For the first factor, discourse parsing is still an active research topic in NLP, and may yet improve. The second factor suggests exploring domain adaptation methods or even direct discourse annotation for genres of interest.

7 Related Work

Early work on text categorization often treated text as a bag of words (e.g., Joachims, 1998; Yang and Pedersen, 1997). Representation learning, for example through matrix decomposition (Deerwester et al., 1990) or latent topic variables (Ramage et al., 2009), has been considered to avoid overfitting in the face of sparse data.

The assumption that all parts of a text should influence categorization equally persists even as more powerful representation learners are considered. Zhang et al. (2015) treat a text as a sequence of characters, proposing to a deep convolutional neural network to build text representation. Xiao and Cho (2016) extended that architecture by inserting a recurrent neural network layer between the convolutional layer and the classification layer.

In contrast, our contributions follow Ko et al. (2004), who sought to weight the influence of different parts of an input text on the task. Two works that sought to learn the importance of sentences in a document are Yessenalina et al. (2010) and Yang et al. (2016). The former used a latent variable for the informativeness of each sentence, and the latter used a neural network to learn an attention function. Neither used any linguistic bias, relying only on task supervision to discover the latent variable distribution or attention function. Our work builds the neural network directly on a discourse dependency tree, favoring the most central EDUs over the others but giving the model the ability to overcome this bias.

Another way to use linguistic information was

presented by Yogatama and Smith (2014), who used a bag-of-words model. The novelty in their approach was a data-driven regularization method that encouraged the model to collectively ignore groups of features found to coocur. Most related to our work is their "sentence regularizer," which encouraged the model to try to ignore training-set sentences that were not informative for the task. Discourse structure was not considered.

Discourse for sentiment analysis. Recently, discourse structure has been considered for sentiment analysis, which can be cast as a text categorization problem. Bhatia et al. (2015) proposed two discourse-motivated models for sentiment polarity prediction. One of the models is also based on discourse dependency trees, but using a handcrafted weighting scheme. Our method's attention mechanism automates the weighting.

8 Conclusion

We conclude that automatically-derived discourse structure can be helpful to text categorization, and the benefit increases with the accuracy of discourse parsing. We did not see a benefit for categorizing legislative bills, a text genre whose discourse structure diverges from that of news. These findings motivate further improvements to discourse parsing, especially for new genres.

Abstract

Implicit discourse relation classification is of great challenge due to the lack of connectives as strong linguistic cues, which motivates the use of annotated implicit connectives to improve the recognition. We propose a feature imitation framework in which an implicit relation network is driven to learn from another neural network with access to connectives, and thus encouraged to extract similarly salient features for accurate classification. We develop an adversarial model to enable an adaptive imitation scheme through competition between the implicit network and a rival feature discriminator. Our method effectively transfers discriminability of connectives to the implicit features, and achieves state-of-the-art performance on the PDTB benchmark.

1 Introduction

Discourse relations connect linguistic units such as clauses and sentences to form coherent semantics. Identification of discourse relations can benefit a variety of downstream applications including question answering (Liakata et al., 2013), machine translation (Li et al., 2014), text summarization (Gerani et al., 2014), opinion spam detection (Chen and Zhao, 2015), and so forth.

Connectives (e.g., *but*, *so*, etc) are one of the most critical linguistic cues for identifying discourse relations. When explicit connectives are present in the text, a simple frequency-based mapping is sufficient to achieve over 85% classification accuracy (Xue et al., 2016; Li et al., 2016). In contrast, *implicit discourse relation recognition* has long been seen as a challenging problem, with the best accuracy so far still lower than 50% (Chen et al., 2015). In the implicit case, discourse relations are not lexicalized by connectives, but to be inferred from relevant sentences (i.e., *arguments*). For example, the following two adjacent sentences Arg1 and Arg2 imply relation *Cause* (i.e., Arg2 is the cause of Arg1).

> [*Arg1*]: Never mind.
>
> [*Arg2*]: You already know the answer.
>
> [*Implicit connective*]: Because
>
> [*Discourse relation*]: Cause

Various attempts have been made to directly infer underlying relations by modeling the semantics of the arguments, ranging from feature-based methods (Lin et al., 2009; Pitler et al., 2009) to the very recent end-to-end neural models (Chen et al., 2016a; Qin et al., 2016c). Despite impressive performance, the absence of strong explicit connective cues has made the inference extremely hard and hindered further improvement. In fact, even the human annotators would make use of connectives to aid relation annotation. For instance, the popular Penn Discourse Treebank (PDTB) benchmark data (Prasad et al., 2008) was annotated by first inserting a connective expression (i.e., *implicit connective*, as shown in the above example) manually, and determining the abstract relation by combining both the implicit connective and contextual semantics.

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1006–1017
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1093

Therefore, the huge performance gap between explicit and implicit parsing (namely, 85% vs 50%), as well as the human annotation practice, strongly motivates to incorporate connective information to guide the reasoning process. This paper aims to advance implicit parsing by making use of annotated implicit connectives available in training data. Few recent work has explored such combination. Zhou et al. (2010) developed a two-step approach by first predicting implicit connectives whose sense is then disambiguated to obtain the relation. However, the pipeline approach usually suffers from error propagation, and the method itself has relied on hand-crafted features which do not necessarily generalize well. Other research leveraged explicit connective examples for data augmentation (Rutherford and Xue, 2015; Braud and Denis, 2015; Ji et al., 2015; Braud and Denis, 2016). Our work is orthogonal and complementary to this line.

In this paper, we propose a novel neural method that incorporates implicit connectives in a principled *adversarial* framework. We use deep neural models for relation classification, and take the intuition that, sentence arguments integrated with connectives would enable highly discriminative neural features for accurate relation inference, and an ideal implicit relation classifier, even though without access to connectives, should mimic the connective-augmented reasoning behavior by extracting similarly salient features. We therefore setup a secondary network in addition to the implicit relation classifier, building upon connective-augmented inputs and serving as a feature learning model for the implicit classifier to emulate.

Methodologically, however, feature imitation in our problem is challenging due to the semantic gap induced by adding the connective cues. It is necessary to develop an adaptive scheme to flexibly drive learning and transfer discriminability. We devise a novel adversarial approach which enables a self-calibrated imitation mechanism. Specifically, we build a discriminator which distinguishes between the features by the two counterpart networks. The implicit relation network is then trained to correctly classify relations and simultaneously to fool the discriminator, resulting in an adversarial framework. The adversarial mechanism has been an emerging method in different context, especially for image generation (Goodfellow et al., 2014) and domain adaptation (Ganin et al., 2016; Chen et al., 2016c). Our adversarial framework is unique to address neural feature emulation between two models. Besides, to the best of our knowledge, this is the first adversarial approach in the context of discourse parsing. Compared to previous connective exploiting work (Zhou et al., 2010; Xu et al., 2012), our method provides a new integration paradigm and an end-to-end procedure that avoids inefficient feature engineering and error propagation.

Our method is evaluated on the PDTB 2.0 benchmark in a variety of experimental settings. The proposed adversarial model greatly improves over standalone neural models and previous best-performing approaches. We also demonstrate that our implicit recognition network successfully imitates and extracts crucial hidden representations.

We begin by briefly reviewing related work in section 2. Section 3 presents the proposed adversarial model. Section 4 shows substantially improved experimental results over previous methods. Section 5 discusses extensions and future work.

2 Related Work

2.1 Implicit Discourse Relation Recognition

There has been a surge of interest in implicit discourse parsing since the release of PDTB (Prasad et al., 2008), the first large discourse corpus distinguishing implicit examples from explicit ones. A large set of work has focused on direct classification based on observed sentences, including structured methods with linguistically-informed features (Lin et al., 2009; Pitler et al., 2009; Zhou et al., 2010), end-to-end neural models (Qin et al., 2016b,c; Chen et al., 2016a; Liu and Li, 2016), and combined approaches (Ji and Eisenstein, 2015; Ji et al., 2016). However, the lacking of connective cues makes learning purely from contextual semantics full of challenges.

Prior work has attempted to leverage connective information. Zhou et al. (2010) also incorporate implicit connectives, but in a pipeline manner by first predicting the implicit connective with a language model and determining discourse relation accordingly. Instead of treating implicit connectives as intermediate prediction targets which can suffer from error propagation, we use the connectives to induce highly discriminative features to guide the learning of an implicit network, serving as an adaptive regularization mechanism for en-

hanced robustness and generalization. Our framework is also end-to-end, avoiding costly feature engineering. Another notable line aims at adapting explicit examples for data synthesis (Biran and McKeown, 2013; Rutherford and Xue, 2015; Braud and Denis, 2015; Ji et al., 2015), multi-task learning (Lan et al., 2013; Liu et al., 2016), and word representation (Braud and Denis, 2016). Our work is orthogonal and complementary to these methods, as we use implicit connectives which have been annotated for implicit examples.

2.2 Adversarial Networks

Deep neural networks have gained impressive success in various natural language processing tasks (Wang et al., 2016; Zhang et al., 2016b; Cai et al., 2017), in which adversarial networks have been shown especially effective in deep generative modeling (Goodfellow et al., 2014) and domain adaptation (Ganin et al., 2016). Generative adversarial nets (Goodfellow et al., 2014) learn to produce realistic samples through competition between a generator and a real/fake discriminator. Professor forcing (Lamb et al., 2016) applies a similar idea to improve long-term generation of a recurrent neural language model. Other approaches (Chen et al., 2016b; Hu et al., 2017; Liang et al., 2017) extend the framework for controllable image/text generation. Li et al. (2015); Salimans et al. (2016) propose feature matching which trains generators to match the statistics of real/fake examples. Their features are extracted by the discriminator rather than the classifier networks as in our case. Our work differs from the above since we consider the context of discriminative modeling. Adversarial domain adaptation forces a neural network to learn domain-invariant features using a classifier that distinguishes the domain of the network's input data based on the hidden feature. Our adversarial framework is distinct in that besides the implicit relation network we construct a second neural network serving as a teacher model for feature emulation.

To the best of our knowledge, this is the first to employ the idea of adversarial learning in the context of discourse parsing. We propose a novel connective exploiting scheme based on feature imitation, and to this end derive a new adversarial framework, achieving substantial performance gain over existing methods. The proposed approach is generally applicable to other tasks for utilizing any indicative side information. We give more discussions in section 5.

3 Adversarial Method

Discourse connectives are key indicators for discourse relation. In the annotation procedure of the PDTB implicit relation benchmark, annotators inserted implicit connective expressions between adjacent sentences to lexicalize abstract relations and help with final decisions. Our model aims at making full use of the provided implicit connectives at training time to regulate learning of implicit relation recognizer, encouraging extraction of highly discriminative semantics from raw arguments, and improving generalization at test time. Our method provides a novel adversarial framework that leverages connective information in a flexible adaptive manner, and is efficiently trained end-to-end through standard back-propagation.

The basic idea of the proposed approach is simple. We want our implicit relation recognizer, which predicts the underlying relation of sentence arguments without discourse connective, to have prediction behaviors close to a *connective-augmented* relation recognizer which is provided with a discourse connective in addition to the arguments. The connective-augmented recognizer is in analogy to an annotator with the help of connectives as in the human annotation process, and the implicit recognizer would be improved by learning from such an "informed" annotator. Specifically, we want the latent features extracted by the two models to match as closely as possible, which explicitly transfers the discriminability of the connective-augmented representations to implicit ones.

To this end, instead of manually selecting a closeness metric, we take advantage of the adversarial framework by constructing a two-player zero-sum game between the implicit recognizer and a rival discriminator. The discriminator attempts to distinguish between the features extracted by the two relation models, while the implicit relation model is trained to maximize the accuracy on implicit data, and at the same time to confuse the discriminator.

In the next we first present the overall architecture of the proposed approach (section 3.1), then develop the training procedure (section 3.2). The components are realized as deep (convolutional) neural networks, with detailed modeling choices

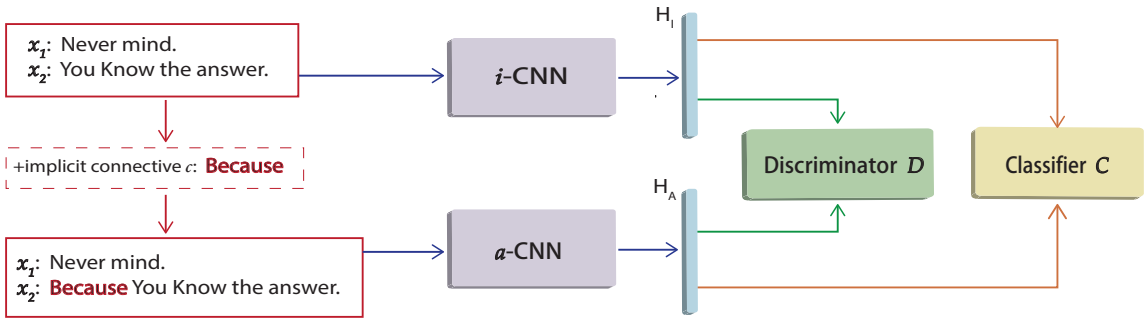

Figure 1: Architecture of the proposed method. The framework contains three main components: 1) an implicit relation network *i-CNN* over raw sentence arguments, 2) a connective-augmented relation network *a-CNN* whose inputs are augmented with implicit connectives, and 3) a discriminator distinguishing between the features by the two networks. The features are fed to the final classifier for relation classification. The discriminator and *i-CNN* form an adversarial pair for feature imitation. At test time, the implicit network *i-CNN* with the classifier is used for prediction.

discussed in section 3.3.

3.1 Model Architecture

Let $(\boldsymbol{x}, y)$ be a pair of input and output of implicit relation classification, where $\boldsymbol{x} = (\boldsymbol{x}_1, \boldsymbol{x}_2)$ is a pair of sentence arguments, and y is the underlying discourse relation. Each training example also includes an annotated implicit connective c that best expresses the relation. Figure 1 shows the architecture of our framework.

The neural model for implicit relation classification (*i-CNN* in the figure) extracts latent representation from the arguments, denoted as $H_I(\boldsymbol{x}_1, \boldsymbol{x}_2)$, and feeds the feature into a classifier C for final prediction $C(H_I(\boldsymbol{x}_1, \boldsymbol{x}_2))$. For ease of notation, we will also use $H_I(\boldsymbol{x})$ to denote the latent feature on data $\boldsymbol{x}$.

The second relation network (*a-CNN*) takes as inputs the sentence arguments along with an implicit connective, to induce the connective-augmented representation $H_A(\boldsymbol{x}_1, \boldsymbol{x}_2, c)$, and obtains relation prediction $C(H_A(\boldsymbol{x}_1, \boldsymbol{x}_2, c))$. Note that the same final classifier C is used for both networks, so that the feature representations by the two networks are ensured to be within the same semantic space, enabling feature emulation as presented shortly.

We further pair the implicit network with a rival discriminator D to form our adversarial game. The discriminator is to differentiate between the reasoning behaviors of the implicit network *i-CNN* and the augmented network *a-CNN*. Specifically, D is a binary classifier that takes as inputs a latent feature H derived from either *i-CNN* or *a-CNN* given appropriate data (where implicit connectives is either missing or present, respectively). The output $D(H)$ estimates the probability that H comes from the connective-augmented *a-CNN* rather than *i-CNN*.

3.2 Training Procedure

The system is trained through an alternating optimization procedure that updates the components in an interleaved manner. In this section, we first present the training objective for each component, and then give the overall training algorithm.

Let $\boldsymbol{\theta}_D$ denote the parameters of the discriminator. The training objective of D is straightforward, i.e., to maximize the probability of correctly distinguishing the input features:

$$\max_{\boldsymbol{\theta}_D} \mathcal{L}_D = \mathbb{E}_{(\boldsymbol{x},c,y)\sim\text{data}}\Big[\log D(H_A(\boldsymbol{x}, c); \boldsymbol{\theta}_D) + \log(1 - D(H_I(\boldsymbol{x}); \boldsymbol{\theta}_D))\Big], \quad (1)$$

where $\mathbb{E}_{(\boldsymbol{x},c,y)\sim\text{data}}[\cdot]$ denotes the expectation in terms of the data distribution.

We denote the parameters of the implicit network *i-CNN* and the classifier C as $\boldsymbol{\theta}_I$ and $\boldsymbol{\theta}_C$, respectively. The model is then trained to (a) correctly classify relations in training data and (b) produce salient features close to connective-augmented ones. The first objective can be fulfilled by minimizing the usual cross-entropy loss:

$$\mathcal{L}_{I,C}(\boldsymbol{\theta}_I, \boldsymbol{\theta}_C) = \mathbb{E}_{(\boldsymbol{x},y)\sim\text{data}}\Big[J\big(C(H_I(\boldsymbol{x}; \boldsymbol{\theta}_I); \boldsymbol{\theta}_C), y\big)\Big], \quad (2)$$

Algorithm 1 Adversarial Model for Implicit Recognition

Input: Training data $\{(\boldsymbol{x}, c, y)_n\}$
Parameters: λ_1, λ_2 – balancing parameters

1: Initialize $\{\boldsymbol{\theta}_I, \boldsymbol{\theta}_C\}$ and $\{\boldsymbol{\theta}_A\}$ by minimizing Eq.(2) and Eq.(4), respectively
2: **repeat**
3: Train the discriminator through Eq.(1)
4: Train the relation models through Eq.(5)
5: **until** convergence

Output: Adversarially enhanced implicit relation network *i-CNN* with classifier C for prediction

where $J(\boldsymbol{p}, y) = -\sum_k \mathbb{I}(y = k) \log p_k$ is the cross-entropy loss between predictive distribution $\boldsymbol{p}$ and ground-truth label y. We achieve objective (b) by minimizing the discriminator's chance of correctly telling apart the features:

$$\mathcal{L}_I(\boldsymbol{\theta}_I) = \mathbb{E}_{\boldsymbol{x}\sim\text{data}}\Big[\log\big(1 - D(H_I(\boldsymbol{x}; \boldsymbol{\theta}_I))\big)\Big]. \quad (3)$$

The parameters of the augmented network *a-CNN*, denoted as $\boldsymbol{\theta}_A$, can be learned by simply fitting to the data, i.e., minimizing the cross-entropy loss as follows:

$$\mathcal{L}_A(\boldsymbol{\theta}_A) = \mathbb{E}_{(\boldsymbol{x},c,y)\sim\text{data}}\Big[J\big(C(H_A(\boldsymbol{x}, c; \boldsymbol{\theta}_A)), y\big)\Big]. \quad (4)$$

As mentioned above, here we use the same classifier C as for the implicit network, forcing a unified feature space of both networks. We combine the above objectives Eqs.(2)-(4) of the relation classifiers and minimize the joint loss:

$$\min_{\boldsymbol{\theta}_I, \boldsymbol{\theta}_A, \boldsymbol{\theta}_C} \mathcal{L}_{I,A,C} = \mathcal{L}_{I,C}(\boldsymbol{\theta}_I, \boldsymbol{\theta}_C) + \lambda_1 \mathcal{L}_I(\boldsymbol{\theta}_I) + \lambda_2 \mathcal{L}_A(\boldsymbol{\theta}_A), \quad (5)$$

where λ_1 and λ_2 are two balancing parameters calibrating the weights of the classification losses and the feature-regulating loss. In practice, we pre-train the implicit and augmented networks independently by minimizing Eq.(2) and Eq.(4), respectively. In the adversarial training process, we found setting $\lambda_2 = 0$ gives stable convergence. That is, the connective-augmented features are fixed after the pre-training stage.

Algorithm 1 summarizes the training procedure, where we interleave the optimization of Eq.(1) and Eq.(5) at each iteration. More practical details are provided in section 4. We instantiate all modules as neural networks (section 3.3) which are differentiable, and perform the optimization efficiently through standard stochastic gradient descent and back-propagation.

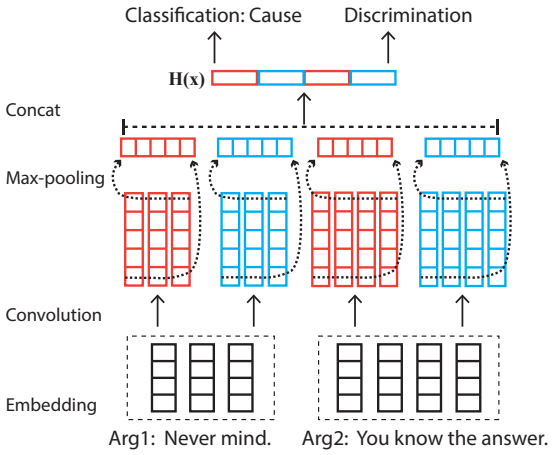

Figure 2: Neural structure of *i-CNN*. Two sets of convolutional filters are shown, with the corresponding features in red and blue, respectively. The weights of the filters on two input arguments are tied.

Through Eq.(1) and Eq.(3), the discriminator and the implicit relation network follow a minimax competition, which drives both to improve until the implicit feature representations are close to the connective-augmented latent representations, encouraging the implicit network to extract highly discriminative features from raw sentence arguments for relation classification. Alternatively, we can see Eq.(3) as an *adaptive* regularization on the implicit model, which, compared to pre-fixed regularizors such as ℓ_2-regularization, provides a more flexible, self-calibrated mechanism to improve generalization ability.

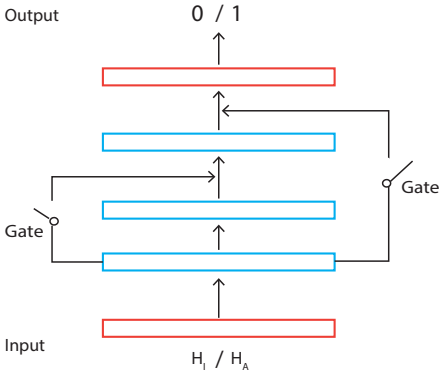

Figure 3: Neural structure of the discriminator D.

3.3 Component Structures

We have presented our adversarial framework for implicit relation classification. We now discuss the model realization of each component. All components of the framework are parameterized with neural networks. Distinct roles of the modules in the framework lead to different modeling choices.

Relation Classification Networks Figure 2 illustrates the structure of the implicit relation network *i-CNN*. We use a convolutional network as it is a common architectural choice for discourse parsing. The network takes as inputs the word vectors of the tokens in each sentence argument, and maps each argument to intermediate features through a shared convolutional layer. The resulting representations are then concatenated and fed into a max pooling layer to select most salient features as the final representation. The final classifier C is a simple fully-connected layer followed by a softmax classifier.

The connective-augmented network *a-CNN* has a similar structure as *i-CNN*, wherein implicit connective is appended to the second sentence as input. The key difference from *i-CNN* is that here we adopt *average k-max* pooling, which takes the average of the top-k maximum values in each pooling window. The reason is to prevent the network from solely selecting the connective induced features (which are typically the most salient features) which would be the case when using max pooling, but instead force it to also attend to contextual features derived from the arguments. This facilitates more homogeneous output features of the two networks, and thus facilitates feature imitation. In all the experiments we fixed $k = 2$.

Discriminator The discriminator is a binary classifier to identify the correct source of an input feature vector. To make it a strong rival to the feature imitating network (*i-CNN*), we model the discriminator as a multi-layer perceptron (MLP) enhanced with gated mechanism for efficient information flow (Srivastava et al., 2015; Qin et al., 2016c), as shown in Figure 3.

4 Experiments

We demonstrate the effectiveness of our approach both quantitatively and qualitatively with extensive experiments. We evaluate prediction performance on the PDTB benchmark in different settings. Our method substantially improves over a diverse set of previous models, especially in the practical multi-class classification task. We perform in-depth analysis of the model behaviors, and show our adversarial framework successfully enables the implicit relation model to imitate and learn discriminative features.

4.1 Experiment Setup

We use PDTB 2.0[1], one of the largest manually annotated discourse relation corpus. The dataset contains 16,224 implicit relation instances in total, with three levels of senses: Level-1 *Class*, Level-2 *Type*, and Level-3 *Subtypes*. The 1st level consists of four major relation *Class*es: COMPARISON, CONTINGENCY, EXPANSION and TEMPORAL. The 2nd level contains 16 *Type*s.

To make extensive comparison with prior work of implicit discourse relation classification, we evaluate on two popular experimental settings: 1) multi-class classification for 2nd-level types (Lin et al., 2009; Ji and Eisenstein, 2015), and 2) one-versus-others binary classifications for 1st-level classes (Pitler et al., 2009). We describe the detailed configurations in the following respective sections. We will focus our analysis on the multi-class classification setting, which is most realistic in practice and serves as a building block for a complete discourse parser such as that for the shared tasks of CoNLL-2015 and 2016 (Xue et al., 2015, 2016).

Model Training Here we provide the detailed architecture configurations of each component we used in the experiments.

- Throughout the experiments *i-CNN* and *a-CNN* contain 3 sets of convolutional filters with the filter sizes selected on the dev set. Table 1 lists the filter configurations of the convolutional layer in *i-CNN* and *a-CNN* in different tasks. As described in section 3.3, following the convolutional layer is a max pooling layer in *i-CNN*, and an average k-max pooling layer with $k = 2$ in *a-CNN*.
- The final single-layer classifier *C* contains 512 neurons with *tanh* activation function.
- The discriminator *D* consists of 4 fully-connected layers, with 2 gated pathways from layer 1 to layer 3 and layer 4 (see Figure 3).

[1] http://www.seas.upenn.edu/∼pdtb/

Task	Filter sizes	Filter number
PDTB-Lin	2, 4, 8	3×256
PDTB-Ji	2, 5, 10	3×256
One-vs-all	2, 5, 10	3×1024

Table 1: The convolutional architectures of *i-CNN* and *a-CNN* in different tasks (section 4). For example, in PDTB-Lin, we use 3 sets of filters, each of which is of size 2, 4, and 8, respectively; and each set has 256 filters.

The size of each layer is set to 1024 and is fixed in all the experiments.

- We set the dimension of the input word vectors to 300 and initialize with pre-trained word2vec (Mikolov et al., 2013). The maximum length of sentence argument is set to 80. Truncation and zero-padding are applied when necessary.

All experiments were performed on a TITAN-X GPU and 128GB RAM, with neural implementation based on Tensorflow[2].

For adversarial model training, it is critical to keep balance between the progress of the two players. We use a simple strategy which at each iteration optimizes the discriminator and the implicit relation network on a randomly-sampled mini-batch. We found this is enough to stabilize the training. The neural parameters are trained using AdaGrad (Duchi et al., 2011) with an initial learning rate of 0.001. For the balancing parameters in Eq.(5), we set $\lambda_1 = 0.1$, while $\lambda_2 = 0$. That is, after the initialization stage the weights of the connective-augmented network *a-CNN* are fixed. This has been shown capable of giving stable and good predictive performance for our system.

4.2 Implicit Relation Classification

We will mainly focus on the general multi-class classification problem in two alternative settings adopted in prior work, showing the superiority of our model over previous state of the arts. We perform in-depth comparison with carefully designed baselines, providing empirical insights into the working mechanism of the proposed framework. For broader comparisons we also report the performance in the one-versus-all setting.

10	Ours	**44.65**	**46.23**

Table 2: Accuracy (%) on the test sets of the PDTB-Lin and PDTB-Ji settings for **multi-class classification**. Please see the text for more details.

Multi-class Classifications

We first adopt the standard PDTB splitting convention following (Lin et al., 2009), denoted as PDTB-Lin, where sections 2-21, 22, and 23 are used as training, dev, and test sets, respectively. The most frequent 11 types of relations are selected in the task. During training, instances with more than one annotated relation types are considered as multiple instances, each of which has one of the annotations. At test time, a prediction that matches one of the gold types is considered as correct. The test set contains 766 examples. More details are in (Lin et al., 2009). An alternative, slightly different multi-class setting is used in (Ji and Eisenstein, 2015), denoted as PDTB-Ji, where sections 2-20, 0-1, and 21-22 are used as training, dev, and test sets, respectively. The resulting test set contains 1039 examples. We also evaluate in this setting for thorough comparisons.

Table 2 shows the classification accuracy in both of the settings. We see that our model (Row 10) achieves state-of-the-art performance, greatly outperforming previous methods (Rows 6-9) with various modeling paradigms, including the linguistic feature-based model (Lin et al., 2009), pure neural methods (Qin et al., 2016c), and combined approach (Ji and Eisenstein, 2015).

To obtain better insights into the working mechanism of our method, we further compare with a set of carefully selected baselines as shown in Rows 1-5. 1) "Word-vector" sums over the word vectors for sentence representation, showing the base effect of word embeddings. 2) "CNN" is a standalone convolutional net having the exact same architecture with our implicit rela-

tion network. Our model trained within the proposed framework provides significant improvement, showing the benefits of utilizing implicit connectives at training time. 3) "Ensemble" has the same neural architecture with the proposed framework except that the input of *a-CNN* is not augmented with implicit connectives. This essentially is an ensemble of two implicit recognition networks. We see that the method performs even inferior to the single CNN model. This further confirms the necessity of exploiting connective information. 4) "Multi-task" is the convolutional net augmented with an additional task of simultaneously predicting the implicit connectives based on the network features. As a straightforward way of incorporating connectives, we see that the method slightly improves over the stand-alone CNN, while falling behind our approach with a large margin. This indicates that our proposed feature imitation is a more effective scheme for making use of implicit connectives. 5) At last, "ℓ_2-reg" also implements feature mimicking by imposing an ℓ_2 distance penalty between the implicit relation features and connective-augmented features. We see that the simple model has obtained improvement over previous best-performing systems in both settings, further validating the idea of imitation. However, in contrast to the fixed ℓ_2 regularization, our adversarial framework provides an adaptive mechanism, which is more flexible and performs better as shown in the table.

Model	COMP.	CONT.	EXP.	TEMP.
Pitler et al. (2009)	21.96	47.13	-	16.76
Qin et al. (2016c)	**41.55**	**57.32**	71.50	35.43
Zhang et al. (2016a)	35.88	50.56	71.48	29.54
Zhou et al. (2010)	31.79	47.16	70.11	20.30
Liu and Li (2016)	36.70	54.48	70.43	**38.84**
Chen et al. (2016a)	40.17	54.76	-	31.32
Ours	40.87	54.56	**72.38**	36.20

Table 3: Comparisons of F_1 scores (%) for binary classification.

One-versus-all Classifications

We also report the results of four one-versus-all binary classifications for more comparisons with prior work. We follow the conventional experimental setting (Pitler et al., 2009) by selecting sections 2-20, 21-22, and 0-1 as training, dev, and test sets. Table 4 lists the statistics of the data.

Following previous work, Table 3 reports the F1 scores. Our method outperforms most of the prior systems in all the tasks. We achieve state-of-the-art performance in recognition of the Expansion relation, and obtain comparable scores with the best-performing methods in each of the other relations, respectively. Notably, our feature imitation scheme greatly improves over (Zhou et al., 2010) which leverages implicit connectives as an intermediate prediction task. This provides additional evidence for the effectiveness of our approach.

Relation	Train	Dev	Test
Comparison	1942/1942	197/986	152/894
Contigency	3342/3342	295/888	279/767
Expansion	7004/7004	671/512	574/472
Temporal	760/760	64/1119	85/961

Table 4: Distributions of positive and negative instances from the train/dev/test sets in four binary relation classification tasks.

4.3 Qualitative Analysis

We now take a closer look into the modeling behavior of our framework, by investigating the process of the adversarial game during training, as well as the feature imitation effects.

Figure 4 demonstrates the training progress of different components. The *a-CNN* network keeps high predictive accuracy as implicit connectives are given, showing the importance of connective cues. The rise-and-fall patterns in the accuracy of the discriminator clearly show its competition with the implicit relation network *i-CNN* as training goes. At first few iterations the accuracy of the discriminator increases quickly to over 0.9, while at late stage the accuracy drops to around 0.6, showing that the discriminator is getting confused by *i-CNN* (an accuracy of 0.5 indicates full confusion). The *i-CNN* network keeps improving in terms of implicit relation classification accuracy, as it is gradually fitting to the data and simultaneously learning increasingly discriminative features by mimicking *a-CNN*. The system exhibits similar learning patterns in the two different settings, showing the stability of the training strategy.

We finally visualize the output feature vectors of *i-CNN* and *a-CNN* using the t-SNE method (Maaten and Hinton, 2008) in Figure 5. Without feature imitation, the extracted features by the two networks are clearly separated (Figure 5(a)). In contrast, as shown in Figures 5(b)-(c), the feature vectors are increasingly mixed as training proceeds. Thus our framework has suc-

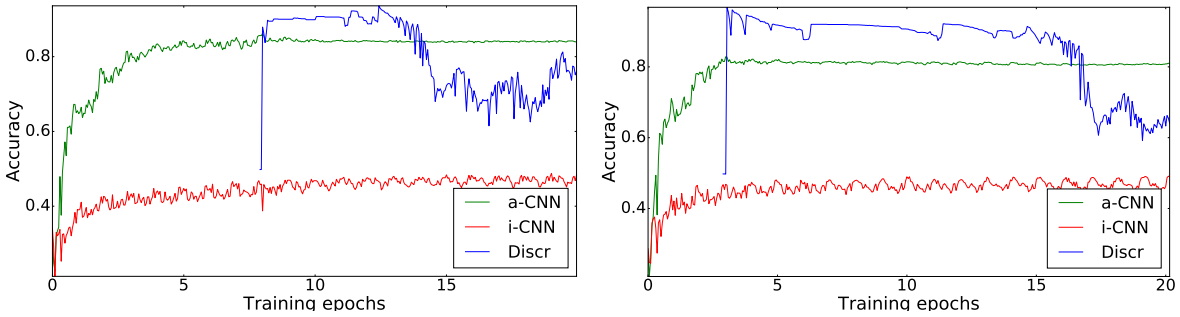

Figure 4: (Best viewed in colors.) Test-set performance of three components over training epochs. Relation networks *a-CNN* and *i-CNN* are measured with multi-class classification accuracy (with or without implicit connectives, respectively), while the discriminator is evaluated with binary classification accuracy. **Top**: the PDTB-Lin setting (Lin et al., 2009), where first 8 epochs are for initialization stage (thus the discriminator is fixed and not shown); **Bottom**: the PDTB-Ji setting (Ji and Eisenstein, 2015), where first 3 epochs are for initialization.

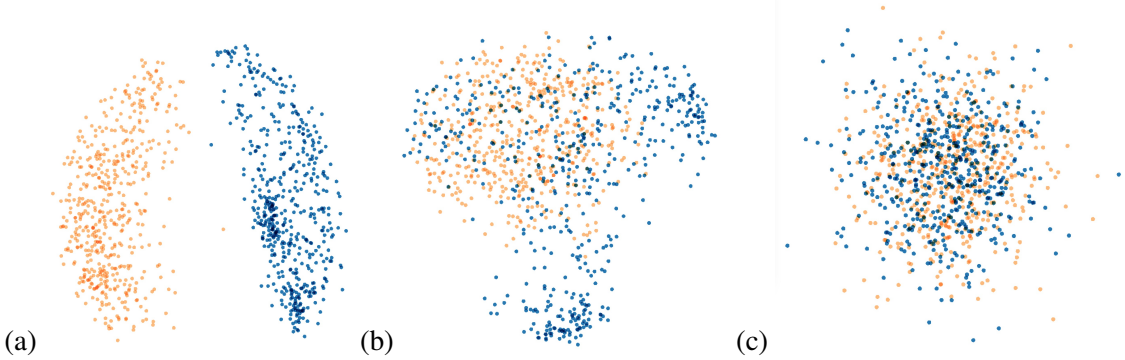

Figure 5: (Best viewed in colors.) Visualizations of the extracted hidden features by the implicit relation network *i-CNN* (blue) and connective-augmented relation network *a-CNN* (orange), in the multi-class classification setting (Lin et al., 2009). **(a)** Two networks are trained without adversary (with shared classifier); **(b)** Two networks are trained within our framework at epoch 10; **(c)** at epoch 20. The implicit relation network successfully imitates the connective-augmented features through the adversarial game. Visualization is conducted with the t-SNE algorithm (Maaten and Hinton, 2008).

cessfully driven *i-CNN* to induce similar representations with *a-CNN*, even though connectives are not present.

5 Discussions

We have developed an adversarial neural framework that facilitates an implicit relation network to extract highly discriminative features by mimicking a connective-augmented network. Our method achieved state-of-the-art performance for implicit discourse relation classification. Besides implicit connective examples, our model can naturally exploit enormous explicit connective data to further improve discourse parsing.

The proposed adversarial feature imitation scheme is also generally applicable to other context to incorporate indicative side information available at training time for enhanced inference. Our framework shares a similar spirit of the iterative knowledge distillation method (Hu et al., 2016a,b) which train a "student" network to mimic the classification behavior of a knowledge-informed "teacher" network. Our approach encourages imitation on the feature level instead of the final prediction level. This allows our approach to apply to regression tasks, and more interestingly, the context in which the student and teacher networks have different prediction outputs, e.g., performing different tasks, while transferring knowledge between each other can be beneficial. Besides, our adversarial mechanism provides an adaptive metric to measure and drive the imitation procedure.

Don't understand a measure? Learn it: Structured Prediction for Coreference Resolution optimizing its measures

Abstract

An assential aspect of structured prediction is the evaluation of an output structure against the gold standard. Especially in the loss-augmented setting, the need of finding the max-violating constraint has severely limited the expressivity of effective loss functions. In this paper, we trade off exact computation for enabling the use of more complex loss functions for coreference resolution (CR). Most noteworthily, we show that such functions can be (i) automatically learned also from controversial but commonly accepted CR measures, e.g., MELA, and (ii) successfully used in learning algorithms. The accurate model comparison on the standard CoNLL–2012 setting shows the benefit of more expressive loss for Arabic and English data.

1 Introduction

In recent years, interesting structured prediction methods have been developed for coreference resolution (CR), e.g., (Fernandes et al., 2014; Björkelund and Kuhn, 2014; Martschat and Strube, 2015). These models are supposed to output clusters but, to better control the exponential nature of the problem, the clusters are converted into tree structures. Although this simplifies the problem, optimal solutions are associated with an exponential set of trees, requiring to maximize over such a set. This originated latent models (Yu and Joachims, 2009) optimizing the so-called loss-augmented objective functions.

In this setting, loss functions need to be factorizable together with the feature representations for finding the max-violating constraints. The consequence is that only simple loss functions, basically just counting incorrect edges, were applied in previous work, giving up expressivity for simplicity. This is a critical limitation as domain experts consider more information than just counting edges.

In this paper, we study the use of more expressive loss functions in the structured prediction framework for CR, although some findings are clearly applicable to more general settings. We attempted to optimize the complicated official MELA measure[1] (Pradhan et al., 2012) of CR within the learning algorithm. Unfortunately, MELA is the average of measures, among which CEAF_e has an excessive computational complexity preventing its direct use. To solve this problem, we defined a model for learning MELA from data using a fast linear regressor, which can be then effectively used in structured prediction algorithms. We defined features to learn such a loss function, e.g., different link counts or aggregations such as Precision and Recall. Moreover, we designed methods for generating training data from which our regression loss algorithm (RL) can generalize well and accurately predict MELA values on unseen data.

Since RL is not factorizable[2] over a mention graph, we designed a latent structured perceptron (LSP) that can optimize non-factorizable loss functions on CR graphs. We tested LSP using RL and other traditional loss functions using the same setting of the CoNLL–2012 Shared Task, thus enabling an exact comparison with previous work. The results confirmed that RL can be effectively learned and used in LSP, although the improvement was smaller than expected, considering that our RL provides the algorithm with a more accurate feedback.

Thus, we analyzed the theory behind this pro-

cess by also contributing to the definition of the properties of loss optimality. These show that the available loss functions, e.g., by Fernandes et al.; Yu and Joachims, are enough for optimizing MELA on the training set, at least when the data is separable. Thus, in such conditions, we cannot expect a very large improvement from RL.

To confirm such a conjecture, we tested the models in a more difficult setting, in terms of separability. We used different feature sets of a smaller size and found out that in such conditions, RL requires less epochs for converging and produces better results than the other simpler loss functions. The accuracy of RL-based model, using 16 times less features, decreases by just 0.3 points, still improving the state of the art in structured prediction. Accordingly, in the Arabic setting, where the available features are less discriminative, our approach highly improves the standard LSP.

2 Related Work

There is a number of works attempting to directly optimize coreference metrics. The solution proposed by Zhao and Ng (2010) consists in finding an optimal weighting (by beam search) of training instances, which would maximize the target coreference metric. Their models, optimizing MUC and B^3, deliver a significant improvement on the MUC and ACE corpora. Uryupina et al. (2011) benefited from applying genetic algorithms for the selection of features and architecture configuration by multi-objective optimization of MUC and the two CEAF variants. Our approach is different in that the evaluation measure (its approximation) is injected directly into the learning algorithm. Clark and Manning (2016) optimize B^3 directly as well within a mention-ranking model. For the efficiency reasons, they omit optimization of CEAF, which we enable in this work.

$SVM^{cluster}$ – a structured output approach by Finley and Joachims (2005) – enables optimization to any clustering loss function (including non-decomposable ones). The authors experimentally show that optimizing particular loss functions results into a better classification accuracy in terms of the same functions. However, these are in general fast to compute, which is not the MELA case.

While Finley and Joachims are compelled to perform approximate inference to overcome the intractability of finding an optimal clustering, the latent variable structural approaches – SVM of Yu and Joachims (2009) and perceptron of Fernandes et al. (2014) – render exact inference possible by introducing auxiliary graph structures. The modeling of Fernandes et al. (also referred to as the *antecedent tree* approach) is exploited in the works of Björkelund and Kuhn (2014), Martschat and Strube (2015), and Lassalle and Denis (2015). Like us, the first couples such approach with approximate inference but for enabling the use of non-local features. The current state-of-the-art model of Wiseman et al. (2016) also employs a greedy inference procedure as it has global features from an RNN as a non-decomposable term in the inference objective.

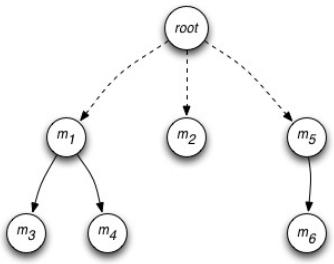

Figure 1: Latent tree used for structural learning

3 Structure Output Learning for CR

We consider online learning algorithms for linking structured input and output patterns. More formally, such algorithms find a linear mapping $f(\mathbf{x}, \mathbf{y}) = \langle \mathbf{w}, \Phi(\mathbf{x}, \mathbf{y}) \rangle$, where $f : X \times Y \rightarrow \mathbb{R}$, $\mathbf{w}$ is a linear model, $\Phi(\mathbf{x}, \mathbf{y})$ is a combined feature vector of input variables X and output variables Y. The predicted structure is derived with the $\operatorname{argmax}_{\mathbf{y} \in Y} f(\mathbf{x}, \mathbf{y})$. In the next sections, we show how to learn $\mathbf{w}$ for CR using structured perceptron. Additionally, we provide a characterization of effective loss functions for separable cases.

3.1 Modeling CR

In this framework, CR is essentially modeled as a clustering problem, where an input-output example is described by a tuple $(\mathbf{x}, \mathbf{y}, \mathbf{h})$, $\mathbf{x}$ is a set of entity mentions contained in a text document, $\mathbf{y}$ is set of the corresponding mention clusters, and $\mathbf{h}$ is a latent variable, i.e., an auxiliary structure that can represent the clusters of $\mathbf{y}$. For example, given the following text:

Although *(she)*$_{m_1}$ was supported by *(President Obama)*$_{m_2}$, *(Mrs. Clinton)*$_{m_3}$ missed *(her)*$_{m_4}$ *(chance)*$_{m_5}$, *(which)*$_{m_6}$ *looked* very good before counting votes.

the clusters of the entity mentions are represented by the latent tree in Figure 1, where its nodes are

2: $\mathbf{w} \leftarrow \mathbf{w}_0$; $t \leftarrow 0$
3: **repeat**
4: **for** $i = 1, ..., n$ **do**
5: $\mathbf{h}_i^* \leftarrow \underset{\mathbf{h} \in H(\mathbf{x}_i, \mathbf{y}_i)}{\text{argmax}} \langle \mathbf{w}_t, \Phi(\mathbf{x}_i, \mathbf{h}) \rangle$
6: $\hat{\mathbf{h}}_i \leftarrow \underset{\mathbf{h} \in H(\mathbf{x}_i)}{\text{argmax}} \langle \mathbf{w}_t, \Phi(\mathbf{x}_i, \mathbf{h}) \rangle + C \times \Delta(\mathbf{y}_i, \mathbf{h}_i^*, \mathbf{h})$
7: **if** $\Delta(\mathbf{y}_i, \mathbf{h}^*{}_i, \hat{\mathbf{h}}_i) > 0$ **then**
8: $\mathbf{w}_{t+1} \leftarrow \mathbf{w}_t + \Phi(\mathbf{x}_i, \mathbf{h}_i^*) - \Phi(\mathbf{x}_i, \hat{\mathbf{h}}_i)$
9: **end if**
10: **end for**
11: $t \leftarrow t + 1$
12: **until** $t < nT$
13: $\mathbf{w} \leftarrow \frac{1}{t} \sum_{i=1}^{t} \mathbf{w}_i$
return $\mathbf{w}$

mentions and the subtrees connected to the additional root node form distinct clusters. The tree $\mathbf{h}$ is called a latent variable as it is consistent with $\mathbf{y}$, i.e., it contains only links between mention nodes that corefer or fall into the same cluster according to $\mathbf{y}$. Clearly, an exponential set of trees, H, can be associated with one and the same clustering $\mathbf{y}$. Using only one tree to represent a clustering makes the search for optimal mention clusters tractable. In particular, structured prediction algorithms select $\mathbf{h}$ that maximizes the model learned at time t as shown in the next section.

3.2 Latent Structured Perceptron (LSP)

The LSP model proposed by Sun et al. (2009) and specialized for solving CR tasks by Fernandes et al. (2012) is described by Alg. 1.

Given a training set $\{(\mathbf{x}_i, \mathbf{y}_i)\}_{i=1}^{n}$, initial $\mathbf{w}_0$[3], a trade off parameter C, and the maximum number of epochs T, LSP iterates the following operations: Line 5 finds a latent tree $\mathbf{h}_i^*$ that maximizes $\langle \mathbf{w}_t, \Phi(\mathbf{x}_i, \mathbf{h}) \rangle$ for the current example $(\mathbf{x}_i, \mathbf{y}_i)$. It basically finds the max ground truth tree with respect to the current $\mathbf{w}_t$. Finding such max requires an exploration over the tree set $H(\mathbf{x}_i, \mathbf{y}_i)$, which only contains arcs between mentions that corefer according to the gold standard clustering $\mathbf{y}_i$. Line 6 seeks for the max-violating tree $\hat{\mathbf{h}}_i$ in $H(\mathbf{x}_i)$, which is the set of all candidate trees using any possible combination of arcs. Line 7 tests if the produced tree $\hat{\mathbf{h}}_i$ has some mistakes with respect to the gold clustering $\mathbf{y}_i$, using loss function $\Delta(\mathbf{y}_i, \mathbf{h}_i^*, \hat{\mathbf{h}}_i)$. Note that some models define a loss exploiting also the current best latent tree $\mathbf{h}_i^*$. If the test is verified, the model is updated with the vector $\Phi(\mathbf{x}_i, \mathbf{h}_i^*) - \Phi(\mathbf{x}_i, \hat{\mathbf{h}}_i)$.

[3]Either 0 or a random vector.

Fernandes et al. (2012) used exactly the directed trees we showed as latent structures and applied Edmonds' spanning tree algorithm (Edmonds, 1967) for finding the max. Their model achieved the best results in the CoNLL–2012 Shared Task, a challenge for CR systems (Pradhan et al., 2012). Their selected loss function also plays an important role as shown in the following.

3.3 Loss functions

When defining a loss, it is very important to preserve the factorization of the model components along the latent tree edges since this leads to efficient maximization algorithms (see Section 5).

Fernandes et al. uses a loss function that (i) compares a predicted tree $\hat{\mathbf{h}}$ against the gold tree $\mathbf{h}^*$ and (ii) factorizes over the edges in the way the model does. Its equation is:

$$\Delta_F(\mathbf{h}^*, \hat{\mathbf{h}}) = \sum_{i=1}^{M} \mathbb{1}_{\hat{\mathbf{h}}(i) \neq \mathbf{h}^*(i)} (1 + r \cdot \mathbb{1}_{\mathbf{h}^*(i)=0}), \quad (1)$$

where $\mathbf{h}^*(i)$ and $\hat{\mathbf{h}}(i)$ output the parent of the mention node i in the gold and predicted tree, respectively, whereas $\mathbb{1}_{\mathbf{h}^*(i) \neq \hat{\mathbf{h}}(i)}$ just checks if the parents are different, and if yes, penalty of 1 (or $1 + r$ if the gold parent is the root) is added.

Yu and Joachims's loss is based on undirected tree without a root and on the gold clustering $\mathbf{y}$. It is computed as:

$$\Delta_{YJ}(\mathbf{y}, \hat{\mathbf{h}}) = n(\mathbf{y}) - k(\mathbf{y}) + \sum_{\mathbf{e} \in \hat{\mathbf{h}}} l(\mathbf{y}, \mathbf{e}), \quad (2)$$

where $n(\mathbf{y})$ is the number of graph nodes, $k(\mathbf{y})$ is the number of clusters in $\mathbf{y}$, and $l(\mathbf{y}, \mathbf{e})$ assigns -1 to any edge $\mathbf{e}$ that connects nodes from the same cluster in $\mathbf{y}$, and r otherwise.

In our experiments, we adopt both loss functions, however, in contrast to Fernandes et al., we always measure Δ_F against the gold label $\mathbf{y}$ and not against the current $\mathbf{h}^*$, i.e., in the way it is done by Martschat and Strube (2015), who employ an equivalent LSP model in their work.

3.4 On optimality of simple loss functions

The above loss functions are rather simple and mainly based on counting the number of mistaken edges. Below, we show that such simple loss functions achieve training data separation (if it exists) of a general task measure reaching its max on their 0 mistakes. The latter is a desirable characteristic of many measures used in CR and NLP research.

Proposition 1 (Sufficient condition for optimality of loss functions for learning graphs)**.** *Let* $\Delta(\mathbf{y}, \mathbf{h}^*, \hat{\mathbf{h}}) \geq 0$ *be a simple, edge-factorizable loss function, which is also monotone in the number of edge errors, and let* $\mu(\mathbf{y}, \hat{\mathbf{h}})$ *be any graph-based measure maximized by no edge errors. Then, if the training set is linearly separable LSP optimizing* Δ *converges to the* μ *optimum.*

Proof. If the data is linearly separable the perceptron converges $\Rightarrow \Delta(\mathbf{y}_i, \mathbf{h^*}_i, \hat{\mathbf{h}}_i) = 0, \forall \mathbf{x}_i$. The loss is factorizable, i.e.,

$$\Delta(\mathbf{y}_i, \mathbf{h^*}_i, \hat{\mathbf{h}}_i) = \sum_{\mathbf{e} \in \hat{\mathbf{h}}_i} l(\mathbf{y}_i, \mathbf{h^*}_i, \mathbf{e}), \qquad (3)$$

where $l(\cdot)$ is an edge loss function. Thus, $\sum_{\mathbf{e} \in \hat{\mathbf{h}}_i} l(\mathbf{y}_i, \mathbf{h^*}_i, \mathbf{e}) = 0$. The latter equation and monotonicity imply $l(\mathbf{y}_i, \mathbf{h^*}_i, \mathbf{e}) = 0, \forall \mathbf{e} \in \hat{\mathbf{h}}_i$, i.e., there are no edge mistakes, otherwise by fixing such edges, we would have a smaller Δ, i.e., negative, contradicting the initial positiveness hypothesis. Thus, no edge mistake in any $\mathbf{x}_i$ implies that $\mu(\mathbf{y}, \hat{\mathbf{h}})$ is maximized on the training set. □

Corollary 1. $\Delta_F(\mathbf{h}^*, \hat{\mathbf{h}})$ and $\Delta_{YJ}(\mathbf{y}, \hat{\mathbf{h}})$ are both optimal loss functions for graphs.

Proof. Equations 1 and 2 show that both are 0 when applied to a clustering with no mistake on the edges. Additionally, for each edge mistake more, both loss functions increase, implying monotonicity. Thus, they satisfy all the assumptions of Proposition 1. □

The above characteristic suggests that Δ_F and Δ_{YJ} can optimize any measure that reasonably targets no mistakes as its best outcome. Clearly, this property does not guarantee loss functions to be suitable for a given task measure, e.g., the latter may have different max points and behave rather discontinuously. However, a common practice in NLP is to optimize the maximum of a measure, e.g., in case of Precision and Recall, or Accuracy, therefore, loss functions able to at least achieve such an optimum are preferable.

4 Automatically learning a loss function

How to measure a complex task such as CR has generated a long and controversial discussion in the research community. While such a debate is progressing, the most accepted and used measure is the so-called Mention, Entity, and Link Average (MELA) score. As it will be clear from the description below, MELA is not easily interpretable and not robust to the mention identification effect (Moosavi and Strube, 2016). Thus, loss functions showing the optimality property may not be enough to optimize it. Our proposal is to use a version of MELA transformed in a loss function optimized by an LSP algorithm with inexact inference. However, the computational complexity of the measure prevents to carry out an effective learning. Our solution is thus to learn MELA with a fast linear regressor, which also produces a continuos version of the measure.

4.1 Measures for CR

MELA is the unweighted average of MUC (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998) and $CEAF_e$ (CEAF variant with entity-based similarity) (Luo, 2005; Cai and Strube, 2010) scores, having heterogeneous nature.

MUC is based on the number of correctly predicted links between mentions. The number of links required for obtaining the key entity set K is $\sum_{k_i \in K}(|k_i| - 1)$, where k_i are key entities in K (cardinality of each entity minus one). MUC recall computes what fraction of these were predicted, and the predicted were as many as $\sum_{k_i \in K}(|k_i| - |p(k_i)|) = \sum_{k_i \in K}(|k_i| - 1 - (|p(k_i)| - 1))$, where $p(k_i)$ is a partition of the key entity k_i formed by intersecting it with the corresponding response entities $r_j \in R$, s.t., $k_i \cap r_j \neq \emptyset$. This number equals to the number of the key links minus the number of missing links, required to unite the parts of the partition $p(k_i)$ to obtain k_i.

B^3 computes Precision and Recall individually for each mention. For mention m: $Recall_m = \frac{|k_i^m \cap r_j^m|}{|k_i^m|}$, where k_i^m and r_j^m, subscripted with m, denote, correspondingly, the key and response entities into which m falls. The over-document Recall is then an average of these taken with respect to the number of the key mentions. The MUC and B^3 Precision is computed by interchanging the roles of the key and response entities.

$CEAF_e$ computes similarity between key and system entities after finding an optimal alignment between them. Using $\psi(k_i, r_j) = \frac{2|k_i \cap r_j|}{|k_i| + |r_j|}$ as the entity similarity measure, it finds an optimal one-to-one map $g^* : K \rightarrow R$, which maps every key entity to a response entity, maximazing an overall similarity $\Psi(g) = \sum_{k_i \in K} \psi(k_i, g(k_i))$ of the example. This is solved as a bipartite matching problem by the Kuhn-Munkres algorithm. Then Preci-

Algorithm 2 Finding a Max-violating Spanning Tree

1: Input: training example $(\mathbf{x}, \mathbf{y})$; graph $G(\mathbf{x})$ with vertices V denoting mentions; set of the incoming candidate edges, $E(\mathbf{v})$, $\mathbf{v} \in V$; weight vector $\mathbf{w}$
2: $\mathbf{h}^* \leftarrow \emptyset$
3: **for** $\mathbf{v} \in V$ **do**
4: $\quad \mathbf{e}^* = \underset{\mathbf{e} \in E(\mathbf{v})}{\operatorname{argmax}} \langle \mathbf{w}, \mathbf{e} \rangle + C \times l(\mathbf{y}, \mathbf{e})$
5: $\quad \mathbf{h}^* = \mathbf{h}^* \cup \mathbf{e}^*$
6: **end for**
7: **return** max-violating tree $\mathbf{h}^*$
8: (clustering $\mathbf{y}^*$ is induced by the tree $\mathbf{h}^*$)

sion and Recall are $\frac{\Psi(g^*)}{\sum_{r_j \in R} \psi(r_j, r_j)}$ and $\frac{\Psi(g^*)}{\sum_{k_i \in K} \psi(k_i, k_i)}$, respectively.

MELA computation is rather expensive mostly because of CEAF$_e$. Its complexity is bounded by $\mathcal{O}(Ml^2 \log l)$ (Luo, 2005), where M and l are, correspondingly, the maximum and minimum number of entities in $\mathbf{y}$ and $\hat{\mathbf{y}}$. Computing CEAF$_e$ is especially slow for the candidate outputs $\hat{\mathbf{y}}$ with a low quality of prediction, i.e, when l is big, and the coherence with the gold $\mathbf{y}$ is scarse.

Finally, B^3 and CEAF$_e$ are strongly influenced by the mention identification effect (Moosavi and Strube, 2016). Thus, Δ_F and Δ_{YJ} may output identical values for different clusterings that can have a big gap in terms of MELA.

4.2 Features for learning measures

As computational reasons prevent to use MELA in LSP (see our inexact search algorithm in Section 5), we study methods for approximating it with a linear regressor. For this purpose, we define nine features, which count either exact or simplified versions of Precision, Recall and F1 of each of the three metric-components of MELA. Clearly, neither Δ_F nor Δ_{YJ} provide the same values.

Apart from the computational complexity, the difficulty of evaluating the quality of the predicted clustering $\hat{\mathbf{y}}$ during training is also due to the fact that CR is carried out on automatically detected mentions, while it needs to be compared against a gold standard clustering of a gold mention set. However, we can use simple information about automatic mentions and how they relate to gold mentions and gold clusters. In particular, we use four numbers: (i) correctly detected automatic mentions, (ii) links they have in the gold standard, (iii) gold mentions, and (iv) gold links. The last one enables the precise computation of Precision, Recall and F1-measure values of MUC; the required partitions $p(k_i)$ of key entities are also available at training time as they contain only automatic mentions. These are the first three features that we design. Likewise for B^3, the feature values can be derived using (ii) and (iii).

For computing CEAF$_e$ heuristics, we do not perform cluster alignment to find an optimal $\Psi(g^*)$. Instead of $\Psi(g^*)$, which can be rewritten as $\sum_{m \in K \cap R} \frac{2}{|k_i^m| + |g^*(k_i^m)|}$ if summing up over the mentions not the entities, we simply use $\tilde{\Psi} = \sum_{m \in K \cap R} \frac{2}{|k_i^m| + |r_j^m|}$, pretending that for each m its key k_i^m and response r_j^m entities are aligned. $\sum_{r_j \in R} \psi(r_j, r_j)$ and $\sum_{k_i \in K} \psi(k_i, k_i)$ in the denominators of the Precision and Recall are the number of predicted and gold clusters, correspondingly. The imprecision of the CEAF$_e$ related features is expected to be leveraged when put together with the exact B^3 and MUC values into the regression learning using the exact MELA values (implicitly exact CEAF$_e$ values as well).

4.3 Generating training and test data

The features described above can be used to characterize the clustering variables $\hat{\mathbf{y}}$. For generating training data, we collected all the max-violating $\hat{\mathbf{y}}$ produced during LSP$_F$ (using Δ_F) learning and associate them with their correct MELA scores from the scorer. This way, we can have both training and test data for our regressor. In our experiments, for the generation purpose, we decided to run LSP$_F$ on each document separately to obtain more variability in $\hat{\mathbf{y}}$'s. We use a simple linear SVM to learn a model $\mathbf{w}_\rho$. Considering that MELA$(\mathbf{y}, \hat{\mathbf{y}})$ score lies in the interval $[100, 0]$, a simple approximation of the loss could be:

$$\Delta_\rho(\mathbf{y}, \hat{\mathbf{y}}) = 100 - \mathbf{w}_\rho \cdot \phi(\mathbf{y}, \hat{\mathbf{y}}). \quad (4)$$

Below, we show its improved version and an LSP for learning with it based on inexact search.

5 Learning with learned loss functions

Our experiments will demonstrate that Δ_ρ can be accurately learned from data. However, the features we used for this are not factorizable over the edges of the latent trees. Thus, we design a new LSP algorithm that can use our learned loss in an approximated max search.

5.1 A general inexact algorithm for CR

If the loss function can be factorized over tree edges (see Equation 3) the max-violating constraint in Line 6 of Alg. 1 can be efficiently found by exact decoding, e.g., using Edmonds' algorithm as in Fernandes et al. (2014) or Kruskal's as

Algorithm 3 Inexact Inference of a Max-violating Spanning Tree with a Global Loss

1: Input: training example $(\mathbf{x}, \mathbf{y})$; graph $G(\mathbf{x})$ with vertices V denoting mentions; set of the incoming candidate edges, $E(\mathbf{v})$, $\mathbf{v} \in V$; $\mathbf{w}$, ground truth tree $\mathbf{h}^*$
2: $\hat{\mathbf{h}} \leftarrow \emptyset$
3: $score \leftarrow 0$
4: **repeat**
5: $\quad prev\_score = score$
6: $\quad score = 0$
7: $\quad$ **for** $\mathbf{v} \in V$ **do**
8: $\quad\quad \mathbf{h} = \hat{\mathbf{h}} \setminus \mathbf{e}(\mathbf{v})$
9: $\quad\quad \hat{\mathbf{e}} = \underset{\mathbf{e} \in E(\mathbf{v})}{\text{argmax}} \langle \mathbf{w}, \mathbf{e} \rangle + C \times \Delta(\mathbf{y}, \mathbf{h}^*, \mathbf{h} \cup \mathbf{e})$
10: $\quad\quad \hat{\mathbf{h}} = \mathbf{h} \cup \hat{\mathbf{e}}$
11: $\quad\quad score = score + \langle \mathbf{w}, \hat{\mathbf{e}} \rangle$
12: $\quad$ **end for**
13: $\quad score = score + \Delta(\mathbf{y}, \mathbf{h}^*, \hat{\mathbf{h}})$
14: **until** $score = prev\_score$
15: **return** max-violating tree $\hat{\mathbf{h}}$

in Yu and Joachims (2009). The candidate graph, by construction, does not contain cycles, and the inference by Edmonds' algorithm does technically the same as the "best-left-link" inference algorithm by Chang et al. (2012). This can be schematically represented in Alg. 2.

When we deal with Δ_ρ, Alg. 2 cannot be longer applied as our new loss function is non-factorizable. Thus, we designed a greedy solution, Alg. 3, which still uses the spanning tree algorithm, though, it is not guaranteed to deliver the max-violating constraint. However, finding even a suboptimal solution optimizing a more accurate loss function may achieve better performance both in terms of speed and accuracy.

We reformulate Step 4 of Alg. 2, where a max-violating incoming edge $\hat{\mathbf{e}}$ is identified for a vertex $\mathbf{v}$. The new max-violating inference objective contains now a global loss measured on the partial structure $\hat{\mathbf{h}}$ built up to now plus a candidate edge $\mathbf{e}$ for a vertex $\mathbf{v}$ in consideration (Line 10 of Alg. 3). On a high level, this resembles the inference procedure of Wiseman et al. (2016), who use it for optimizing global features coming from an RNN. Differently though, after processing all the vertices, we repeat the procedure until the score of $\hat{\mathbf{h}}$ no longer improves.

Note that Björkelund and Kuhn (2014) perform inexact search on the same latent tree structures to extend the model to non-local features. In contrast to our approach, they use beam search and accumulate the early updates.

In addition to the design of an algorithm enabling the use of our Δ_ρ, there are other intricacies caused by the lack of factorization that need to be taken into account (see the next section).

Samples		# examples	MSE	SCC
Train	Test			
S_1	S_2	$6,011$	2.650	99.68
S_2	S_1	$5,496$	2.483	99.70

Table 1: Accuracy of the loss regressor on two different sets of examples generated from different documents samples.

5.2 Approaching factorization properties

The Δ_ρ defined by Equation 4 approximately falls into the interval $[0, 100]$. However, the simple optimal loss functions, Δ_F and Δ_{YJ}, output a value dependent on the size of the input training document in terms of edges (as they factorize in terms of edges). Since this property cannot be learned from MELA by our regression algorithm, we calibrate our loss with respect to the number of correctly predicted mentions, c, in that document, obtaining $\Delta'_\rho = \frac{c}{100}\Delta_\rho$.

Finally, another important issue is connected to the fact that on the way as we incrementally construct a max-violating tree according to Alg. 3, Δ_ρ decreases (and MELA grows), as we add more mentions to the output, traversing the tree nodes $\mathbf{v}$. Thus, to equalize the contribution of the loss among the candidate edges of different nodes, we also scale the loss of the candidate edges of the node $\mathbf{v}$ having order i in the document, according to the formula $\Delta''_\rho = \frac{i}{|V|}\Delta'_\rho$. This can be interpreted as giving more weight to the hard-to-classify instances – an important issue alleviated by Zhao and Ng (2010). Towards the end of the document, the probability of correctly predicting an incoming edge for a node generally decreases, as increases the number of hypotheses.

6 Experiments

In our experiments, we first show that our regressor for learning MELA approximates it rather accurately. Then, we examine the impact of our Δ_ρ on state-of-the-art systems in comparison with other loss functions. Finally, we show that the impact of our model is amplified when learning in smaller feature spaces.

6.1 Setup

Data We conducted our experiments on English and Arabic parts of the corpus from CoNLL 2012-Shared Task[4]. The English data contains 2,802, 343, and 348 documents in the training,

[4] conll.cemantix.org/2012/data.html

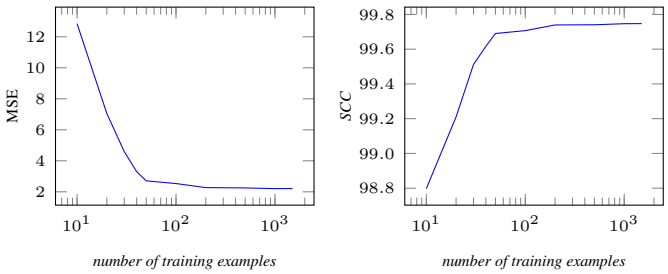

Figure 2: Regressor Learning curves.

dev. and test parts, respectively. The Arabic data includes 359, 44, and 44 documents for training, dev. and test sets, respectively.

Models We implement our version of LSP, where LSP_F, LSP_{YJ}, and LSP_ρ use the loss functions, Δ_F, Δ_{YJ}, and Δ_ρ, defined in Section 3.3 and 5.2, respectively. We used cort[5] – coreference toolkit by Martschat and Strube (2015) both to preprocess the English data and to extract candidate mentions and features (the basic set). For Arabic, we used mentions and features from BART[6] (Uryupina et al., 2012). We extended the initial feature set for Arabic with the feature combinations proposed by Durrett and Klein (2013), those permitted by the available initial features.

Parametrization All the perceptron models require tuning of a regularization parameter C. LSP_F and LSP_{YJ} – also tuning of a specific loss parameter r. We select the parameters on the entire dev. set by training on 100 random documents from the training set. We pick up $C \in \{1.0, 100.0, 1000.0, 2000.0\}$, the r values for LSP_F from the interval $[0.5, 2.5]$ with step 0.5, and the r values for LSP_{YJ} – from $\{0.05, 0.1, 0.5\}$. Ultimately, for English, we used $C = 1000.0$ in all the models; $r = 1.0$ in LSP_F and $r = 0.1$ in LSP_{YJ}. And wider ranges of parameter values were considered for Arabic, due to the lower mention detection rate: $C = 1000.0$, $r = 6.0$ for LSP_F, $C = 1000.0$, $r = 0.01$ for LSP_{YJ}, and $C = 5000.0$ – for LSP_ρ. A standard previous work setting for the number of epochs T of LSP is 5 (Martschat and Strube, 2015). Fernandes et al. (2014) noted that $T = 50$ was sufficient for convergence. We selected the best T from 1 to 50 on the dev. set.

Evaluation measure We used MUC, B^3, CEAF_e and their average MELA for evaluation, computed by the version 8 of the official CoNLL scorer.

Table 2: Results of our and previous work models evaluated on the dev. and test sets following the exact CoNLL-2012 English setting, using all training documents with All and $1M$ features. T_{best} is evaluated on the dev. set.

6.2 Learning loss functions

For learning MELA, we generated training and test examples from LSP_F according to the procedure described in Section 4.3. In the first experiment, we trained the $\mathbf{w}_\rho$ model on a set of examples S_1, generated from a sample of 100 English documents and tested on a set of examples S_2, generated from another sample of the same size, and vice versa. The results in Table 1 show that with just $5,000/6,000$, the Mean Squared Error (MSE) is roughly between $\sim 2.4 - 2.7$: these are rather small numbers considering that the regression output values in the interval $[0, 100]$. Squared Correlation Coefficient (SCC) reaches a correlation of about 99.7%, demonstrating that our regression approach is effective in estimating MELA.

Additionally, Figure 2 shows the regression learning curves evaluated with MSE and SCC. The former rapidly decreases and, with about $1,000$ examples, reaches a plateau of around 2.3. The latter shows a similar behaviour, approaching a correlation of about 99.8% with real MELA.

6.3 State of the art and model comparison

We first experimented with the standard CoNLL setting to compare the LSP accuracy in terms of MELA using the three different loss functions, i.e., LSP_F, LSP_{YJ} and LSP_ρ. In particular, we used all the documents of the training set and all $N \sim 16.8$M features from cort, and tested on the both dev. and test sets. The results are reported in Columns All of Table 2.

We note first that our Δ_ρ is effective as it stays on a par with Δ_F and Δ_{YJ} on the dev. set. This is interesting as Corollary 1 shows that such functions can optimize MELA, the reported values refer to the optimal epoch numbers. Also, LSP_ρ improves the other models on the test set by 0.3 percent points (statistical significant at the 93% level of confidence).

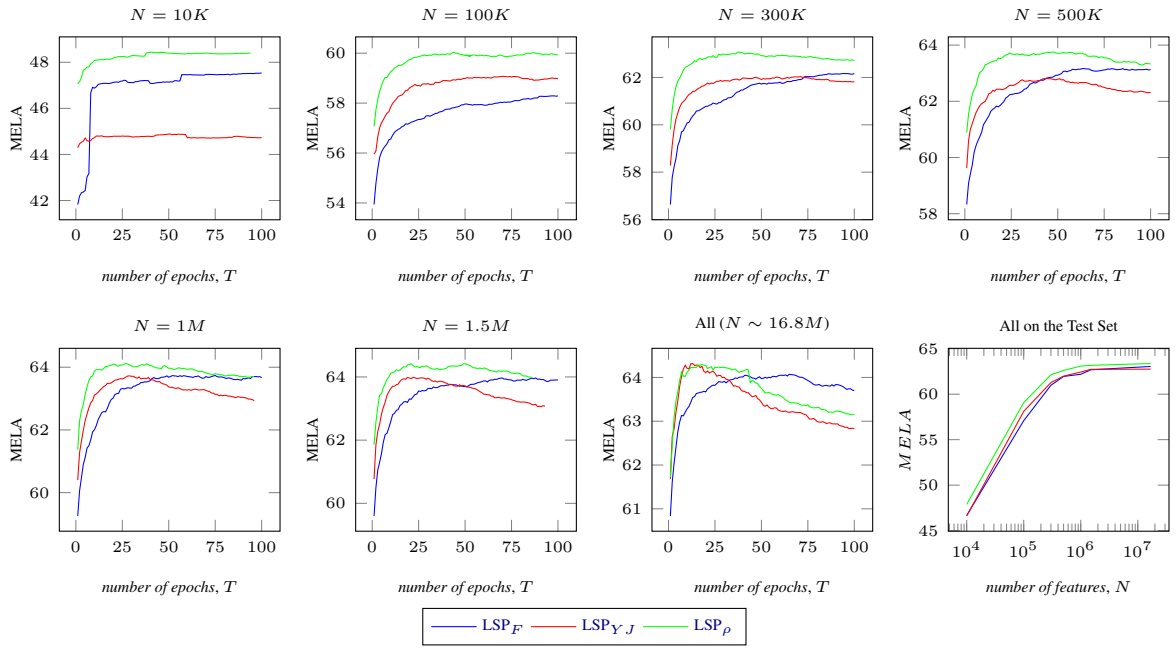

Figure 3: Results of LSP models on the dev. set using different number of features, N. The last plot reports MELA score on the test set of the models using the optimal number of epochs tuned on the dev. set.

#Feat.	Model	Test Set			
		MUC	B^3	$CEAF_e$	$MELA$
All	LSP$_F$	72.66	59.94	56.54	63.05
	LSP$_{YJ}$	72.18	59.31	55.82	62.76
	LSP$_\rho$	72.34	60.36	57.40	63.37
1M	LSP$_F$	71.95	59.03	55.59	62.19
	LSP$_{YJ}$	72.35	59.54	56.38	62.44
	LSP$_\rho$	72.09	60.11	57.07	63.09

Table 3: Results on the test set using the same setting of Table 2 and the measures composing MELA.

Secondly, all the three models improve the state of the art on CR using LSP, i.e., by Martschat and Strube (2015) using antecedent trees (M&S AT) or mention ranking (M&S MR), Björkelund and Kuhn (2014) using a global feature model (B&K) and Fernandes et al. (2014) (Fer). Noted that all the LSP models were trained on the training set only, without retraining on the training and dev. sets together, thus our scores can be improved.

Thirdly, Table 3 shows the breakdown of the MELA results in terms of its components on the test set. Interestingly, LSP$_\rho$ is noticeably better in terms of B^3 and CEAF$_e$, while LSP with simple losses, as expected, deliver higher MUC score.

Finally, the overall improvement of Δ_ρ is not impressive. This mainly depends on the optimality of the competing loss functions, which in a setting of $\sim$ 16.8M features, satisfy the separability condition of Proposition 1.

6.4 Learning in more challenging conditions

In these experiments, we verify the hypothesis that when the optimality property is partially or totally missing Δ_ρ is more visibly superior to Δ_F and Δ_{YJ}. As we do not want to degrade their effectiveness, the only condition dependent on the setting is the data inseparability or at least harder to be separated. These conditions can be obtained by reducing the size of the feature space. However, since we aim at testing conditions, where Δ_ρ is practically useful, we filter out less important features, preserving the model accuracy (at least when the selection is not extremely harsh). For this purpose, we use a feature selection approach using a basic binary classifier trained to discriminate between correct and incorrect mention pairs. It is typically used in non structured CR methods and has a nice property of using the same features of LSP (we do not use global features in our study). We carried out a selection using the absolute values of the model weights of the classifier for ranking features and then selecting those having higher rank (Haponchyk and Moschitti, 2017).

The MELA produced by our models using all the training data is presented in Figure 3. The first 7 plots show learning curves in terms of LSP epochs for different feature sets with increasing size N, evaluated on the dev. set. We note that: firstly, the fewer features are available, the better LSP$_\rho$ curves are than those of LSP$_F$ and LSP$_{YJ}$ in terms of accuracy and convergence speed. The intuition is that finding a separation of the training set (generalizing well) becomes more challenging (e.g., with 10k features, the data is not linearly sep-

arable) thus a loss function which is closer to the real measure provides some advantages.

Secondly, when using all features, LSP$_\rho$ is still overall better than the other models but clearly the latter can achieve the same MELA on the dev. set.

Thirdly, the last plot shows the MELA produced by LSP models on the test set, when trained with the best epoch derived from the dev. set (previous plots). We observe that LSP$_\rho$ is constantly better than the other models, though decreasing its effect as the feature number increases.

Next, in Column 1 (Selected) of Table 2, we report the model MELA using 1 million features. We note that LSP$_\rho$ improves the other models by at least 0.6 percent points, achieving the same accuracy as the best of its competitors, i.e., LSP$_F$, using all the features.

Finally, Δ_ρ does not satisfy Proposition 1, therefore, generally, we do not know if it can optimize any μ-type measure over graphs. However, being learned to optimize MELA, it clearly separates data maximizing such a measure. We empirically verified this by checking the MELA score obtained on the training set: we found that LSP$_\rho$ always optimizes MELA, iterating for fewer epochs than the other loss functions.

6.5 Generalization to other languages

Here, we test the effectiveness of the proposed method on Arabic using all available data and features. The results in Table 4 reveal an indisputable superiority of LSP$_\rho$ over the counterparts optimizing simple loss functions. They support the results of the previous section as we had to deal with the insufficiency of the expert-based features for Arabic. In such an uneasy case, LSP$_\rho$ was able to improve over LSP$_F$ by more than 4.7 points.

We also tested the loss model $\mathbf{w}_\rho$ trained for the experiments on the English data (resp. setting All of Section 6.3) in LSP$_\rho$ on Arabic. This corresponds to LSP$_\rho^{EN}$ model. Notably, it performs even better, 1.5 points more, than LSP$_\rho$ using a loss learned from Arabic examples. This suggests a nice property of data invariance of Δ_ρ. The improvement delivered by the "English" $\mathbf{w}_\rho$ is due to the fact that it was trained on the data which is richer: (i) quantitatively, since coming from almost 8 times more training documents in comparison to Arabic and (ii) qualitatively, in a sense of diversity with respect to the RL target value. Indeed, the Arabic data is much less separable than the English data and this prevents to have examples where MELA values are higher.

7 Conclusions

In this paper, we studied the use of complex loss functions in structured prediction for CR. Given the scale of our investigation, we limited our study to LSP, which is anyway considered state of the art. We derived several findings: (i) for the first time, up to our knowledge, we showed that a complex measure, such as MELA, can be learned by a linear regressor (RL) with high accuracy and effective generalization. (ii) The latter was essential for designing a new LSP based on inexact search and RL. (iii) We showed that an automatically learned loss can be optimized and provides state-of-the-art performance in a real setting, including thousands of documents and millions of features, such as CoNLL–2012 Shared Task. (iv) We defined a property of optimal loss functions for CR, which shows that in separable cases, such losses are enough to get the state of the art. However, as soon as separability becomes more complex simple loss functions lose optimality and RL becomes more accurate and faster. (v) Our MELA approximation provides a loss that is data invariant which, once learned, can be optimized in LSP on different datasets and in different languages.

Our study opens several future directions, ranging from defining algorithms based on automatically learned loss functions to learning more effective measures from expert examples.

Acknowledgements

We would like to thank Olga Uryupina for providing us with the preprocessed data from BART for Arabic. This work has been supported by the EC project CogNet, 671625 (H2020-ICT-2014-2, Research and Innovation action). Many thanks to the anonymous reviewers for their valuable suggestions.

Bayesian Modeling of Lexical Resources for Low-Resource Settings

Abstract

Lexical resources such as dictionaries and gazetteers are often used as auxiliary data for tasks such as part-of-speech induction and named-entity recognition. However, discriminative training with lexical features requires annotated data to reliably estimate the lexical feature weights and may result in overfitting the lexical features at the expense of features which generalize better. In this paper, we investigate a more robust approach: we stipulate that the lexicon is the result of an assumed generative process. Practically, this means that we may treat the lexical resources as *observations* under the proposed generative model. The lexical resources provide training data for the generative model without requiring separate data to estimate lexical feature weights. We evaluate the proposed approach in two settings: part-of-speech induction and low-resource named-entity recognition.

1 Introduction

Dictionaries and gazetteers are useful in many natural language processing tasks. These lexical resources may be derived from freely available sources (such as Wikidata and Wiktionary) or constructed for a particular domain. Lexical resources are typically used to complement existing annotations for a given task (Ando and Zhang, 2005; Collobert et al., 2011). In this paper, we focus instead on low-resource settings where task annotations are unavailable or scarce. Specifically, we use lexical resources to guide part-of-speech induction (§4) and to bootstrap named-entity recognizers in low-resource languages (§5).

Given their success, it is perhaps surprising that incorporating gazetteers or dictionaries into discriminative models (e.g. conditional random fields) may sometimes *hurt performance*. This phenomena is called *weight under-training*, in which lexical features—which detect whether a name is listed in the dictionary or gazetteer—are given excessive weight at the expense of other useful features such as spelling features that would generalize to unlisted names (Smith et al., 2005; Sutton et al., 2006; Smith and Osborne, 2006). Furthermore, discriminative training with lexical features requires sufficient annotated training data, which poses challenges for the unsupervised and low-resource settings we consider here.

Our observation is that Bayesian modeling provides a principled solution. The lexicon is itself a dataset that was generated by some process. Practically, this means that lexicon entries (words or phrases) may be treated as additional observations. As a result, these entries provide information about how names are spelled. The presence of the lexicon therefore now *improves* training of the spelling features, rather than *competing with* the spelling features to help explain the labeled corpus.

A downside is that generative models are typically less feature-rich than their globally normalized discriminative counterparts (e.g. conditional random fields). In designing our approach—the *hierarchical sequence memoizer (HSM)*—we aim to be reasonably expressive while retaining practically useful inference algorithms. We propose a Bayesian nonparametric model to serve as a generative distribution responsible for both lexicon and corpus data. The proposed model *memoizes* previously used lexical entries (words or phrases) but backs off to a character-level distribution when generating novel types (Teh, 2006; Mochihashi et al., 2009). We propose an efficient inference algorithm for the proposed model using particle Gibbs sampling (§3). Our code is available at https://github.com/noa/bayesner.

2 Model

Our goal is to fit a model that can automatically annotate text. We observe a supervised or unsupervised training corpus. For each label y in the annotation scheme, we also observe a lexicon of strings of type y. For example, in our tagging task (§4), a dictionary provides us with a list of words for each part-of-speech tag y. (These lists need not be disjoint.) For named-entity recognition (NER, §5), we use a list of words or phrases for each named-entity type y (PER, LOC, ORG, etc.).[1]

2.1 Modeling the lexicon

We may treat the lexicon for type y, of size m_y, as having been produced by a set of m_y IID draws from an unknown distribution P_y over the words or named entities of type y. It therefore provides some evidence about P_y. We will later assume that P_y is also used when generating mentions of these words or entities in text. Thanks to this sharing of P_y, if $x = \texttt{Washington}$ is listed in the gazetteer of locations ($y = \text{LOC}$), we can draw the same conclusions as if we had seen a LOC-labeled instance of `Washington` in a supervised corpus.

Generalizing this a bit, we may suppose that one observation of string x in the lexicon is equivalent to c labeled tokens of x in a corpus, where the constant $c > 0$ is known as a *pseudocount*. In other words, observing a lexicon of m_y distinct types $\{x_1, \ldots, x_{m_y}\}$ is equivalent to observing a labeled *pseudocorpus* of cm_y tokens. Notice that given such an observation, the prior probability of any candidate distribution P_y is reweighted by the likelihood $\frac{(cm_y)!}{(c!)^{m_y}} \cdot (P_y(x_1)P_y(x_2)\cdots P_y(x_{m_y}))^c$. Therefore, this choice of P_y can have relatively high posterior probability only to the extent that it assigns high probability to all of the lexicon types.

2.2 Discussion

We employ the above model because it has reasonable qualitative behavior and because computationally, it allows us to condition on observed lexicons as easily as we condition on observed corpora. However, we caution that as a generative model of the lexicon, it is deficient, in the sense that it allocates probability mass to events that cannot actually correspond to any lexicon. After all, drawing cm_y IID tokens from P_y is highly unlikely to result in exactly c tokens of each of m_y different types, and yet a run of our system will always assume that precisely this happened to produce each observed lexicon! To avoid the deficiency, one could assume that the lexicon was generated by rejection sampling: that is, the gazetteer author repeatedly drew samples of size cm_y from P_y until one was obtained that had this property, and then returned the set of distinct types in that sample as the lexicon for y. But this is hardly a realistic description of how gazetteers are actually constructed. Rather, one imagines that the gazetteer author simply harvested a lexicon of frequent types from P_y or from a corpus of tokens generated from P_y. For example, a much better generative story is that the lexicon was constructed as the first m_y distinct types to appear $\geq c$ times in an unbounded sequence of IID draws from P_y. When $c = 1$, this is equivalent to modeling the lexicon as m_y draws *without replacement* from P_y.[2] Unfortunately, draws without replacement are no longer IID or exchangeable: order matters. It would therefore become difficult to condition inference and learning on an observed lexicon, because we would need to explicitly sum or sample over the possibilities for the latent *sequence* of tokens (or stick segments). We therefore adopt the simpler deficient model.

A version of our lexicon model (with $c = 1$) was previously used by Dreyer and Eisner (2011, Appendix C), who observed a list of verb paradigm types rather than word or entity-name types.

2.3 Prior distribution over P_y

We assume *a priori* that P_y was drawn from a Pitman-Yor process (PYP) (Pitman and Yor, 1997). Both the lexicon and the ordinary corpus are observations that provide information about P_y. The PYP is defined by three parameters: a concentration parameter α, a discount parameter d, and a base distribution H_y. In our case, H_y is a distribution over $\mathcal{X} = \Sigma^*$, the set of possible strings over a finite character alphabet Σ.

For example, H_{LOC} is used to choose new place names, so it describes what place names tend to

[1] Dictionaries and knowledge bases provide more information than we use in this paper. For instance, Wikidata also provides a wealth of attributes and other metadata for each entity s. In principle, this additional information could also be helpful in estimating $P_y(s)$; we leave this intriguing possibility for future work.

[2] If we assume that P_y was drawn from a Pitman-Yor process prior (as in §2.3) using the stick-breaking method (Pitman, 1996), it is also equivalent to modeling the lexicon as the set of labels of the *first* m_y stick segments (which tend to have high probability).

look like in the language. The draw $P_{\text{LOC}} \sim \text{PYP}(d, \alpha, H_{\text{LOC}})$ is an "adapted" version of H_{LOC}. It is P_{LOC} that determines how often each name is mentioned in text (and whether it is mentioned in the lexicon). Some names such as `Washington` that are merely plausible under H_{LOC} are far more frequent under P_{LOC}, presumably because they were chosen as the names of actual, significant places. These place names were randomly drawn from H_{LOC} as part of the procedure for drawing P_y.

The expected value of P_y is H (i.e., H is the mean of the PYP distribution), but if α and d are small, then a typical draw of P_y will be rather different from H, with much of the probability mass falling on a subset of the strings.

At training or test time, when deciding whether to label a corpus token of $x = \texttt{Washington}$ as a place or person, we will be interested in the relative values of $P_{\text{LOC}}(x)$ and $P_{\text{PER}}(x)$. In practice, we do not have to represent the unknown infinite object P_y, but can integrate over its possible values. When $P_y \sim \text{PYP}(d, \alpha, H_y)$, then a sequence of draws $X_1, X_2, \ldots \sim P_y$ is distributed according to a Chinese restaurant process, via

$$\begin{aligned} P_y(X_{i+1} = x \mid X_1, \ldots, X_i) &= \frac{\text{customers}(x) - d \cdot \text{tables}(x)}{\alpha + i} \\ &\quad + \frac{\alpha + d \cdot \sum_{x'} \text{tables}(x')}{\alpha + i} H_y(x) \end{aligned} \tag{1}$$

where $\text{customers}(x) \leq i$ is the number of times that x appeared among $X_1, \ldots, X_i$, and $\text{tables}(x) \leq \text{customers}(x)$ is the number of those times that x was drawn from H_y (where each $P_y(X_i \mid \cdots)$ defined by (1) is interpreted as a mixture distribution that *sometimes* uses H_y).

2.4 Form of the base distribution H_y

By fitting H_y on corpus and lexicon data, we learn what place names or noun strings tend to look like in the language. By simultaneously fitting P_y, we learn which ones are commonly mentioned. Recall that under our model, tokens are drawn from P_y but the underlying types are drawn from H_y, e.g., H_y is responsible for (at least) the first token of each type.

A simple choice for H_y is a Markov process that emits characters in $\Sigma \cup \{\$\}$, where $\$$ is a distinguished stop symbol that indicates the end of the string. Thus, the probability of producing $\$$ controls the typical string length under H_y.

We use a more sophisticated model of strings—a sequence memoizer (SM), which is a (hierarchical) Bayesian treatment of variable-order Markov modeling (Wood et al., 2009). The SM allows dependence on an unbounded history, and the probability of a given sequence (string) can be found efficiently much as in equation (1).

Given a string $x = a_1 \cdots a_J \in \Sigma^*$, the SM assigns a probability to it via

$$\begin{aligned} H_y(\boldsymbol{a}_{1:J}) &= \Big(\prod_{j=1}^{J} H_y(a_j \mid \boldsymbol{a}_{1:j-1}) \Big) H_y(\$ \mid \boldsymbol{a}_{1:J}) \\ &= \Big(\prod_{j=1}^{J} H_{y,\boldsymbol{a}_{1:j-1}}(a_j) \Big) H_{y,\boldsymbol{a}_{1:J}}(\$) \end{aligned} \tag{2}$$

where $H_{y,\boldsymbol{u}}(a)$ denotes the conditional probability of character a given the left context $\boldsymbol{u} \in \Sigma^*$. Each $H_{y,\mathbf{u}}$ is a distribution over Σ, defined recursively as

$$\begin{aligned} H_{y,\epsilon} &\sim \text{PYP}(d_\epsilon, \alpha_\epsilon, \mathcal{U}_\Sigma) \\ H_{y,\boldsymbol{u}} &\sim \text{PYP}(d_{|\mathbf{u}|}, \alpha_{|\mathbf{u}|}, H_{y,\sigma(\mathbf{u})}) \end{aligned} \tag{3}$$

where ϵ is the empty sequence, $\mathcal{U}_\Sigma$ is the uniform distribution over $\Sigma \cup \{\$\}$, and $\sigma(\mathbf{u})$ drops the first symbol from $\mathbf{u}$. The discount and concentration parameters $(d_{|\mathbf{u}|}, \alpha_{|\mathbf{u}|})$ are associated with the lengths of the contexts $|\boldsymbol{u}|$, and should generally be larger for longer (more specific) contexts, implying stronger backoff from those contexts.[3]

Our inference procedure is largely indifferent to the form of H_y, so the SM is not the only option. It would be possible to inject more assumptions into H_y, for instance via structured priors for morphology or a grammar of name structure. Another possibility is to use a parametric model such as a neural language model (e.g., Jozefowicz et al. (2016)), although this would require an inner-loop of gradient optimization.

2.5 Modeling the sequence of tags y

We now turn to modeling the corpus. We assume that each sentence is generated via a sequence of latent labels $\boldsymbol{y} = \boldsymbol{y}_{1:T} \in \mathcal{Y}^*$.[4] The observations

[3] We fix these hyperparameters using the values suggested in (Wood et al., 2009; Gasthaus and Teh, 2010), which we find to be quite robust in practice. One could also resample their values (Blunsom and Cohn, 2010); we experimented with this but did not observe any consistent advantage to doing so in our setting.

[4] The label sequence is terminated by a distinguished end-of-sequence label, again written as $\$$.

$\boldsymbol{x}_{1:T}$ are then generated conditioned on the label sequence via the corresponding P_y distribution (defined in §2.3). All observations with the *same* label y are drawn from the same P_y, and thus this *subsequence* of observations is distributed according to the Chinese restaurant process (1).

We model $\boldsymbol{y}$ using another sequence memoizer model. This is similar to other hierarchical Bayesian models of latent sequences (Goldwater and Griffiths, 2007; Blunsom and Cohn, 2010), but again, it does not limit the Markov order (the number of preceding labels that are conditioned on). Thus, the probability of a sequence of latent types is computed in the same way as the base distribution in §2.4, that is,

$$p(\boldsymbol{y}_{1:T}) := \Big(\prod_{t=1}^{T} G_{\boldsymbol{y}_{1:t-1}}(y_t)\Big) G_{\boldsymbol{y}_{1:T}}(\$) \quad (4)$$

where $G_{\boldsymbol{v}}(y)$ denotes the conditional probability of latent label $y \in \mathcal{Y}$ given the left context $\boldsymbol{v} \in \mathcal{Y}^*$. Each $G_{\mathbf{v}}$ is a distribution over $\mathcal{Y}$, defined recursively as

$$G_{\epsilon} \sim \mathrm{PYP}(d_{\epsilon}, \alpha_{\epsilon}, \mathcal{U}_{\mathcal{Y}}) \quad (5)$$
$$G_{\boldsymbol{v}} \sim \mathrm{PYP}(d_{|\mathbf{v}|}, \alpha_{|\mathbf{v}|}, G_{\sigma(\mathbf{v})})$$

The probability of transitioning to label y_t depends on the assignments of all previous labels $y_1 \cdots y_{t-1}$.

For part-of-speech induction, each label y_t is the part-of-speech associated with the corresponding word x_t. For named-entity recognition, we say that each word token is labeled with a named entity type (LOC, PER, ...),[5] or with *itself* if it is not a named entity but rather a "context word." For example, the word token x_t = `Washington` could have been emitted from the label y_t = LOC, or from y_t = PER, or from y_t = `Washington` itself (in which case $p(x_t \mid y_t) = 1$). This uses a much larger set of labels $\mathcal{Y}$ than in the traditional setup where all context words are emitted from the same latent label type `O`. Of course, most labels are impossible at most positions (e.g., y_t cannot be `Washington` *unless* x_t = `Washington`). This scheme makes our generative model sensitive to specific contexts (which is accomplished in discriminative NER systems by contextual features). For example, the SM for $\boldsymbol{y}$ can learn that `spoke to` PER `yesterday` is a common 4-gram in the label sequence $\boldsymbol{y}$, and thus we are more likely to label `Washington` as a person if $\boldsymbol{x}$ = `...spoke to Washington yesterday...`.

We need one change to make this work, since now $\mathcal{Y}$ must include not only the standard NER labels $\mathcal{Y}' = \{\text{PER}, \text{LOC}, \text{ORG}, \text{GPE}\}$ but also words like `Washington`. Indeed, now $\mathcal{Y} = \mathcal{Y}' \cup \Sigma^*$. But no uniform distribution exists over the infinite set Σ^*, so how should we replace the base distribution $\mathcal{U}_{\mathcal{Y}}$ over labels in equation (5)? Answer: To draw from the new base distribution, sample $y \sim \mathcal{U}_{\mathcal{Y}' \cup \{\text{CONTEXT}\}}$. If y = CONTEXT, however, then "expand" it by resampling $y \sim H_{\text{CONTEXT}}$. Here H_{CONTEXT} is the base distribution over spellings of context words, and is learned just like the other H_y distributions in §2.4.

3 Inference via particle Markov chain Monte Carlo

3.1 Sequential sampler

Taking $\boldsymbol{Y}$ to be a random variable, we are interested in the posterior distribution $p(\boldsymbol{Y} = \boldsymbol{y} \mid \boldsymbol{x})$ over label sequences $\boldsymbol{y}$ given the emitted word sequence $\boldsymbol{x}$. Our model does not admit an efficient dynamic programming algorithm, owing to the dependencies introduced among the $\boldsymbol{Y}_t$ when we marginalize over the unknown G and P distributions that govern transitions and emissions, respectively. In contrast to tagging with a hidden Markov model tagging, the distribution of each label Y_t depends on *all* previous labels $\boldsymbol{y}_{1:t-1}$, for two reasons: ① The transition distribution $p(Y_t = y \mid \boldsymbol{y}_{1:t-1})$ has unbounded dependence because of the PYP prior (4). ② The emission distribution $p(x_t \mid Y_t = y)$ depends on the emissions observed from any earlier tokens of y, because of the Chinese restaurant process (1). When ② is the only complication, block Metropolis-Hastings samplers have proven effective (Johnson et al., 2007). However, this approach uses dynamic programming to sample from a proposal distribution efficiently, which ① precludes in our case. Instead, we use sequential Monte Carlo (SMC)—sometimes called *particle filtering*—as a proposal distribution. Particle filtering is typically used in online settings, including word segmentation (Borschinger and Johnson, 2011), to make decisions before all of $\boldsymbol{x}$ has been observed. However, we are interested in the inference (or *smoothing*) problem that conditions on all of $\boldsymbol{x}$ (Dubbin and Blunsom, 2012; Tripuraneni et al., 2015).

SMC employs a *proposal distribution* $q(\boldsymbol{y} \mid \boldsymbol{x})$

[5] In §3.2, we will generalize this labeling scheme to allow multi-word named entities such as `New York`.

whose definition decomposes as follows:

$$q(y_1 \mid x_1) \prod_{t=2}^{T} q(y_t \mid \boldsymbol{y}_{1:t-1}, \boldsymbol{x}_{1:t}) \tag{6}$$

for $T = |\boldsymbol{x}|$. To sample a sequence of latent labels, first sample an initial label y_1 from q_1, then proceed incrementally by sampling y_t from $q_t(\cdot \mid \boldsymbol{y}_{1:t-1}, \boldsymbol{x}_{1:t})$ for $t = 2, \ldots, T$. The final sampled sequence $\boldsymbol{y}$ is called a *particle*, and is given an *unnormalized importance weight* of $\tilde{w} = \tilde{w}_T \cdot p(\$ \mid \boldsymbol{y}_{1:T})$ where $\tilde{w}_T$ was built up via

$$\tilde{w}_t := \tilde{w}_{t-1} \cdot \frac{p(\boldsymbol{y}_{1:t}, \boldsymbol{x}_{1:t})}{p(\boldsymbol{y}_{1:t-1}, \boldsymbol{x}_{1:t-1})\, q(y_t \mid \boldsymbol{y}_{1:t-1}, \boldsymbol{x}_{1:t})} \tag{7}$$

The SMC procedure consists of generating a system of M weighted particles whose unnormalized importance weights $\tilde{w}^{(m)} : 1 \leq m \leq M$ are normalized into $w^{(m)} := \tilde{w}^{(m)} / \sum_{m=1}^{M} \tilde{w}^{(m)}$. As $M \to \infty$, SMC provides a consistent estimate of the marginal likelihood $p(\boldsymbol{x})$ as $\frac{1}{M} \sum_{m=1}^{M} \tilde{w}^{(m)}$, and samples from the weighted particle system are distributed as samples from the desired posterior $p(\boldsymbol{y} \mid \boldsymbol{x})$ (Doucet and Johansen, 2009).

Particle Gibbs. We employ SMC as a kernel in an MCMC sampler (Andrieu et al., 2010). In particular, we use a block Gibbs sampler in which we iteratively resample the hidden labeling $\boldsymbol{y}$ of a sentence $\boldsymbol{x}$ conditioned on the current labelings for all other sentences in the corpus. In this context, the algorithm is called *conditional* SMC since one particle is always fixed to the previous sampler state for the sentence being resampled, which ensures that the MCMC procedure is ergodic. At a high level, this procedure is analogous to other Gibbs samplers (e.g. for topic models), except that the conditional SMC (CSMC) kernel uses auxiliary variables (particles) in order to generate the new block variable assignments. The procedure is outlined in Algorithm 1. Given a previous latent state assignment $\boldsymbol{y}'_{1:T}$ and observations $\boldsymbol{x}_{1:T}$, the CSMC kernel produces a new latent state assignment via M auxiliary particles where one particle is fixed to the previous assignment. For ergodicity, $M \geq 2$, where larger values of M may improve mixing rate at the expense of increased computation per step.

Proposal distribution. The choice of proposal distribution q is crucial to the performance of SMC methods. In the case of continuous latent variables, it is common to propose y_t from the transition probability $p(Y_t \mid \boldsymbol{y}_{1:t-1})$ because this distribution usually has a simple form that permits efficient sampling. However, it is possible to do better in the case of discrete latent variables. The optimal proposal distribution is the one which minimizes the variance of the importance weights, and is given by

$$\begin{aligned} q(y_t \mid \boldsymbol{y}_{1:t-1}, \boldsymbol{x}_{1:t}) &:= p(y_t \mid \boldsymbol{y}_{1:t-1}, \boldsymbol{x}_{1:t}) \qquad (8) \\ &= \frac{p(y_t \mid \boldsymbol{y}_{1:t-1}) p(x_t \mid y_t)}{p(x_t \mid \boldsymbol{y}_{1:t-1})} \end{aligned}$$

where

$$p(x_t \mid \boldsymbol{y}_{1:t-1}) = \sum_{y_t \in \mathcal{Y}} p(y_t \mid \boldsymbol{y}_{1:t-1}) p(x_t \mid y_t) \tag{9}$$

Substituting this expression in equation (7) and simplifying yields the incremental weight update:

$$\tilde{w}_t := \tilde{w}_{t-1} \cdot p(x_t \mid \boldsymbol{y}_{1:t-1}) \tag{10}$$

Resampling. In filtering applications, it is common to use resampling operations to prevent weight degeneracy. We do not find resampling necessary here for three reasons. First, note that we resample hidden label sequences that are only as long as the number of words in a given sentence. Second, we use a proposal which minimizes the variance of the weights. Finally, we use SMC as a kernel embedded in an MCMC sampler; asymptotically, this procedure yields samples from the desired posterior regardless of degeneracy (which only affects the mixing rate). Practically speaking, one can diagnose the need for resampling via the effective sample size (ESS) of the particle system:

$$\text{ESS} := \frac{1}{\sum_{m=1}^{M} (\tilde{w}^{(m)})^2} = \frac{(\sum_{m=1}^{M} w^{(m)})^2}{\sum_{m=1}^{M} (w^{(m)})^2}$$

In our experiments, we find that ESS remains high (a significant fraction of M) even for long sentences, suggesting that resampling is not necessary to enable mixing of the the Gibbs sampler.

Decoding. In order to obtain a single latent variable assignment for evaluation purposes, we simply take the state of the Markov chain after a fixed number of iterations of particle Gibbs. In principle, one could collect many samples during particle Gibbs and use them to perform minimum Bayes risk decoding under a given loss function. However, this approach is somewhat slower and did not appear to improve performance in preliminary experiments

Algorithm 1 Conditional SMC

procedure CSMC($\boldsymbol{x}_{1:T}$, $\boldsymbol{y}'_{1:T}$, M)
  Draw $y_1^{(m)}$ (eqn. 8) for $m \in [1, M-1]$
  Set $y_1^{(M)} = y'_1$
  Set $\tilde{w}_1^{(m)}$ (eqn. 10) for $m \in [1, M]$
  for $t = 2$ to T **do**
    Draw $y_t^{(m)}$ (eqn. 8) for $m \in [1, M-1]$
    Set $y_t^M = y'_t$
    Set $\tilde{w}_t^{(m)}$ (eqn. 10) for $m \in [1, M]$
  Set $\tilde{w}^{(m)} = \tilde{w}_T^{(m)} p(\$ | \boldsymbol{y}_{1:T})$ for $m \in [1, M]$
  Draw index k where $p(k = m) \propto \tilde{w}^{(m)}$
  return $\boldsymbol{y}_{1:T}^{(k)}$

3.2 Segmental sampler

We now present an sampler for settings such as NER where each latent label emits a *segment* consisting of 1 or more words. We make use of the same transition distribution $p(y_t \mid \boldsymbol{y}_{1:t-1})$, which determines the probability of a label in a given context, and an emission distribution $p(x_t \mid y_t)$ (namely P_{y_t}); these are assumed to be drawn from hierarchical Pitman-Yor processes described in §2.5 and §2.1, respectively. To allow the x_t to be a multi-word string, we simply augment the character set with a distinguished space symbol $\_ \in \Sigma$ that separates words within a string. For instance, `New` `York` would be generated as the 9-symbol sequence `New_York$`.

Although the *model* emits `New_York` all at once, we still formulate our *inference procedure* as a particle filter that proposes one tag for each word. Thus, for a given segment label type y, we allow two tag types for its words:

- I-y corresponds to a non-final word in a segment of type y (in effect, a word with a following _ attached).
- E-y corresponds to the final word in a segment of type y.

For instance, $\boldsymbol{x}_{1:2} =$ `New York` would be annotated as a location segment by defining $\boldsymbol{y}_{1:2} =$ I-LOC E-LOC. This says that $\boldsymbol{y}_{1:2}$ has *jointly* emitted $\boldsymbol{x}_{1:2}$, an event with prior probability $P_{\text{LOC}}(\texttt{New\_York})$. Each word that is not part of a named entity is considered to be a single-word segment. For example, if the next word were $x_3 =$ `hosted` then it should be tagged with $y_3 =$ `hosted` as in §2.5, in which case x_3 was emitted with probability 1.

To adapt the sampler described in §3.1 for the segmental case, we need only to define the transition and emission probabilities used in equation (8) and its denominator (9).

For the transition probabilities, we want to model the sequence of segment labels. If y_{t-1} is an I- tag, we take $p(y_t \mid \boldsymbol{y}_{1:t-1}) = 1$, since then y_t merely continues an existing segment. Otherwise y_t starts a new segment, and we take $p(y_t \mid \boldsymbol{y}_{1:t-1}) = 1$ to be defined by the PYP's probability $G_{\boldsymbol{y}_{1:t-1}}(y_t)$ as usual, but where we interpret the subscript $\boldsymbol{y}_{1:t-1}$ to refer to the possibly shorter sequence of segment labels implied by those $t-1$ tags.

For the emission probabilities, if y_t has the form I-y or E-y, then its associated emission probability no longer has the form $p(x_t \mid y_t)$, since the choice of x_t also depends on any words emitted earlier in the segment. Let $s \leq t$ be the starting position of the segment that contains t. If $y_t =$ E-y, then the emission probability is proportional to $P_y(x_s \_ x_{s+1} \_ \ldots \_ x_t)$. If $y_t =$ I-y then the emission probability is proportional to the *prefix probability* $\sum_x P_y(x)$ where x ranges over all strings in Σ^* that have $x_s \_ x_{s+1} \_ \ldots \_ x_t \_$ as a proper prefix. Prefix probabilities in H_y are easy to compute because H_y has the form of a language model, and prefix probabilities in P_y are therefore also easy to compute (using a prefix tree for efficiency).

This concludes the description of the segmental sampler. Note that the particle Gibbs procedure is unchanged.

4 Inducing parts-of-speech with type-level supervision

Automatically inducing parts-of-speech from raw text is a challenging problem (Goldwater et al., 2005). Our focus here is on the easier problem of type-supervised part-of-speech induction, in which (partial) dictionaries are used to guide inference (Garrette and Baldridge, 2012; Li et al., 2012). Conditioned on the unlabeled corpus and dictionary, we use the MCMC procedure described in §3.1 to impute the latent parts-of-speech.

Since dictionaries are freely available for hundreds of languages,[6] we see this as a mild additional requirement in practice over the purely unsupervised setting.

In prior work, dictionaries have been used as constraints on possible parts-of-speech: words appearing in the dictionary take one of their known parts-

[6] https://www.wiktionary.org/

of-speech. In our setting, however, the dictionaries are not constraints but evidence. If `monthly` is listed in (only) the adjective lexicon, this tells us that P_{ADJ} sometimes generates `monthly` and therefore that H_{ADJ} may also tend to generate other words that end with `-ly`. However, for us, $P_{\text{ADV}}(\texttt{monthly}) > 0$ as well, allowing us to still correctly treat `monthly` as a possible adverb if we later encounter it in a training or test corpus.

4.1 Experiments

We follow the experimental procedure described in Li et al. (2012), and use their released code and data to compare to their best model: a second-order maximum entropy Markov model parametrized with log-linear features (SHMM-ME). This model uses hand-crafted features designed to distinguish between different parts-of-speech, and it has special handling for rare words. This approach is surprisingly effective and outperforms alternate approaches such as cross-lingual transfer (Das and Petrov, 2011). However, it also has limitations, since words that do not appear in the dictionary will be unconstrained, and spurious or incorrect lexical entries may lead to propagation of errors.

The lexicons are taken from the Wiktionary project; their size and coverage are documented by (Li et al., 2012). We evaluate our model on multi-lingual data released as part of the CoNLL 2007 and CoNLL-X shared tasks. In particular, we use the same set of languages as Li et al. (2012).[7] For our method, we impute the parts-of-speech by running particle Gibbs for 100 epochs, where one epoch consists of resampling the states for a each sentence in the corpus. The final sampler state is then taken as a 1-best tagging of the unlabeled data.

Results. The results are reported in Table 1. We find that our hierarchical sequence memoizer (HSM) matches or exceeds the performance of the baseline (SHMM-ME) for nearly all the tested languages, particularly for morphologically rich languages such as German where the spelling distributions H_y may capture regularities. It is interesting to note that our model performs worse relative to the baseline for English; one possible explanation is that the baseline uses hand-engineered features whereas ours does not, and these features may have been tuned using English data for validation.

[7] With the exception of Dutch. Unlike the other CoNLL languages, Dutch includes phrases, and the procedure by which these were split into tokens was not fully documented.

Our generative model is supposed to exploit lexicons well. To see what is lost from using a generative model, we also compared with Li et al. (2012) on standard supervised tagging without any lexicons. Even here our generative model is very competive, losing only on English and Swedish.

5 Boostrapping NER with type-level supervision

Name lists and dictionaries are useful for NER particularly when in-domain annotations are scarce. However, with little annotated data, discriminative training may be unable to reliably estimate lexical feature weights and may overfit. In this section, we are interested in evaluating our proposed Bayesian model in the context of low-resource NER.

5.1 Data

Most languages do not have corpora annotated for parts-of-speech, named-entities, syntactic parses, or other linguistic annotations. Therefore, rapidly deploying natural language technologies in a new language may be challenging. In the context of facilitating relief responses in emergencies such as natural disasters, the DARPA LORELEI (Low Resource Languages for Emergent Incidents) program has sponsored the development and release of representative "language packs" for Turkish and Uzbek with more languages planned (Strassel and Tracey, 2016). We use the named-entity annotations as part of these language packs which include persons, locations, organizations, and geo-political entities, in order to explore bootstrapping named-entity recognition from small amounts of data. We consider two types of data: ① in-context annotations, where sentences are fully annotated for named-entities, and ② lexical resources.

The LORELEI language packs lack adequate in-domain lexical resources for our purposes. Therefore, we simulate in-domain lexical resources by holding out portions of the annotated development data and deriving dictionaries and name lists from them. For each label $y \in \{\text{PER}, \text{LOC}, \text{ORG}, \text{GPE}, \text{CONTEXT}\}$, our lexicon for y lists all distinct y-labeled strings that appear in the held-out data. This setup ensures that the labels associated with lexicon entries correspond to the annotation guidelines used in the data we use for evaluation. It avoids possible problems that might arise when leveraging noisy out-of-domain knowledge bases, which we may explore in future.

	Model	Danish	German	Greek	English	Italian	Portuguese	Spanish	Swedish	**Mean**
Wiktionary	SHMM-ME	83.3	85.8	79.2	87.1	86.5	84.5	86.4	86.1	84.9
	HSM	83.7	90.7	81.7	84.0	86.7	85.5	87.6	86.8	85.8
Supervised	SHMM-ME	93.9	97.4	95.1	95.8	93.8	95.5	93.8	95.5	95.1
	HSM	95.2	97.4	97.4	95.2	94.5	96.0	95.6	92.2	95.3

Table 1: Part-of-speech induction results in multiple languages.

5.2 Evaluation

In this section we report supervised NER experiments on two low-resource languages: Turkish and Uzbek. We vary both the amount of supervision as well as the size of the lexical resources. A challenge when evaluating the performance of a model with small amounts of training data is that there may be high-variance in the results. In order to have more confidence in our results, we perform bootstrap resampling experiments in which the training set, evaluation set, and lexical resources are randomized across several replications of the same experiment (for each of the data conditions). We use 10 replications for each of the data conditions reported in Figures 1–2, and report both the mean performance and 95% confidence intervals.

Baseline. We use the Stanford NER system with a standard set of language-independent features (Finkel et al., 2005).[8]. This model is a conditional random field (CRF) with feature templates which include character n-grams as well as word shape features. Crucially, we also incorporate lexical features. The CRF parameters are regularized using an L1 penalty and optimized via Orthant-wise limited-memory quasi-Newton optimization (Andrew and Gao, 2007). For both our proposed method and the discriminative baseline, we use a fixed set of hyperparameters (i.e. we do not use a separate validation set for tuning each data condition). In order to make a fair comparison to the CRF, we use our sampler for forward inference only, without resampling on the test data.

Results. We show learning curves as a function of supervised training corpus size. Figure 1 shows that our generative model strongly beats the baseline in this low-data regime. In particular, when there is little annotated training data, our proposed generative model can compensate by exploiting the lexicon, while the discriminative baseline scores terribly. The performance gap decreases with larger supervised corpora, which is consistent with prior results comparing generative and discriminative training (Ng and Jordan, 2002).

In Figure 2, we show the effect of the lexicon's size: as expected, larger lexicons are better. The generative approach significantly outperforms the discriminative baseline at any lexicon size, although its advantage drops for smaller lexicons or larger training corpora.

In Figure 1 we found that increasing the pseudocount c consistently *decreases* performance, so we used $c = 1$ in our other experiments.[9]

6 Conclusion

This paper has described a generative model for low-resource sequence labeling and segmentation tasks using lexical resources. Experiments in semi-supervised and low-resource settings have demonstrated its applicability to part-of-speech induction and low-resource named-entity recognition. There are many potential avenues for future work. Our model may be useful in the context of active learning where efficient re-estimation and performance in low-data conditions are important. It would also be interesting to explore more expressive parameterizations, such recurrent neural networks for H_y. In the space of neural methods, differentiable memory (Santoro et al., 2016) may be more flexible than the PYP prior, while retaining the ability of the model to cache strings observed in the gazetteer.

Acknowledgments

This work was supported by the JHU Human Language Technology Center of Excellence, DARPA LORELEI, and NSF grant IIS-1423276. Thanks to Jay Feldman for early discussions.

[8] We also experimented with neural models, but found that the CRF outperformed them in low-data conditions.

[9] Why? Even a pseudocount of $c = 1$ is enough to ensure that $P_y(s) \gg H_y(s)$, since the prior probability $H_y(s)$ is rather small for most strings in the lexicon. Indeed, perhaps $c < 1$ would have increased performance, particularly if the lexicon reflects out-of-domain data. This could be arranged, in effect, by using a hierarchical Bayesian model in which the lexicon and corpus emissions are not drawn from the identical distribution P_y but only from similar (coupled) distributions.

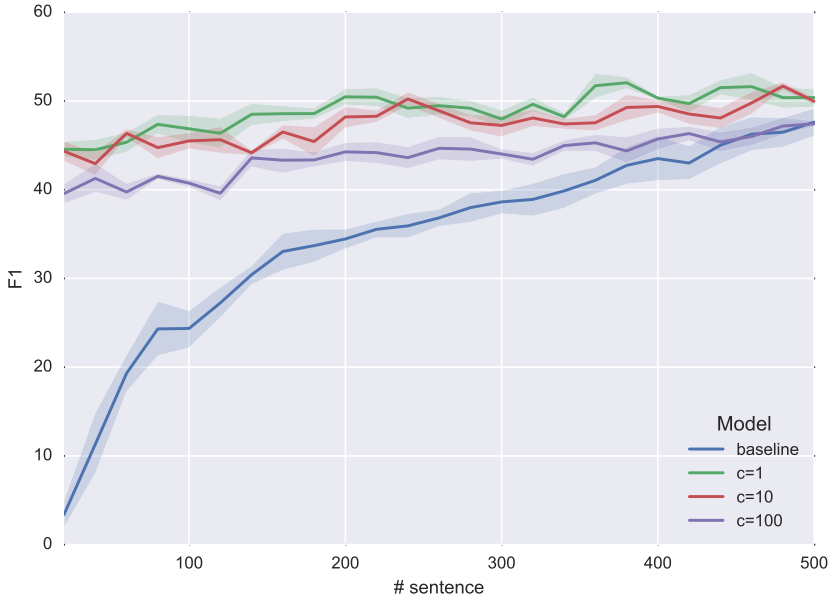

Figure 1: **Absolute** NER performance for Turkish (y-axis) as a function of corpus size (x-axis). The y-axis gives the F1 score on a held-out evaluation set (averaged over 10 bootstrap replicates, with error bars showing 95% confidence intervals). Our generative approach is compared to a baseline discriminative model with lexicon features (lowest curve). 500 held-out sentences were used to create the lexicon for both methods. Note that increasing the pseudocount c for lexicon entries (upper curves) tends to *decrease* performance for the generative model; we therefore take $c = 1$ in all other experiments. This graph shows Turkish; the corresponding Uzbek figure is available as supplementary material.

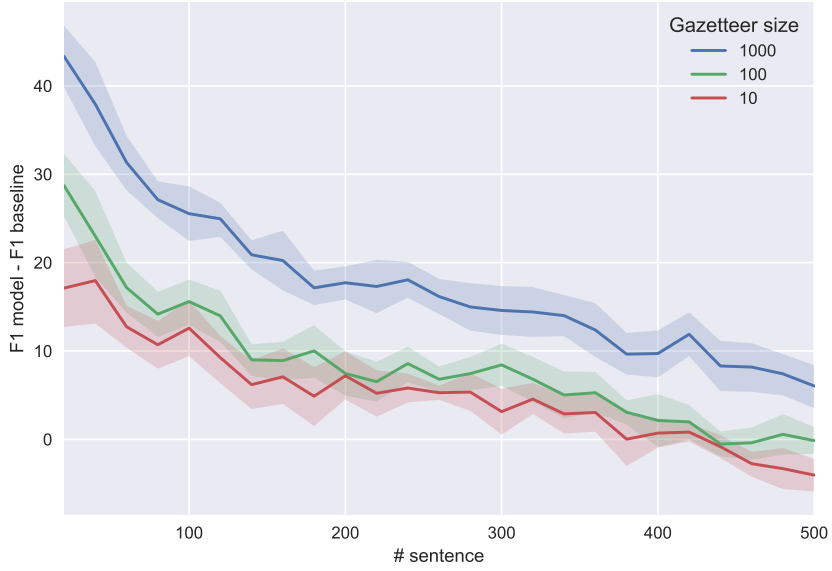

Figure 2: **Relative** NER performance for Turkish (y-axis) as a function of corpus size (x-axis). In this graph, $c = 1$ is constant and the curves instead compare different lexicon sizes derived from 10, 100, and 1000 held-out sentences. The y-axis now gives the *difference* $\text{F1}_{\text{model}} - \text{F1}_{\text{baseline}}$, so positive values indicate *improvement over the baseline* due to the proposed model. Gains are highest for large lexicons and for small corpora. Again, the corresponding Uzbek figure is available as supplementary material.

Abstract

We study the problem of semi-supervised question answering—-utilizing unlabeled text to boost the performance of question answering models. We propose a novel training framework, the *Generative Domain-Adaptive Nets*. In this framework, we train a generative model to generate questions based on the unlabeled text, and combine model-generated questions with human-generated questions for training question answering models. We develop novel domain adaptation algorithms, based on reinforcement learning, to alleviate the discrepancy between the model-generated data distribution and the human-generated data distribution. Experiments show that our proposed framework obtains substantial improvement from unlabeled text.

1 Introduction

Recently, various neural network models were proposed and successfully applied to the tasks of questions answering (QA) and/or reading comprehension (Xiong et al., 2016; Dhingra et al., 2016; Yang et al., 2017). While achieving state-of-the-art performance, these models rely on a large amount of labeled data. However, it is extremely difficult to collect large-scale question answering datasets. Historically, many of the question answering datasets have only thousands of question answering pairs, such as WebQuestions (Berant et al., 2013), MCTest (Richardson et al., 2013), WikiQA (Yang et al., 2015), and TREC-QA (Voorhees and Tice, 2000). Although larger question answering datasets with hundreds of thousands of question-answer pairs have been collected, including SQuAD (Rajpurkar et al., 2016), MSMARCO (Nguyen et al., 2016), and NewsQA (Trischler et al., 2016a), the data collection process is expensive and time-consuming in practice. This hinders real-world applications for domain-specific question answering.

Compared to obtaining labeled question answer pairs, it is trivial to obtain unlabeled text data. In this work, we study the following problem of semi-supervised question answering: is it possible to leverage unlabeled text to boost the performance of question answering models, especially when only a small amount of labeled data is available? The problem is challenging because conventional manifold-based semi-supervised learning algorithms (Zhu and Ghahramani, 2002; Yang et al., 2016a) cannot be straightforwardly applied. Moreover, since the main foci of most question answering tasks are extraction rather than generation, it is also not sensible to use unlabeled text to improve language modeling as in machine translation (Gulcehre et al., 2015).

To better leverage the unlabeled text, we propose a novel neural framework called *Generative Domain-Adaptive Nets* (GDANs). The starting point of our framework is to use linguistic tags to extract possible answer chunks in the unlabeled text, and then train a generative model to generate questions given the answer chunks and their contexts. The model-generated question-answer pairs and the human-generated question-answer pairs can then be combined to train a question answering model, referred to as a *discriminative model* in the following text. However, there is discrepancy between the model-generated data distribution and the human-generated data distribution, which leads to suboptimal discriminative models. To address this issue, we further propose two domain adaptation techniques that treat the model-generated data distribution as a different domain. First, we use an additional *domain tag* to

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1040–1050
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1096

indicate whether a question-answer pair is model-generated or human-generated. We condition the discriminative model on the domain tags so that the discriminative model can learn to factor out domain-specific and domain-invariant representations. Second, we employ a reinforcement learning algorithm to fine-tune the generative model to minimize the loss of the discriminative model in an adversarial way.

In addition, we present a simple and effective baseline method for semi-supervised question answering. Although the baseline method performs worse than our GDAN approach, it is extremely easy to implement and can still lead to substantial improvement when only limited labeled data is available.

We experiment on the SQuAD dataset (Rajpurkar et al., 2016) with various labeling rates and various amounts of unlabeled data. Experimental results show that our GDAN framework consistently improves over both the supervised learning setting and the baseline methods, including adversarial domain adaptation (Ganin and Lempitsky, 2014) and dual learning (Xia et al., 2016). More specifically, the GDAN model improves the F1 score by 9.87 points in F1 over the supervised learning setting when 8K labeled question-answer pairs are used.

Our contribution is four-fold. First, different from most of the previous neural network studies on question answering, we study a critical but challenging problem, semi-supervised question answering. Second, we propose the Generative Domain-Adaptive Nets that employ domain adaptation techniques on generative models with reinforcement learning algorithms. Third, we introduce a simple and effective baseline method. Fourth, we empirically show that our framework leads to substantial improvements.

2 Semi-Supervised Question Answering

Let us first introduce the problem of *semi-supervised question answering*.

Let $L = \{q^{(i)}, a^{(i)}, p^{(i)}\}_{i=1}^{N}$ denote a question answering dataset of N instances, where $q^{(i)}$, $a^{(i)}$, and $p^{(i)}$ are the question, answer, and paragraph of the i-th instance respectively. The goal of question answering is to produce the answer $a^{(i)}$ given the question $q^{(i)}$ along with the paragraph $p^{(i)}$. We will drop the superscript $\cdot^{(i)}$ when the context is unambiguous. In our formulation, following the setting in SQuAD (Rajpurkar et al., 2016), we specifically focus on extractive question answering, where a is always a consecutive chunk of text in p. More formally, let $p = (p_1, p_2, \cdots, p_T)$ be a sequence of word tokens with T being the length, then a can always be represented as $a = (p_j, p_{j+1}, \cdots, p_{k-1}, p_k)$, where j and k are the start and end token indices respectively. The questions can also be represented as a sequence of word tokens $q = (q_1, q_2, \cdots, q_{T'})$ with length T'.

In addition to the labeled dataset L, in the semi-supervised setting, we are also given a set of unlabeled data, denoted as $U = \{a^{(i)}, p^{(i)}\}_{i=1}^{M}$, where M is the number of unlabeled instances. Note that it is usually trivial to have access to an almost infinite number of paragraphs p from sources such as Wikipedia articles and other web pages. And since the answer a is always a consecutive chunk in p, we argue that it is also sensible to extract possible answer chunks from the unlabeled text using linguistic tags. We will discuss the technical details of answer chunk extraction in Section 4.1, and in the formulation of our framework, we assume that the answer chunks a are available.

Given both the labeled data L and the unlabeled data U, the goal of semi-supervised question answering is to learn a question answering model D that captures the probability distribution $\mathbb{P}(a|p, q)$. We refer to this question answering model D as the *discriminative model*, in contrast to the generative model that we will present in Section 3.2.

2.1 A Simple Baseline

We now present a simple baseline for semi-supervised question answering. Given a paragraph $p = (p_1, p_2, \cdots, p_T)$ and the answer $a = (p_j, p_{j+1}, \cdots, p_{k-1}, p_k)$, we extract $(p_{j-W}, p_{j-W+1}, \cdots, p_{j-1}, p_{k+1}, p_{k+2}, p_{k+W})$ from the paragraph and treat it as the question. Here W is the window size and is set at 5 in our experiments so that the lengths of the questions are similar to human-generated questions. The context-based question-answer pairs on U are combined with human-generated pairs on L for training the discriminative model. Intuitively, this method extracts the contexts around the answer chunks to serve as hints for the question answering model. Surprisingly, this simple baseline method leads to substantial improvements when labeled data is limited.

3 Generative Domain-Adaptive Nets

Though the simple method described in Section 2.1 can lead to substantial improvement, we aim to design a learning-based model to move even further. In this section, we will describe the model architecture and the training algorithms for the GDANs. We will use a notation in the context of question answering following Section 2, but one should be able to extend the notion of GDANs to other applications as well.

The GDAN framework consists of two models, *a discriminative model* and a *generative model*. We will first discuss the two models in detail in the context of question answering, and then present an algorithm based on reinforcement learning to combine the two models.

3.1 Discriminative Model

The discriminative model learns the conditional probability of an answer chunk given the paragraph and the question, i.e., $\mathbb{P}(a|p,q)$. We employ a gated-attention (GA) reader (Dhingra et al., 2016) as our base model in this work, but our framework does not make any assumptions about the base models being used. The discriminative model is referred to as D.

The GA model consists of K layers with K being a hyper-parameter. Let $\mathbf{H}_p^k$ be the intermediate paragraph representation at layer k, and $\mathbf{H}_q$ be the question representation. The paragraph representation $\mathbf{H}_p^k$ is a $T \times d$ matrix, and the question representation $\mathbf{H}_q$ is a $T' \times d$ matrix, where d is the dimensionality of the representations. Given the paragraph p, we apply a bidirectional Gated Recurrent Unit (GRU) network (Chung et al., 2014) on top of the embeddings of the sequence $(p_1, p_2, \cdots, p_T)$, and obtain the initial paragraph representation $\mathbf{H}_p^0$. Given the question q, we also apply another bidirectional GRU to obtain the question representation $\mathbf{H}_q$.

The question and paragraph representations are combined with the gated-attention (GA) mechanism (Dhingra et al., 2016). More specifically, for each paragraph token p_i, we compute

$$\alpha_j = \frac{\exp \mathbf{h}_{q,j}^T \mathbf{h}_{p,i}^{k-1}}{\sum_{j'=1}^{T'} \exp \mathbf{h}_{q,j'}^T \mathbf{h}_{p,i}^{k-1}}$$

$$\mathbf{h}_{p,i}^k = \sum_{j=1}^{T'} \alpha_j \mathbf{h}_{q,j} \odot \mathbf{h}_{p,i}^{k-1}$$

where $\mathbf{h}_{p,i}^k$ is the i-th row of $\mathbf{H}_p^k$ and $\mathbf{h}_{q,j}$ is the j-th row of $\mathbf{H}_q$.

Since the answer a is a sequence of consecutive word tokens in the paragraph p, we apply two softmax layers on top of $\mathbf{H}_p^K$ to predict the start and end indices of a, following Yang et al. (2017).

3.1.1 Domain Adaptation with Tags

We will train our discriminative model on both model-generated question-answer pairs and human-generated pairs. However, even a well-trained generative model will produce questions somewhat different from human-generated ones. Learning from both human-generated data and model-generated data can thus lead to a biased model. To alleviate this issue, we propose to view the model-generated data distribution and the human-generated data distribution as two different data domains and explicitly incorporate domain adaptation into the discriminative model.

More specifically, we use a *domain tag* as an additional input to the discriminative model. We use the tag "d_true" to represent the domain of human-generated data (i.e., the *true* data), and "d_gen" for the domain of model-generated data. Following a practice in domain adaptation (Johnson et al., 2016; Chu et al., 2017), we append the domain tag to the end of both the questions and the paragraphs. By introducing the domain tags, we expect the discriminative model to factor out domain-specific and domain-invariant representations. At test time, the tag "d_true" is appended.

3.2 Generative Model

The generative model learns the conditional probability of generating a question given the paragraph and the answer, i.e., $\mathbb{P}(q|p,a)$. We implement the generative model as a sequence-to-sequence model (Sutskever et al., 2014) with a copy mechanism (Gu et al., 2016; Gulcehre et al., 2016).

The generative model consists of an encoder and a decoder. An encoder is a GRU that encodes the input paragraph into a sequence of hidden states $\mathbf{H}$. We inject the answer information by appending an additional zero/one feature to the word embeddings of the paragraph tokens; i.e., if a word token appears in the answer, the feature is set at one, otherwise zero.

The decoder is another GRU with an attention mechanism over the encoder hidden states $\mathbf{H}$. At each time step, the generation probabilities over all

word types are defined with a copy mechanism:

$$\mathbf{p}_{\text{overall}} = g_t \mathbf{p}_{\text{vocab}} + (1 - g_t)\mathbf{p}_{\text{copy}} \quad (1)$$

where g_t is the probability of generating the token from the vocabulary, while $(1 - g_t)$ is the probability of copying a token from the paragraph. The probability g_t is computed based on the current hidden state $\mathbf{h}_t$:

$$g_t = \sigma(\mathbf{w}_g^T \mathbf{h}_t)$$

where σ denotes the logistic function and $\mathbf{w}_g$ is a vector of model parameters. The generation probabilities $\mathbf{p}_{\text{vocab}}$ are defined as a softmax function over the word types in the vocabulary, and the copying probabilities $\mathbf{p}_{\text{copy}}$ are defined as a softmax function over the word types in the paragraph. Both $\mathbf{p}_{\text{vocab}}$ and $\mathbf{p}_{\text{copy}}$ are defined as a function of the current hidden state $\mathbf{h}_t$ and the attention results (Gu et al., 2016).

3.3 Training Algorithm

We first define the objective function of the GDANs, and then present an algorithm to optimize the given objective function. Similar to the Generative Adversarial Nets (GANs) (Goodfellow et al., 2014) and adversarial domain adaptation (Ganin and Lempitsky, 2014), the discriminative model and the generative model have different objectives in our framework. However, rather than formulating the objective as an adversarial game between the two models (Goodfellow et al., 2014; Ganin and Lempitsky, 2014), in our framework, the discriminative model relies on the data generated by the generative model, while the generative model aims to match the model-generated data distribution with the human-generated data distribution using the signals from the discriminative model.

Given a labeled dataset $L = \{p^{(i)}, q^{(i)}, a^{(i)}\}_{i=1}^N$, the objective function of a discriminative model D for a supervised learning setting can be written as $\sum_{p^{(i)},q^{(i)},a^{(i)} \in L} \log \mathbb{P}_D(a^{(i)}|p^{(i)}, q^{(i)})$, where $\mathbb{P}_D$ is a probability distribution defined by the model D. Since we also incorporate domain tags into the model D, we denote the objective function as

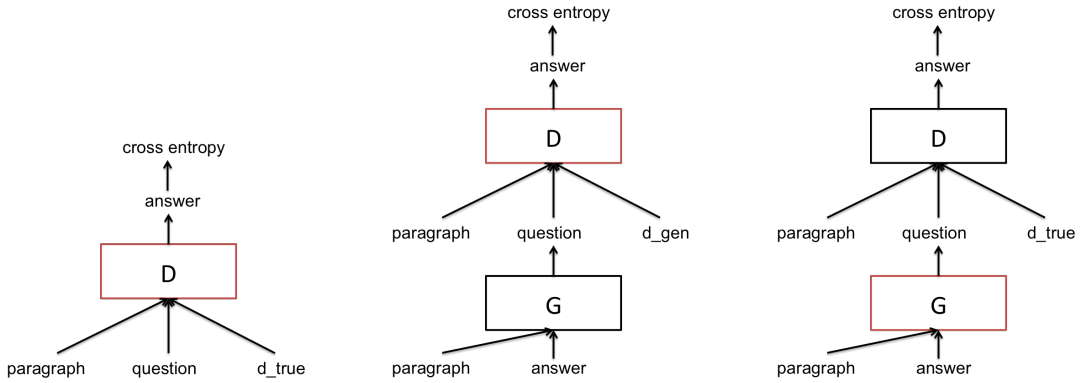
$$J(L, \text{tag}, D) = \frac{1}{|L|} \sum_{p^{(i)},q^{(i)},a^{(i)} \in L} \log \mathbb{P}_{D,\text{tag}}(a^{(i)}|p^{(i)}, q^{(i)})$$

meaning that the domain tag, "tag", is appended to the dataset L. We use $|L| = N$ to denote the number of the instances in the dataset L. The objective function is averaged over all instances such that we can balance labeled and unlabeled data.

Let U_G denote the dataset obtained by generating questions on the unlabeled dataset U with the generative model G. The objective of the discriminative model is then to maximize J for both labeled and unlabeled data under the domain adaptation notions, i.e., $J(L, \text{d\_true}, D) + J(U_G, \text{d\_gen}, D)$.

Now we discuss the objective of the generative model. Similar to the dual learning (Xia et al., 2016) framework, one can define an auto-encoder objective. In this case, the generative model aims to generate questions that can be reconstructed by the discriminative model, i.e., maximizing $J(U_G, \text{d\_gen}, D)$. However, this objective function can lead to degenerate solutions because the questions can be thought of as an overcomplete representation of the answers (Vincent et al., 2010). For example, given p and a, the generative model might learn to generate trivial questions such as copying the answers, which does not contributed to learning a better D.

Instead, we leverage the discriminative model to better match the model-generated data distribution with the human-generated data distribution. We propose to define an adversarial training objective $J(U_G, \text{d\_true}, D)$. We append the tag "d_true" instead of "d_gen" for the model-generated data to "fool" the discriminative model. Intuitively, the goal of G is to generate "useful" questions where the usefulness is measured by the probability that the generated questions can be answered correctly by D.



(a) Training the discriminative model on labeled data.

(b) Training the discriminative model on unlabeled data.

(c) Training the generative model on unlabeled data.

Figure 1: Model architecture and training. Red boxes denote the modules being updated. "d_true" and "d_gen" are two domain tags. D is the discriminative model and G is the generative model. The objectives for the three cases are all to minimize the cross entropy loss of the answer chunks.

The overall objective function now can be written as

$$\begin{aligned} \max_D \quad & J(L, \text{d\_true}, D) + J(U_G, \text{d\_gen}, D) \\ \max_G \quad & J(U_G, \text{d\_true}, D) \end{aligned}$$

With the above objective function in mind, we present a training algorithm in Algorithm 1 to train a GDAN. We first pretrain the generative model on the labeled data L with maximum likelihood estimation (MLE):

$$\max_G \sum_{i=1}^{N} \sum_{t=1}^{T'} \log \mathbb{P}_G(q_t^{(i)} | q_{<t}^{(i)}, p^{(i)}, a^{(i)})$$

where $\mathbb{P}_G$ is the probability defined by Eq. 1.

We then alternatively update D and G based on their objectives. To update D, we sample one batch from the labeled data L and one batch from the unlabeled data U_G, and combine the two batches to perform a gradient update step. Since the output of G is discrete and non-differentiable, we use the Reinforce algorithm (Williams, 1992) to update G. The action space is all possible questions with length T' (possibly with padding) and the reward is the objective function $J(U_G, \text{d\_true}, D)$. Let θ_G be the parameters of G. The gradient can be written as

$$\begin{aligned} & \frac{\partial J(U_G, \text{d\_true}, D)}{\partial \theta_G} \\ = \quad & \mathbb{E}_{\mathbb{P}_G(q|p,a)}(\log \mathbb{P}_{D,\text{d\_true}}(a|p,q) - b) \frac{\partial \log \mathbb{P}_G(q|p,a)}{\partial \theta_G} \end{aligned}$$

where we use an average reward from samples as the baseline b. We approximate the expectation $\mathbb{E}_{\mathbb{P}_G(q|p,a)}$ by sampling one instance at a time from $\mathbb{P}_G(q|p,a)$ and then do an update step. This training algorithm is referred to as reinforcement learning (RL) training in the following sections. The overall architecture and training algorithm are illustrated in Figure 1.

MLE vs RL. The generator G has two training phases–MLE training and RL training, which are different in that: 1) RL training does not require labels, so G can explore a broader data domain of p using unlabeled data, while MLE training requires labels; 2) MLE maximizes $\log P(q|p,a)$, while RL maximizes $\log P_D(a|q,p)$. Since $\log P(q|a,p)$ is the sum of $\log P(q|p)$ and $\log P(a|q,p)$ (plus a constant), maximizing $\log P(a|q,p)$ does not require modeling $\log P(q|p)$ that is irrelevant to QA, which makes optimization easier. Moreover, maximizing $\log P(a|q,p)$ is consistent with the goal of QA.

4 Experiments

4.1 Answer Extraction

As discussed in Section 2, our model assumes that answers are available for unlabeled data. In this section, we introduce how we use linguistic tags and rules to extract answer chunks from unlabeled text.

To extract answers from massive unlabelled Wikipedia articles, we first sample 205,511 Wikipedia articles that are not used in the training, development and test sets in the SQuAD dataset. We extract the paragraphs from each article, and limit the length of each paragraph at the word level to be less than 850. In total, we obtain 950,612

Table 1: Sampled generated questions given the paragraphs and the answers. *P* means paragraphs, *A* means answers, *GQ* means groundtruth questions, and *Q* means questions generated by our models. *MLE* refers to maximum likelihood training, and *RL* refers to reinforcement learning so as to maximize $J(U_G, \text{d\_true}, D)$. We truncate the paragraphs to only show tokens around the answer spans with a window size of 20.

paragraphs from unlabelled articles.

Answers in the SQuAD dataset can be categorized into ten types, i.e., "Date", "Other Numeric", "Person", "Location", "Other Entity", "Common Noun Phrase", "Adjective Phrase", "Verb Phrase", "Clause" and "Other" (Rajpurkar et al., 2016). For each paragraph from the unlabeled articles, we utilize Stanford Part-Of-Speech (POS) tagger (Toutanova et al., 2003) to label each word with the corresponding POS tag, and implement a simple constituency parser to extract the noun phrase, verb phrase, adjective and clause based on a small set of constituency grammars. Next, we use Stanford Named Entity Recognizer (NER) (Finkel et al., 2005) to assign each word with one of the seven labels, i.e., "Date", "Money", "Percent", "location", "Organization" and "Time". We then categorize a span of consecutive words with the same NER tags of either "Money" or "Percent" as the answer of the type "Other Numeric". Similarly, we categorize a span of consecutive words with the same NER tags of "Organization" as the answer of the type "Other Entity". Finally, we subsample five answers from all the extracted answers for each paragraph according to the percentage of answer types in the SQuAD dataset. We obtain 4,753,060 answers in total, which is about 50 times larger than the number of answers in the SQuAD dataset.

4.2 Settings and Comparison Methods

The original SQuAD dataset consists of 87,636 training instances and 10,600 development instances. Since the test set is not published, we split 10% of the training set as the test set, and the remaining 90% serves as the actual training set. Instances are split based on articles; i.e., paragraphs in one article always appear in only one set. We tune the hyper-parameters and perform early stopping on the development set using the F1 scores, and the performance is evaluated on the test set using both F1 scores and exact matching (EM) scores (Rajpurkar et al., 2016).

We compare the following methods. **SL** is

the supervised learning setting where we train the model D solely on the labeled data L. **Context** is the simple context-based method described in Section 2.1. **Context + domain** is the "Context" method with domain tags as described in Section 3.1.1. **Gen** is to train a generative model and use the generated questions as additional training data. **Gen + GAN** refers to the domain adaptation method using GANs (Ganin and Lempitsky, 2014); in contrast to the original work, the generative model is updated using Reinforce. **Gen + dual** refers to the dual learning method (Xia et al., 2016). **Gen + domain** is "Gen" with domain tags, while the generative model is trained with MLE and fixed. **Gen + domain + adv** is the approach we propose (Cf. Figure 1 and Algorithm 1), with "adv" meaning adversarial training based on Reinforce. We use our own implementation of "Gen + GAN" and "Gen + dual", since the GAN model (Ganin and Lempitsky, 2014) does not handle discrete features and the dual learning model (Xia et al., 2016) cannot be directly applied to question answering. When implementing these two baselines, we adopt the learning schedule introduced by Ganin and Lempitsky (2014), i.e., gradually increasing the weights of the gradients for the generative model G.

4.3 Results and Analysis

We study the performance of different models with varying labeling rates and unlabeled dataset sizes. Labeling rates are the percentage of training instances that are used to train D. The results are reported in Table 2. Though the unlabeled dataset we collect consists of around 5 million instances, we also sample a subset of around 50,000 instances to evaluate the effects of the size of unlabeled data. The highest labeling rate in Table 2 is 0.9 because 10% of the training instances are used for testing. Since we do early stopping on the development set using the F1 scores, we also report the development F1. We report two metrics, the F1 scores and the exact matching (EM) scores (Rajpurkar et al., 2016), on the test set. All metrics are computed using the official evaluation scripts.

SL v.s. SSL. We observe that semi-supervised learning leads to consistent improvements over supervised learning in all cases. Such improvements are substantial when labeled data is limited. For example, the GDANs improve over supervised learning by 9.87 points in F1 and 7.26 points in EM when the labeling rate is 0.1. With our semi-supervised learning approach, we can use only 0.1 training instances to obtain even better performance than a supervised learning approach with 0.2 training instances, saving more than half of the labeling costs.

Comparison with Baselines. By comparing "Gen + domain + adv" with "Gen + GAN" and "Gen + Dual", it is clear that the GDANs perform substantially better than GANs and dual learning. With labeling rate 0.1, GDANs outperform dual learning and GANs by 2.47 and 4.29 points respectively in terms of F1.

Ablation Study. We also perform an ablation study by examining the effects of "domain" and "adv" when added to "gen". It can be seen that both the domain tags and the adversarial training contribute to the performance of the GDANs when the labeling rate is equal to or less than 0.5. With labeling rate 0.9, adding domain tags still leads to better performance but adversarial training does not seem to improve the performance by much.

Unlabeled Data Size. Moreover, we observe that the performance can be further improved when a larger unlabeled dataset is used, though the gain is relatively less significant compared to changing the model architectures. For example, increasing the unlabeled dataset size from 50K to 5M, the performance of GDANs increases by 0.38 points in F1 and 0.52 points in EM.

Context-Based Method. Surprisingly, the simple context-based method, though performing worse than GDANs, still leads to substantial gains; e.g., 7.00 points in F1 with labeling rate 0.1. Adding domain tags can improve the performance of the context-based method as well.

MLE vs RL. We plot the loss curve of $-J(U_G, \text{d\_gen}, D)$ for both the MLE-trained generator ("Gen + domain") and the RL-trained generator ("Gen + domain + adv") in Figure 2. We observe that the training loss for D on RL-generated questions is lower than MLE-generated questions, which confirms that RL training maximizes $\log P(a|p, q)$.

Samples of Generated Questions. We present some questions generated by our model in Table 1. The generated questions are post-processed by removing repeated subs-sequences. Compared to MLE-generated questions, RL-generated questions are more informative (Cf., P1, P2, and P4), and contain less "UNK" (unknown) tokens (Cf.,

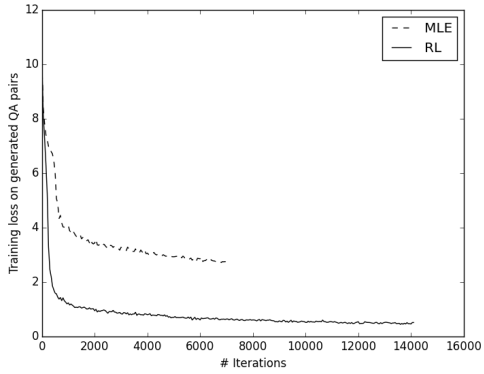

Figure 2: Comparison of discriminator training loss $-J(U_G, \text{d\_gen}, D)$ on generated QA pairs. The lower the better. MLE refers to questions generated by maximum likelihood training, and RL refers to questions generated by reinforcement learning.

P1). Moreover, both semantically and syntactically, RL-generated questions are more accurate (Cf., P3 and P5).

5 Related Work

Semi-Supervised Learning. Semi-supervised learning has been extensively studied in literature (Zhu, 2005). A batch of novel models have been recently proposed for semi-supervised learning based on representation learning techniques, such as generative models (Kingma et al., 2014), ladder networks (Rasmus et al., 2015) and graph embeddings (Yang et al., 2016a). However, most of the semi-supervised learning methods are based on combinations of the supervised loss $p(\mathbf{y}|\mathbf{x})$ and an unsupervised loss $p(\mathbf{x})$. In the context of reading comprehension, directly modeling the likelihood of a paragraph would not possibly improve the supervised task of question answering. Moreover, traditional graph-based semi-supervised learning (Zhu and Ghahramani, 2002) cannot be easily extended to modeling the unlabeled answer chunks.

Domain Adaptation. Domain adaptation has been successfully applied to various tasks, such as classification (Ganin and Lempitsky, 2014) and machine translation (Johnson et al., 2016; Chu et al., 2017). Several techniques on domain adaptation (Glorot et al., 2011) focus on learning distribution invariant features by sharing the intermediate representations for downstream tasks. Another line of research on domain adaptation attempt to match the distance between different domain distributions in a low dimensional space (Long et al., 2015; Baktashmotlagh et al., 2013). There are also methods seeking a domain transition from the source domain to the target domain (Gong et al., 2012; Gopalan et al., 2011; Pan et al., 2011). Our work gets inspiration from a practice in Johnson et al. (2016) and Chu et al. (2017) based on appending domain tags. However, our method is different from the above methods in that we apply domain adaptation techniques to the outputs of a generative model rather than a natural data domain.

Question Answering. Various neural models based on attention mechanisms (Wang and Jiang, 2016; Seo et al., 2016; Xiong et al., 2016; Wang et al., 2016; Dhingra et al., 2016; Kadlec et al., 2016; Trischler et al., 2016b; Sordoni et al., 2016; Cui et al., 2016; Chen et al., 2016) have been proposed to tackle the tasks of question answering and reading comprehension. However, the performance of these neural models largely relies on a large amount of labeled data available for training.

Learning with Multiple Models. GANs (Goodfellow et al., 2014) formulated a adversarial game between a discriminative model and a generative model for generating realistic images. Ganin and Lempitsky (Ganin and Lempitsky, 2014) employed a similar idea to use two models for domain adaptation. Review networks (Yang et al., 2016b) employ a discriminative model as a regularizer for training a generative model. In the context of machine translation, given a language pair, various recent work studied jointly training models to learn the mappings in both directions (Tu et al., 2016; Xia et al., 2016).

6 Conclusions

We study a critical and challenging problem, semi-supervised question answering. We propose a novel neural framework called Generative Domain-Adaptive Nets, which incorporate domain adaptation techniques in combination with generative models for semi-supervised learning. Empirically, we show that our approach leads to substantial improvements over supervised learning models and outperforms several strong baselines including GANs and dual learning. In the future, we plan to apply our approach to more question answering datasets in different domains. It will also be intriguing to generalize GDANs to other applications.

Abstract

Our goal is to learn a semantic parser that maps natural language utterances into executable programs when only indirect supervision is available: examples are labeled with the correct execution result, but not the program itself. Consequently, we must search the space of programs for those that output the correct result, while not being misled by *spurious programs*: incorrect programs that coincidentally output the correct result. We connect two common learning paradigms, reinforcement learning (RL) and maximum marginal likelihood (MML), and then present a new learning algorithm that combines the strengths of both. The new algorithm guards against spurious programs by combining the systematic search traditionally employed in MML with the randomized exploration of RL, and by updating parameters such that probability is spread more evenly across consistent programs. We apply our learning algorithm to a new neural semantic parser and show significant gains over existing state-of-the-art results on a recent context-dependent semantic parsing task.

1 Introduction

We are interested in learning a semantic parser that maps natural language utterances into executable programs (e.g., logical forms). For example, in Figure 1, a program corresponding to the utterance transforms an initial world state into a new world state. We would like to learn from indirect supervision, where each training example is only labeled with the correct output (e.g. a target world state), but not the program that produced that output (Clarke et al., 2010; Liang et al., 2011; Krishnamurthy and Mitchell, 2012; Artzi and Zettlemoyer, 2013; Liang et al., 2017).

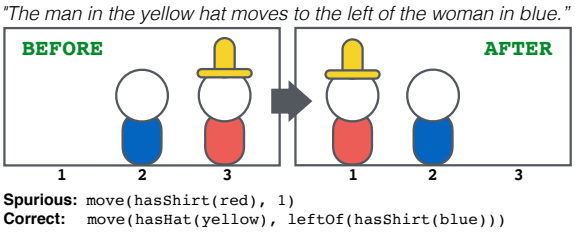

Figure 1: The task is to map natural language utterances to a program that manipulates the world state. The correct program captures the true meaning of the utterances, while spurious programs arrive at the correct output for the wrong reasons. We develop methods to prevent the model from being drawn to spurious programs.

The process of constructing a program can be formulated as a sequential decision-making process, where feedback is only received at the end of the sequence when the completed program is executed. In the natural language processing literature, there are two common approaches for handling this situation: 1) reinforcement learning (RL), particularly the REINFORCE algorithm (Williams, 1992; Sutton et al., 1999), which maximizes the expected reward of a sequence of actions; and 2) maximum marginal likelihood (MML), which treats the sequence of actions as a latent variable, and then maximizes the marginal likelihood of observing the correct program output (Dempster et al., 1977).

While the two approaches have enjoyed success on many tasks, we found them to work poorly out of the box for our task. This is because in addition to the sparsity of correct programs, our task also requires weeding out *spurious programs* (Pasupat and Liang, 2016): incorrect interpretations

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1051–1062
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1097

of the utterances that accidentally produce the correct output, as illustrated in Figure 1.

We show that MML and RL optimize closely related objectives. Furthermore, both MML and RL methods have a mechanism for exploring program space in search of programs that generate the correct output. We explain why this exploration tends to quickly concentrate around short spurious programs, causing the model to sometimes overlook the correct program. To address this problem, we propose RANDOMER, a new learning algorithm with two parts:

First, we propose *randomized beam search*, an exploration strategy which combines the systematic beam search traditionally employed in MML with the randomized off-policy exploration of RL. This increases the chance of finding correct programs even when the beam size is small or the parameters are not pre-trained.

Second, we observe that even with good exploration, the gradients of both the RL and MML objectives may still upweight entrenched spurious programs more strongly than correct programs with low probability under the current model. We propose a *meritocratic parameter update rule*, a modification to the MML gradient update, which more equally upweights all programs that produce the correct output. This makes the model less likely to overfit spurious programs.

We apply RANDOMER to train a new neural semantic parser, which outputs programs in a stack-based programming language. We evaluate our resulting system on SCONE, the context-dependent semantic parsing dataset of Long et al. (2016). Our approach outperforms standard RL and MML methods in a direct comparison, and achieves new state-of-the-art results, improving over Long et al. (2016) in all three domains of SCONE, and by over 30% accuracy on the most challenging one.

2 Task

We consider the semantic parsing task in the SCONE dataset[1] (Long et al., 2016). As illustrated in Figure 1, each example consists of a *world* containing several objects (e.g., people), each with certain properties (e.g., shirt color and hat color). Given the initial world state w_0 and a sequence of M natural language utterances $\mathbf{u} = (u_1, \ldots, u_M)$, the task is to generate a program that manipulates the world state according to the utterances. Each utterance u_m describes a single action that transforms the world state w_{m-1} into a new world state w_m. For training, the system receives weakly supervised examples with input $x = (\mathbf{u}, w_0)$ and the target final world state $y = w_M$.

The dataset includes 3 domains: ALCHEMY, TANGRAMS, and SCENE. The description of each domain can be found in Appendix B. The domains highlight different linguistic phenomena: ALCHEMY features ellipsis (e.g., "throw the rest out", "mix"); TANGRAMS features anaphora on actions (e.g., "repeat step 3", "bring it back"); and SCENE features anaphora on entities (e.g., "he moves back", "...to his left"). Each domain contains roughly 3,700 training and 900 test examples. Each example contains 5 utterances and is labeled with the target world state after each utterance, but not the target program.

Spurious programs. Given a training example $(\mathbf{u}, w_0, w_M)$, our goal is to find the true underlying program $\mathbf{z}^*$ which reflects the meaning of $\mathbf{u}$. The constraint that $\mathbf{z}^*$ must transform w_0 into w_M, i.e. $\mathbf{z}(w_0) = w_M$, is not enough to uniquely identify the true $\mathbf{z}^*$, as there are often many $\mathbf{z}$ satisfying $\mathbf{z}(w_0) = w_M$: in our experiments, we found at least 1600 on average for each example. Almost all do not capture the meaning of $\mathbf{u}$ (see Figure 1). We refer to these incorrect $\mathbf{z}$'s as *spurious programs*. Such programs encourage the model to learn an incorrect mapping from language to program operations: e.g., the spurious program in Figure 1 would cause the model to learn that "man in the yellow hat" maps to `hasShirt(red)`.

Spurious programs in SCONE. In this dataset, utterances often reference objects in different ways (e.g. a person can be referenced by shirt color, hat color, or position). Hence, any target programming language must also support these different reference strategies. As a result, even a single action such as moving a person to a target destination can be achieved by many different programs, each selecting the person and destination in a different way. Across multiple actions, the number of programs grows combinatorially.[2] Only a few programs actually implement the correct reference strategy as defined by the utterance. This problem would be more severe in any more general-purpose language (e.g. Python).

[1] https://nlp.stanford.edu/projects/scone

[2] The number of well-formed programs in SCENE exceeds 10^{15}

3 Model

We formulate program generation as a sequence prediction problem. We represent a program as a sequence of program tokens in postfix notation; for example, `move(hasHat(yellow), leftOf(hasShirt(blue)))` is linearized as `yellow hasHat blue hasShirt leftOf move`. This representation also allows us to incrementally execute programs from left to right using a stack: constants (e.g., `yellow`) are pushed onto the stack, while functions (e.g., `hasHat`) pop appropriate arguments from the stack and push back the computed result (e.g., the list of people with yellow hats). Appendix B lists the full set of program tokens, $\mathcal{Z}$, and how they are executed. Note that each action always ends with an *action token* (e.g., `move`).

Given an input $x = (\mathbf{u}, w_0)$, the model generates program tokens $z_1, z_2, \ldots$ from left to right using a neural encoder-decoder model with attention (Bahdanau et al., 2015). Throughout the generation process, the model maintains an utterance pointer, m, initialized to 1. To generate z_t, the model's encoder first encodes the utterance u_m into a vector e_m. Then, based on e_m and previously generated tokens $z_{1:t-1}$, the model's decoder defines a distribution $p(z_t \mid x, z_{1:t-1})$ over the possible values of $z_t \in \mathcal{Z}$. The next token z_t is sampled from this distribution. If an action token (e.g., `move`) is generated, the model increments the utterance pointer m. The process terminates when all M utterances are processed. The final probability of generating a particular program $\mathbf{z} = (z_1, \ldots, z_T)$ is $p(\mathbf{z} \mid x) = \prod_{t=1}^{T} p(z_t \mid x, z_{1:t-1})$.

Encoder. The utterance u_m under the pointer is encoded using a bidirectional LSTM:

$$h_i^{\mathrm{F}} = \mathrm{LSTM}(h_{i-1}^{\mathrm{F}}, \Phi_{\mathrm{u}}(u_{m,i}))$$
$$h_i^{\mathrm{B}} = \mathrm{LSTM}(h_{i+1}^{\mathrm{B}}, \Phi_{\mathrm{u}}(u_{m,i}))$$
$$h_i = [h_i^{\mathrm{F}}; h_i^{\mathrm{B}}],$$

where $\Phi_{\mathrm{u}}(u_{m,i})$ is the fixed GloVe word embedding (Pennington et al., 2014) of the ith word in u_m. The final utterance embedding is the concatenation $e_m = [h_{|u_m|}^{\mathrm{F}}; h_1^{\mathrm{B}}]$.

Decoder. Unlike Bahdanau et al. (2015), which used a recurrent network for the decoder, we opt for a feed-forward network for simplicity. We use e_m and an embedding $f(z_{1:t-1})$ of the previous execution history (described later) as inputs to compute an attention vector c_t:

$$q_t = \mathrm{ReLU}(W_{\mathrm{q}}[e_m; f(z_{1:t-1})])$$
$$\alpha_i \propto \exp(q_t^\top W_{\mathrm{a}} h_i) \qquad (i = 1, \ldots, |u_m|)$$
$$c_t = \sum_i \alpha_i h_i.$$

Finally, after concatenating q_t with c_t, the distribution over the set $\mathcal{Z}$ of possible program tokens is computed via a softmax:

$$p(z_t \mid x, z_{1:t-1}) \propto \exp(\Phi_{\mathrm{z}}(z_t)^\top W_{\mathrm{s}}[q_t; c_t]),$$

where $\Phi_{\mathrm{z}}(z_t)$ is the embedding for token z_t.

Execution history embedding. We compare two options for $f(z_{1:t-1})$, our embedding of the execution history. A standard approach is to simply take the k most recent tokens $z_{t-k:t-1}$ and concatenate their embeddings. We will refer to this as TOKENS and use $k = 4$ in our experiments.

We also consider a new approach which leverages our ability to incrementally execute programs using a stack. We summarize the execution history by embedding the state of the stack at time $t-1$, achieved by concatenating the embeddings of all values on the stack. (We limit the maximum stack size to 3.) We refer to this as STACK.

4 Reinforcement learning versus maximum marginal likelihood

Having formulated our task as a sequence prediction problem, we must still choose a learning algorithm. We first compare two standard paradigms: reinforcement learning (RL) and maximum marginal likelihood (MML). In the next section, we propose a better alternative.

4.1 Comparing objective functions

Reinforcement learning. From an RL perspective, given a training example (x, y), a policy makes a sequence of decisions $\mathbf{z} = (z_1, \ldots, z_T)$, and then receives a reward at the end of the episode: $R(\mathbf{z}) = 1$ if $\mathbf{z}$ executes to y and 0 otherwise (dependence on x and y has been omitted from the notation).

We focus on *policy gradient* methods, in which a stochastic policy function is trained to maximize the expected reward. In our setup, $p_\theta(\mathbf{z} \mid x)$ is the policy (with parameters θ), and its expected reward on a given example (x, y) is

$$G(x, y) = \sum_{\mathbf{z}} R(\mathbf{z})\, p_\theta(\mathbf{z} \mid x), \qquad (1)$$

where the sum is over all possible programs. The overall RL objective, J_{RL}, is the expected reward across examples:

$$J_{\text{RL}} = \sum_{(x,y)} G(x, y). \tag{2}$$

Maximum marginal likelihood. The MML perspective assumes that y is generated by a partially-observed random process: conditioned on x, a latent program $\mathbf{z}$ is generated, and conditioned on $\mathbf{z}$, the observation y is generated. This implies the marginal likelihood:

$$p_\theta(y \mid x) = \sum_{\mathbf{z}} p(y \mid \mathbf{z})\, p_\theta(\mathbf{z} \mid x). \tag{3}$$

Note that since the execution of $\mathbf{z}$ is deterministic, $p_\theta(y \mid \mathbf{z}) = 1$ if $\mathbf{z}$ executes to y and 0 otherwise. The log marginal likelihood of the data is then

$$J_{\text{MML}} = \log \mathcal{L}_{\text{MML}}, \tag{4}$$

$$\text{where} \quad \mathcal{L}_{\text{MML}} = \prod_{(x,y)} p_\theta(y \mid x). \tag{5}$$

To estimate our model parameters θ, we maximize J_{MML} with respect to θ.

With our choice of reward, the RL expected reward (1) is equal to the MML marginal probability (3). Hence the only difference between the two formulations is that in RL we optimize the *sum* of expected rewards (2), whereas in MML we optimize the *product* (5).[3]

4.2 Comparing gradients

In both policy gradient and MML, the objectives are typically optimized via (stochastic) gradient ascent. The gradients of J_{RL} and J_{MML} are closely related. They both have the form:

$$\begin{aligned} \nabla_\theta J &= \sum_{(x,y)} \mathbb{E}_{\mathbf{z}\sim q}\left[R(\mathbf{z}) \nabla \log p_\theta(\mathbf{z} \mid x)\right] \\ &= \sum_{(x,y)} \sum_{\mathbf{z}} q(\mathbf{z}) R(\mathbf{z}) \nabla \log p_\theta(\mathbf{z} \mid x), \end{aligned} \tag{6}$$

where $q(\mathbf{z})$ equals

$$q_{\text{RL}}(\mathbf{z}) = p_\theta(\mathbf{z} \mid x) \quad \text{for } J_{\text{RL}}, \tag{7}$$

$$\begin{aligned} q_{\text{MML}}(\mathbf{z}) &= \frac{R(\mathbf{z}) p_\theta(\mathbf{z} \mid x)}{\sum_{\tilde{\mathbf{z}}} R(\tilde{\mathbf{z}}) p_\theta(\tilde{\mathbf{z}} \mid x)} \\ &= p_\theta(\mathbf{z} \mid x, R(\mathbf{z}) \neq 0) \quad \text{for } J_{\text{MML}}. \end{aligned} \tag{8}$$

[3] Note that the log of the product in (5) does *not* equal the sum in (2).

Taking a step in the direction of $\nabla \log p_\theta(\mathbf{z} \mid x)$ upweights the probability of $\mathbf{z}$, so we can heuristically think of the gradient as attempting to upweight each reward-earning program $\mathbf{z}$ by a *gradient weight* $q(\mathbf{z})$. In Subsection 5.2, we argue why q_{MML} is better at guarding against spurious programs, and propose an even better alternative.

4.3 Comparing gradient approximation strategies

It is often intractable to compute the gradient (6) because it involves taking an expectation over all possible programs. So in practice, the expectation is approximated.

In the policy gradient literature, *Monte Carlo integration* (MC) is the typical approximation strategy. For example, the popular REINFORCE algorithm (Williams, 1992) uses Monte Carlo sampling to compute an unbiased estimate of the gradient:

$$\Delta_{\text{MC}} = \frac{1}{B} \sum_{\mathbf{z}\in\mathcal{S}} [R(\mathbf{z}) - c] \nabla \log p_\theta(\mathbf{z} \mid x), \tag{9}$$

where $\mathcal{S}$ is a collection of B samples $\mathbf{z}^{(b)} \sim q(\mathbf{z})$, and c is a *baseline* (Williams, 1992) used to reduce the variance of the estimate without altering its expectation.

In the MML literature for latent sequences, the expectation is typically approximated via *numerical integration* (NUM) instead:

$$\Delta_{\text{NUM}} = \sum_{\mathbf{z}\in\mathcal{S}} q(\mathbf{z}) R(\mathbf{z}) \nabla \log p_\theta(\mathbf{z} \mid x). \tag{10}$$

where the programs in $\mathcal{S}$ come from beam search.

Beam search. Beam search generates a set of programs via the following process. At step t of beam search, we maintain a beam $\mathcal{B}_t$ of at most B *search states*. Each state $s \in \mathcal{B}_t$ represents a partially constructed program, $s = (z_1, \ldots, z_t)$ (the first t tokens of the program). For each state s in the beam, we generate all possible *continuations*,

$$\begin{aligned} \texttt{cont}(s) &= \texttt{cont}((z_1, \ldots, z_t)) \\ &= \{(z_1, \ldots, z_t, z_{t+1}) \mid z_{t+1} \in \mathcal{Z}\}. \end{aligned}$$

We then take the union of these continuations, $\texttt{cont}(\mathcal{B}_t) = \bigcup_{s\in\mathcal{B}_t} \texttt{cont}(s)$. The new beam $\mathcal{B}_{t+1}$ is simply the highest scoring B continuations in $\texttt{cont}(\mathcal{B}_t)$, as scored by the policy, $p_\theta(s \mid x)$. Search is halted after a fixed number of iterations

or when there are no continuations possible. $\mathcal{S}$ is then the set of all complete programs discovered during beam search. We will refer to this as *beam search MML* (BS-MML).

In both policy gradient and MML, we think of the procedure used to produce the set of programs $\mathcal{S}$ as an *exploration strategy* which searches for programs that produce reward. One advantage of numerical integration is that it allows us to decouple the *exploration strategy* from the *gradient weights* assigned to each program.

5 Tackling spurious programs

In this section, we illustrate why spurious programs are problematic for the most commonly used methods in RL (REINFORCE) and MML (beam search MML). We describe two key problems and propose a solution to each, based on insights gained from our comparison of RL and MML in Section 4.

5.1 Spurious programs bias exploration

As mentioned in Section 4, REINFORCE and BS-MML both employ an *exploration strategy* to approximate their respective gradients. In both methods, exploration is guided by the current model policy, whereby programs with high probability under the current policy are more likely to be explored. A troubling implication is that programs with low probability under the current policy are likely to be overlooked by exploration.

If the current policy incorrectly assigns low probability to the correct program $\mathbf{z}^*$, it will likely fail to discover $\mathbf{z}^*$ during exploration, and will consequently fail to upweight the probability of $\mathbf{z}^*$. This repeats on every gradient step, keeping the probability of $\mathbf{z}^*$ perpetually low. The same feedback loop can also cause already high-probability spurious programs to gain even more probability. From this, we see that exploration is sensitive to initial conditions: the rich get richer, and the poor get poorer.

Since there are often thousands of spurious programs and only a few correct programs, spurious programs are usually found first. Once spurious programs get a head start, exploration increasingly biases towards them.

As a remedy, one could try initializing parameters such that the model puts a uniform distribution over all possible programs. A seemingly reasonable tactic is to initialize parameters such that the model policy puts near-uniform probability over the decisions at each time step. However, this causes shorter programs to have orders of magnitude higher probability than longer programs, as illustrated in Figure 2 and as we empirically observe. A more sophisticated approach might involve approximating the total number of programs reachable from each point in the program-generating decision tree. However, we instead propose to reduce sensitivity to the initial distribution over programs.

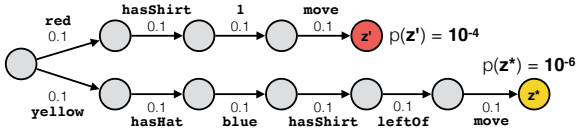

Figure 2: Two possible paths in the tree of all possible programs. One path leads to the spurious program $\mathbf{z}'$ (red) while the longer path leads to the correct program $\mathbf{z}^*$ (gold). Each edge represents a decision and shows the probability of that decision under a uniform policy. The shorter program has two orders of magnitude higher probability.

Solution: randomized beam search

One solution to biased exploration is to simply rely less on the untrustworthy current policy. We can do this by injecting random noise into exploration.

In REINFORCE, a common solution is to sample from an ϵ-greedy variant of the current policy. On the other hand, MML exploration with beam search is deterministic. However, it has a key advantage over REINFORCE-style sampling: even if one program occupies almost all probability under the current policy (a peaky distribution), beam search will still use its remaining beam capacity to explore at least $B-1$ other programs. In contrast, sampling methods will repeatedly visit the mode of the distribution.

To get the best of both worlds, we propose a simple *ϵ-greedy randomized beam search*. Like regular beam search, at iteration t we compute the set of all continuations $\texttt{cont}(\mathcal{B}_t)$ and sort them by their model probability $p_\theta(s \mid x)$. But instead of selecting the B highest-scoring continuations, we choose B continuations one by one without replacement from $\texttt{cont}(\mathcal{B}_t)$. When choosing a continuation from the remaining pool, we either uniformly sample a random continuation with probability ϵ, or pick the highest-scoring continuation in the pool with probability $1-\epsilon$. Empirically, we

find that this performs much better than both classic beam search and ϵ-greedy sampling (Table 3).

5.2 Spurious programs dominate gradients

In both RL and MML, even if exploration is perfect and the gradient is exactly computed, spurious programs can still be problematic.

Even if perfect exploration visits every program, we see from the gradient weights $q(\mathbf{z})$ in (7) and (8) that programs are weighted proportional to their current policy probability. If a spurious program $\mathbf{z}'$ has 100 times higher probability than $\mathbf{z}^*$ as in Figure 2, the gradient will spend roughly 99% of its magnitude upweighting towards $\mathbf{z}'$ and only 1% towards $\mathbf{z}^*$ even though the two programs get the same reward.

This implies that it would take many updates for $\mathbf{z}^*$ to catch up. In fact, $\mathbf{z}^*$ may never catch up, depending on the gradient updates for other training examples. Simply increasing the learning rate is inadequate, as it would cause the model to take overly large steps towards $\mathbf{z}'$, potentially causing optimization to diverge.

Solution: the meritocratic update rule

To solve this problem, we want the upweighting to be more "meritocratic": any program that obtains reward should be upweighted roughly equally.

We first observe that J_{MML} already improves over J_{RL} in this regard. From (6), we see that the gradient weight $q_{\text{MML}}(\mathbf{z})$ is the policy distribution restricted to and renormalized over only reward-earning programs. This renormalization makes the gradient weight uniform *across examples*: even if all reward-earning programs for a particular example have very low model probability, their combined gradient weight $\sum_{\mathbf{z}} q_{\text{MML}}(\mathbf{z})$ is always 1. In our experiments, J_{MML} performs significantly better than J_{RL} (Table 4).

However, while J_{MML} assigns uniform weight across examples, it is still not uniform over the programs *within each example*. Hence we propose a new update rule which goes one step further in pursuing uniform updates. Extending $q_{\text{MML}}(\mathbf{z})$, we define a β-smoothed version:

$$q_\beta(\mathbf{z}) = \frac{q_{\text{MML}}(\mathbf{z})^\beta}{\sum_{\tilde{\mathbf{z}}} q_{\text{MML}}(\tilde{\mathbf{z}})^\beta}. \quad (11)$$

When $\beta = 0$, our weighting is completely uniform across all reward-earning programs within an example while $\beta = 1$ recovers the original MML weighting. Our new update rule is to simply take a modified gradient step where $q = q_\beta$.[4] We will refer to this as the *β-meritocratic* update rule.

5.3 Summary of the proposed approach

We described two problems[5] and their solutions: we reduce exploration bias using *ϵ-greedy randomized beam search* and perform more balanced optimization using the *β-meritocratic parameter update rule*. We call our resulting approach RANDOMER. Table 1 summarizes how RANDOMER combines desirable qualities from both REINFORCE and BS-MML.

6 Experiments

Evaluation. We evaluate our proposed methods on all three domains of the SCONE dataset. Accuracy is defined as the percentage of test examples where the model produces the correct final world state w_M. All test examples have $M = 5$ (5utts), but we also report accuracy after processing the first 3 utterances (3utts). To control for the effects of randomness, we train 5 instances of each model with different random seeds. We report the median accuracy of the instances unless otherwise noted.

Training. Following Long et al. (2016), we decompose each training example into smaller examples. Given an example with 5 utterances, $\mathbf{u} = [u_1, \ldots, u_5]$, we consider all length-1 and length-2 substrings of $\mathbf{u}$: $[u_1], [u_2], \ldots, [u_3, u_4], [u_4, u_5]$ (9 total). We form a new training example from each substring, e.g., $(\mathbf{u}', w_0', w_M')$ where $\mathbf{u}' = [u_4, u_5]$, $w_0' = w_3$ and $w_M' = w_5$.

All models are implemented in TensorFlow (Abadi et al., 2015). Model parameters are randomly initialized (Glorot and Bengio, 2010), with no pre-training. We use the Adam optimizer (Kingma and Ba, 2014) (which is applied to the gradient in (6)), a learning rate of 0.001, a mini-batch size of 8 examples (different from the beam size), and train until accuracy on the validation set converges (on average about 13,000 steps). We

[4] Also, note that if exploration were exhaustive, $\beta = 0$ would be equivalent to supervised learning using the set of all reward-earning programs as targets.

[5] These problems concern the gradient w.r.t. a single example. The full gradient averages over multiple examples, which helps separate correct from spurious. E.g., if multiple examples all mention "yellow hat", we will find a correct program parsing this as `hasHat(yellow)` for each example, whereas the spurious programs we find will follow no consistent pattern. Consequently, spurious gradient contributions may cancel out while correct program gradients will all "vote" in the same direction.

Method	Approximation of $E_q[\cdot]$	Exploration strategy	Gradient weight $q(\mathbf{z})$
REINFORCE	Monte Carlo integration	independent sampling	$p_\theta(\mathbf{z} \mid x)$
BS-MML	numerical integration	beam search	$p_\theta(\mathbf{z} \mid x, R(\mathbf{z}) \neq 0)$
RANDOMER	numerical integration	randomized beam search	$q_\beta(\mathbf{z})$

Table 1: RANDOMER combines qualities of both REINFORCE (RL) and BS-MML. For approximating the expectation over q in the gradient, we use numerical integration as in BS-MML. Our exploration strategy is a hybrid of search (MML) and off-policy sampling (RL). Our gradient weighting is equivalent to MML when $\beta = 1$ and more "meritocratic" than both MML and REINFORCE for lower values of β.

use fixed GloVe vectors (Pennington et al., 2014) to embed the words in each utterance.

Hyperparameters. For all models, we performed a grid search over hyperparameters to maximize accuracy on the validation set. Hyperparameters include the learning rate, the baseline in REINFORCE, ϵ-greediness and β-meritocraticness. For REINFORCE, we also experimented with a regression-estimated baseline (Ranzato et al., 2015), but found it to perform worse than a constant baseline.

6.1 Main results

Comparison to prior work. Table 2 compares RANDOMER to results from Long et al. (2016) as well as two baselines, REINFORCE and BS-MML (using the same neural model but different learning algorithms). Our approach achieves new state-of-the-art results by a significant margin, especially on the SCENE domain, which features the most complex program syntax. We report the results for REINFORCE, BS-MML, and RANDOMER on the seed and hyperparameters that achieve the best validation accuracy.

We note that REINFORCE performs very well on TANGRAMS but worse on ALCHEMY and very poorly on SCENE. This might be because the program syntax for TANGRAMS is simpler than the other two: there is no other way to refer to objects except by index.

We also found that REINFORCE required ϵ-greedy exploration to make any progress. Using ϵ-greedy greatly skews the Monte Carlo approximation of ∇J_{RL}, making it more uniformly weighted over programs in a similar spirit to using β-meritocratic gradient weights q_β. However, q_β increases uniformity over reward-earning programs only, rather than over all programs.

Effect of randomized beam search. Table 3 shows that ϵ-greedy randomized beam search consistently outperforms classic beam search. Even when we increase the beam size of classic beam search to 128, it still does not surpass randomized beam search with a beam of 32, and further increases yield no additional improvement.

Table 3: **Randomized beam search.** All listed models use gradient weight q_{MML} and TOKENS to represent execution history.

Effect of β-meritocratic updates. Table 4 evaluates the impact of β-meritocratic parameter updates (gradient weight q_β). More uniform upweighting across reward-earning programs leads to higher accuracy and fewer spurious programs, especially in SCENE. However, no single value of β performs best over all domains.

Choosing the right value of β in RANDOMER significantly accelerates training. Figure 3 illustrates that while $\beta = 0$ and $\beta = 1$ ultimately achieve similar accuracy on ALCHEMY, $\beta = 0$ reaches good performance in half the time.

Since lowering β reduces trust in the model policy, $\beta < 1$ helps in early training when the current policy is untrustworthy. However, as it grows more trustworthy, $\beta < 1$ begins to pay a price for ignoring it. Hence, it may be worthwhile to anneal β towards 1 over time.

HISTORY	61.3	48.3	**65.2**	**34.3**	50.8	33.5
STACK	**64.2**	**53.2**	63.0	32.4	**59.5**	**43.1**

Table 5: **TOKENS vs STACK embedding.** Both models use $\epsilon = 0.15$ and gradient weight q_{MML}.

Effect of execution history embedding. Table 5 compares our two proposals for embedding the execution history: TOKENS and STACK. STACK performs better in the two domains where an object can be referenced in multiple ways (SCENE and ALCHEMY). STACK directly embeds objects on the stack, invariant to the way in which they were pushed onto the stack, unlike TOKENS. We hypothesize that this invariance increases robustness to spurious behavior: if a program accidentally pushes the right object onto the stack via spurious means, the model can still learn the remaining steps of the program without conditioning on a spurious history.

Fitting vs overfitting the training data. Table 6 reveals that BS-MML and RANDOMER use different strategies to fit the training data. On the depicted training example, BS-MML actually achieves higher expected reward / marginal probability than RANDOMER, but it does so by putting most of its probability on a spurious program—a form of overfitting. In contrast, RANDOMER spreads probability mass over multiple reward-earning programs, including the correct ones.

As a consequence of overfitting, we observed at test time that BS-MML only references people by positional indices instead of by shirt or hat color, whereas RANDOMER successfully learns to use multiple reference strategies.

7 Related work and discussion

Semantic parsing from indirect supervision. Our work is motivated by the classic problem of learning semantic parsers from indirect supervision (Clarke et al., 2010; Liang et al., 2011; Artzi and Zettlemoyer, 2011, 2013; Reddy et al., 2014; Pasupat and Liang, 2015). We are interested in the initial stages of training from scratch, where getting any training signal is difficult due to the combinatorially large search space. We also highlighted the problem of spurious programs which capture reward but give incorrect generalizations.

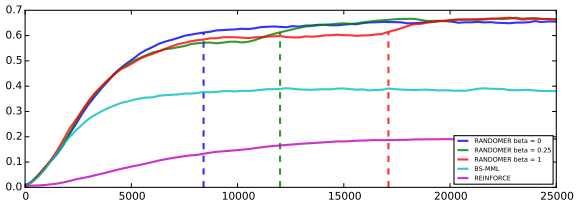

Figure 3: Validation set accuracy (y-axis) across training iterations (x-axis) on ALCHEMY. We compare RANDOMER, BS-MML and REINFORCE. Vertical lines mark the first time each model surpasses 60% accuracy. RANDOMER with $\beta = 0$ reaches this point twice as fast as $\beta = 1$. REINFORCE plateaus for a long time, then begins to climb after 40k iterations (not shown). Training runs are averaged over 5 seeds.

Maximum marginal likelihood with beam search (BS-MML) is traditionally used to learn semantic parsers from indirect supervision.

Reinforcement learning. Concurrently, there has been a recent surge of interest in reinforcement learning, along with the wide application of the classic REINFORCE algorithm (Williams, 1992)—to troubleshooting (Branavan et al., 2009), dialog generation (Li et al., 2016), game playing (Narasimhan et al., 2015), coreference resolution (Clark and Manning, 2016), machine translation (Norouzi et al., 2016), and even semantic parsing (Liang et al., 2017). Indeed, the challenge of training semantic parsers from indirect supervision is perhaps better captured by the notion of sparse rewards in reinforcement learning.

The RL answer would be better exploration, which can take many forms including simple action-dithering such as ϵ-greedy, entropy regularization (Williams and Peng, 1991), Monte Carlo tree search (Coulom, 2006), randomized value functions (Osband et al., 2014, 2016), and methods which prioritize learning environment dynamics (Duff, 2002) or under-explored states (Kearns and Singh, 2002; Bellemare et al., 2016; Nachum et al., 2016). The majority of these methods employ Monte Carlo sampling for exploration. In

x	`move(index(allPeople, 2), 3)`	0.008

Table 6: Top-scoring predictions for a *training* example from SCENE (* = correct, o = spurious, x = incorrect). RANDOMER distributes probability mass over numerous reward-earning programs (including the correct ones), while classic beam search MML overfits to one spurious program, giving it very high probability.

contrast, we find randomized beam search to be more suitable in our setting, because it explores low-probability states even when the policy distribution is peaky. Our β-meritocratic update also depends on the fact that beam search returns an *entire set* of reward-earning programs rather than one, since it renormalizes over the reward-earning set. While similar to entropy regularization, β-meritocratic update is more targeted as it only increases uniformity of the gradient among reward-earning programs, rather than across all programs.

Our strategy of using randomized beam search and meritocratic updates lies closer to MML than RL, but this does not imply that RL has nothing to offer in our setting. With the simple connection between RL and MML we established, much of the literature on exploration and variance reduction in RL can be directly applied to MML problems. Of special interest are methods which incorporate a value function such as actor-critic.

Maximum likelihood and RL. It is tempting to group our approach with sequence learning methods which interpolate between supervised learning and reinforcement learning (Ranzato et al., 2015; Venkatraman et al., 2015; Ross et al., 2011; Norouzi et al., 2016; Bengio et al., 2015; Levine, 2014). These methods generally seek to make RL training easier by pre-training or "warm-starting" with fully supervised learning. This requires each training example to be labeled with a reasonably correct output sequence. In our setting, this would amount to labeling each example with the correct program, which is not known. Hence, these methods cannot be directly applied.

Without access to correct output sequences, we cannot directly maximize likelihood, and instead resort to maximizing the *marginal* likelihood (MML). Rather than proposing MML as a form of pre-training, we argue that MML is a superior substitute for the standard RL objective, and that the β-meritocratic update is even better.

Simulated annealing. Our β-meritocratic update employs exponential smoothing, which bears resemblance to the simulated annealing strategy of Och (2003); Smith and Eisner (2006); Shen et al. (2015). However, a key difference is that these methods smooth the objective function whereas we smooth an expectation in the gradient. To underscore the difference, we note that fixing $\beta = 0$ in our method (total smoothing) is quite effective, whereas total smoothing in the simulated annealing methods would correspond to a completely flat objective function, and an uninformative gradient of zero everywhere.

Neural semantic parsing. There has been recent interest in using recurrent neural networks for semantic parsing, both for modeling logical forms (Dong and Lapata, 2016; Jia and Liang, 2016; Liang et al., 2017) and for end-to-end execution (Yin et al., 2015; Neelakantan et al., 2016). We develop a neural model for the context-dependent setting, which is made possible by a new stack-based language similar to Riedel et al. (2016).

token	type	semantics
Shared across ALCHEMY, TANGRAMS, SCENE		
`1`, `2`, `3`, ... `-1`, `-2`, `-3`, ...	constant	**push:** number
`red`, `yellow`, `green`, `orange`, `purple`, `brown`	constant	**push:** color
`allObjects`	constant	**push:** the list of all objects
`index`	function	**pop:** a list L and a number i **push:** the object $L[i]$ (the index starts from 1; negative indices are allowed)
`prevArg`j ($j = 1, 2$)	function	**pop:** a number i **push:** the j argument from the ith action
`prevAction`	action	**pop:** a number i **perform:** fetch the ith action and execute it using the arguments on the stack
Additional tokens for the ALCHEMY domain An ALCHEMY world contains 7 beakers. Each beaker may contain up to 4 units of colored chemical.		
`1/1`	constant	**push:** fraction (used in the `drain` action)
`hasColor`	function	**pop:** a color c **push:** list of beakers with chemical color c
`drain`	action	**pop:** a beaker b and a number or fraction a **perform:** remove a units of chemical (or all chemical if $a =$ `1/1`) from b
`pour`	action	**pop:** two beakers b_1 and b_2 **perform:** transfer all chemical from b_1 to b_2
`mix`	action	**pop:** a beaker b **perform:** turn the color of the chemical in b to `brown`
Additional tokens for the TANGRAMS domain A TANGRAMS world contains a row of tangram pieces with different shapes. The shapes are anonymized; a tangram can be referred to by an index or a history reference, but not by shape.		
`swap`	action	**pop:** two tangrams t_1 and t_2 **perform:** exchange the positions of t_1 and t_2
`remove`	action	**pop:** a tangram t **perform:** remove t from the stage
`add`	action	**pop:** a number i and a previously removed tangram t **perform:** insert t to position i
Additional tokens for the SCENE domain A SCENE world is a linear stage with 10 positions. Each position may be occupied by a person with a colored shirt and optionally a colored hat. There are usually 1-5 people on the stage.		
`noHat`	constant	**push:** pseudo-color (indicating that the person is not wearing a hat)
`hasShirt`, `hasHat`	function	**pop:** a color c **push:** the list of all people with shirt or hat color c
`hasShirtHat`	function	**pop:** two colors c_1 and c_2 **push:** the list of all people with shirt color c_1 and hat color c_2
`leftOf`, `rightOf`	function	**pop:** a person p **push:** the location index left or right of p
`create`	action	**pop:** a number i and two colors c_1, c_2 **perform:** add a new person at position i with shirt color c_1 and hat color c_2
`move`	action	**pop:** a person p and a number i **perform:** move p to position i
`swapHats`	action	**pop:** two people p_1 and p_2 **perform:** have p_1 and p_2 exchange their hats
`leave`	action	**pop:** a person p **perform:** remove p from the stage

Diversity driven attention model for query-based abstractive summarization

Abstract

Abstractive summarization aims to generate a shorter version of the document covering all the salient points in a compact and coherent fashion. On the other hand, query-based summarization highlights those points that are relevant in the context of a given query. The encode-attend-decode paradigm has achieved notable success in machine translation, extractive summarization, dialog systems, etc. But it suffers from the drawback of generation of repeated phrases. In this work we propose a model for the query-based summarization task based on the encode-attend-decode paradigm with two key additions (i) a query attention model (in addition to document attention model) which learns to focus on different portions of the query at different time steps (instead of using a static representation for the query) and (ii) a new diversity based attention model which aims to alleviate the problem of repeating phrases in the summary. In order to enable the testing of this model we introduce a new query-based summarization dataset building on debatepedia. Our experiments show that with these two additions the proposed model clearly outperforms vanilla encode-attend-decode models with a gain of 28% (absolute) in ROUGE-L scores.

1 Introduction

Over the past few years neural models based on the encode-attend-decode (Bahdanau et al., 2014) paradigm have shown great success in various natural language generation (NLG) tasks such as machine translation (Bahdanau et al., 2014), abstractive summarization ((Rush et al., 2015),(Nallapati et al., 2016)) dialog (Li et al., 2016), *etc*. One such NLG problem which has not received enough attention in the past is query based abstractive text summarization where the aim is to generate the summary of a document in the context of a query. In general, abstractive summarization, aims to cover all the salient points of a document in a compact and coherent fashion. On the other hand, query focused summarization highlights those points that are relevant in the context of the query. Thus given a document on "the super bowl", the query "How was the half-time show?", would result in a summary that would not cover the actual game itself.

Note that there has been some work on query based extractive summarization in the past where the aim is to simply extract the most salient sentence(s) from a document and treat these as a summary. There is no natural language generation involved. Since, we were interested in abstractive (as opposed to extractive) summarization we created a new dataset based on debatepedia. This dataset contains triplets of the form (query, document, summary). Further, each summary is abstractive and not extractive in the sense that the summary does not necessarily comprise of a sentence which is simply copied from the original document.

Using this dataset as a testbed, we focus on a recurring problem in models based on the encode-attend-decode paradigm. Specifically, it is observed that the summaries produced by such models contain repeated phrases. Table 1 shows a few such examples of summaries gener-

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1063–1072

Document Snippet: The "natural death" alternative to euthanasia is not keeping someone alive via life support until they die on life support. That would, indeed, be unnatural. The natural alternative is, instead, to allow them to die off of life support. **Query**: Is euthanasia better than withdrawing life support (non-treatment)? **Ground Truth Summary**: The alternative to euthanasia is a natural death without life support. **Predicted Summary**: the large to euthanasia is a natural death **life life** use
Document Snippet: Legalizing same-sex marriage would also be a recognition of basic American principles, and would represent the culmination of our nation's commitment to equal rights. It is, some have said, the last major civil-rights milestone yet to be surpassed in our two-century struggle to attain the goals we set for this nation at its formation. **Query:** Is gay marriage a civil right? **Ground Truth Summary**: Gay marriage is a fundamental equal right. **Predicted Summary**: gay marriage is a appropriate **right right**

Table 1: Examples showing repeated words in the output of encoder-decoder models

ated by such a model when trained on this new dataset. This problem has also been reported by (Chen et al., 2016) in the context of summarization and by (Sankaran et al., 2016) in the context of machine translation.

We first provide an intuitive explanation for this problem and then propose a solution for alleviating it. A typical encode-attend-decode model first computes a vectorial representation for the document and the query and then produces a contextual summary one word at a time. Each word is produced by feeding a new context vector to the decoder at each time step by attending to different parts of the document and query. If the decoder produces the same word or phrase repeatedly then it could mean that the context vectors fed to the decoder at these time steps are very similar.

We propose a model which explicitly prevents this by ensuring that successive context vectors are orthogonal to each other. Specifically, we subtract out any component that the current context vector has in the direction of the previous context vector. Notice that, we do not require the current context vector to be orthogonal to all previous context vectors but just its immediate predecessor. This enables the model to attend to words repeatedly if required later in the process. To account for the complete history (or all previous context vectors) we also propose an extension of this idea where we pass the sequence of context vectors through a LSTM (Hochreiter and Schmidhuber, 1997) and ensure that the current state produced by the LSTM is orthogonal to the history. At each time step, the state of the LSTM is then fed to the decoder to produce one word in the summary.

Our contributions can be summarized as follows: (i) We propose a new dataset for query based abstractive summarization and evaluate encode-attend-decode models on this dataset (ii) We study the problem of repeating phrases in NLG in the context of this dataset and propose two solutions for countering this problem. We show that our method outperforms a vanilla encoder-decoder model with a gain of 28% (absolute) in ROUGE-L score (iii) We also demonstrate that our method clearly outperforms a recent state of the art method proposed for handling the problem of repeating phrases with a gain of 7% (absolute) in ROUGE-L scores (iv) We do a qualitative analysis of the results and show that our model indeed produces outputs with fewer repetitions.

2 Related Work

Summarization has been studied in the context of text ((Mani, 2001), (Das and Martins, 2007), (Nenkova and McKeown, 2012)) as well as speech ((Zhu and Penn, 2006), (Zhu et al., 2009)). A vast majority of this work has focused on extractive summarization where the idea is to construct a summary by selecting the most relevant sentences from the document ((Neto et al., 2002), (Erkan and Radev, 2004), (Filippova and Altun, 2013), (Colmenares et al., 2015), (Riedhammer et al., 2010), (Ribeiro et al., 2013)). There has been some work on abstractive summarization in the context of DUC-2003 and DUC-2004 contests (Zajic et al.). We refer the reader to (Das and Martins, 2007) and (Nenkova and McKeown, 2012) for an excellent survey of

the field.

Recent research in abstractive summarization has focused on data driven neural models based on the encode-attend-decode paradigm (Bahdanau et al., 2014). For example, (Rush et al., 2015), report state of the art results on the GigaWord and DUC corpus using such a model. Similarly, the work of Lopyrev (2015) uses neural networks to generate news headline from short news stories. Chopra et al. (2016) extend the work of Rush et al. (2015) and report further improvements on the two datasets. Hu et al. (2015) introduced a dataset for Chinese short text summarization and evaluated a similar RNN encoder-decoder model on it.

One recurring problem in encoder-decoder models for NLG is that they often repeat the same phrase/word multiple times in the summary (at the cost of both coherency and fluency). Sankaran et al. (2016) study this problem in the context of MT and propose a temporal attention model which enforces the attention weights for successive time steps to be different from each other. Similarly, and more relevant to this work, Chen et al. (2016) propose a distraction based attention model which maintains a history of attention vectors and context vectors. It then subtracts this history from the current attention and context vector. When evaluated on our dataset their method performs poorly. This could be because their method is very aggressive in dealing with the history (as explained later in the Experiments section). On the other hand, our method has a better way of handling history (by passing context vectors through an LSTM recurrent network) which gives us the flexibility to forget/retain some portions of the history and at the same time produce diverse context vectors at successive time steps.

We evaluate our method in the context of query based abstractive summarization - a problem which has received almost no attention in the past due to unavailability of datasets. We create a new dataset for this task and show that our method indeed produces better output by reducing the number of repeated phrases produced by encoder decoder models.

Average number of words per		
Document	Summary	Query
66.4	11.16	9.97

Table 2: Average length of documents/queries/summaries in the dataset

3 Dataset

As mentioned earlier, there are no existing datasets for query based abstractive summarization. We create such a dataset from Debatepedia an encyclopedia of pro and con arguments and quotes on critical debate topics. There are 663 debates in the corpus (we have considered only those debates which have at least one query with one document). These 663 debates belong to 53 overlapping categories such as Politics, Law, Crime, Environment, Health, Morality, Religion, etc. A given topic can belong to more than one category. For example, the topic "Eye for an Eye philosophy" belongs to both "Law" as well as "Morality". The average number of queries per debate is 5 and the average number of documents per query is 4. Please refer to the dataset url[1] for more details about number of debates per category.

For example, Figure 1 shows the queries associated with the topic "Algae Biofuel". It also lists the set of documents and an abstractive summary associated with each query. As is obvious from the example, the summary is an abstractive summary and not extracted directly from the document. We crawled 12695 such {query, document, summary} triples from debatepedia (these were all the triples that were available). Table 2 reports the average length of the query, summary and documents in this dataset.

We used 10 fold cross validation for all our experiments. Each fold uses 80% of the documents for training, 10% for validation and 10% for testing.

4 Proposed model

Given a query $\mathbf{q} = q_1, q_2, ..., q_k$ containing k words, a document $\mathbf{d} = d_1, d_2, ..., d_n$ containing n words, the task is to generate a contextual summary $\mathbf{y} = y_1, y_2, ..., y_m$ containing

[1] http://www.cse.iitm.ac.in/~miteshk/datasets/qbas.html

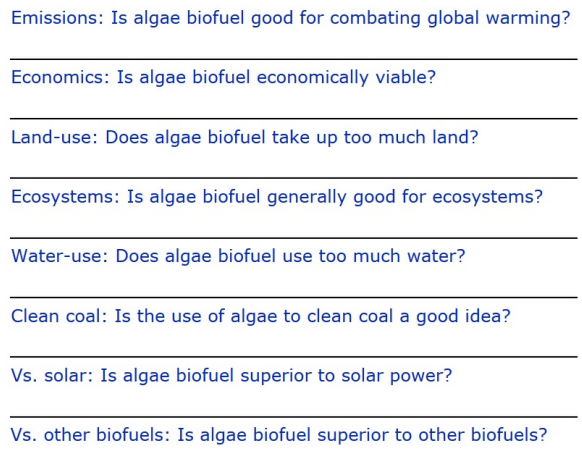

Figure 1: Queries associated with the topic "algae biofuel"

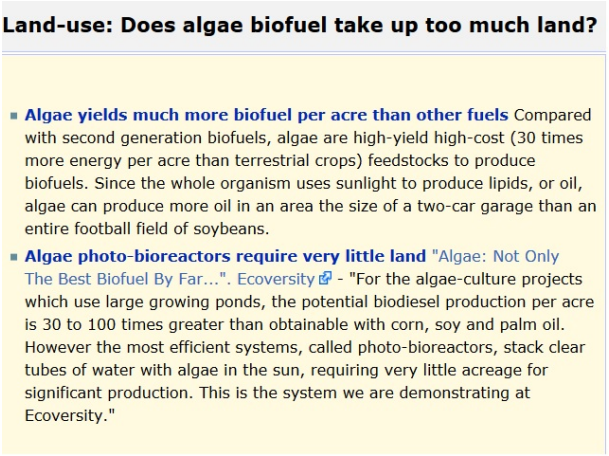

Figure 2: Documents and summaries for a given query

m words. This can be modeled as the problem of finding a $\mathbf{y}^*$ that maximizes the probability $p(\mathbf{y}|\mathbf{q}, \mathbf{d})$ which can be further decomposed as:

$$y^* = \arg\max_y \prod_{t=1}^{m} p(y_t|y_1, ..., y_{t-1}, \mathbf{q}, \mathbf{d}) \quad (1)$$

We now describe a way of modeling $p(y_t|y_1, ..., y_{t-1}, \mathbf{q}, \mathbf{d})$ using the neural encoder-attention-decoder paradigm. The proposed model contains the following components: (i) an encoder RNN for the query (ii) an encoder RNN for the document (iii) attention mechanism for the query (iv) attention mechanism for the document and (v) a decoder RNN. All the RNNs use a GRU cell.

Encoder for the query: We use a recurrent neural network with Gated Recurrent Units (GRU) for encoding the query. It reads the query $\mathbf{q} = q_1, q_2, ..., q_k$ from left to right and computes a hidden representation for each time-step as:

$$h_i^q = \text{GRU}_q(h_{i-1}^q, e(q_i)) \quad (2)$$

where $e(q_i) \in \mathbb{R}^d$ is the d-dimensional embedding of the query word q_i.

Encoder for the document: This is similar to the query encoder and reads the document $\mathbf{d} = d_1, d_2, ..., d_n$ from left to right and computes a hidden representation for each time-step as:

$$h_i^d = \text{GRU}_d(h_{i-1}^d, e(d_i)) \quad (3)$$

where $e(d_i) \in \mathbb{R}^d$ is the d-dimensional embedding of the document word d_i.

Attention mechanism for the query : At each time step, the decoder produces an output word by focusing on different portions of the query (document) with the help of a query (document) attention model. We first describe the query attention model which assigns weights $\alpha_{t,i}^q$ to each word in the query at each decoder timestep using the following equations.

$$a_{t,i}^q = v_q^T \tanh(W_q s_t + U_q h_i^q) \quad (4)$$

$$\alpha_{t,i}^q = \frac{\exp(a_{t,i}^q)}{\sum_{j=1}^{k} \exp(a_{t,j}^q)} \quad (5)$$

where s_t is the current state of the decoder at time step t (we will see an exact formula for this soon). $W_q \in \mathbb{R}^{l_2 \times l_1}$, $U_q \in \mathbb{R}^{l_2 \times l_2}$, $v_q \in \mathbb{R}^{l_2}$, l_1 is the size of the decoder's hidden state, l_2 is both the size of h_i^q and also the size of the final query representation at time step t, which is computed as:

$$q_t = \sum_{i=1}^{k} \alpha_{t,i}^q h_i^q \quad (6)$$

Attention mechanism for the document : We now describe the document attention model which assigns weights to each word in the document using the following equations.

$$a_{t,i}^d = v_d^T \tanh(W_d s_t + U_d h_i^d + Z q_t) \quad (7)$$

$$\alpha_{t,i}^d = \frac{\exp(a_{t,i}^d)}{\sum_{j=1}^{n} \exp(a_{t,j}^d)}$$

where s_t is the current state of the decoder at time step t (we will see an exact formula for this

soon). $W_d \in \mathbb{R}^{l_4 \times l_1}$, $U_d \in \mathbb{R}^{l_4 \times l_4}$, $Z \in \mathbb{R}^{l_4 \times l_2}$, $v_d \in \mathbb{R}^{l_2}$, l_4 is the size of h_i^d and also the size of the final document representation d_t which is passed to the decoder at time step t as:

$$d_t = \sum_{i=1}^{n} \alpha_{t,i}^d h_i^d \tag{8}$$

Note that d_t now encodes the relevant information from the document as well as the query (see Equation (7)) at time step t. We refer to this as the *context vector* for the decoder.

Decoder: The hidden state of the decoder s_t at each time t is again computed using a GRU as follows:

$$s_t = \text{GRU}_{dec}(s_{t-1}, [e(y_{t-1}), d_{t-1}]) \tag{9}$$

where, y_{t-1} gives a distribution over the vocabulary words at timestep $t-1$ and is computed as:

$$y_t = \text{softmax}(W_o f(W_{dec} s_t + V_{dec} d_t)) \tag{10}$$

where $W_o \in \mathbb{R}^{N \times l_1}$, $W_{dec} \in \mathbb{R}^{l_1 \times l_1}$, $V_{dec} \in \mathbb{R}^{l_1 \times l_4}$, N is the vocabulary size, y_t is the final output of the model which defines a probability distribution over the output vocabulary. This is exactly the quantity defined in Equation (1) that we wanted to model $(p(y_t|y_1, ..., y_{t-1}, \mathbf{q}, \mathbf{d}))$. Further, note that, $e(y_{t-1})$ is the d-dimensional embedding of the word which has the highest probability under the distribution y_{t-1}. Also $[e(y_{t-1}), d_{t-1}]$ means a concatenation of the vectors $e(y_{t-1}), d_{t-1}$. We chose f to be the identity function.

The model as described above is an instantiation of the encoder-attention-decoder idea applied to query based abstractive summarization. As mentioned earlier (and demonstrated later through experiments), this model suffers from the problem of repeating the same phrase/word in the output. We now propose a new attention model which we refer to as diversity based attention model to address this problem.

4.1 Diversity based attention model

As hypothesized earlier, if the decoder produces the same phrase/word multiple times then it is possible that the context vectors being fed to the decoder at consecutive time steps are very similar. We propose four models ($\mathbf{D_1}$, $\mathbf{D_2}$, $\mathbf{SD_1}$, $\mathbf{SD_2}$) to directly address this problem.

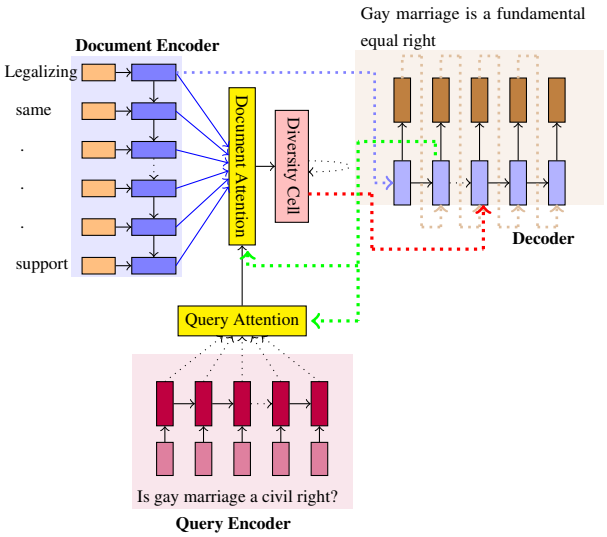

Figure 3: Proposed model for Query based Abstractive Summarization with (i) query encoder (ii) document encoder (iii) query attention model (iv) diversity based document attention model and (v) decoder. The green and red arrows show the connections for timestep 3 of the decoder.

$\mathbf{D_1}$: In this model, after computing d_t as described in Equation (8), we make it orthogonal to the context vector at time $t-1$:

$$d_t' = d_t - \frac{d_t^T d_{t-1}'}{d_{t-1}'^T d_{t-1}'} d_{t-1}' \tag{11}$$

$\mathbf{SD_1}$: The above model imposes a hard orthogonality constraint on the context vector(d_t'). We also propose a relaxed version of the above model which uses a gating parameter. This gating parameter decides what fraction of the previous context vector should be subtracted from the current context vector using the following equations:

$$\gamma_t = W_g d_{t-1} + b_g$$
$$d_t' = d_t - \gamma_t \frac{d_t^T d_{t-1}'}{d_{t-1}'^T d_{t-1}'} d_{t-1}'$$

where $W_g \in \mathbb{R}^{l_4 \times l_4}$, $b_g \in \mathbb{R}^{l_4}$, l_4 is the dimension of d_t as defined in equation (8).

$\mathbf{D_2}$: The above model only ensures that the current context vector is diverse w.r.t the previous context vector. It ignores all history before time step $t-1$. To account for the history, we treat successive context vectors as a sequence and use

a modified LSTM cell to compute the new state at each time step. Specifically, we use the following set of equations to compute a diverse context at time t:

$$
\begin{aligned}
i_t &= \sigma(W_i d_t + U_i h_{t-1} + b_i) \\
f_t &= \sigma(W_f d_t + U_f h_{t-1} + b_f) \\
o_t &= \sigma(W_o d_t + U_o h_{t-1} + b_o) \\
\hat{c}_t &= \tanh(W_c d_t + U_c h_{t-1} + b_c) \\
c_t &= i_t \odot \hat{c}_t + f_t \odot c_{t-1} \\
c_t^{diverse} &= c_t - \frac{{c_t}^T c_{t-1}}{c_{t-1}^T c_{t-1}} c_{t-1} \qquad (12) \\
h_t &= o_t \odot \tanh(c_t^{diverse}) \\
d_t^{'} &= h_t \qquad (13)
\end{aligned}
$$

where $W_i, W_f, W_o, W_c \in \mathbb{R}^{l_5 \times l_4}$, $U_i, U_f, U_o, U_c \in \mathbb{R}^{l_5 \times l_4}$, d_t is the l_4-dimensional output of Equation (8); l_5 is number of hidden units in the LSTM cell. This final $d_t^{'}$ from Equation (13) is then used in Equation (9). Note that Equation (12) ensures that state of the LSTM at time step t is orthogonal to the previous history. Figure 3 shows a pictorial representation of the model with a diversity LSTM cell.

$\mathbf{SD_2}$: This model again uses a relaxed version of the orthogonality constraint used in $\mathbf{D_2}$. Specifically, we define a gating parameter g_t and replace (12) above by (14) as define below:

$$
\begin{aligned}
g_t &= \sigma(W_g d_t + U_g h_{t-1} + b_o) \\
c_t^{diverse} &= c_t - g_t \frac{{c_t}^T c_{t-1}}{c_{t-1}^T c_{t-1}} c_{t-1} \qquad (14)
\end{aligned}
$$

where $W_g \in \mathbb{R}^{l_5 \times l_4}$, $U_g \in \mathbb{R}^{l_5 \times l_4}$

5 Baseline Methods

We compare with two recently proposed baseline diversity methods (Chen et al., 2016) as described below. Note that these methods were proposed in the context of abstractive summarization (not query based abstractive summarization) and we adapt them for the task of query based abstractive summarization. Below we just highlight the key differences from our model in computing the context vector $d_t^{'}$ passed to the decoder.

M1: This model accumulates all the previous context vectors as $\sum_{j=1}^{t-1} d_j^{'}$ and incorporates this history while computing a diverse context vector:

$$
d_t^{'} = \tanh(W_c d_t - U_c \sum_{j=1}^{t-1} d_j^{'}) \qquad (15)
$$

where $W_c, U_c \in \mathbb{R}^{l_4 \times l_4}$ are diagonal matrices. We then use this diversity driven context $d_t^{'}$ in Equation (9) and (10).

M2: In this model, in addition to computing a diverse context as described in Equation (15), the attention weights at each time step are also forced to be diverse from the attention weights at the previous time step.

$$
\alpha_{t,i}^{'} = v_a^T \tanh(W_a s_t^{'} + U_a d_t - b_a \sum_{j=1}^{t-1} \alpha_{j,i}^{'})
$$

where $W_a \in \mathbb{R}^{l_1 \times l_1}$, $U_a \in \mathbb{R}^{l_1 \times l_4}$, $b_a, v_a \in \mathbb{R}^{l_1}$, l_1 is the number of hidden units in the decoder GRU. Once again, they maintain a history of attention weights and compute a diverse attention vector by subtracting the history from the current attention vector.

6 Experimental Setup

We evaluate our models on the dataset described in section 3. Note that there are no prior baselines on query based abstractive summarization so we could only compare with different variations of the encoder decoder models as described above. Further, we compare our diversity based attention models with existing models for diversity by suitably adapting them to this problem as described earlier. Specifically, we compare the performance of the following models:

- **Vanilla e-a-d**: This is the vanilla encoder-attention-decoder model adapted to the problem of abstractive summarization. It contains the following components (i) document encoder (ii) document attention model (iii) decoder. It does not contain an encoder or attention model for the query. This helps us understand the importance of the query.
- $\mathbf{Query}_{enc}$: This model contains the query encoder in addition to the three components used in the vanilla model above. It does not contain any attention model for the query.

- $\mathbf{Query}_{att}$: This model contains the query attention model in addition to all the components in $Query_{enc}$.
- $\mathbf{D}_1$: The diversity attention model as described in Section 4.1.
- $\mathbf{D}_2$: The LSTM based diversity attention model as described in Section 4.1.
- $\mathbf{SD}_1$: The soft diversity attention model as described in Section 4.1
- $\mathbf{SD}_2$: The soft LSTM based diversity attention model as described in Section 4.1
- $\mathbf{B}_1$: Diversity cell in Figure3 is replaced by the basic LSTM cell (i.e. $c_t^{diverse} = c_t$ instead of using Equation (12). This helps us understand whether simply using an LSTM to track the history of context vectors (without imposing a diversity constraint) is sufficient.
- $\mathbf{M}_1$: The baseline model which operates on the context vector as described in Section 5.
- $\mathbf{M}_2$: The baseline model which operates on the attention weights in addition to the context vector as described in Section 5.

We used 80% of the data for training, 10% for validation and 10% for testing. We create 10 such folds and report the average Rouge-1, Rouge-2, Rouge-L scores across the 10 folds. The hyperparameters (batch size and GRU cell sizes) of all the models are tuned on the validation set. We tried the following batch sizes : 32, 64 and the following GRU cell sizes 200, 300, 400. We used Adam (Kingma and Ba, 2014) as the optimization algorithm with the initial learning rate set to 0.0004, $\beta_1 = 0.9$, $\beta_2 = 0.999$. We used pre-trained publicly available Glove word embeddings[2] and fine-tuned them during training. The same word embeddings are used for the query words and the document words.

Table 3 summarizes the results of our experiments.

[2]http://nlp.stanford.edu/projects/glove/

Models	ROUGE-1	ROUGE-2	ROUGE-L
Vanilla e-a-d	13.73	2.06	12.84
$Query_{enc}$	20.87	3.39	19.38
$Query_{att}$	29.28	10.24	28.21
B1	23.18	6.46	22.03
M1	33.06	13.35	32.17
M2	18.42	4.47	17.45
D1	33.85	13.65	32.99
SD1	31.36	11.23	30.5
D2	38.12	16.76	37.31
SD2	**41.26**	**18.75**	**40.43**

Table 3: Performance on various models using full-length ROUGE metrics

7 Discussions

In this section, we discuss the results of the experiments reported in Table 3.

1. Effect of Query: Comparing rows 1 and 2 we observe that adding an encoder for the query and allowing it to influence the outputs of the decoder indeed improves the performance. This is expected as the query contains some keywords which could help in sharpening the focus of the summary.

2. Effect of Query attention model: Comparing rows 2 and 3 we observe that using an attention model to dynamically compute the query representation at each time step improves the results. This suggests that the attention model indeed learns to focus on relevant portions of the query at different time steps.

3. Effect of Diversity models: All the diversity models introduced in the paper (rows 7, 8, 9, 10) give significant improvement over the non-diversity models. In particular, the modified LSTM based diversity model gives the best results. This is indeed very encouraging and Table 4 shows some sample summaries comparing the performance of different models.

4. Comparison with baseline diversity models: The baseline diversity model M1 performs at par with our models D1 and SD1 but not as good as D2 and SD2. However, the model M2 performs very poorly. We believe that simultaneously adding a constraint on the context vectors as well as attention weights (as is indeed the case with M2) is a bit too aggressive and leads to poor performance (although this needs further investigation).

5. Quantitative Analysis: In addition to the qualitative analysis reported in Table 4 we also did a quantitative analysis by counting the num-

Source: Although cannabis does indeed have some harmful effects, it is no more harmful than legal substances like alcohol and tobacco. As a matter of fact, research by the British Medical Association shows that nicotine is far more addictive than cannabis. Furthermore, the consumption of alcohol and the smoking of cigarettes cause more deaths per year than does the use of cannabis (e.g. through lung cancer, stomach ulcers, accidents caused by drunk driving etc.). The legalization of cannabis will remove an anomaly in the law whereby substances that are more dangerous than cannabis are legal whilst the possession and use of cannabis remains unlawful. **Query:** is marijuana harmless enough to be considered a medicine **G:** marijuana is no more harmful than tobacco and alcohol $Query_{attn}$: marijuana is no the **drug drug** for **tobacco and tobacco** **D1:** marijuana is no more harmful than tobacco and tobacco **SD1:** marijuana is more for evidence than tobacco and health **D2:** marijuana is no more harmful than tobacco and use **SD2:** marijuana is no more harmful than tobacco and alcohol
Source: Fuel cell critics point out that hydrogen is flammable, but so is gasoline. Unlike gasoline, which can pool up and burn for a long time, hydrogen dissipates rapidly. Gas tanks tend to be easily punctured, thin-walled containers, while the latest hydrogen tanks are made from Kevlar. Also, gaseous hydrogen isn't the only method of storage under consideration–BMW is looking at liquid storage while other researchers are looking at chemical compound storage, such as boron pellets. **Query:** safety are hydrogen fuel cell vehicles safe **G:** hydrogen in cars is less dangerous than gasoline $Query_{attn}$: hydrogen is **hydrogen hydrogen hydrogen** fuel energy **D1:**hydrogen in cars is less natural than gasoline **SD1:** hydrogen in cars is reduce risk than fuel **D2:** hydrogen in waste is less effective than gasoline **SD2:**hydrogen in cars is less dangerous than gasoline
Source: The basis of all animal rights should be the Golden Rule: we should treat them as we would wish them to treat us, were any other species in our dominant position. **Query:** do animals have rights that makes eating them inappropriate **G:** animals should be treated as we would want to be treated $Query_{att}$: animals should be **treated** as we would protect to be **treated** **D1:** animals should be **treated** as we most individual to be **treated** **SD1:** animals should be **treated** as we would physically to be treated **D2:** animals should be **treated** as we would illegal to be **treated** **SD2:** animals should be **treated** as those would want to be **treated**

Table 4: Summaries generated by different models. In general, we observed that the baseline models which do not use a diversity based attention model tend to produce more repetitions. Notice that the last example shows that our model is not very aggressive in dealing with the history and is able to produce valid repetitions (treated ... treated) when needed

ber of sentences containing repeated words generated by different models. Specifically for the 1268 test instances we counted the number of sentences containing repeated words as generated by different modes. Table 5 summarizes this analysis.

Model	Number
$\mathbf{Query}_{attn}$	498
$\mathbf{SD}_1$	352
$\mathbf{SD}_2$	344
$\mathbf{D}_1$	191
$\mathbf{D}_2$	179

Table 5: Average number of sentences with repeating words across 10 folds

8 Conclusion

In this work we proposed a query-based summarization method. The unique feature of

the model is a novel diversification mechanism based on successive orthogonalization. This gives us the flexibility to: (i) provide diverse context vectors at successive time steps and (ii) pay attention to words repeatedly if need be later in the summary (as opposed to existing models which aggressively delete the history). We also introduced a new data set and empirically verified we perform significantly better (gain of 28% (absolute) in ROUGE-L score) than applying a plain encode-attend-decode mechanism to this problem. We observe that adding an attention mechanism on the query string gives significant improvements. We also compare with a state of the art diversity model and outperform it by a good margin (gain of 7% (absolute) in ROUGE-L score). The diversification model proposed is general enough to apply to other NLG tasks with suitable modifications and we are currently working on extending this to dialog systems and general summarization.

Abstract

Neural sequence-to-sequence models have provided a viable new approach for *abstractive* text summarization (meaning they are not restricted to simply selecting and rearranging passages from the original text). However, these models have two shortcomings: they are liable to reproduce factual details inaccurately, and they tend to repeat themselves. In this work we propose a novel architecture that augments the standard sequence-to-sequence attentional model in two orthogonal ways. First, we use a hybrid pointer-generator network that can copy words from the source text via *pointing*, which aids accurate reproduction of information, while retaining the ability to produce novel words through the *generator*. Second, we use *coverage* to keep track of what has been summarized, which discourages repetition. We apply our model to the *CNN / Daily Mail* summarization task, outperforming the current abstractive state-of-the-art by at least 2 ROUGE points.

Original Text (truncated): lagos, nigeria (cnn) a day after winning nigeria's presidency, ***muhammadu buhari*** told cnn's christiane amanpour that **he plans to aggressively fight corruption that has long plagued nigeria** and go after the root of the nation's unrest. *buhari* said he'll "rapidly give attention" to curbing violence in the northeast part of nigeria, where the terrorist group boko haram operates. by cooperating with neighboring nations chad, cameroon and niger, **he said his administration is confident it will be able to thwart criminals** and others contributing to nigeria's instability. for the first time in nigeria's history, the opposition defeated the ruling party in democratic elections. *buhari* defeated incumbent goodluck jonathan by about 2 million votes, according to nigeria's independent national electoral commission. **the win comes after a long history of military rule, coups and botched attempts at democracy in africa's most populous nation.**

Baseline Seq2Seq + Attention: **UNK UNK** says his administration is confident it will be able to **destabilize nigeria's economy**. **UNK** says his administration is confident it will be able to thwart criminals and other **nigerians**. **he says the country has long nigeria and nigeria's economy.**

Pointer-Gen: *muhammadu buhari* says he plans to aggressively fight corruption **in the northeast part of nigeria**. he says he'll "rapidly give attention" to curbing violence **in the northeast part of nigeria**. he says his administration is confident it will be able to thwart criminals.

Pointer-Gen + Coverage: *muhammadu buhari* says he plans to aggressively fight corruption that has long plagued nigeria. he says his administration is confident it will be able to thwart criminals. the win comes after a long history of military rule, coups and botched attempts at democracy in africa's most populous nation.

Figure 1: Comparison of output of 3 abstractive summarization models on a news article. The baseline model makes **factual errors**, a **nonsensical sentence** and struggles with OOV words *muhammadu buhari*. The pointer-generator model is accurate but **repeats itself**. Coverage eliminates repetition. The final summary is composed from **several fragments**.

1 Introduction

Summarization is the task of condensing a piece of text to a shorter version that contains the main information from the original. There are two broad approaches to summarization: *extractive* and *abstractive*. *Extractive methods* assemble summaries exclusively from passages (usually whole sentences) taken directly from the source text, while *abstractive methods* may generate novel words and phrases not featured in the source text – as a human-written abstract usually does. The extractive approach is easier, because copying large chunks of text from the source document ensures baseline levels of grammaticality and accuracy. On the other hand, sophisticated abilities that are crucial to high-quality summarization, such as paraphrasing, generalization, or the incorporation of real-world knowledge, are possible only in an abstractive framework (see Figure 5).

Due to the difficulty of abstractive summarization, the great majority of past work has been extractive (Kupiec et al., 1995; Paice, 1990; Saggion and Poibeau, 2013). However, the recent success of *sequence-to-sequence* models (Sutskever

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1073–1083
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1099

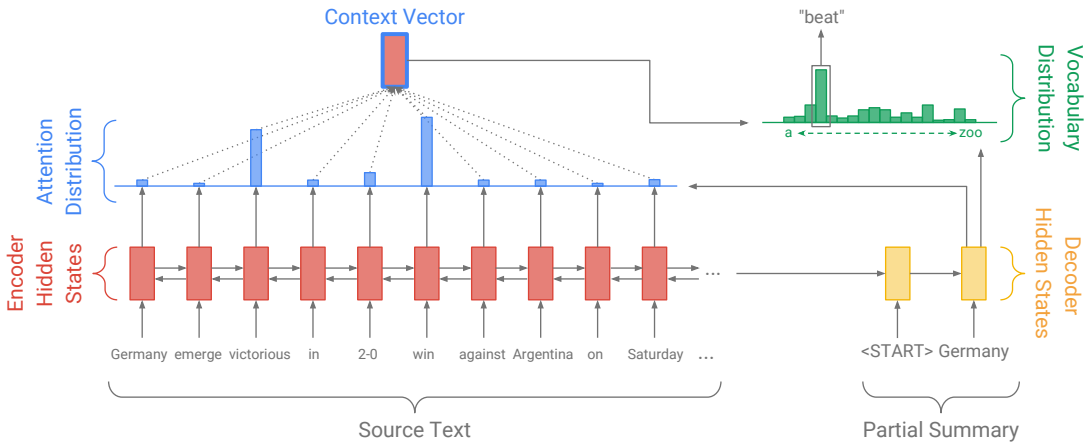

Figure 2: Baseline sequence-to-sequence model with attention. The model may attend to relevant words in the source text to generate novel words, e.g., to produce the novel word *beat* in the abstractive summary *Germany* ***beat*** *Argentina 2-0* the model may attend to the words *victorious* and *win* in the source text.

et al., 2014), in which recurrent neural networks (RNNs) both read and freely generate text, has made abstractive summarization viable (Chopra et al., 2016; Nallapati et al., 2016; Rush et al., 2015; Zeng et al., 2016). Though these systems are promising, they exhibit undesirable behavior such as inaccurately reproducing factual details, an inability to deal with out-of-vocabulary (OOV) words, and repeating themselves (see Figure 1).

In this paper we present an architecture that addresses these three issues in the context of multi-sentence summaries. While most recent abstractive work has focused on headline generation tasks (reducing one or two sentences to a single headline), we believe that longer-text summarization is both more challenging (requiring higher levels of abstraction while avoiding repetition) and ultimately more useful. Therefore we apply our model to the recently-introduced *CNN/ Daily Mail* dataset (Hermann et al., 2015; Nallapati et al., 2016), which contains news articles (39 sentences on average) paired with multi-sentence summaries, and show that we outperform the state-of-the-art abstractive system by at least 2 ROUGE points.

Our hybrid *pointer-generator* network facilitates copying words from the source text via *pointing* (Vinyals et al., 2015), which improves accuracy and handling of OOV words, while retaining the ability to *generate* new words. The network, which can be viewed as a balance between extractive and abstractive approaches, is similar to Gu et al.'s (2016) CopyNet and Miao and Blunsom's (2016) Forced-Attention Sentence Compression, that were applied to short-text summarization. We propose a novel variant of the *coverage vector* (Tu et al., 2016) from Neural Machine Translation, which we use to track and control coverage of the source document. We show that coverage is remarkably effective for eliminating repetition.

2 Our Models

In this section we describe (1) our baseline sequence-to-sequence model, (2) our pointer-generator model, and (3) our coverage mechanism that can be added to either of the first two models. The code for our models is available online.[1]

2.1 Sequence-to-sequence attentional model

Our baseline model is similar to that of Nallapati et al. (2016), and is depicted in Figure 2. The tokens of the article w_i are fed one-by-one into the encoder (a single-layer bidirectional LSTM), producing a sequence of *encoder hidden states* h_i. On each step t, the decoder (a single-layer unidirectional LSTM) receives the word embedding of the previous word (while training, this is the previous word of the reference summary; at test time it is the previous word emitted by the decoder), and has *decoder state* s_t. The *attention distribution* a^t is calculated as in Bahdanau et al. (2015):

$$e_i^t = v^T \tanh(W_h h_i + W_s s_t + b_{\text{attn}}) \quad (1)$$

$$a^t = \text{softmax}(e^t) \quad (2)$$

where v, W_h, W_s and b_{attn} are learnable parameters. The attention distribution can be viewed as

[1] www.github.com/abisee/pointer-generator

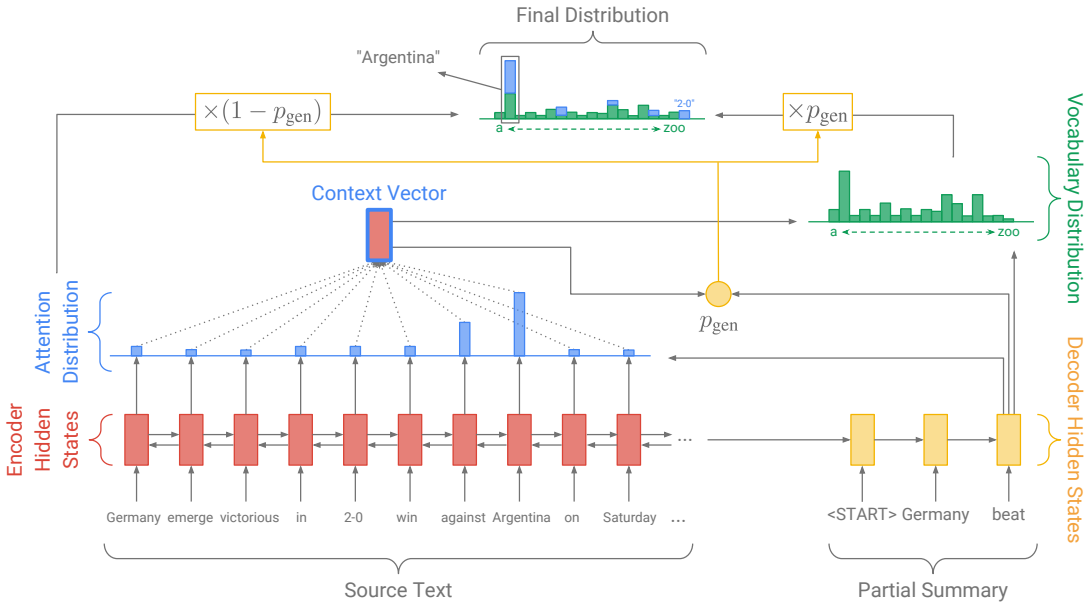

Figure 3: Pointer-generator model. For each decoder timestep a generation probability $p_{\text{gen}} \in [0,1]$ is calculated, which weights the probability of *generating* words from the vocabulary, versus *copying* words from the source text. The vocabulary distribution and the attention distribution are weighted and summed to obtain the final distribution, from which we make our prediction. Note that out-of-vocabulary article words such as *2-0* are included in the final distribution. Best viewed in color.

a probability distribution over the source words, that tells the decoder where to look to produce the next word. Next, the attention distribution is used to produce a weighted sum of the encoder hidden states, known as the *context vector* h_t^*:

$$h_t^* = \sum_i a_i^t h_i \tag{3}$$

The context vector, which can be seen as a fixed-size representation of what has been read from the source for this step, is concatenated with the decoder state s_t and fed through two linear layers to produce the vocabulary distribution P_{vocab}:

$$P_{\text{vocab}} = \text{softmax}(V'(V[s_t, h_t^*] + b) + b') \tag{4}$$

where V, V', b and b' are learnable parameters. P_{vocab} is a probability distribution over all words in the vocabulary, and provides us with our final distribution from which to predict words w:

$$P(w) = P_{\text{vocab}}(w) \tag{5}$$

During training, the loss for timestep t is the negative log likelihood of the target word w_t^* for that timestep:

$$\text{loss}_t = -\log P(w_t^*) \tag{6}$$

and the overall loss for the whole sequence is:

$$\text{loss} = \frac{1}{T}\sum_{t=0}^{T} \text{loss}_t \tag{7}$$

2.2 Pointer-generator network

Our pointer-generator network is a hybrid between our baseline and a pointer network (Vinyals et al., 2015), as it allows both copying words via pointing, and generating words from a fixed vocabulary. In the pointer-generator model (depicted in Figure 3) the attention distribution a^t and context vector h_t^* are calculated as in section 2.1. In addition, the *generation probability* $p_{\text{gen}} \in [0,1]$ for timestep t is calculated from the context vector h_t^*, the decoder state s_t and the decoder input x_t:

$$p_{\text{gen}} = \sigma(w_{h^*}^T h_t^* + w_s^T s_t + w_x^T x_t + b_{\text{ptr}}) \tag{8}$$

where vectors w_{h^*}, w_s, w_x and scalar b_{ptr} are learnable parameters and σ is the sigmoid function. Next, p_{gen} is used as a soft switch to choose between *generating* a word from the vocabulary by sampling from P_{vocab}, or *copying* a word from the input sequence by sampling from the attention distribution a^t. For each document let the *extended vocabulary* denote the union of the vocabulary, and all words appearing in the source document. We obtain the following probability distribution over the extended vocabulary:

$$P(w) = p_{\text{gen}} P_{\text{vocab}}(w) + (1 - p_{\text{gen}}) \sum_{i:w_i=w} a_i^t \tag{9}$$

Note that if w is an out-of-vocabulary (OOV) word, then $P_{\text{vocab}}(w)$ is zero; similarly if w does

not appear in the source document, then $\sum_{i:w_i=w} a_i^t$ is zero. The ability to produce OOV words is one of the primary advantages of pointer-generator models; by contrast models such as our baseline are restricted to their pre-set vocabulary.

The loss function is as described in equations (6) and (7), but with respect to our modified probability distribution $P(w)$ given in equation (9).

2.3 Coverage mechanism

Repetition is a common problem for sequence-to-sequence models (Tu et al., 2016; Mi et al., 2016; Sankaran et al., 2016; Suzuki and Nagata, 2016), and is especially pronounced when generating multi-sentence text (see Figure 1). We adapt the *coverage model* of Tu et al. (2016) to solve the problem. In our coverage model, we maintain a *coverage vector* c^t, which is the sum of attention distributions over all previous decoder timesteps:

$$c^t = \sum_{t'=0}^{t-1} a^{t'} \tag{10}$$

Intuitively, c^t is a (unnormalized) distribution over the source document words that represents the degree of coverage that those words have received from the attention mechanism so far. Note that c^0 is a zero vector, because on the first timestep, none of the source document has been covered.

The coverage vector is used as extra input to the attention mechanism, changing equation (1) to:

$$e_i^t = v^T \tanh(W_h h_i + W_s s_t + w_c c_i^t + b_{\text{attn}}) \tag{11}$$

where w_c is a learnable parameter vector of same length as v. This ensures that the attention mechanism's current decision (choosing where to attend next) is informed by a reminder of its previous decisions (summarized in c^t). This should make it easier for the attention mechanism to avoid repeatedly attending to the same locations, and thus avoid generating repetitive text.

We find it necessary (see section 5) to additionally define a *coverage loss* to penalize repeatedly attending to the same locations:

$$\text{covloss}_t = \sum_i \min(a_i^t, c_i^t) \tag{12}$$

Note that the coverage loss is bounded; in particular $\text{covloss}_t \leq \sum_i a_i^t = 1$. Equation (12) differs from the coverage loss used in Machine Translation. In MT, we assume that there should be a roughly one-to-one translation ratio; accordingly the final coverage vector is penalized if it is more or less than 1. Our loss function is more flexible: because summarization should not require uniform coverage, we only penalize the overlap between each attention distribution and the coverage so far – preventing repeated attention. Finally, the coverage loss, reweighted by some hyperparameter λ, is added to the primary loss function to yield a new composite loss function:

$$\text{loss}_t = -\log P(w_t^*) + \lambda \sum_i \min(a_i^t, c_i^t) \tag{13}$$

3 Related Work

Neural abstractive summarization. Rush et al. (2015) were the first to apply modern neural networks to abstractive text summarization, achieving state-of-the-art performance on DUC-2004 and Gigaword, two sentence-level summarization datasets. Their approach, which is centered on the attention mechanism, has been augmented with recurrent decoders (Chopra et al., 2016), Abstract Meaning Representations (Takase et al., 2016), hierarchical networks (Nallapati et al., 2016), variational autoencoders (Miao and Blunsom, 2016), and direct optimization of the performance metric (Ranzato et al., 2016), further improving performance on those datasets.

However, large-scale datasets for summarization of *longer* text are rare. Nallapati et al. (2016) adapted the DeepMind question-answering dataset (Hermann et al., 2015) for summarization, resulting in the *CNN/Daily Mail* dataset, and provided the first abstractive baselines. The same authors then published a neural *extractive* approach (Nallapati et al., 2017), which uses hierarchical RNNs to select sentences, and found that it significantly outperformed their abstractive result with respect to the ROUGE metric. To our knowledge, these are the only two published results on the full dataset.

Prior to modern neural methods, abstractive summarization received less attention than extractive summarization, but Jing (2000) explored cutting unimportant parts of sentences to create summaries, and Cheung and Penn (2014) explore sentence fusion using dependency trees.

Pointer-generator networks. The pointer network (Vinyals et al., 2015) is a sequence-to-sequence model that uses the soft attention distribution of Bahdanau et al. (2015) to produce an output sequence consisting of elements from

the input sequence. The pointer network has been used to create hybrid approaches for NMT (Gulcehre et al., 2016), language modeling (Merity et al., 2016), and summarization (Gu et al., 2016; Gulcehre et al., 2016; Miao and Blunsom, 2016; Nallapati et al., 2016; Zeng et al., 2016).

Our approach is close to the Forced-Attention Sentence Compression model of Miao and Blunsom (2016) and the CopyNet model of Gu et al. (2016), with some small differences: (i) We calculate an explicit switch probability p_{gen}, whereas Gu et al. induce competition through a shared softmax function. (ii) We recycle the attention distribution to serve as the copy distribution, but Gu et al. use two separate distributions. (iii) When a word appears multiple times in the source text, we sum probability mass from all corresponding parts of the attention distribution, whereas Miao and Blunsom do not. Our reasoning is that (i) calculating an explicit p_{gen} usefully enables us to raise or lower the probability of all generated words or all copy words at once, rather than individually, (ii) the two distributions serve such similar purposes that we find our simpler approach suffices, and (iii) we observe that the pointer mechanism often copies a word while attending to multiple occurrences of it in the source text.

Our approach is considerably different from that of Gulcehre et al. (2016) and Nallapati et al. (2016). Those works train their pointer components to activate only for out-of-vocabulary words or named entities (whereas we allow our model to freely learn when to use the pointer), and they do not mix the probabilities from the copy distribution and the vocabulary distribution. We believe the mixture approach described here is better for abstractive summarization – in section 6 we show that the copy mechanism is vital for accurately reproducing rare but in-vocabulary words, and in section 7.2 we observe that the mixture model enables the language model and copy mechanism to work together to perform abstractive copying.

Coverage. Originating from Statistical Machine Translation (Koehn, 2009), coverage was adapted for NMT by Tu et al. (2016) and Mi et al. (2016), who both use a GRU to update the coverage vector each step. We find that a simpler approach – summing the attention distributions to obtain the coverage vector – suffices. In this respect our approach is similar to Xu et al. (2015), who apply a coverage-like method to image captioning, and Chen et al. (2016), who also incorporate a coverage mechanism (which they call 'distraction') as described in equation (11) into neural summarization of longer text.

Temporal attention is a related technique that has been applied to NMT (Sankaran et al., 2016) and summarization (Nallapati et al., 2016). In this approach, each attention distribution is divided by the sum of the previous, which effectively dampens repeated attention. We tried this method but found it too destructive, distorting the signal from the attention mechanism and reducing performance. We hypothesize that an early intervention method such as coverage is preferable to a post hoc method such as temporal attention – it is better to *inform* the attention mechanism to help it make better decisions, than to *override* its decisions altogether. This theory is supported by the large boost that coverage gives our ROUGE scores (see Table 1), compared to the smaller boost given by temporal attention for the same task (Nallapati et al., 2016).

4 Dataset

We use the *CNN/Daily Mail* dataset (Hermann et al., 2015; Nallapati et al., 2016), which contains online news articles (781 tokens on average) paired with multi-sentence summaries (3.75 sentences or 56 tokens on average). We used scripts supplied by Nallapati et al. (2016) to obtain the same version of the the data, which has 287,226 training pairs, 13,368 validation pairs and 11,490 test pairs. Both the dataset's published results (Nallapati et al., 2016, 2017) use the *anonymized* version of the data, which has been pre-processed to replace each named entity, e.g., *The United Nations*, with its own unique identifier for the example pair, e.g., `@entity5`. By contrast, we operate directly on the original text (or *non-anonymized* version of the data),[2] which we believe is the favorable problem to solve because it requires no pre-processing.

5 Experiments

For all experiments, our model has 256-dimensional hidden states and 128-dimensional word embeddings. For the pointer-generator models, we use a vocabulary of 50k words for both source and target – note that due to the pointer network's ability to handle OOV words, we can use

extractive model (Nallapati et al., 2017)*	39.6	16.2	35.3	-	-

Table 1: ROUGE F_1 and METEOR scores on the test set. Models and baselines in the top half are abstractive, while those in the bottom half are extractive. Those marked with * were trained and evaluated on the anonymized dataset, and so are not strictly comparable to our results on the original text. All our ROUGE scores have a 95% confidence interval of at most ± 0.25 as reported by the official ROUGE script. The METEOR improvement from the 50k baseline to the pointer-generator model, and from the pointer-generator to the pointer-generator+coverage model, were both found to be statistically significant using an approximate randomization test with $p < 0.01$.

a smaller vocabulary size than Nallapati et al.'s (2016) 150k source and 60k target vocabularies. For the baseline model, we also try a larger vocabulary size of 150k.

Note that the pointer and the coverage mechanism introduce very few additional parameters to the network: for the models with vocabulary size 50k, the baseline model has 21,499,600 parameters, the pointer-generator adds 1153 extra parameters (w_{h^*}, w_s, w_x and b_{ptr} in equation 8), and coverage adds 512 extra parameters (w_c in equation 11).

Unlike Nallapati et al. (2016), we do not pretrain the word embeddings – they are learned from scratch during training. We train using Adagrad (Duchi et al., 2011) with learning rate 0.15 and an initial accumulator value of 0.1. (This was found to work best of Stochastic Gradient Descent, Adadelta, Momentum, Adam and RMSProp). We use gradient clipping with a maximum gradient norm of 2, but do not use any form of regularization. We use loss on the validation set to implement early stopping.

During training and at test time we truncate the article to 400 tokens and limit the length of the summary to 100 tokens for training and 120 tokens at test time.[3] This is done to expedite training and testing, but we also found that truncating the article can *raise* the performance of the model (see section 7.1 for more details). For training, we found it efficient to start with highly-truncated sequences, then raise the maximum length once converged. We train on a single Tesla K40m GPU with a batch size of 16. At test time our summaries are produced using beam search with beam size 4.

We trained both our baseline models for about 600,000 iterations (33 epochs) – this is similar to the 35 epochs required by Nallapati et al.'s (2016) best model. Training took 4 days and 14 hours for the 50k vocabulary model, and 8 days 21 hours for the 150k vocabulary model. We found the pointer-generator model quicker to train, requiring less than 230,000 training iterations (12.8 epochs); a total of 3 days and 4 hours. In particular, the pointer-generator model makes much quicker progress in the early phases of training. To obtain our final coverage model, we added the coverage mechanism with coverage loss weighted to $\lambda = 1$ (as described in equation 13), and trained for a further 3000 iterations (about 2 hours). In this time the coverage loss converged to about 0.2, down from an initial value of about 0.5. We also tried a more aggressive value of $\lambda = 2$; this reduced coverage loss but increased the primary loss function, thus we did not use it.

We tried training the coverage model without the loss function, hoping that the attention mechanism may learn by itself not to attend repeatedly to the same locations, but we found this to be ineffective, with no discernible reduction in repetition. We also tried training with coverage from the first

[3]The upper limit of 120 is mostly invisible: the beam search algorithm is self-stopping and almost never reaches the 120th step.

iteration rather than as a separate training phase, but found that in the early phase of training, the coverage objective interfered with the main objective, reducing overall performance.

6 Results

6.1 Preliminaries

Our results are given in Table 1. We evaluate our models with the standard ROUGE metric (Lin, 2004b), reporting the F_1 scores for ROUGE-1, ROUGE-2 and ROUGE-L (which respectively measure the word-overlap, bigram-overlap, and longest common sequence between the reference summary and the summary to be evaluated). We obtain our ROUGE scores using the `pyrouge` package.[4] We also evaluate with the METEOR metric (Denkowski and Lavie, 2014), both in exact match mode (rewarding only exact matches between words) and full mode (which additionally rewards matching stems, synonyms and paraphrases).[5]

In addition to our own models, we also report the lead-3 baseline (which uses the first three sentences of the article as a summary), and compare to the only existing abstractive (Nallapati et al., 2016) and extractive (Nallapati et al., 2017) models on the full dataset. The output of our models is available online.[6]

Given that we generate plain-text summaries but Nallapati et al. (2016; 2017) generate anonymized summaries (see Section 4), our ROUGE scores are not strictly comparable. There is evidence to suggest that the original-text dataset may result in higher ROUGE scores in general than the anonymized dataset – the lead-3 baseline is higher on the former than the latter. One possible explanation is that multi-word named entities lead to a higher rate of n-gram overlap. Unfortunately, ROUGE is the only available means of comparison with Nallapati et al.'s work. Nevertheless, given that the disparity in the lead-3 scores is (+1.1 ROUGE-1, +2.0 ROUGE-2, +1.1 ROUGE-L) points respectively, and our best model scores exceed Nallapati et al. (2016) by (+4.07 ROUGE-1, +3.98 ROUGE-2, +3.73 ROUGE-L) points, we may estimate that we outperform the only previous abstractive system by at least 2 ROUGE points all-round.

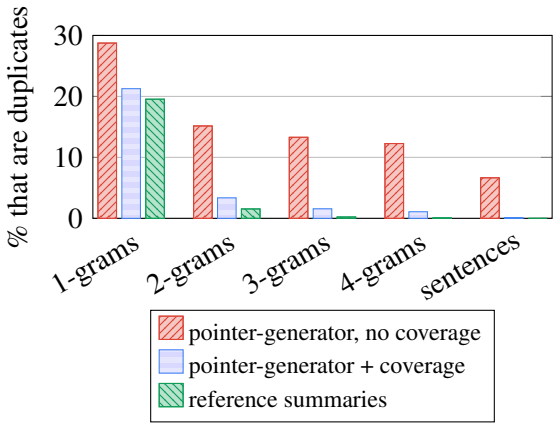

Figure 4: Coverage eliminates undesirable repetition. Summaries from our **non-coverage model** contain many duplicated n-grams while our **coverage model** produces a similar number as the **reference summaries**.

6.2 Observations

We find that both our baseline models perform poorly with respect to ROUGE and METEOR, and in fact the larger vocabulary size (150k) does not seem to help. Even the better-performing baseline (with 50k vocabulary) produces summaries with several common problems. Factual details are frequently reproduced incorrectly, often replacing an uncommon (but in-vocabulary) word with a more-common alternative. For example in Figure 1, the baseline model appears to struggle with the rare word *thwart*, producing *destabilize* instead, which leads to the fabricated phrase *destabilize nigeria's economy*. Even more catastrophically, the summaries sometimes devolve into repetitive nonsense, such as the third sentence produced by the baseline model in Figure 1. In addition, the baseline model can't reproduce out-of-vocabulary words (such as *muhammadu buhari* in Figure 1). Further examples of all these problems are provided in the supplementary material.

Our pointer-generator model achieves much better ROUGE and METEOR scores than the baseline, despite many fewer training epochs. The difference in the summaries is also marked: out-of-vocabulary words are handled easily, factual details are almost always copied correctly, and there are no fabrications (see Figure 1). However, repetition is still very common.

Our pointer-generator model with coverage improves the ROUGE and METEOR scores further, convincingly surpassing the best abstractive model

Article: smugglers lure arab and african migrants by offering discounts to get onto overcrowded ships if people bring more potential passengers, a cnn investigation has revealed. (...)

Figure 5: Examples of highly abstractive reference summaries (**bold** denotes novel words).

of Nallapati et al. (2016) by several ROUGE points. Despite the brevity of the coverage training phase (about 1% of the total training time), the repetition problem is almost completely eliminated, which can be seen both qualitatively (Figure 1) and quantitatively (Figure 4). However, our best model does not quite surpass the ROUGE scores of the lead-3 baseline, nor the current best extractive model (Nallapati et al., 2017). We discuss this issue in section 7.1.

7 Discussion

7.1 Comparison with extractive systems

It is clear from Table 1 that extractive systems tend to achieve higher ROUGE scores than abstractive, and that the extractive lead-3 baseline is extremely strong (even the best extractive system beats it by only a small margin). We offer two possible explanations for these observations.

Firstly, news articles tend to be structured with the most important information at the start; this partially explains the strength of the lead-3 baseline. Indeed, we found that using only the first 400 tokens (about 20 sentences) of the article yielded significantly higher ROUGE scores than using the first 800 tokens.

Secondly, the nature of the task and the ROUGE metric make extractive approaches and the lead-3 baseline difficult to beat. The choice of content for the reference summaries is quite subjective – sometimes the sentences form a self-contained summary; other times they simply showcase a few interesting details from the article. Given that the articles contain 39 sentences on average, there are many equally valid ways to choose 3 or 4 highlights in this style. Abstraction introduces even more options (choice of phrasing), further decreasing the likelihood of matching the reference summary. For example, *smugglers profit from desperate migrants* is a valid alternative abstractive summary for the first example in Figure 5, but it scores 0 ROUGE with respect to the reference summary. This inflexibility of ROUGE is exacerbated by only having one reference summary, which has been shown to lower ROUGE's reliability compared to multiple reference summaries (Lin, 2004a).

Due to the subjectivity of the task and thus the diversity of valid summaries, it seems that ROUGE rewards safe strategies such as selecting the first-appearing content, or preserving original phrasing. While the reference summaries *do* sometimes deviate from these techniques, those deviations are unpredictable enough that the safer strategy obtains higher ROUGE scores on average. This may explain why extractive systems tend to obtain higher ROUGE scores than abstractive, and even extractive systems do not significantly exceed the lead-3 baseline.

To explore this issue further, we evaluated our systems with the METEOR metric, which rewards not only exact word matches, but also matching stems, synonyms and paraphrases (from a predefined list). We observe that all our models receive over 1 METEOR point boost by the inclusion of stem, synonym and paraphrase matching, indicating that they may be performing some abstraction. However, we again observe that the lead-3 baseline is not surpassed by our models. It may be that news article style makes the lead-3 baseline very strong with respect to any metric. We believe that investigating this issue further is an important direction for future work.

7.2 How abstractive is our model?

We have shown that our pointer mechanism makes our abstractive system more reliable, copying factual details correctly more often. But does the ease of copying make our system any less *abstractive*?

Figure 6 shows that our final model's summaries contain a much lower rate of novel n-grams (i.e., those that don't appear in the article) than the reference summaries, indicating a lower degree of abstraction. Note that the baseline model produces novel n-grams more frequently – however, this statistic includes all the incorrectly copied words, *UNK* tokens and fabrications alongside the good instances of abstraction.

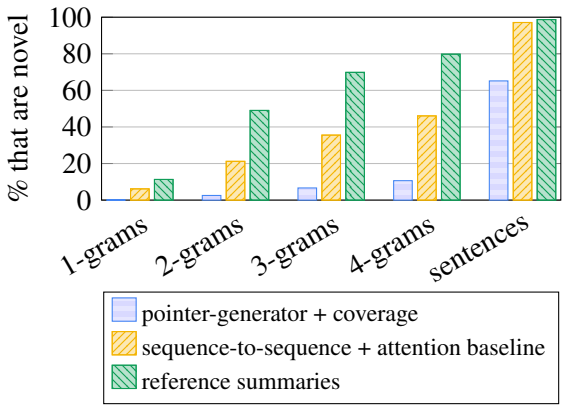

Figure 6: Although our **best model** is abstractive, it does not produce novel n-grams (i.e., n-grams that don't appear in the source text) as often as the **reference summaries**. The **baseline model** produces more novel n-grams, but many of these are erroneous (see section 7.2).

Article: andy murray (...) is into the semi-finals of the miami open , but not before getting a scare from 21 year-old austrian dominic thiem, who pushed him to 4-4 in the second set before going down 3-6 6-4, 6-1 in an hour and three quarters. (...)

Article: (...) wayne rooney smashes home during manchester united 's 3-1 win over aston villa on saturday. (...)
Summary: manchester united **beat** aston villa 3-1 at old trafford on saturday.

Figure 7: Examples of abstractive summaries produced by our model (**bold** denotes novel words).

In particular, Figure 6 shows that our final model copies whole article sentences 35% of the time; by comparison the reference summaries do so only 1.3% of the time. This is a main area for improvement, as we would like our model to move beyond simple sentence extraction. However, we observe that the other 65% encompasses a range of abstractive techniques. Article sentences are truncated to form grammatically-correct shorter versions, and new sentences are composed by stitching together fragments. Unnecessary interjections, clauses and parenthesized phrases are sometimes omitted from copied passages. Some of these abilities are demonstrated in Figure 1, and the supplementary material contains more examples.

Figure 7 shows two examples of more impressive abstraction – both with similar structure. The dataset contains many sports stories whose summaries follow the *X beat Y* ⟨*score*⟩ *on* ⟨*day*⟩ template, which may explain why our model is most confidently abstractive on these examples. In general however, our model does not routinely produce summaries like those in Figure 7, and is not close to producing summaries like in Figure 5.

The value of the generation probability p_{gen} also gives a measure of the abstractiveness of our model. During training, p_{gen} starts with a value of about 0.30 then increases, converging to about 0.53 by the end of training. This indicates that the model first learns to mostly copy, then learns to generate about half the time. However at test time, p_{gen} is heavily skewed towards copying, with a mean value of 0.17. The disparity is likely due to the fact that during training, the model receives word-by-word supervision in the form of the reference summary, but at test time it does not. Nonetheless, the generator module is useful even when the model is copying. We find that p_{gen} is highest at times of uncertainty such as the beginning of sentences, the join between stitched-together fragments, and when producing periods that truncate a copied sentence. Our mixture model allows the network to copy while simultaneously consulting the language model – enabling operations like stitching and truncation to be performed with grammaticality. In any case, encouraging the pointer-generator model to write more abstractively, while retaining the accuracy advantages of the pointer module, is an exciting direction for future work.

8 Conclusion

In this work we presented a hybrid pointer-generator architecture with coverage, and showed that it reduces inaccuracies and repetition. We applied our model to a new and challenging long-text dataset, and significantly outperformed the abstractive state-of-the-art result. Our model exhibits many abstractive abilities, but attaining higher levels of abstraction remains an open research question.

Abstract

We present a new supervised framework that learns to estimate automatic Pyramid scores and uses them for optimization-based extractive multi-document summarization. For learning automatic Pyramid scores, we developed a method for automatic training data generation which is based on a genetic algorithm using automatic Pyramid as the fitness function. Our experimental evaluation shows that our new framework significantly outperforms strong baselines regarding automatic Pyramid, and that there is much room for improvement in comparison with the upper-bound for automatic Pyramid.

1 Introduction

We consider extractive text summarization, the task of condensing a textual source, e.g., a set of source documents in multi-document summarization (MDS), into a short summary text. The quality of an automatic system summary is traditionally evaluated by comparing it against one or more reference summaries written by humans. This comparison is performed by means of an evaluation metric measuring indicators of summary quality and combining them into an aggregated score.

Many state-of-the-art summarization systems cast extractive summarization as an optimization problem and maximize an objective function in order to create good, i.e., high-scoring summaries. To this end, optimization-based systems commonly use an objective function which encodes exactly those quality indicators which are measured by the particular evaluation metric being used. Some systems even employ an approximation of the evaluation metric as objective function.

Consider as an example the ROUGE metric which has become a de-facto standard for summary evaluation (Lin, 2004). ROUGE computes the n-gram overlap between a system summary and a pool of reference summaries. There are several previous approaches which have used an approximation of ROUGE as the optimization objective (e.g., Sipos et al. (2012); Peyrard and Eckle-Kohler (2016a)).

However, ROUGE has been widely criticized for being too simplistic and not suitable for capturing important quality aspects we are interested in. In particular, ROUGE does not capture sentences which are semantically equivalent but expressed with different words (Nenkova et al., 2007).

Ideally, we would like to evaluate our summaries based on human judgments. A well-known example of such a human evaluation method is the so-called Pyramid method (Nenkova et al., 2007): it evaluates the particular quality aspect of content selection and is based on a manual comparison of Summary Content Units (SCUs) in reference summaries against SCUs in system summaries. While the resulting Pyramid score is much more meaningful and informative than ROUGE, it is very expensive to obtain, and – worse – not reproducible.

These issues have been addressed by a line of research aimed at automating the Pyramid evaluation (Harnly et al., 2005; Passonneau et al., 2013). Recently, Yang et al. (2016) developed a freely available off-the-shelf system for automatic Pyramid scoring called PEAK, which uses open Information Extraction (open IE) propositions as SCUs and relies on proposition comparison. Automatic Pyramid (AP) scores are reproducible, and unlike ROUGE, they are based on semantically motivated content units (SCUs) rather than word n-grams. Moreover, they correlate better with human judgments than ROUGE (Yang et al., 2016).

Given these recent advances in the automatic

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1084–1094
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1100

evaluation of summaries regarding content selection, we believe that research in optimization-based summarization should move away from ROUGE towards AP as a more meaningful evaluation metric to approximate and to optimize.

In our work, we are the first to explore this new direction and to systematically investigate the use of AP in optimization-based extractive summarization. We make the following contributions:

- We compute an upper-bound for AP with a Genetic Algorithm (GA), and compare it to the ROUGE upper-bound.
- We develop a new extractive MDS system specifically optimizing for an approximation of AP. Our system uses a supervised learning setup to learn an approximation of AP from automatically generated training data. We constrain the learned approximation of AP to be linear so that we can extract summaries efficiently via Integer Linear Programming (ILP). Our experimental evaluation shows that our approach significantly outperforms strong baselines on the AP metric.

The code both for the new upper-bound and for our ILP is available at `github.com/UKPLab/acl2017-optimize_pyramid`.

2 Background

In this section, we summarize the Pyramid method and the PEAK system, the automated version of Pyramid we consider in this work.

Pyramid The Pyramid method (Nenkova et al., 2007) is a manual evaluation method which determines to what extent a system summary covers the content expressed in a set of reference summaries. The comparison of system summary content to reference summary content is performed on the basis of SCUs which correspond to semantically motivated, subsentential units, such as phrases or clauses.

The Pyramid method consists of two steps: the creation of a *Pyramid set* from reference summaries, and second, *Pyramid scoring* of system summaries based on the Pyramid set. In the first step, humans annotate phrasal content units in the reference summaries and group them into clusters of semantically equivalent phrases. The resulting clusters are called SCUs and the annotators assign an *SCU label* to each cluster, which is a sentence describing the cluster content in their own words. The final set of SCUs forms the Pyramid set. Each SCU has a weight corresponding to the number of reference summaries in which the SCU appears. Since each SCU must not appear more than once in each reference summary, the maximal weight of an SCU is the total number of reference summaries. In the second step, humans annotate phrasal content units in a system summary and align them to the corresponding SCUs in the Pyramid set. The Pyramid score of a system summary is then calculated as the sum of the SCU weights for all Pyramid set SCUs being aligned to annotated system summary phrases.

PEAK The AP system PEAK by Yang et al. (2016) uses *clauses* as the content expressing units and represents them as propositions in the open IE paradigm. An open IE proposition is a triple of subject, predicate and object phrases. PEAK uses the state-of-the-art system clausIE (Del Corro and Gemulla, 2013) for proposition extraction.

While PEAK includes the automatic creation of Pyramid sets from reference summaries, as well as automatic Pyramid scoring of system summaries, in this work, we use PEAK for automatic scoring only. As for the Pyramid sets, we can assume that these have already been created, either via PEAK or by humans (e.g., using the TAC 2009 data[1]).

Since automatic scoring with PEAK requires that the Pyramid sets consist of representative open IE propositions which constitute the automated counterparts of the SCUs, we first need to represent the manually constructed SCUs as open IE propositions, too. To this end, we use clausIE to extract an open IE proposition from each SCU *label* – a sentence describing the cluster content. As a result, each pyramid set is represented as a list of propositions $\{p_j\}$ with a weight taken from the underlying SCU.

For scoring, PEAK processes a system summary with clausIE, converting it from a list of sentences to a list of propositions $\{s_i\}$. A bipartite graph G is constructed, where the two sets of nodes are the summary propositions $\{s_i\}$ and the pyramid propositions $\{p_j\}$. An edge is drawn between s_i and p_j if the similarity is above a given threshold. PEAK computes the similarity with the ADW system (*Align, Disambiguate and Walk*), a system for computing text similarity based on WordNet, which reaches state-of-the-

[1] `http://tac.nist.gov/2009/Summarization`

art performance but is slow (Pilehvar et al., 2013). Since each system summary unit can be aligned to at most one SCU, the alignment of the summary propositions $\{s_i\}$ and the pyramid propositions $\{p_j\}$ is equivalent to finding a maximum weight matching, which PEAK solves using the Munkres-Kuhn bipartite graph algorithm. From the matched pyramid propositions $\{p_j\}$ the final pyramid score is computed.

3 Approach

3.1 Upper-bound for Automatic Pyramid

We start by computing upper-bound summaries according to AP in order to gain a better understanding of the metric.

Notations Let $D = \{s_i\}$ be a document collection considered as a set of sentences. A summary S is simply a subset of D. We use p^{pyr} to denote the set of propositions in the Pyramid sets extracted from the SCU labels using clausIE.

The upper-bound is the set of sentences S^* with the best AP score.

Method The task is to extract the set of sentences which contains the propositions matching most of the highest-weighted SCUs, thus resulting in the best matching of propositions, i.e., the highest AP score possible. Formally, we have to solve the following optimization problem:

$$S^* = \underset{S}{\operatorname{argmax}}\, AutoPyr(S) \qquad (1)$$

Unfortunately, it cannot be solved directly via ILP because of the Munkres-Kuhn bipartite graph algorithm within AP. While Munkres-Kuhn is an ILP, we solve a different problem. In our problem, Munkres-Kuhn would act as constraint because we are looking for the best matching among all valid matchings. Munkres-Kuhn only yields the valid matching for one particular set of sentences. One global ILP can be written down by enumerating all possible matchings in the constraints but it will have a completely unrealistic runtime.

Instead, we have to rely on search-based algorithms and compute summaries close to the upper-bound. We search for such an approximate solution by employing a meta-heuristic solver introduced recently for extractive MDS by Peyrard and Eckle-Kohler (2016a). Specifically, we use the tool published with their paper.[2] Their meta-heuristic solver implements a Genetic Algorithm (**GA**) to create and iteratively optimize summaries over time.

In this implementation, the individuals of the population are the candidate solutions which are valid extractive summaries. Valid means that the summary meets the length constraint. Each summary is represented by a binary vector indicating for each sentence in the source document whether it is included in the summary or not. The size of the population is a hyper-parameter that we set to 100. Two evolutionary operators are applied: the mutation and the reproduction. The mutation happens to several randomly chosen summaries by randomly removing one of its sentences and adding a new one that does not violate the length constraint. The reproduction is performed by randomly extracting a valid summary from the union of sentences of randomly selected parent summaries. Both operators are controlled by hyper-parameters which we set to their default values.

In our scenario, *the fitness function is the AP metric*, which takes a summary S as input and outputs its AP score. S is converted into a list of propositions p^S by looking-up the propositions of each sentence in S from a pre-computed hash-map. For all sentences in the document collection D, the hash-map stores the corresponding propositions. Then the Munkres-Kuhn algorithm is applied to p^S and p^{pyr} in order to find matching propositions, and finally the scores of their corresponding SCUs are used to evaluate the fitness of the summary.

The runtime might become an issue, because the similarity computation between propositions via ADW is slow. However, all the necessary information is present in the similarity matrix A defined by:

$$A_{ij} = ADW(p_i^D, p_j^{pyr}) \qquad (2)$$

Here A_{ij} is the semantic similarity between the proposition p_i^D from the source document i and the proposition p_j^P from the Pyramid set j. A has dimensions $m \times n$ if m is the number of propositions in the document collection and n the number of propositions in the Pyramid set. We keep the runtime low by pre-computing the similarity matrix A.

With a population of 100 summaries in the GA, the algorithm converges in less than a minute to high scoring summaries, which we can expect to be close to the real upper-bound.

[2] https://github.com/UKPLab/coling2016-genetic-swarm-MDS

3.2 Supervised Setup to Learn an Approximation of AP

We denote the true AP scoring function by π^*. π^* scores summaries by matching the summary propositions to the Pyramid propositions in P_{pyr} as described before. In this work, we aim to learn a function π, which approximates π^* without having access to P_{pyr}, but only to the document collection D.

Formally, it means that over all document collections $\mathcal{D}$ and all summaries $\mathcal{S}$, we look for π which minimizes the following loss:

$$\mathcal{L}(\pi) = \sum_{D \in \mathcal{D}} \sum_{S \in \mathcal{S}} \|\pi(D, S) - \pi^*(P_{pyr}, S)\|^2 \quad (3)$$

This states that the learned π minimizes the squared distance from π^* over the available training data.

Model Note that we simply denote $\pi(D, S)$ by $\pi(S)$ as it is not ambiguous which document collection is used when S is a summary of D.

In order to be able to use an exact and efficient solver like ILP, we constrain π to be a linear function. Therefore, we look for π of the following form:

$$\pi(S) = \sum_{s \in S} f_\theta(s) - \sum_{i>j} g_\gamma(s_i \cap s_j) \quad (4)$$

Two functions are jointly learned: f_θ is a function scoring individual sentences, and g_γ is a function scoring the intersection of sentences. $\theta \cup \gamma$ is the set of learned paramaters.

We can interpret this learning scenario as jointly learning the sentence importance and the redundancy to get π as close as possible to the true AP π^*. f_θ represents the notion of importance learned in the context of AP, while g_γ contains notions of coherence and redundancy by scoring sentence intersections. This scenario is intuitive and inspired by previous work on summarization (McDonald, 2007).

Now, we explain how to learn these two functions while enforcing π to be linear. Suppose each sentence is represented by a feature set ϕ and each sentence intersections is represented by $\phi_\cap$, then the set of features for a summary S is:

$$\Phi(S) = \{\bigcup_{s \in S} \phi(s) \cup \bigcup_{i>j} \phi_\cap(s_i \cap s_j)\} \quad (5)$$

It is clear that the number of features is variable and depends on the number m of sentences in S. In order to deal with a variable number of sentences as input, one could use recurrent neural networks, but at the cost of loosing linearity.

Instead, to keep the linearity and to cope with variable sized inputs, we employ linear models for both f_θ and g_γ:

$$\pi(S) = \sum_{s \in S} \theta \cdot \phi(s) - \sum_{i>j} \gamma \cdot \phi_\cap(s_i \cap s_j) \quad (6)$$

By leveraging the properties of linear models we end-up with the following formulation:

$$\pi(S) = \theta \cdot \sum_{s \in S} \phi(s) - \gamma \cdot \sum_{i \geq j} \phi_\cap(s_i \cap s_j) \quad (7)$$

Because of the linear models, we can sum features over sentences and over sentence intersections to obtain a fixed size feature set:

$$\Phi^\Sigma(S) = \{\phi^\Sigma(S) \cup \phi^\Sigma_\cap(S)\} \quad (8)$$

where we introduced the following notations:

$$\phi^\Sigma(S) = \sum_{s \in S} \phi(s)$$
$$\phi^\Sigma_\cap(S) = \sum_{i>j} \phi(s_i \cap s_j)$$

Suppose ϕ is composed of k features and $\phi_\cap$ of n features. Then $\phi^\Sigma(S)$ is a vector of dimension k, and similarly $\phi^\Sigma_\cap(S)$ is of dimension n. Finally, Φ_Σ is a fixed size feature set of dimension $k + n$.

The function π as defined in equation 6 is still linear with respect to sentence and sentence intersection features, which is convenient for the subsequent summary extraction stage.

Features While any feature set for sentences ϕ and for sentence intersections $\phi_\cap$ could be used, we focused on simple ones in this work.

For a sentence s, $\phi(s)$ consists of the following features:

- **Sentence length** in number of words.
- **Sentence position** as an integer number starting from 0.
- **Word overlap with title:** Jaccard similarity between the unigrams in the title t and a sentence s:

$$Jaccard(s, t) = \frac{|t \cap s|}{|t \cup s|} \quad (9)$$

- **Sum of frequency** of unigrams and bigrams in the sentence.

- **Sum of TF*IDF** of unigrams and bigrams in the sentence. The idf of unigrams and bigrams is trained on a background corpus of DBpedia articles.[3]

- **Centrality** of the sentence computed via PageRank: A similarity matrix is built between sentences in the document collection based on their TF*IDF vector similarity. Then a power method is applied on the similarity matrix to get PageRank scores of individual sentences. It is similar to the classic LexRank algorithm (Erkan and Radev, 2004).

- **Propositions centrality:** We also use the centrality feature for propositions. Each sentence is scored by the sum of the centrality of its propositions. As PEAK is based on propositions, we expect proposition-level features to provide a useful signal.

Finally, $\phi_\cap(s_i \cap s_j)$ consists of the unigram, bigram and trigram **overlap** between the two sentences s_i and s_j.

Training The model is trained with a standard linear least squares regression using pairs of $(\Phi(S), \pi^*(S))$ as training examples. Because our approach relies on an automatic metric, an arbitrarily large number of summaries and their corresponding scores can be generated. In contrast, getting manual Pyramid annotations for a large number of summaries would be expensive and time-consuming.

As training examples we take the population of scored summaries created by the same GA we use for computing upper-bound summaries. It is important to note that this GA is also a perfect generator of training instances: the summaries in its population are already scored because the fitness function is the AP metric. Indeed, for each topic, an arbitrarily large amount of scored summaries can be generated by adjusting the size of the population. Moreover, the summaries in the population are very diverse and have a wide range of scores, from almost upper-bound to completely random.

Optimization-based Summary Extraction Since the function π is constrained to be linear, we can extract the best scoring summary by solving an ILP.

Let x be a binary vector indicating whether sentence i is in the summary or not. Similarly, let α be a binary matrix indicating whether both sentence i and j are in the summary. Finally, let K be the length constraint. With these notations, the best summary is extracted by solving the follwogin ILP:

$$\begin{aligned}\underset{S}{\operatorname{argmax}} \sum_{s_i \in S} x_i * \theta \cdot \phi(s_i) - \sum_{i \geq j} \alpha_{i,j} * \gamma \cdot \phi_\cap(s_i \cap s_j) \\ \sum_{i=1}^{m} x_i * len(s_i) \leq K \\ \forall (i,j), \alpha_{i,j} - x_i \leq 0 \\ \forall (i,j), \alpha_{i,j} - x_j \leq 0 \\ \forall (i,j), x_i + x_j - \alpha_{i,j} \leq 1\end{aligned}$$

Which is the ILP directly corresponding to maximizing π as defined by equation 6. Note that $\cdot$ is the dot product while $*$ is the scalar multiplication in $\mathbb{R}$.

4 Experiments

4.1 Setup

Dataset We perform our experiments on a multi-document summarization dataset from the Text Analysis Conference (TAC) shared task in 2009, TAC-2009.[4] TAC-2009 contains 44 topics, each consisting of 10 news articles to be summarized in a maximum of 100 words. In our experiments, we use only the so-called initial summaries (A summaries), but not the update summaries. For each topic, there are 4 human reference summaries and a manually created Pyramid set. As described in section 2, we pre-processed these Pyramid sets with clausIE in order to make them compatible with PEAK.

Metrics We primarily evaluate our system via automatic Pyramid scoring from PEAK, after pre-processing the summaries with clausIE. PEAK has a parameter t which is the minimal similarity value required for matching a summary proposition and a Pyramid proposition. We use two different values: $t = 0.6$ (AP-60) and $t = 0.7$ (AP-70).

For completeness, we also report the ROUGE scores identified by Owczarzak et al. (2012a) as strongly correlating with human evaluation methods: ROUGE-1 (R-1) and ROUGE-2 (R-2) recall with stemming and stopwords not removed.

Finally, we perform significance testing with t-test to compare differences between two means.[5]

[3] http://wiki.dbpedia.org/nif-abstract-datasets

[4] http://tac.nist.gov/2009/Summarization/

[5] The symbol * indicates that the difference compared to

4.2 Automatic Evalution

Upper-bound Comparison We compute the set of upper-bound summaries for both ROUGE-2 (R-UB) and for AP (AP-UB).[6] Both sets of upper-bound summaries are evaluated with ROUGE and AP, and the results are reported in Table 1.

	R-1	R-2	AP-60	AP-70
R-UB	**0.4722***	**0.2062***	0.5088	0.3074
AP-UB	0.3598	0.1057	**0.5789***	**0.3790***

Table 1: Upper bound comparison between ROUGE and Automatic Pyramid (AP).

Interestingly, we observe significant differences between the two upper-bounds. While it is obvious that each set of upper-bound summaries reaches the best score on the metric it maximizes, the same summary set scores much worse when evaluated with the other metric. This observation empirically confirms that the two metrics measure different properties of system summaries.

Moreover, the upper-bound for AP gives us information about the room for improvement that summarization systems have with respect to AP. This is relevant in the next paragraph, where we compare systems in an end-to-end evaluation.

End-to-end Evaluation We evaluate the quality of the summaries extracted by the summarizer $\pi - ILP$ in a standard end-to-end evaluation scenario. $\pi - ILP$ is the system composed of the learned function π and the ILP defined in the previous section.

Learning π Using our GA data generation method, we produce 100 scored summaries for each of the 44 topics in TAC2009 while computing the upper-bound. We use the threshold value of 0.65 as a compromise between AP-60 and AP-70. The data generated have scores ranging from 0. to 0.4627 with an average of 0.1615. The data is well distributed because the standard deviation is 0.1449. A highly diverse set of summaries is produced, because on average two summaries in the training set only have 1.5% sentences in common, and most of the sentences of the source documents are contained in at least one summary.

The model is then trained in a leave-one-out cross-validation setup. The parameters θ and γ are trained on all topics but one. The trained model is used to extract a high-scoring summary on the remaining topic by solving the ILP defined above.

	R-1	R-2	AP-60	AP-70
TF*IDF	0.3251	0.0626	0.2857	0.1053
LexRank	0.3539	0.0900	0.3969	0.1854
ICSI	**0.3670**	**0.1030**	0.3520	0.1568
JS-Gen	0.3381	0.0868	0.3745	0.1463
π-ILP	0.3498	0.0867	**0.4402***	**0.2109***

Table 2: End-to-end evaluation of our approach on TAC-2009.

Our framework is compared to the following baselines:

TF*IDF weighting A simple heuristic introduced by Luhn (1958) where each sentence receives a score from the TF*IDF of its terms. The best sentences are greedily extracted until the length constraint is met. We use the implementation available in the sumy package.[7]

LexRank (Erkan and Radev, 2004) is a popular graph-based approach. A similarity graph $G(V, E)$ is constructed where V is the set of sentences and an edge e_{ij} is drawn between sentences v_i and v_j if and only if the cosine similarity between them is above a given threshold. Sentences are scored according to their PageRank score in G. It is also available in the sumy package.

ICSI (Gillick and Favre, 2009) is a recent system that has been identified as one of the state-of-the-art systems by Hong et al. (2014). It is an ILP framework that extracts a summary by solving a maximum coverage problem considering the most frequent bigrams in the source documents. We use the Python implementation released by Boudin et al. (2015).

JS-Gen (Peyrard and Eckle-Kohler, 2016a) is a recent approach which uses a GA to minimize the Jensen-Shannon (JS) divergence between the extracted summary and the source documents. JS divergence measures the difference between probability distributions of words in the source documents and in the summary.

Results We report the performance of $\pi - ILP$ in comparison to the baselines in Table 2.

The results confirm an expected behavior. Our supervised framework which aims at approximating and maximizing AP, easily and significantly outperforms all the other baselines when evaluated

the previous best baseline is significant with $p \leq 0.05$.

[6] We use the parameter $t = 0.6$ during the upper-bound computation of AP-UB.

[7] https://github.com/miso-belica/sumy

with AP for both values of the threshold. While the system is not designed with ROUGE in mind, it still performs reasonably well in the ROUGE evaluation, even though it does not outperform previous works.

In general, the two metrics ROUGE and AP do not produce the same rankings of systems. This is another piece of empirical evidence that they measure different properties of summaries.

When we compare the system performances to the upper-bound scores reported in Table 1, we see that there is still a large room for improvements. We take a closer look at this performance gap in the next paragraph where we evaluate the learning component of our approach.

Evaluation of Learned π In this paragraph, we evaluate the learning of π as an approximation of π^*. We do so by measuring the correlation between π and the true AP π^*.

We report three correlation metrics to evaluate and compare the ranking of summaries induced by π and π^*: Pearson's r, Spearman's ρ and NDCG. Pearson's r is a value correlation metric which depicts linear relationship between the scores produced by two ranking lists.

Spearman's ρ is a rank correlation metric which compares the ordering of systems induced by the two ranking lists.

NDCG is a metric from information retrieval which compares ranked lists and puts a special emphasis on the top elements by applying logarithm decay weighting for elements further down in the list. Intuitively, it describes how well the π function is able to recognize the best scoring summaries. In our case, it is particularly desirable to have a high NDCG score, because the optimizer extracts summaries with high π scores; we want to confirm that top scoring summaries are also among top scoring summaries according to the true π^*.

For comparison, we report how well our baselines correlate with π^*. For this, we consider the scoring function for summaries which is part of all our baselines, and which they explicitly or implicitly optimize: **TF*IDF** greedily maximizes f_{TF*IDF}, the sum of the frequency of the words in the summary. **ICSI** maximizes the sum of the document frequency of bigrams (f_{ICSI}). **LexRank** maximizes $f_{LexRank}$, the sum of the PageRank of sentences in the summary, and f_{JS} is the JS divergence between the summary and the source documents optimized by **JS-Gen**.

	Pearson's r	Spearman's ρ	NDCG
f_{TF*IDF}	0.1246	0.0765	0.8869
$f_{LexRank}$	0.1733	0.0879	0.8774
f_{ICSI}	0.3742	0.3295	0.8520
f_{JS}	0.4074	0.3833	0.8803
π	**0.4929***	**0.4667***	**0.9429***

Table 3: Performance of the supervised learning of π on TAC-2009 in a leave-one-out cross-validation.

For our supervised learning of π, the training procedure is the same as described in the previous section. The correlation scores are averaged over topics and reported in Table 3.

We observe that π is able to approximate AP significantly better than any baseline for all metrics. This explains why optimizing π with ILP outperforms the baseline systems in the end-to-end evaluation (Table 2).

The learned π achieves a high NDCG, indicating that optimizing π produces summaries very likely to have high π^* scores. This means that π is capable of accurately identifying high-scoring summaries, which again explains the strong performance of $\pi - ILP$. The fact that the overall correlations are lower for every system shows that it is difficult to predict π for poor and average quality summaries.

It is interesting to observe that features such as unigram and bigram frequency, which are known to be strong features to approximate ROUGE, are less useful to approximate the more complex AP.

Feature Weights The advantage of linear models is their interpretability. One can investigate the contribution of each feature by looking at its corresponding weight learned during training. The sign of the weight indicates whether the feature correlates positively or negatively with the results, and its amplitude determines the importance of this feature in the final estimation.

We observe that the most useful feature is the proposition centrality, which confirms our expectation that proposition-based features are useful for approximating PEAK. The bigram coverage has also a high weight explaining the strong performance of ICSI. The least useful feature is the sentence position, even if it still contains some useful signal.

Interestingly, the analysis of features from the

	Pearson's r	Spearman's ρ	NDCG
$ROUGE-1$	0.3292	0.3187	0.7195
$ROUGE-2$	0.3292	0.2936	0.7259

Table 4: Correlation between ROUGE-1 and ROUGE-2 with AP on the automatically generated training data for TAC-2009.

sentence intersection reveals a slightly positive correlation for the unigram and bigram overlap, but a negative correlation for trigram overlap. Our interpretation is that the model learns that good summaries tend to have repeated unigrams and bigrams to ensure some coherence, while the repeated trigrams are more indicative of undesired redundancy.

Agreement between ROUGE and AP In the previous paragraphs, we already saw that different metrics produce different rankings of systems. We want to investigate this further and understand to what extent ROUGE and AP disagree. To that end, we use the summaries automatically generated by the genetic algorithm during the upper-bound computation. Remember that for each topic of TAC-2009 it produces 100 summaries with a wide range of AP scores. We then score these summaries with both ROUGE-1 and ROUGE-2 and compare how ROUGE metrics correlate with AP. In order to get a meaningful picture, we use the same three correlation metrics as above: Pearson's, Spearman's ρ and NDCG. The results are presented in Table 4.

We observe a low correlation between ROUGE metrics and AP in terms of both rank correlation (Spearman's ρ) and value correlation (Pearson's r). Even though the NDCG numbers are better, the correlation is also relatively low given that higher numbers are usually expected for NDCG (also observed in Table 3).

This analysis confirms the initial claim that ROUGE and AP behave quite differently and measure different aspects of summary quality. Therefore, we believe systems developed and trained for AP are worth studying because they necessarily capture different aspects of summarization.

5 Related Work

We discuss (i) related work in extractive summarization where an approximation of an automatic evaluation metric was optimized, and (ii) work related to AP specifically.

As ROUGE is the metric predominantly used for evaluation of extractive summarization, there are several previous optimization-based approaches which included an approximation of ROUGE in the objective function to maximize. For example, Takamura and Okumura (2010) and Sipos et al. (2012) performed structured output learning (using pairs of summaries and their ROUGE scores available in benchmark datasets as training examples) and thereby learned to maximize the ROUGE scores of the system summaries. Peyrard and Eckle-Kohler (2016b) on the other hand, learned an approximation of ROUGE scores for individual sentences in a supervised setup, and subsequently employed these estimated sentence scores in an ILP formulation to extract summaries.

There is also recent work on considering fully automatic evaluation metrics (not relying on human reference summaries), such as the JS divergence as optimization objective. Peyrard and Eckle-Kohler (2016a) used metaheuristics to minimize JS divergence in a multi-document summarization approach and showed that the resulting extractive summaries also scored competitively using ROUGE.

Regarding AP, there is not much prior work apart from the papers where the different variants of AP have been presented (Harnly et al., 2005; Passonneau et al., 2013; Yang et al., 2016). Especially, there is no prior work in optimization-based extractive summarization which has developed an approximation of AP and used it in an objective function.

However, AP as an evaluation metric is becoming ever more important in the context of abstractive summarization, a research topic which has been gaining momentum in the last few years. For example Li (2015) and Bing et al. (2015) use an earlier version of AP based on distributional semantics (Passonneau et al., 2013) to evaluate abstractive multi-document summarization.

6 Discussion and Future Work

We presented a supervised framework that learns automatic Pyramid scores and uses them for optimization-based summary extraction. Using the TAC-2009 multi-document summarization dataset, we performed an upper-bound analysis for AP, and we evaluated the summaries extracted with our framework in an end-to-end evaluation

using automatic evaluation metrics. We observed that the summaries extracted with our framework achieve significantly better AP scores than several strong baselines, but compared to the upper-bound for AP, there is still a large room for improvement.

We show that AP and ROUGE catch different aspects of summary quality, but further work would be needed in order to substantiate the claim that AP is indeed better than ROUGE. One way of doing so would be to perform a human evaluation of high-scoring summaries according to ROUGE and AP. In general, ROUGE-1 and ROUGE-2 were considered as the baselines for validating the performance of AP because these variants strongly correlate with human evaluation methods (Owczarzak et al., 2012a,b). However, the comparison could be repeated with ROUGE-3, ROUGE-4 and ROUGE-BE, which have been found to predict manual Pyramid better than ROUGE-1 and ROUGE-2 (Rankel et al., 2013).

More generally, we see two main directions for future research: (i) the more specific question on how to improve the approximation of AP and (ii) the general need for more research on AP.

There are several possible ways how to improve the approximation of AP. First, more semantically-oriented features could be developed, e.g., features based on propositions rather than sentences or n-grams, or word embedding features encoding a large amount of distributional semantic knowledge (Mikolov et al., 2013). Second, the linearity constraint we used for efficiency reasons could be relaxed. Modeling AP as a non-linear function will presumably enhance the approximation. For the extraction of summaries based on a non-linear function, greedy algorithms or search-based strategies could be used, e.g., the GA we used in this work for the upper-bound computation.

We see a general need for more research on AP, because the way AP measures the quality aspect of content selection is not only more meaningful than ROUGE, but also applicable to the growing field of abstractive summarization.

An important direction would be the improvement of AP itself, both in terms of methods used to compute AP, and in terms of tools: while the current off-the-shelf system PEAK is a promising start, it is very slow and therefore difficult to apply in practice.

In this context, we would like to stress that our GA-based method to create training data for learning a model of AP can easily be adapted to any automatic scoring metric, and specifically to other or future AP variants.

Finally, we hope to encourage the community to move away from ROUGE and instead consider AP as the main summary evaluation metric. This would be especially interesting for optimization-based approaches, since the quality of the summaries created by such approaches depends on the quality of the underlying scoring metric.

7 Conclusion

We presented the first work on AP in optimization-based extractive summarization. We computed an upper-bound for AP and developed a supervised framework which learns an approximation of AP based on automatically generated training instances. We could access a large number of high-quality training data by using the population of a genetic algorithm. Our end-to-end evaluation showed that of our framework significantly outperforms strong baselines on the AP metric, but also revealed a large room for improvement in comparison to the upper-bound, which motivates future work on developing systems with better performance on the semantically motivated AP metric.

Abstract

We propose a selective encoding model to extend the sequence-to-sequence framework for abstractive sentence summarization. It consists of a sentence encoder, a selective gate network, and an attention equipped decoder. The sentence encoder and decoder are built with recurrent neural networks. The selective gate network constructs a second level sentence representation by controlling the information flow from encoder to decoder. The second level representation is tailored for sentence summarization task, which leads to better performance. We evaluate our model on the English Gigaword, DUC 2004 and MSR abstractive sentence summarization datasets. The experimental results show that the proposed selective encoding model outperforms the state-of-the-art baseline models.

1 Introduction

Sentence summarization aims to shorten a given sentence and produce a brief summary of it. This is different from document level summarization task since it is hard to apply existing techniques in extractive methods, such as extracting sentence level features and ranking sentences. Early works propose using rule-based methods (Zajic et al., 2007), syntactic tree pruning methods (Knight and Marcu, 2002), statistical machine translation techniques (Banko et al., 2000) and so on for this task. We focus on abstractive sentence summarization task in this paper.

Recently, neural network models have been applied in this task. Rush et al. (2015) use auto-constructed sentence-headline pairs to train a neural network summarization model. They use a Convolutional Neural Network (CNN) encoder and feed-forward neural network language model decoder for this task. Chopra et al. (2016) extend their work by replacing the decoder with Recurrent Neural Network (RNN). Nallapati et al. (2016) follow this line and change the encoder to RNN to make it a full RNN based sequence-to-sequence model (Sutskever et al., 2014).

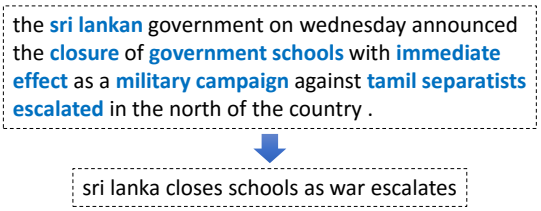

Figure 1: An abstractive sentence summarization system may produce the output summary by distilling the salient information from the highlight to generate a fluent sentence. We model the distilling process with selective encoding.

All the above works fall into the encoding-decoding paradigm, which first encodes the input sentence to an abstract representation and then decodes the intended output sentence based on the encoded information. As an extension of the encoding-decoding framework, attention-based approach (Bahdanau et al., 2015) has been broadly used: the encoder produces a list of vectors for all tokens in the input, and the decoder uses an attention mechanism to dynamically extract encoded information and align with the output tokens. This approach achieves huge success in tasks like machine translation, where alignment between all parts of the input and output are required. However, in abstractive sentence summarization, there is no explicit alignment relationship between the input sentence and the summary ex-

cept for the extracted common words. The challenge here is not to infer the alignment, but to select the highlights while filtering out secondary information in the input. A desired work-flow for abstractive sentence summarization is encoding, selection, and decoding. After selecting the important information from an encoded sentence, the decoder produces the output summary using the selected information. For example, in Figure 1, given the input sentence, the summarization system first selects the important information, and then rephrases or paraphrases to produce a well-organized summary. Although this is implicitly modeled in the encoding-decoding framework, we argue that abstractive sentence summarization shall benefit from explicitly modeling this selection process.

In this paper we propose **S**elective **E**ncoding for **A**bstractive **S**entence **S**ummarization (**SEASS**). We treat the sentence summarization as a three-phase task: encoding, selection, and decoding. It consists of a sentence encoder, a selective gate network, and a summary decoder. First, the sentence encoder reads the input words through an RNN unit to construct the first level sentence representation. Then the selective gate network selects the encoded information to construct the second level sentence representation. The selective mechanism controls the information flow from encoder to decoder by applying a gate network according to the sentence information, which helps improve encoding effectiveness and release the burden of the decoder. Finally, the attention-equipped decoder generates the summary using the second level sentence representation. We conduct experiments on English Gigaword, DUC 2004 and Microsoft Research Abstractive Text Compression test sets. Our SEASS model achieves 17.54 ROUGE-2 F1, 9.56 ROUGE-2 recall and 10.63 ROUGE-2 F1 on these test sets respectively, which improves performance compared to the state-of-the-art methods.

2 Related Work

Abstractive sentence summarization, also known as sentence compression and similar to headline generation, is used to help compress or fuse the selected sentences in extractive document summarization systems since they may inadvertently include unnecessary information. The sentence summarization task has been long connected to the headline generation task. There are some previous methods to solve this task, such as the linguistic rule-based method (Dorr et al., 2003). As for the statistical machine learning based methods, Banko et al. (2000) apply statistical machine translation techniques by modeling headline generation as a translation task and use 8000 article-headline pairs to train the system.

Rush et al. (2015) propose leveraging news data in Annotated English Gigaword (Napoles et al., 2012) corpus to construct large scale parallel data for sentence summarization task. They propose an ABS model, which consists of an attentive Convolutional Neural Network encoder and an neural network language model (Bengio et al., 2003) decoder. On this Gigaword test set and DUC 2004 test set, the ABS model produces the state-of-the-art results. Chopra et al. (2016) extend this work, which keeps the CNN encoder but replaces the decoder with recurrent neural networks. Their experiments showes that the CNN encoder with RNN decoder model performs better than Rush et al. (2015). Nallapati et al. (2016) further change the encoder to an RNN encoder, which leads to a full RNN sequence-to-sequence model. Besides, they enrich the encoder with lexical and statistic features which play important roles in traditional feature based summarization systems, such as NER and POS tags, to improve performance. Experiments on the Gigaword and DUC 2004 test sets show that the above models achieve state-of-the-art results.

Gu et al. (2016) and Gulcehre et al. (2016) come up similar ideas that summarization task can benefit from copying words from input sentences. Gu et al. (2016) propose CopyNet to model the copying action in response generation, which also applies for summarization task. Gulcehre et al. (2016) propose a switch gate to control whether to copy from source or generate from decoder vocabulary. Zeng et al. (2016) also propose using copy mechanism and add a scalar weight on the gate of GRU/LSTM for this task. Cheng and Lapata (2016) use an RNN based encoder-decoder for extractive summarization of documents.

Yu et al. (2016) propose a segment to segment neural transduction model for sequence-to-sequence framework. The model introduces a latent segmentation which determines correspondences between tokens of the input sequence and the output sequence. Experiments on this task show that the proposed transduction model per-

forms comparable to the ABS model. Shen et al. (2016) propose to apply Minimum Risk Training (MRT) in neural machine translation to directly optimize the evaluation metrics. Ayana et al. (2016) apply MRT on abstractive sentence summarization task and the results show that optimizing for ROUGE improves the test performance.

3 Problem Formulation

For sentence summarization, given an input sentence $x = (x_1, x_2, \ldots, x_n)$, where n is the sentence length, $x_i \in \mathcal{V}_s$ and $\mathcal{V}_s$ is the source vocabulary, the system summarizes x by producing $y = (y_1, y_2, \ldots, y_l)$, where $l \leq n$ is the summary length , $y_i \in \mathcal{V}_t$ and $\mathcal{V}_t$ is the target vocabulary.

If $|y| \subseteq |x|$, which means all words in summary y must appear in given input, we denote this as *extractive* sentence summarization. If $|y| \nsubseteq |x|$, which means not all words in summary come from input sentence, we denote this as *abstractive* sentence summarization. Table 1 provides an example. We focus on *abstracive* sentence summarization task in this paper.

Table 1: An abstractive sentence summarization example.

4 Model

As shown in Figure 2, our model consists of a sentence encoder using the Gated Recurrent Unit (GRU) (Cho et al., 2014), a selective gate network and an attention-equipped GRU decoder. First, the bidirectional GRU encoder reads the input words $x = (x_1, x_2, \ldots, x_n)$ and builds its representation $(h_1, h_2, \ldots, h_n)$. Then the selective gate selects and filters the word representations according to the sentence meaning representation to produce a tailored sentence word representation for abstractive sentence summarization task. Lastly, the GRU decoder produces the output summary with attention to the tailored representation. In the following sections, we introduce the sentence encoder, the selective mechanism, and the summary decoder respectively.

4.1 Sentence Encoder

The role of the sentence encoder is to read the input sentence and construct the basic sentence representation. Here we employ a bidirectional GRU (BiGRU) as the recurrent unit, where GRU is defined as:

$$z_i = \sigma(\mathbf{W}_z[x_i, h_{i-1}]) \quad (1)$$

$$r_i = \sigma(\mathbf{W}_r[x_i, h_{i-1}]) \quad (2)$$

$$\widetilde{h}_i = \tanh(\mathbf{W}_h[x_i, r_i \odot h_{i-1}]) \quad (3)$$

$$h_i = (1 - z_i) \odot h_{i-1} + z_i \odot \widetilde{h}_i \quad (4)$$

where $\mathbf{W}_z$, $\mathbf{W}_r$ and $\mathbf{W}_h$ are weight matrices.

The BiGRU consists of a forward GRU and a backward GRU. The forward GRU reads the input sentence word embeddings from left to right and gets a sequence of hidden states, $(\vec{h}_1, \vec{h}_2, \ldots, \vec{h}_n)$. The backward GRU reads the input sentence embeddings reversely, from right to left, and results in another sequence of hidden states, $(\overleftarrow{h}_1, \overleftarrow{h}_2, \ldots, \overleftarrow{h}_n)$:

$$\vec{h}_i = \text{GRU}(x_i, \vec{h}_{i-1}) \quad (5)$$

$$\overleftarrow{h}_i = \text{GRU}(x_i, \overleftarrow{h}_{i+1}) \quad (6)$$

The initial states of the BiGRU are set to zero vectors, i.e., $\vec{h}_1 = 0$ and $\overleftarrow{h}_n = 0$. After reading the sentence, the forward and backward hidden states are concatenated, i.e., $h_i = [\vec{h}_i; \overleftarrow{h}_i]$, to get the basic sentence representation.

4.2 Selective Mechanism

In the sequence-to-sequence machine translation (MT) model, the encoder and decoder are responsible for mapping input sentence information to a list of vectors and decoding the sentence representation vectors to generate an output sentence (Bahdanau et al., 2015). Some previous works apply this framework to summarization generation tasks (Nallapati et al., 2016; Gu et al., 2016; Gulcehre et al., 2016). However, abstractive sentence summarization is different from MT in two ways. First, there is no explicit alignment relationship between the input sentence and the output summary except for the common words. Second, summarization task needs to keep the highlights and remove the unnecessary information, while MT needs to keep all information literally.

Herein, we propose a selective mechanism to model the selection process for abstractive sentence summarization. The selective mechanism

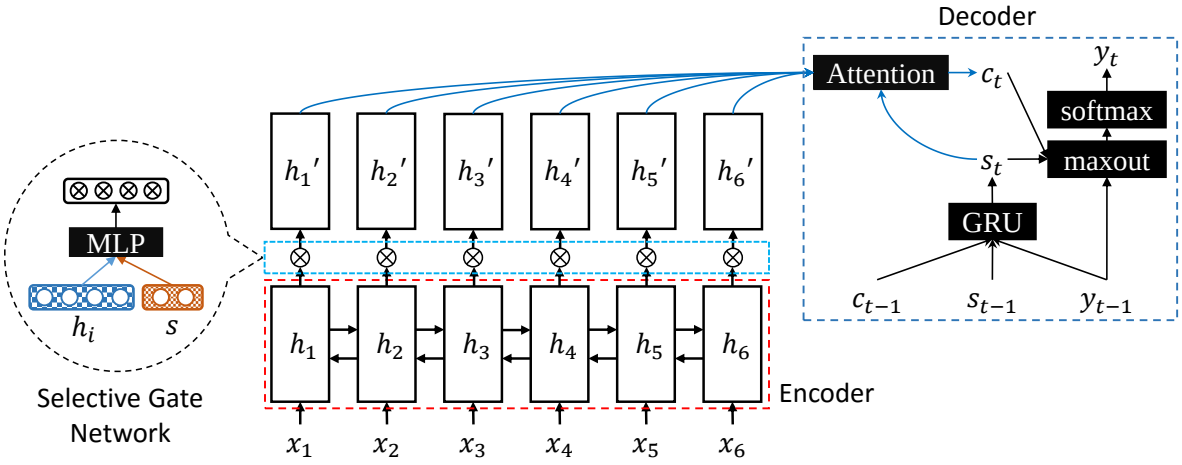

Figure 2: Overview of the **S**elective **E**ncoding for **A**bstractive **S**entence **S**ummarization (**SEASS**).

extends the sequence-to-sequence model by constructing a tailored representation for abstractive sentence summarization task. Concretely, the selective gate network in our model takes two vector inputs, the sentence word vector h_i and the sentence representation vector s. The sentence word vector h_i is the output of the BiGRU encoder and represents the meaning and context information of word x_i. The sentence vector s is used to represent the meaning of the sentence. For each word x_i, the selective gate network generates a gate vector $sGate_i$ using h_i and s, then the tailored representation is constructed, i.e., h'_i.

In detail, we concatenate the last forward hidden state $\vec{h}_n$ and backward hidden state $\overleftarrow{h}_1$ as the sentence representation s:

$$s = \begin{bmatrix} \overleftarrow{h}_1 \\ \vec{h}_n \end{bmatrix} \tag{7}$$

For each time step i, the selective gate takes the sentence representation s and BiGRU hidden h_i as inputs to compute the gate vector $sGate_i$:

$$sGate_i = \sigma(\mathbf{W}_s h_i + \mathbf{U}_s s + b) \tag{8}$$

$$h'_i = h_i \odot sGate_i \tag{9}$$

where $\mathbf{W}_s$ and $\mathbf{U}_s$ are weight matrices, b is the bias vector, σ denotes sigmoid activation function, and $\odot$ is element-wise multiplication. After the selective gate network, we obtain another sequence of vectors $(h'_1, h'_2, \ldots, h'_n)$. This new sequence is then used as the input sentence representation for the decoder to generate the summary.

4.3 Summary Decoder

On top of the sentence encoder and the selective gate network, we use GRU with attention as the decoder to produce the output summary.

At each decoding time step t, the GRU reads the previous word embedding w_{t-1} and previous context vector c_{t-1} as inputs to compute the new hidden state s_t. To initialize the GRU hidden state, we use a linear layer with the last backward encoder hidden state $\overleftarrow{h}_1$ as input:

$$s_t = \text{GRU}(w_{t-1}, c_{t-1}, s_{t-1}) \tag{10}$$

$$s_0 = \tanh(\mathbf{W}_d \overleftarrow{h}_1 + b) \tag{11}$$

where $\mathbf{W}_d$ is the weight matrix and b is the bias vector.

The context vector c_t for current time step t is computed through the concatenate attention mechanism (Luong et al., 2015), which matches the current decoder state s_t with each encoder hidden state h'_i to get an importance score. The importance scores are then normalized to get the current context vector by weighted sum:

$$e_{t,i} = v_a^\top \tanh(\mathbf{W}_a s_{t-1} + \mathbf{U}_a h'_i) \tag{12}$$

$$\alpha_{t,i} = \frac{\exp(e_{t,i})}{\sum_{i=1}^{n} \exp(e_{t,i})} \tag{13}$$

$$c_t = \sum_{i=1}^{n} \alpha_{t,i} h'_i \tag{14}$$

We then combine the previous word embedding w_{t-1}, the current context vector c_t, and the decoder state s_t to construct the readout state r_t. The readout state is then passed through a maxout hidden layer (Goodfellow et al., 2013) to predict the

next word with a softmax layer over the decoder vocabulary.

$$r_t = \mathbf{W}_r w_{t-1} + \mathbf{U}_r c_t + \mathbf{V}_r s_t \quad (15)$$

$$m_t = [\max\{r_{t,2j-1}, r_{t,2j}\}]^\top_{j=1,\dots,d} \quad (16)$$

$$p(y_t|y_1, \dots, y_{t-1}) = \text{softmax}(\mathbf{W}_o m_t) \quad (17)$$

where $\mathbf{W}_a$, $\mathbf{U}_a$, $\mathbf{W}_r$, $\mathbf{U}_r$, $\mathbf{V}_r$ and $\mathbf{W}_o$ are weight matrices. Readout state r_t is a $2d$-dimensional vector, and the maxout layer (Equation 16) picks the max value for every two numbers in r_t and produces a d-dimensional vector m_t.

4.4 Objective Function

Our goal is to maximize the output summary probability given the input sentence. Therefore, we optimize the negative log-likelihood loss function:

$$J(\theta) = -\frac{1}{|\mathcal{D}|} \sum_{(x,y)\in\mathcal{D}} \log p(y|x) \quad (18)$$

where $\mathcal{D}$ denotes a set of parallel sentence-summary pairs and θ is the model parameter. We use Stochastic Gradient Descent (SGD) with mini-batch to learn the model parameter θ.

5 Experiments

In this section we introduce the dataset we use, the evaluation metric, the implementation details, the baselines we compare to, and the performance of our system.

5.1 Dataset

Training Set For our training set, we use a parallel corpus which is constructed from the Annotated English Gigaword dataset (Napoles et al., 2012) as mentioned in Rush et al. (2015). The parallel corpus is produced by pairing the first sentence and the headline in the news article with some heuristic rules. We use the script[1] released by Rush et al. (2015) to pre-process and extract the training and development datasets. The script performs various basic text normalization, including PTB tokenization, lower-casing, replacing all digit characters with #, and replacing word types seen less than 5 times with $\langle unk \rangle$. The extracted corpus contains about 3.8M sentence-summary pairs for the training set and 189K examples for the development set.

For our test set, we use the English Gigaword, DUC 2004, and Microsoft Research Abstractive Text Compression test sets.

[1] https://github.com/facebook/NAMAS

English Gigaword Test Set We randomly sample 8000 pairs from the extracted development set as our development set since it is relatively large. For the test set, we use the same randomly held-out test set of 2000 sentence-summary pairs as Rush et al. (2015).[2]

We also find that except for the empty titles, this test set has some invalid lines like the input sentence containing only one word. Therefore, we further sample 2000 pairs as our internal test set and release it for future works[3].

DUC 2004 Test Set We employ DUC 2004 data for tasks 1 & 2 (Over et al., 2007) in our experiments as one of the test sets since it is too small to train a neural network model on. The dataset pairs each document with 4 different human-written reference summaries which are capped at 75 bytes. It has 500 input sentences with each sentence paired with 4 summaries.

MSR-ATC Test Set Toutanova et al. (2016) release a new dataset for sentence summarization task by crowdsourcing. This dataset contains approximately 6,000 source text sentences with multiple manually-created summaries (about 26,000 sentence-summary pairs in total). Toutanova et al. (2016) provide a standard split of the data into training, development, and test sets, with 4,936, 448 and 785 input sentences respectively. Since the training set is too small, we only use the test set as one of our test sets. We denote this dataset as MSR-ATC (Microsoft Research Abstractive Text Compression) test set in the following.

Table 2 summarizes the statistic information of the three datasets we used.

5.2 Evaluation Metric

We employ ROUGE (Lin, 2004) as our evaluation metric. ROUGE measures the quality of summary by computing overlapping lexical units, such as unigram, bigram, trigram, and longest common subsequence (LCS). It becomes the standard evaluation metric for DUC shared tasks and popular for summarization evaluation. Following previous work, we use ROUGE-1 (unigram), ROUGE-2 (bi-

[2] Thanks to Rush et al. (2015), we acquired the test set they used. Following Chopra et al. (2016), we remove pairs with empty titles resulting in slightly different accuracy compared to Rush et al. (2015) for their systems. The cleaned test set contains 1951 sentence-summary pairs.

[3] Our development and test sets can be found at https://res.qyzhou.me

Data Set	Giga	DUC†	MSR†
#(sent)	3.99M	500	785
#(sentWord)	125M	17.8K	29K
#(summWord)	33M	20.9K	85.9K
#(ref)	1	4	3-5
AvgInputLen	31.35	35.56	36.97
AvgSummLen	8.23	10.43	25.5

Table 2: Data statistics for the English Gigaword, DUC 2004 and MSR-ATC datasets. #(x) denotes the number of x, e.g., #(ref) is the number of reference summaries of an input sentence. AvgInputLen is the average input sentence length and AvgSummLen is the average summary length. †DUC 2004 and MSR-ATC datasets are for test purpose only.

gram) and ROUGE-L (LCS) as the evaluation metrics in the reported experimental results.

5.3 Implementation Details

Model Parameters The input and output vocabularies are collected from the training data, which have 119,504 and 68,883 word types respectively. We set the word embedding size to 300 and all GRU hidden state sizes to 512. We use dropout (Srivastava et al., 2014) with probability $p = 0.5$.

Model Training We initialize model parameters randomly using a Gaussian distribution with Xavier scheme (Glorot and Bengio, 2010). We use Adam (Kingma and Ba, 2015) as our optimizing algorithm. For the hyperparameters of Adam optimizer, we set the learning rate $\alpha = 0.001$, two momentum parameters $\beta_1 = 0.9$ and $\beta_2 = 0.999$ respectively, and $\epsilon = 10^{-8}$. During training, we test the model performance (ROUGE-2 F1) on development set for every 2,000 batches. We halve the Adam learning rate α if the ROUGE-2 F1 score drops for twelve consecutive tests on development set. We also apply gradient clipping (Pascanu et al., 2013) with range $[-5, 5]$ during training. To both speed up the training and converge quickly, we use mini-batch size 64 by grid search.

Beam Search We use beam search to generate multiple summary candidates to get better results. To avoid favoring shorter outputs, we average the ranking score along the beam path by dividing it by the number of generated words. To both decode fast and get better results, we set the beam size to 12 in our experiments.

5.4 Baseline

We compare SEASS model with the following state-of-the-art baselines:

ABS Rush et al. (2015) use an attentive CNN encoder and NNLM decoder to do the sentence summarization task. We trained this baseline model with the released code[1] and evaluate it with our internal English Gigaword test set and MSR-ATC test set.

ABS+ Based on ABS model, Rush et al. (2015) further tune their model using DUC 2003 dataset, which leads to improvements on DUC 2004 test set.

CAs2s As an extension of the ABS model, Chopra et al. (2016) use a convolutional attention-based encoder and RNN decoder, which outperforms the ABS model.

Feats2s Nallapati et al. (2016) use a full RNN sequence-to-sequence encoder-decoder model and add some features to enhance the encoder, such as POS tag, NER, and so on.

Luong-NMT Neural machine translation model of Luong et al. (2015) with two-layer LSTMs for the encoder-decoder with 500 hidden units in each layer implemented in (Chopra et al., 2016).

s2s+att We also implement a sequence-to-sequence model with attention as our baseline and denote it as "s2s+att".

5.5 Results

We report ROUGE F1, ROUGE recall and ROUGE F1 for English Gigaword, DUC 2004 and MSR-ATC test sets respectively. We use the official ROUGE script (version 1.5.5) [4] to evaluate the summarization quality in our experiments. For English Gigaword[5] and MSR-ATC[6] test sets, the outputs have different lengths so we evaluate the system with F1 metric. As for the DUC 2004 test set[7], the task requires the system to produce a fixed length summary (75 bytes), therefore we employ ROUGE recall as the evaluation metric. To satisfy the length requirement, we decode the output summary to a roughly expected length following Rush et al. (2015).

[4] http://www.berouge.com/

[5] The ROUGE evaluation option is the same as Rush et al. (2015), -m -n 2 -w 1.2

[6] The ROUGE evaluation option is, -m -n 2 -w 1.2

[7] The ROUGE evaluation option is, -m -b 75 -n 2 -w 1.2

English Gigaword We acquire the test set from Rush et al. (2015) so we can make fair comparisons to the baselines.

Models	RG-1	RG-2	RG-L
ABS (beam)‡	29.55-	11.32-	26.42-

CAs2s (beam)‡	33.78-	15.97-	31.15-
Luong-NMT (beam)‡	33.10-	14.45-	30.71-
s2s+att (greedy)	33.18-	14.79-	30.80-
s2s+att (beam)	34.04-	15.95-	31.68-
SEASS (greedy)	35.48	16.50	32.93
SEASS (beam)	**36.15**	**17.54**	**33.63**

Table 3: Full length ROUGE F1 evaluation results on the English Gigaword test set used by Rush et al. (2015). RG in the Table denotes ROUGE. Results with ‡ mark are taken from the corresponding papers. The superscript - indicates that our SEASS model with beam search performs significantly better than it as given by the 95% confidence interval in the official ROUGE script.

Models	RG-1	RG-2	RG-L
ABS (beam)	37.41-	15.87-	34.70-
s2s+att (greedy)	42.41-	20.76-	39.84-
s2s+att (beam)	43.76-	22.28-	41.14-
SEASS (greedy)	45.27	22.88	42.20
SEASS (beam)	**46.86**	**24.58**	**43.53**

Table 4: Full length ROUGE F1 evaluation on our internal English Gigaword test data. The superscript - indicates that our SEASS model performs significantly better than it as given by the 95% confidence interval in the official ROUGE script.

In Table 3, we report the ROUGE F1 score of our model and the baseline methods. Our SEASS model with beam search outperforms all baseline models by a large margin. Even for greedy search, our model still performs better than other methods which used beam search. For the popular ROUGE-2 metric, our SEASS model achieves 17.54 F1 score and performs better than the previous works. Compared to the ABS model, our model has a 6.22 ROUGE-2 F1 relative gain. Compared to the highest CAs2s baseline, our model achieves 1.57 ROUGE-2 F1 improvement and passes the significant test according to the official ROUGE script.

Table 4 summarizes our results on our internal test set using ROUGE F1 evaluation metrics. The performance on our internal test set is comparable to our development set, which achieves 24.58 ROUGE-2 F1 and outperforms the baselines.

DUC 2004 We evaluate our model using the ROUGE recall score since the reference summaries of the DUC 2004 test set are capped at 75 bytes. Therefore, we decode the summary to a fixed length 18 to ensure that the generated summary satisfies the minimum length requirement. As summarized in Table 5, our SEASS outperforms all the baseline methods and achieves 29.21, 9.56 and 25.51 for ROUGE 1, 2 and L recall. Compared to the ABS+ model which is tuned using DUC 2003 data, our model performs significantly better by 1.07 ROUGE-2 recall score and is trained only with English Gigaword sentence-summary data without being tuned using DUC data.

Models	RG-1	RG-2	RG-L
ABS (beam)‡	26.55-	7.06-	22.05-
ABS+ (beam)‡	28.18-	8.49-	23.81-

SEASS (greedy)	28.68	8.55	25.04
SEASS (beam)	**29.21**	**9.56**	**25.51**

Table 5: ROUGE recall evaluation results on DUC 2004 test set. All these models are tested using beam search. Results with ‡ mark are taken from the corresponding papers. The superscript - indicates that our SEASS model performs significantly better than it as given by the 95% confidence interval in the official ROUGE script.

MSR-ATC We report the full length ROUGE F1 score on the MSR-ATC test set in Table 6. To the best of our knowledge, this is the first work that reports ROUGE metric scores on the MSR-ATC dataset. Note that we only compare our model with ABS since the others are not publicly available. Our SEASS achieves 10.63 ROUGE-2 F1 and outperforms the s2s+att baseline by 1.02 points.

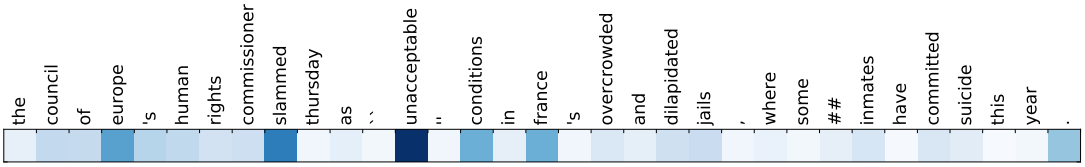

Figure 3: First derivative heat map of the output with respect to the selective gate. The important words are selected in the input sentence, such as "europe", "slammed" and "unacceptable". The output summary of our system is "council of europe slams french prison conditions" and the true summary is "council of europe again slams french prison conditions".

Models	RG-1	RG-2	RG-L
ABS (beam)	20.27$^-$	5.26$^-$	17.10$^-$
s2s+att (greedy)	15.15$^-$	4.48$^-$	13.62$^-$

SEASS (beam)	**25.75**	**10.63**	**22.90**

Table 6: Full length ROUGE F1 evaluation on MSR-ATC test set. Beam search are used in both the baselines and our method. The superscript $^-$ indicates that our SEASS model performs significantly better than it as given by the 95% confidence interval in the official ROUGE script.

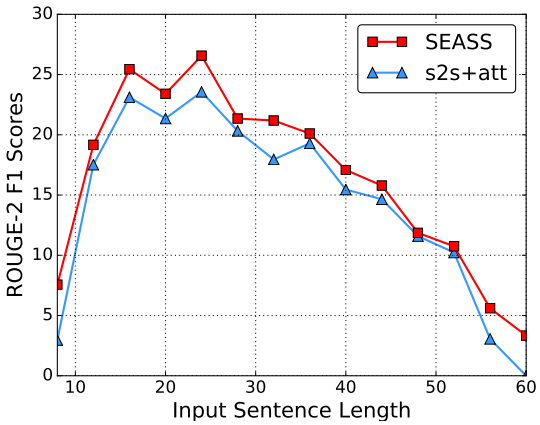

Figure 4: ROUGE-2 F1 score on different groups of input sentences in terms of their length for s2s+att baseline and our SEASS model on English Gigaword test sets.

6 Discussion

In this section, we first compare the performance of SEASS with the s2s+att baseline model to illustrate that the proposed method succeeds in selecting information and building tailored representation for abstractive sentence summarization. We then analyze selective encoding by visualizing the heat map.

Effectiveness of Selective Encoding We further test the SEASS model with different sentence lengths on English Gigaword test sets, which are merged from the Rush et al. (2015) test set and our internal test set. The length of sentences in the test sets ranges from 10 to 80. We group the sentences with an interval of 4 and get 18 different groups and we draw the first 14 groups. We find that the performance curve of our SEASS model always appears to be on the top of that of s2s+att with a certain margin. For the groups of 16, 20, 24, 32, 56 and 60, the SEASS model obtains big improvements compared to the s2s+att model. Overall, these improvements on all groups indicate that the selective encoding method benefits the abstractive sentence summarization task.

Saliency Heat Map of Selective Gate Since the output of the selective gate network is a high dimensional vector, it is hard to visualize all the gate values. We use the method in Li et al. (2016) to visualize the contribution of the selective gate to the final output, which can be approximated by the first derivative. Given sentence words x with associated output summary y, the trained model associates the pair (x, y) with a score $S_y(x)$. The goal is to decide which gate g associated with a specific word makes the most significant contribution to $S_y(x)$. We approximate the $S_y(g)$ by computing the first-order Taylor expansion since the score $S_y(x)$ is a highly non-linear function in the deep neural network models:

$$S_y(g) \approx w(g)^T g + b \tag{19}$$

where $w(g)$ is first the derivative of S_y with respect to the gate g:

$$w(g) = \frac{\partial(S_y)}{\partial g}|_g \tag{20}$$

We then draw the Euclidean norm of the first derivative of the output y with respect to the selective gate g associated with each input words.

Figure 3 shows an example of the first derivative heat map, in which most of the important words are selected by the selective gate such as "europe", "slammed", "unacceptable", "conditions", and "france". We can observe that the selective gate determines the importance of each word before decoder, which releases the burden of it by providing tailored sentence encoding.

7 Conclusion

This paper proposes a selective encoding model which extends the sequence-to-sequence model for abstractive sentence summarization task. The selective mechanism mimics one of the human summarizers' behaviors, selecting important information before writing down the summary. With the proposed selective mechanism, we build an end-to-end neural network summarization model which consists of three phases: encoding, selection, and decoding. Experimental results show that the selective encoding model greatly improves the performance with respect to the state-of-the-art methods on English Gigaword, DUC 2004 and MSR-ATC test sets.

PositionRank: An Unsupervised Approach to Keyphrase Extraction from Scholarly Documents

Corina Florescu and **Cornelia Caragea**
Computer Science and Engineering
University of North Texas, USA
CorinaFlorescu@my.unt.edu, ccaragea@unt.edu

Abstract

The large and growing amounts of online scholarly data present both challenges and opportunities to enhance knowledge discovery. One such challenge is to automatically extract a small set of keyphrases from a document that can accurately describe the document's content and can facilitate fast information processing. In this paper, we propose PositionRank, an unsupervised model for keyphrase extraction from scholarly documents that incorporates information from all positions of a word's occurrences into a biased PageRank. Our model obtains remarkable improvements in performance over PageRank models that do not take into account word positions as well as over strong baselines for this task. Specifically, on several datasets of research papers, PositionRank achieves improvements as high as 29.09%.

1 Introduction

The current Scholarly Web contains many millions of scientific documents. For example, Google Scholar is estimated to have more than 100 million documents. On one hand, these rapidly-growing scholarly document collections offer benefits for knowledge discovery, and on the other hand, finding useful information has become very challenging. Keyphrases associated with a document typically provide a high-level topic description of the document and can allow for efficient information processing. In addition, keyphrases are shown to be rich sources of information in many natural language processing and information retrieval tasks such as scientific paper summarization, classification, recommendation, clustering, and search (Abu-Jbara and Radev, 2011; Qazvinian et al., 2010; Jones and Staveley, 1999; Zha, 2002; Zhang et al., 2004; Hammouda et al., 2005). Due to their importance, many approaches to keyphrase extraction have been proposed in the literature along two lines of research: supervised and unsupervised (Hasan and Ng, 2014, 2010).

In the supervised line of research, keyphrase extraction is formulated as a binary classification problem, where candidate phrases are classified as either positive (i.e., keyphrases) or negative (i.e., non-keyphrases) (Frank et al., 1999; Hulth, 2003). Various feature sets and classification algorithms yield different extraction systems. For example, Frank et al. (1999) developed a system that extracts two features for each candidate phrase, i.e., the *tf-idf* of the phrase and its distance from the beginning of the target document, and uses them as input to Naïve Bayes classifiers. Although supervised approaches typically perform better than unsupervised approaches (Kim et al., 2013), the requirement for large human-annotated corpora for each field of study has led to significant attention towards the design of unsupervised approaches.

In the unsupervised line of research, keyphrase extraction is formulated as a ranking problem with graph-based ranking techniques being considered state-of-the-art (Hasan and Ng, 2014). These graph-based techniques construct a word graph from each target document, such that nodes correspond to words and edges correspond to word association patterns. Nodes are then ranked using graph centrality measures such as PageRank (Mihalcea and Tarau, 2004; Liu et al., 2010) or HITS (Litvak and Last, 2008), and the top ranked phrases are returned as keyphrases. Since their introduction, many graph-based extensions have been proposed, which aim at modeling various types of information. For example, Wan and Xiao (2008) proposed a model that incorporates a local

Factorizing Personalized **Markov Chains** for Next-**Basket Recommendation**
by Steffen Rendle, Christoph Freudenthaler and Lars Schmidt-Thieme

Recommender systems are an important component of many websites. Two of the most popular approaches are based on **matrix factorization** (MF) and **Markov chains** (MC). MF methods learn the general taste of a user by factorizing the matrix over observed user-item preferences. [...] we present a method bringing both approaches together. Our method is based on personalized transition graphs over underlying **Markov chains**. [...] our factorized personalized MC (FPMC) model subsumes both a common **Markov chain** and the normal **matrix factorization** model. [...] we introduce an adaption of the Bayesian Personalized Ranking (BPR) framework for sequential basket data. [...]

Author-input keyphrases: *Basket Recommendation, Markov Chain, Matrix Factorization*

Figure 1: The title and abstract of a WWW paper by Rendle et al. (2010) and the author-input keyphrases for the paper. Red bold phrases represent the gold-standard keyphrases for the document.

neighborhood of the target document corresponding to its textually-similar documents, computed using the cosine similarity between the *tf-idf* vectors of documents. Liu et al. (2010) assumed a mixture of topics over documents and proposed to use topic models to decompose these topics in order to select keyphrases from all major topics. Keyphrases are then ranked by aggregating the topic-specific scores obtained from several topic-biased PageRanks. We posit that other information can be leveraged that has the potential to improve unsupervised keyphrase extraction.

For example, in a scholarly domain, keyphrases generally occur on positions very close to the beginning of a document and occur frequently. Figure 1 shows an anecdotal example illustrating this behavior using the 2010 best paper award winner in the World Wide Web conference. The author input keyphrases are marked with red bold in the figure. Notice in this example the high frequency of the keyphrase "Markov chain" that occurs very early in the document (even from its title). Hence, *can we design an effective unsupervised approach to keyphrase extraction by jointly exploiting words' position information and their frequency in documents?* We specifically address this question using *research papers* as a case study. The result of this extraction task will aid indexing of documents in digital libraries, and hence, will lead to improved organization, search, retrieval, and recommendation of scientific documents. The importance of keyphrase extraction from research papers is also emphasized by the SemEval Shared Tasks on this topic from 2017[1] and 2010 (Kim et al., 2010). Our contributions are as follows:

- We propose an unsupervised graph-based model, called PositionRank, that incorporates information from all positions of a word's occurrences into a biased PageRank to score keywords that are later used to score and rank keyphrases in research papers.
- We show that PositionRank that aggregates information from all positions of a word's occurrences performs better than a model that uses only the first position of a word.
- We experimentally evaluate PositionRank on three datasets of research papers and show statistically significant improvements over PageRank-based models that do not take into account word positions, as well as over strong baselines for keyphrase extraction.

The rest of the paper is organized as follows. We summarize related work in the next section. PositionRank is described in Section 3. We then present the datasets of research papers, and our experiments and results in Section 4. Finally, we conclude the paper in Section 5.

2 Related Work

Many supervised and unsupervised approaches to keyphrase extraction have been proposed in the literature (Hasan and Ng, 2014).

Supervised approaches use annotated documents with "correct" keyphrases to train classifiers for discriminating keyphrases from non-keyphrases for a document. KEA (Frank et al., 1999) and GenEx (Turney, 2000) are two representative supervised approaches with the most important features being the frequency and the position of a phrase in a target document. Hulth

[1] http://alt.qcri.org/semeval2017/task10/

(2003) used a combination of lexical and syntactic features such as the collection frequency and the part-of-speech tag of a phrase in conjunction with a bagging technique. Nguyen and Kan (2007) extended KEA to include features such as the distribution of candidate phrases in different sections of a research paper, and the acronym status of a phrase. In a different work, Medelyan et al. (2009) extended KEA to integrate information from Wikipedia. Lopez and Romary (2010) used bagged decision trees learned from a combination of features including structural features (e.g., the presence of a phrase in particular sections of a document) and lexical features (e.g., the presence of a candidate phrase in WordNet or Wikipedia). Chuang et al. (2012) proposed a model that incorporates a set of statistical and linguistic features (e.g., *tf-idf*, BM25, part-of-speech filters) for identifying descriptive terms in a text. Caragea et al. (2014a) designed features based on information available in a document network (such as a citation network) and used them with traditional features in a supervised framework.

In unsupervised approaches, various measures such as *tf-idf* and topic proportions are used to score words, which are later aggregated to obtain scores for phrases (Barker and Cornacchia, 2000; Zhang et al., 2007; Liu et al., 2009). The ranking based on *tf-idf* has been shown to work well in practice (Hasan and Ng, 2014, 2010), despite its simplicity. Graph-based ranking methods and centrality measures are considered state-of-the-art for unsupervised keyphrase extraction. Mihalcea and Tarau (2004) proposed TextRank for scoring keyphrases by applying PageRank on a word graph built from adjacent words within a document. Wan and Xiao (2008) extended TextRank to SingleRank by adding weighted edges between words that co-occur in a window of variable size $w \geq 2$. Textually-similar neighboring documents are included in ExpandRank (Wan and Xiao, 2008) to compute more accurate word co-occurrence information. Gollapalli and Caragea (2014) extended ExpandRank to integrate information from citation networks where papers cite one another.

Lahiri et al. (2014) extracted keyphrases from documents using various centrality measures such as node degree, clustering coefficient and closeness. Martinez-Romo et al. (2016) used information from WordNet to enrich the semantic relationships between the words in the graph.

Several unsupervised approaches leverage word clustering techniques such as first grouping candidate words into topics and then, extracting one representative keyphrase from each topic (Liu et al., 2009; Bougouin et al., 2013). Liu et al. (2010) extended topic-biased PageRank (Haveliwala, 2003) to kephrase extraction. In particular, they decomposed a document into multiple topics, using topic models, and applied a separate topic-biased PageRank for each topic. The PageRank scores from each topic were then combined into a single score, using as weights the topic proportions returned by topic models for the document.

The best performing keyphrase extraction system in SemEval 2010 (El-Beltagy and Rafea, 2010) used statistical observations such as term frequencies to filter out phrases that are unlikely to be keyphrases. More precisely, thresholding on the frequency of phrases is applied, where the thresholds are estimated from the data. The candidate phrases are then ranked using the *tf-idf* model in conjunction with a boosting factor which aims at reducing the bias towards single word terms. Danesh et al. (2015) computed an initial weight for each phrase based on a combination of statistical heuristics such as the *tf-idf* score and the first position of a phrase in a document. Phrases and their initial weights are then incorporated into a graph-based algorithm which produces the final ranking of keyphrase candidates. Le et al. (2016) showed that the extraction of keyphrases from a document can benefit from considering candidate phrases with part of speech tags other than nouns or adjectives. Adar and Datta (2015) extracted keyphrases by mining abbreviations from scientific literature and built a semantically hierarchical keyphrase database. Word embedding vectors were also employed to measure the relatedness between words in graph based models (Wang et al., 2014). Many of the above approaches, both supervised and unsupervised, are compared and analyzed in the ACL survey on keyphrase extraction by Hasan and Ng (2014).

In contrast to the above approaches, we propose PositionRank, aimed at capturing both highly frequent words or phrases and their position in a document. Despite that the *relative position* of a word in a document is shown to be a very effective feature in supervised keyphrase extraction (Hulth, 2003; Zhang et al., 2007), to our knowledge, the position information has not been used before in unsupervised methods. The strong contribution of

this paper is the design of a position-biased PageRank model that successfully incorporates all positions of a word's occurrences, which is different from supervised models that use only the first position of a word. Our model assigns higher probabilities to words found early on in a document instead of using a uniform distribution over words.

3 Proposed Model

In this section, we describe PositionRank, our fully unsupervised, graph-based model, that simultaneously incorporates the position of words and their frequency in a document to compute a biased PageRank score for each candidate word. Graph-based ranking algorithms such as PageRank (Page et al., 1998) measure the importance of a vertex within a graph by taking into account global information computed recursively from the entire graph. For each word, we compute a weight by aggregating information from all positions of the word's occurrences. This weight is then incorporated into a biased PageRank algorithm in order to assign a different "preference" to each word.

3.1 PositionRank

The PositionRank algorithm involves three essential steps: (1) the graph construction at word level; (2) the design of Position-Biased PageRank; and (3) the formation of candidate phrases. These steps are detailed below.

3.1.1 Graph Construction

Let d be a target document for extracting keyphrases. We first apply the part-of-speech filter using the NLP Stanford toolkit and then select as candidate words only nouns and adjectives, similar to previous works (Mihalcea and Tarau, 2004; Wan and Xiao, 2008). We build a word graph $G = (V, E)$ for d such that each unique word that passes the part-of-speech filter corresponds to a node in G. Two nodes v_i and v_j are connected by an edge $(v_i, v_j) \in E$ if the words corresponding to these nodes co-occur within a window of w contiguous tokens in the content of d. The weight of an edge $(v_i, v_j) \in E$ is computed based on the co-occurrence count of the two words within a window of w successive tokens in d. Note that the graph can be constructed both directed and undirected. However, Mihalcea and Tarau (2004) showed that the type of graph used to represent the text does not significantly influence the performance of keyphrase extraction. Hence, in this work, we build undirected graphs.

3.1.2 Position-Biased PageRank

Formally, let G be an undirected graph constructed as above and let M be its adjacency matrix. An element $m_{ij} \in M$ is set to the weight of edge (v_i, v_j) if there exist an edge between nodes v_i and v_j, and is set to 0 otherwise. The PageRank score of a node v_i is recursively computed by summing the normalized scores of nodes v_j, which are linked to v_i (as explained below).

Let S denote the vector of PageRank scores, for all $v_i \in V$. The initial values of S are set to $\frac{1}{|V|}$. The PageRank score of each node at step $t+1$, can then be computed recursively using:

$$S(t+1) = \widetilde{M} \cdot S(t) \tag{1}$$

where $\widetilde{M}$ is the normalized form of matrix M with $\widetilde{m_{ij}} \in \widetilde{M}$ defined as:

$$\widetilde{m_{ij}} = \begin{cases} m_{ij} / \sum_{j=1}^{|V|} m_{ij} & \text{if } \sum_{j=1}^{|V|} m_{ij} \neq 0 \\ 0 & \text{otherwise} \end{cases}$$

The PageRank computation can be seen as a Markov Chain process in which nodes represent states and the links between them are the transitions. By recursively applying Eq. (1), we obtain the principal eigenvector, which represents the stationary probability distribution of each state, in our case of each node (Manning et al., 2008).

To ensure that the PageRank (or the random walk) does not get stuck into cycles of the graph, a damping factor α is added to allow the "teleport" operation to another node in the graph. Hence, the computation of S becomes:

$$S = \alpha \cdot \widetilde{M} \cdot S + (1 - \alpha) \cdot \widetilde{p} \tag{2}$$

where S is the principal eigenvector and $\widetilde{p}$ is a vector of length $|V|$ with all elements $\frac{1}{|V|}$. The vector $\widetilde{p}$ indicates that, being in a node v_i, the random walk can jump to any other node in the graph with equal probability.

By biasing $\widetilde{p}$, the random walk would prefer nodes that have higher probability in the graph (Haveliwala, 2003).

The idea of PositionRank is to assign larger weights (or probabilities) to words that are found early in a document and are frequent. Specifically, we want to assign a higher probability to a word found on the 2^{nd} position as compared to a word

found on the 50^{th} position in the same document. We weigh each candidate word with its inverse position in the document before any filters are applied. If the same word appears multiple times in the target document, then we sum all its position weights. For example, if a word is found on the following positions: 2^{nd}, 5^{th} and 10^{th}, its weight is: $\frac{1}{2} + \frac{1}{5} + \frac{1}{10} = \frac{4}{5} = 0.8$. Summing up the position weights for a given word aims to grant more confidence to frequently occurring words by taking into account the position weight of each occurrence. Then, the vector $\widetilde{p}$ is set to the normalized weights for each candidate word as follows:

$$\widetilde{p} = \left[\frac{p_1}{p_1+p_2+...+p_{|V|}}, \frac{p_2}{p_1+p_2+...+p_{|V|}}, ..., \frac{p_{|V|}}{p_1+p_2+...+p_{|V|}}\right]$$

The PageRank score of a vertex v_i, i.e., $S(v_i)$, can be obtained in an algebraic way by recursively computing the following equation:

$$S(v_i) = (1-\alpha) \cdot \widetilde{p}_i + \alpha \cdot \sum_{v_j \in Adj(v_i)} \frac{w_{ji}}{O(v_j)} S(v_j)$$

where $O(v_j) = \sum_{v_k \in Adj(v_j)} w_{jk}$ and $\widetilde{p}_i$ is the weight found in the vector $\widetilde{p}$ for vertex v_i.

In our experiments, the words' PageRank scores are recursively computed until the difference between two consecutive iterations is less than 0.001 or a number of 100 iterations is reached.

3.1.3 Forming Candidate Phrases

Candidate words that have contiguous positions in a document are concatenated into phrases. We consider noun phrases that match the regular expression (adjective)*(noun)+, of length up to three, (i.e., unigrams, bigrams, and trigrams).

Finally, phrases are scored by using the sum of scores of individual words that comprise the phrase (Wan and Xiao, 2008). The top-scoring phrases are output as predictions (i.e., the predicted keyphrases for the document).

4 Experiments and Results

4.1 Datasets and Evaluation Metrics

In order to evaluate the performance of PositionRank, we carried out experiments on three datasets. The first and second datasets were made available by Gollapalli and Caragea (2014).[2] These datasets are compiled from the CiteSeerX digital library (Giles et al., 1998) and consist of research papers from the ACM Conference on Knowledge Discovery and Data Mining (KDD) and the World Wide Web Conference (WWW). The third dataset was made available by Nguyen and Kan (2007) and consist of research papers from various disciplines. In experiments, we use the title and abstract of each paper to extract keyphrases. The author-input keyphrases are used as gold-standard for evaluation. All three datasets are summarized in Table 1, which shows the number of papers in each dataset, the total number of keyphrases (Kp), the average number of keyphrases per document (AvgKp), and a brief insight into the length and number of available keyphrases.

Evaluation Metrics. We use mean reciprocal rank (MRR) curves to illustrate our experimental findings. MRR gives the averaged ranking of the first correct prediction and is defined as:

$$MRR = \frac{1}{|D|} \sum_{d \in D} \frac{1}{r_d}$$

where D is the collection of documents and r_d is the rank at which the first correct keyphrase of document d was found. We also summarize the results in terms of Precision, Recall, and F1-score in a table to contrast PositionRank with previous models since these metrics are widely used in previous works (Hulth, 2003; Wan and Xiao, 2008; Mihalcea and Tarau, 2004; Hasan and Ng, 2014). To compute "performance@k" (such as MRR@k), we examine the top-k predictions (with k ranging from 1 to 10). We use *average* k to refer to the average number of keyphrases for a particular dataset as listed in Table 1. For example, *average* $k = 5$ for the WWW dataset. For comparison purposes, we used Porter Stemmer to reduce both predicted and gold keyphrases to a base form.

4.2 Results and Discussion

Our experiments are organized around several questions, which are discussed below.

How sensitive is PositionRank to its parameters? One parameter of our model that can influence its performance is the window size w, which determines how edges are added between candidate words in the graph. We experimented with values of w ranging from 2 to 10 in steps of 1 and chose several configurations for illustration. Figure 2 shows the MRR curves of PositionRank for different values of w, on all three datasets. As can be seen from the figure, the performance of our model does not change significantly as w changes.

[2] http://www.cse.unt.edu/∼ccaragea/keyphrases.html

Dataset	#Docs	Kp	AvgKp	unigrams	bigrams	trigrams	n-grams ($n \geq 4$)
KDD	834	3093	3.70	810	1770	471	42
WWW	1350	6405	4.74	2254	3139	931	81
Nguyen	211	882	4.18	260	457	132	33

Table 1: A summary of our datasets.

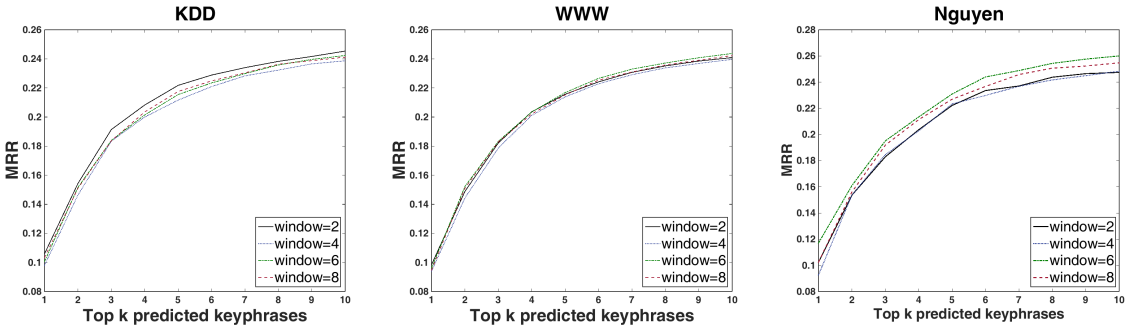

Figure 2: MRR curves for PositionRank that uses different values for the window size.

In addition to the window size, our model has one more parameter, i.e., the damping factor α. In order to understand its influence on the performance of PositionRank, we experimented with several values of α, e.g., $0.75, 0.8, 0.85, 0.9$, and did not find significant differences in the performance of PositionRank (results not shown due to highly overlapping curves). Hence, in Equation 2, we set $\alpha = 0.85$ as in (Haveliwala, 2003).

What is the impact of aggregating information from all positions of a word over using a word's first position only? In this experiment, we analyze the influence that position-weighted frequent words in a document would have on the performance of PositionRank. Specifically, we compare the performance of the model that aggregates information from all positions of a word's occurrences, referred as PositionRank - *full model* with that of the model that uses only the first position of a word, referred as PositionRank - *fp*. In the example from the previous section, a word occurring on positions 2^{nd}, 5^{th}, and 10^{th} will have a weight of $\frac{1}{2} + \frac{1}{5} + \frac{1}{10} = \frac{4}{5} = 0.8$ in the *full model*, and a weight of $\frac{1}{2} = 0.5$ in the *first position* (*fp*) model. Note that the weights of words are normalized before they are used in the biased PageRank.

Figure 3 shows the results of this experiment in terms of MRR for the top k predicted keyphrases, with k from 1 to 10, for all datasets, KDD, WWW, and Nguyen. As we can see from the figure, the performance of PositionRank - *full model* consistently outperforms its counterpart that uses the *first position* only, on all datasets. We can conclude from this experiment that aggregating information from all occurrences of a word acts as an important component in PositionRank. Hence, we use PositionRank - *full model* for further comparisons.

How well does position information aid in unsupervised keyphrase extraction from research papers? In this experiment, we compare our position-biased PageRank model (PositionRank) with two PageRank-based models, TextRank and SingleRank, that do not make use of the position information. In TextRank, an undirected graph is built for each target paper, so that nodes correspond to words and edges are drawn between two words that occur next to each other in text, i.e., the window size w is 2. SingleRank extends TextRank by adding edges between two words that co-occur in a window of $w \geq 2$ contiguous words in text.

Figure 4 shows the MRR curves comparing PositionRank with TextRank and SingleRank. As can be seen from the figure, PositionRank substantially outperforms both TextRank and SingleRank on all three datasets, illustrating that the words' positions contain significant hints that aid the keyphrase extraction task. PositionRank can successfully harness this information in an unsupervised setting to obtain good improvements in the extraction performance. For example, PositionRank that uses information from all positions of a word's occurrences yields improvements in MRR@average k of 17.46% for KDD, 20.18% for WWW, and 17.03% for Nguyen over SingleRank.

How does PositionRank compare with other existing state-of-the-art methods? In Figure 5, we

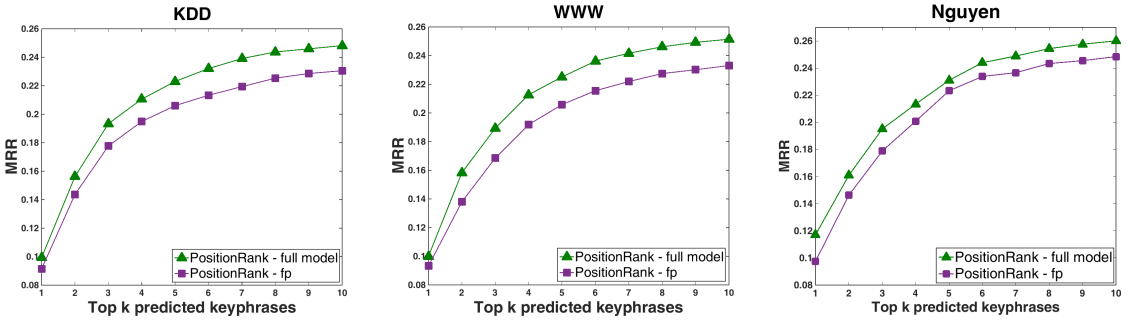

Figure 3: The comparison of PositionRank that aggregates information from all positions of a word's occurrences (full model) with the PositionRank that uses only the first position of a word (fp).

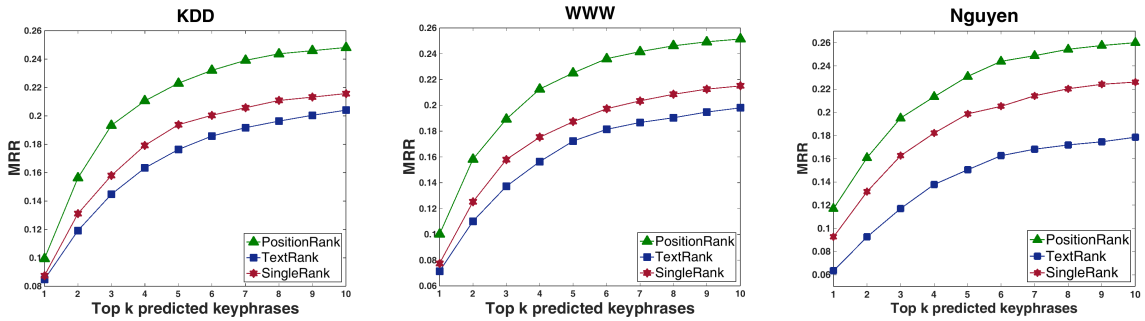

Figure 4: MRR curves for PositionRank and two unbiased PageRank-based models that do not consider position information.

compare PositionRank with several strong baselines: TF-IDF, ExpandRank, and TopicalPageRank (TPR) (Hasan and Ng, 2014; Wan and Xiao, 2008; Liu et al., 2010). We selected these baselines based on the ACL survey on keyphrase extraction by Hasan and Ng (2014). In TF-IDF, we calculate the *tf* score of each candidate word in the target document, whereas the *idf* component is estimated from all three datasets. In ExpandRank, we build an undirected graph from each paper and its local textual neighborhood and calculate the candidate words' importance scores using PageRank. We performed experiments with various numbers of textually-similar neighbors and present the best results for each dataset. In TPR, we build an undirected graph using information from the target paper. We then perform topic decomposition of the target document using topic models to infer the topic distribution of a document and to compute the probability of words in these topics. Last, we calculate the candidate words' importance scores by aggregating the scores from several topic-biased PageRanks (one PageRank per topic). We used the implementation of topic models from Mallet.[3] To train the topic model, we used a subset of about $45,000$ paper abstracts extracted from the CiteSeer^x scholarly big dataset introduced by Caragea et al. (2014b). For all models, the score of a phrase is obtained by summing the score of the constituent words in the phrase.

From Figure 5, we can see that PositionRank achieves a significant increase in MRR over the baselines, on all datasets. For example, the highest relative improvement in MRR@average k for this experiment is as high as 29.09% achieved on the Nguyen collection. Among all models compared in Figure 5, ExpandRank is clearly the best performing baseline, while TPR achieves the lowest MRR values, on all datasets.

4.3 Overall Performance

As already mentioned, prior works on keyphrase extraction report results also in terms of precision (P), recall (R), and F1-score (F1) (Hulth, 2003; Hasan and Ng, 2010; Liu et al., 2010; Wan and Xiao, 2008). Consistent with these works, in Table 2, we show the results of the comparison of PositionRank with all baselines, in terms of P, R and F1 for top $k = 2, 4, 6, 8$ predicted keyphrases, on all three datasets. As can be seen from the ta-

Table 2: PositionRank against baselines in terms of Precision, Recall and F1-score. Best results are shown in **bold blue**.

ble, PositionRank outperforms all baselines, on all datasets. For example, on WWW at top 6 predicted keyphrases, PositionRank achieves an F1-score of 12.1% as compared to 11.2% achieved by ExpandRank and 10.7% achieved by both TF-IDF and TPR. From the table, we can also see that ExpandRank is generally the best performing baseline on all datasets. However, it is interesting to note that, unlike PositionRank that uses information only from the target paper, ExpandRank adds external information from a textually-similar neighborhood of the target paper, and hence, is computationally more expensive.

PositionRank-*first position only* (*fp*) typically performs worse than PositionRank-*full model*, but it still outperforms the baseline methods for most top k predicted keyphrases, on all datasets. For example, on Nguyen at top 4, PositionRank-*fp* achieves an F1-score of 10.5% compared to the best baseline (TF-IDF in this case), which reaches only a score of 9.6%.

A striking observation is that PositionRank outperforms TPR on all datasets. Compared with our model, TPR is a very complex model, which uses topic models to learn topics of words and infer the topic proportion of documents. Additionally, TPR has more parameters (e.g., the number of topics) that need to be tuned separately for each dataset. PositionRank is much less complex, it does not require an additional dataset (e.g., to train a topic model) and its performance is better than that of TPR. TF-IDF and ExpandRank are the best performing baselines, on all datasets, KDD, WWW, and Nguyen. For example, on KDD at $k = 4$, TF-IDF and ExpandRank yield an F1-score of 9.4% and 10.1%, respectively, compared with 8.4%, 9.0% and 8.9% achieved by TextRank, SingleRank and TPR, respectively.

by Weizheng Gao, Hyun Chul Lee and Yingbo Miao A **collaborative**$^{0.142}$ **crawler**$^{0.165}$ is a group$^{0.025}$ of crawling$^{0.165}$ nodes$^{0.033}$, in which each crawling$^{0.165}$ node$^{0.033}$ is responsible$^{0.012}$ for a specific$^{0.010}$ portion$^{0.010}$ of the web$^{0.015}$. We study the problem$^{0.007}$ of collecting$^{0.011}$ geographically$^{0.274}$ aware$^{0.006}$ pages$^{0.018}$ using **collaborative**$^{0.142}$ **crawling**$^{0.165}$ strategies$^{0.017}$. We first propose several **collaborative**$^{0.142}$ **crawling**$^{0.165}$ strategies$^{0.017}$ for the **geographically**$^{0.274}$ **focused**$^{0.134}$ **crawling**$^{0.165}$, whose goal$^{0.004}$ is to collect web$^{0.015}$ pages$^{0.018}$ about specified$^{0.010}$ geographic$^{0.274}$ locations$^{0.003}$ by considering features$^{0.005}$ like URL$^{0.006}$ address$^{0.005}$ of page$^{0.018}$ [...] More precisely, features$^{0.005}$ like URL$^{0.006}$ address$^{0.005}$ of page$^{0.018}$ and extended$^{0.004}$ anchor$^{0.004}$ text$^{0.004}$ of link$^{0.004}$ are shown to yield the best overall performance$^{0.003}$ for the **geographically**$^{0.274}$ **focused**$^{0.134}$ **crawling**$^{0.165}$.

Author-input keyphrases: *collaborative crawling, geographically focused crawling, geographic entities*

Figure 6: The title and abstract of a WWW paper by Gao et al. (2006) and the author-input keyphrases for the paper. **Bold dark red** phrases represent predicted keyphrases for the document.

With a paired t-test on our results, we found that the improvements in MRR, precision, recall, and F1-score for PositionRank are statistically significant (p-values < 0.05).

4.4 Anecdotal Evidence

We show anecdotal evidence using a paper by Gao et al. (2006) that is part of the Nguyen dataset. Figure 6 shows the title and abstract of this paper together with the author-input keyphrases. We marked in bold dark red the candidate phrases that are predicted as keyphrases by our proposed model (PositionRank), in black the words that are selected as candidate phrases and in gray the words that are filtered out based on their part-of-speech tags or the stopwords list being used. We show the probability (or weight) of each candidate word in its upper right corner. These weights are computed based on both the word's position and its frequency in the text. Note that our model uses these weights to bias the PageRank algorithm to prefer specific nodes in the graph.

As we can see from the figure, component words of author's keyphrases such as: "collaborative," "crawling," "focused," and "geographically" are assigned the highest scores while candidates such as "performance," "anchor," or "features" are assigned very low weights, making them less likely to be chosen as keyphrases.

5 Conclusion and Future Work

We proposed a novel unsupervised graph-based algorithm, called PositionRank, which incorporates both the position of words and their frequency in a document into a biased PageRank. To our knowledge, we are the first to integrate the position information in novel ways in unsupervised keyphrase extraction. Specifically, unlike supervised approaches that use only the first position information, we showed that modeling the entire distribution of positions for a word outperforms models that use only the first position.

Our experiments on three datasets of research papers show that our proposed model achieves better results than strong baselines, with relative improvements in performance as high as 29.09%. In the future, it would be interesting to explore the performance of PositionRank on other types of documents, e.g., web pages and emails.

Acknowledgments

We are grateful to Dr. C. Lee Giles for the CiteSeerX data that we used to create our KDD and WWW datasets as well as to train the topic models. We very much thank our anonymous reviewers for their constructive comments and feedback. This research was supported by the NSF award #1423337 to Cornelia Caragea. Abstract

Automatically evaluating the quality of dialogue responses for unstructured domains is a challenging problem. Unfortunately, existing automatic evaluation metrics are biased and correlate very poorly with human judgements of response quality. Yet having an accurate automatic evaluation procedure is crucial for dialogue research, as it allows rapid prototyping and testing of new models with fewer expensive human evaluations. In response to this challenge, we formulate automatic dialogue evaluation as a learning problem. We present an evaluation model (ADEM) that learns to predict human-like scores to input responses, using a new dataset of human response scores. We show that the ADEM model's predictions correlate significantly, and at a level much higher than word-overlap metrics such as BLEU, with human judgements at both the utterance and system-level. We also show that ADEM can generalize to evaluating dialogue models unseen during training, an important step for automatic dialogue evaluation.

1 Introduction

Building systems that can naturally and meaningfully converse with humans has been a central goal of artificial intelligence since the formulation of the Turing test (Turing, 1950). Research on one type of such systems, sometimes referred to as non-task-oriented dialogue systems, goes back to the mid-60s with Weizenbaum's famous program *ELIZA*: a rule-based system mimicking a Rogerian psychotherapist by persistently either rephrasing statements or asking questions (Weizenbaum, 1966). Recently, there has been a surge of interest towards building large-scale non-task-oriented dialogue systems using neural networks (Sordoni et al., 2015b; Shang et al., 2015; Vinyals and Le, 2015; Serban et al., 2016a; Li et al., 2015). These models are trained in an end-to-end manner to optimize a single objective, usually the likelihood of generating the responses from a fixed corpus. Such models have already had a substantial impact in industry, including Google's Smart Reply system (Kannan et al., 2016), and Microsoft's Xiaoice chatbot (Markoff and Mozur, 2015), which has over 20 million users.

Context of Conversation
Speaker A: Hey, what do you want to do tonight?
Speaker B: Why don't we go see a movie?
Model Response
Nah, let's do something active.
Reference Response
Yeah, the film about Turing looks great!

Figure 1: Example where word-overlap scores fail for dialogue evaluation; although the model response is reasonable, it has no words in common with the reference response, and thus would be given low scores by metrics such as BLEU.

One of the challenges when developing such systems is to have a good way of measuring progress, in this case the performance of the chatbot. The Turing test provides one solution to the evaluation of dialogue systems, but there are limitations with its original formulation. The test requires live human interactions, which is expensive and difficult to scale up. Furthermore, the test requires carefully designing the instructions to the human interlocutors, in order to balance their behaviour and expectations so that different systems may be ranked accurately by performance. Although unavoidable, these instructions introduce bias into the evaluation measure. The more common approach of having

https://doi.org/10.18653/v1/P17-1103

humans evaluate the quality of dialogue system responses, rather than distinguish them from human responses, induces similar drawbacks in terms of time, expense, and lack of scalability. In the case of chatbots designed for specific conversation domains, it may also be difficult to find sufficient human evaluators with appropriate background in the topic (Lowe et al., 2015).

Despite advances in neural network-based models, evaluating the quality of dialogue responses automatically remains a challenging and understudied problem in the non-task-oriented setting. The most widely used metric for evaluating such dialogue systems is BLEU (Papineni et al., 2002), a metric measuring word overlaps originally developed for machine translation. However, it has been shown that BLEU and other word-overlap metrics are biased and correlate poorly with human judgements of response quality (Liu et al., 2016). There are many obvious cases where these metrics fail, as they are often incapable of considering the semantic similarity between responses (see Figure 1). Despite this, many researchers still use BLEU to evaluate their dialogue models (Ritter et al., 2011; Sordoni et al., 2015b; Li et al., 2015; Galley et al., 2015; Li et al., 2016a), as there are few alternatives available that correlate with human judgements. While human evaluation should always be used to evaluate dialogue models, it is often too expensive and time-consuming to do this for every model specification (for example, for every combination of model hyperparameters). Therefore, having an accurate model that can evaluate dialogue response quality automatically — what could be considered an *automatic Turing test* — is critical in the quest for building human-like dialogue agents.

To make progress towards this goal, we make the simplifying assumption that a 'good' chatbot is one whose responses are scored highly on appropriateness by human evaluators. We believe this is sufficient for making progress as current dialogue systems often generate inappropriate responses. We also find empirically that asking evaluators for other metrics results in either low inter-annotator agreement, or the scores are highly correlated with appropriateness (see supp. material). Thus, we collect a dataset of appropriateness scores to various dialogue responses, and we use this dataset to train an *automatic dialogue evaluation model* (ADEM). The model is trained in a semi-supervised manner using a hierarchical recurrent neural network (RNN) to predict human scores. We show that ADEM scores correlate significantly with human judgement at both the utterance-level and system-level. We also show that ADEM can often generalize to evaluating new models, whose responses were unseen during training, making ADEM a strong first step towards effective automatic dialogue response evaluation.[1]

2 Data Collection

To train a model to predict human scores to dialogue responses, we first collect a dataset of human judgements (scores) of Twitter responses using the crowdsourcing platform Amazon Mechanical Turk (AMT).[2] The aim is to have accurate human scores for a variety of conversational responses — conditioned on dialogue contexts — which span the full range of response qualities. For example, the responses should include both relevant and irrelevant responses, both coherent and non-coherent responses and so on. To achieve this variety, we use candidate responses from several different models. Following (Liu et al., 2016), we use the following 4 sources of candidate responses: (1) a response selected by a TF-IDF retrieval-based model, (2) a response selected by the Dual Encoder (DE) (Lowe et al., 2015), (3) a response generated using the hierarchical recurrent encoder-decoder (HRED) model (Serban et al., 2016a), and (4) human-generated responses. It should be noted that the human-generated candidate responses are *not* the reference responses from a fixed corpus, but novel human responses that are different from the reference. In addition to increasing response variety, this is necessary because we want our evaluation model to learn to compare the reference responses to the candidate responses. We provide the details of our

[1] Code and trained model parameters are available online: https://github.com/mike-n-7/ADEM.

[2] All data collection was conducted in accordance with the policies of the host institutions' ethics board.

AMT experiments in the supplemental material, including additional experiments suggesting that several other metrics are currently unlikely to be useful for building evaluation models. Note that, in order to maximize the number of responses obtained with a fixed budget, we only obtain one evaluation score per dialogue response in the dataset.

To train evaluation models on human judgements, it is crucial that we obtain scores of responses that lie near the distribution produced by advanced models. This is why we use the Twitter Corpus (Ritter et al., 2011), as such models are pre-trained and readily available. Further, the set of topics discussed is quite broad — as opposed to the very specific Ubuntu Dialogue Corpus (Lowe et al., 2015) — and therefore the model may also be suited to other chit-chat domains. Finally, since it does not require domain specific knowledge (e.g. technical knowledge), it should be easy for AMT workers to annotate.

3 Technical Background

3.1 Recurrent Neural Networks

Recurrent neural networks (RNNs) are a type of neural network with time-delayed connections between the internal units. This leads to the formation of a *hidden state* h_t, which is updated for every input: $h_t = f(W_{hh}h_{t-1} + W_{ih}x_t)$, where W_{hh} and W_{ih} are parameter matrices, f is a non-linear activation function such as tanh, and x_t is the input at time t. The hidden state allows for RNNs to better model sequential data, such as language.

In this paper, we consider RNNs augmented with long-short term memory (LSTM) units (Hochreiter and Schmidhuber, 1997). LSTMs add a set of gates to the RNN that allow it to learn how much to update the hidden state. LSTMs are one of the most well-established methods for dealing with the vanishing gradient problem in recurrent networks (Hochreiter, 1991; Bengio et al., 1994).

3.2 Word-Overlap Metrics

One of the most popular approaches for automatically evaluating the quality of dialogue responses is by computing their *word overlap* with the reference response. In particular, the most popular metrics are the BLEU and METEOR scores used for machine translation, and the ROUGE score used for automatic summarization. While these metrics tend to correlate with human judgements in their target domains, they have recently been shown to highly biased and correlate very poorly with human judgements for dialogue response evaluation (Liu et al., 2016). We briefly describe BLEU here, and provide a more detailed summary of word-overlap metrics in the supplemental material.

BLEU BLEU (Papineni et al., 2002) analyzes the co-occurrences of n-grams in the reference and the proposed responses. It computes the n-gram precision for the whole dataset, which is then multiplied by a brevity penalty to penalize short translations. For BLEU-N, N denotes the largest value of n-grams considered (usually $N = 4$).

Drawbacks One of the major drawbacks of word-overlap metrics is their failure in capturing the semantic similarity (and other structure) between the model and reference responses when there are few or no common words. This problem is less critical for machine translation; since the set of reasonable translations of a given sentence or document is rather small, one can reasonably infer the quality of a translated sentence by only measuring the word-overlap between it and one (or a few) reference translations. However, in dialogue, the set of appropriate responses given a context is much larger (Artstein et al., 2009); in other words, there is a very high *response diversity* that is unlikely to be captured by word-overlap comparison to a single response.

Further, word-overlap scores are computed directly between the model and reference responses. As such, they do not consider the context of the conversation. While this may be a reasonable assumption in machine translation, it is not the case for dialogue; whether a model response is an adequate substitute for the reference response is clearly context-dependent. For example, the two responses in Figure 1 are equally appropriate given the context. However, if we simply change the context to: *"Have you heard of any good movies recently?"*, the model response is no longer relevant while the reference response remains valid.

4 An Automatic Dialogue Evaluation Model (ADEM)

To overcome the problems of evaluation with word-overlap metrics, we aim to construct a dialogue evaluation model that: (1) captures semantic similarity beyond word overlap statistics, and (2) exploits both the context and the reference response to calculate its score for the model response. We

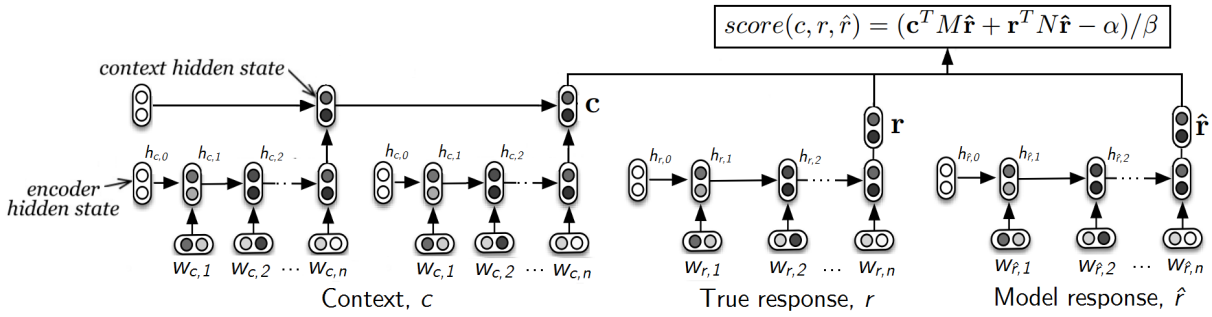

Figure 2: The ADEM model, which uses a hierarchical encoder to produce the context embedding $\mathbf{c}$.

call this evaluation model ADEM.

ADEM learns distributed representations of the context, model response, and reference response using a hierarchical RNN encoder. Given the dialogue context c, reference response r, and model response $\hat{r}$, ADEM first encodes each of them into vectors ($\mathbf{c}$, $\hat{\mathbf{r}}$, and $\mathbf{r}$, respectively) using the RNN encoder. Then, ADEM computes the score using a dot-product between the vector representations of c, r, and $\hat{r}$ in a linearly transformed space: :

$$score(c, r, \hat{r}) = (\mathbf{c}^T M \hat{\mathbf{r}} + \mathbf{r}^T N \hat{\mathbf{r}} - \alpha)/\beta \quad (1)$$

where $M, N \in \mathbb{R}^n$ are learned matrices initialized to the identity, and α, β are scalar constants used to initialize the model's predictions in the range $[1, 5]$. The model is shown in Figure 2.

The matrices M and N can be interpreted as linear projections that map the model response $\hat{\mathbf{r}}$ into the space of contexts and reference responses, respectively. The model gives high scores to responses that have similar vector representations to the context and reference response after this projection. The model is end-to-end differentiable; all the parameters can be learned by backpropagation. In our implementation, the parameters $\theta = \{M, N\}$ of the model are trained to minimize the squared error between the model predictions and the human score, with L2-regularization:

$$\mathcal{L} = \sum_{i=1:K} [score(c_i, r_i, \hat{r}_i) - human_i]^2 + \gamma ||\theta||_2 \quad (2)$$

where γ is a scalar constant. The simplicity of our model leads to both accurate predictions and fast evaluation (see supp. material), which is important to allow rapid prototyping of dialogue systems.

The hierarchical RNN encoder in our model consists of two layers of RNNs (El Hihi and Bengio, 1995; Sordoni et al., 2015a). The lower-level RNN, the *utterance-level encoder*, takes as input words from the dialogue, and produces a vector output at the end of each utterance. The *context-level encoder* takes the representation of each utterance as input and outputs a vector representation of the context. This hierarchical structure is useful for incorporating information from early utterances in the context (Serban et al., 2016a). Following previous work, we take the last hidden state of the context-level encoder as the vector representation of the input utterance or context. The parameters of the RNN encoder are pretrained and are not learned from the human scores.

An important point is that the ADEM procedure above *is not a dialogue retrieval model*: the fundamental difference is that ADEM has access to the reference response. Thus, ADEM can compare a model's response to a known good response, which is significantly easier than inferring response quality from solely the context.

Pre-training with VHRED We would like an evaluation model that can make accurate predictions from few labeled examples, since these examples are expensive to obtain. We therefore employ semi-supervised learning, and use a pre-training procedure to learn the parameters of the encoder. In particular, we train the encoder as part of a neural dialogue model; we attach a third *decoder RNN* that takes the output of the encoder as input, and train it to predict the next utterance of a dialogue conditioned on the context.

The dialogue model we employ for pre-training is the latent variable hierarchical recurrent encoder-decoder (VHRED) model (Serban et al., 2016b), shown in Figure 3. The VHRED model is an extension of the original hierarchical recurrent encoder-decoder (HRED) model (Serban et al., 2016a) with a turn-level stochastic latent variable. The dialogue context is encoded into a vector using our hierarchical encoder, and the VHRED then samples a Gaus-

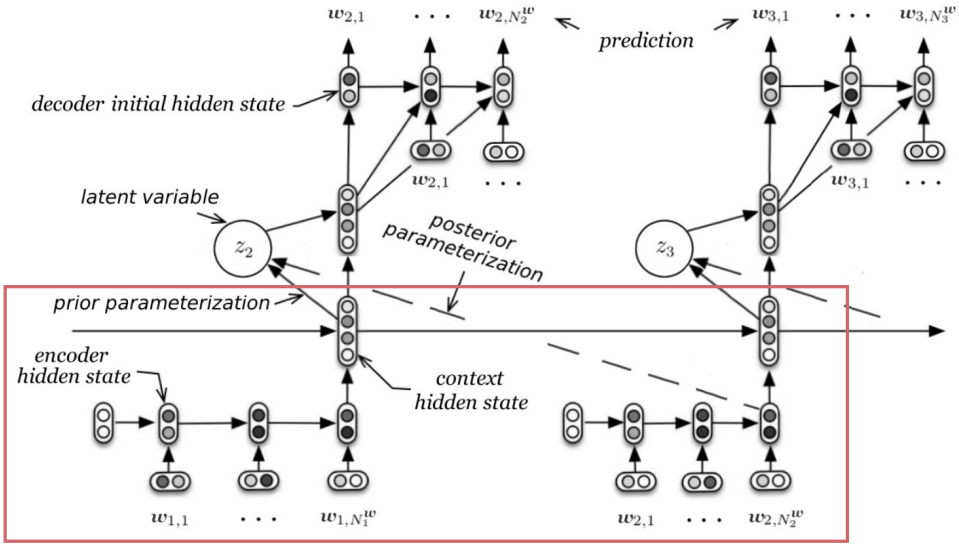

Figure 3: The VHRED model used for pre-training. The hierarchical structure of the RNN encoder is shown in the red box around the bottom half of the figure. After training using the VHRED procedure, the last hidden state of the context-level encoder is used as a vector representation of the input text.

sian variable that is used to condition the decoder (see supplemental material for further details). After training VHRED, we use the last hidden state of the context-level encoder, when c, r, and $\hat{r}$ are fed as input, as the vector representations for $\mathbf{c}$, $\mathbf{r}$, and $\hat{\mathbf{r}}$, respectively. We use representations from the VHRED model as it produces more diverse and coherent responses compared to HRED.

5 Experiments

5.1 Experimental Procedure

In order to reduce the effective vocabulary size, we use byte pair encoding (BPE) (Gage, 1994; Sennrich et al., 2015), which splits each word into sub-words or characters. We also use layer normalization (Ba et al., 2016) for the hierarchical encoder, which we found worked better at the task of dialogue generation than the related recurrent batch normalization (Ioffe and Szegedy, 2015; Cooijmans et al., 2016). To train the VHRED model, we employed several of the same techniques found in (Serban et al., 2016b) and (Bowman et al., 2016): we drop words in the decoder with a fixed rate of 25%, and we anneal the KL-divergence term linearly from 0 to 1 over the first 60,000 batches. We use Adam as our optimizer (Kingma and Ba, 2014).

When training ADEM, we also employ a subsampling procedure based on the model response length. In particular, we divide the training examples into bins based on the number of words in a response and the score of that response. We then over-sample from bins across the same score to ensure that ADEM does not use response length to predict the score. This is because humans have a tendency to give a higher rating to shorter responses than to longer responses (Serban et al., 2016b), as shorter responses are often more generic and thus are more likely to be suitable to the context. Indeed, the test set Pearson correlation between response length and human score is 0.27.

For training VHRED, we use a context embedding size of 2000. However, we found the ADEM model learned more effectively when this embedding size was reduced. Thus, after training VHRED, we use principal component analysis (PCA) (Pearson, 1901) to reduce the dimensionality of the context, model response, and reference response embeddings to n. We found experimentally that $n = 50$ provided the best performance.

When training our models, we conduct early stopping on a separate validation set. For the evaluation dataset, we split the train/ validation/ test sets such that there is no context overlap (i.e. the contexts in the test set are unseen during training).

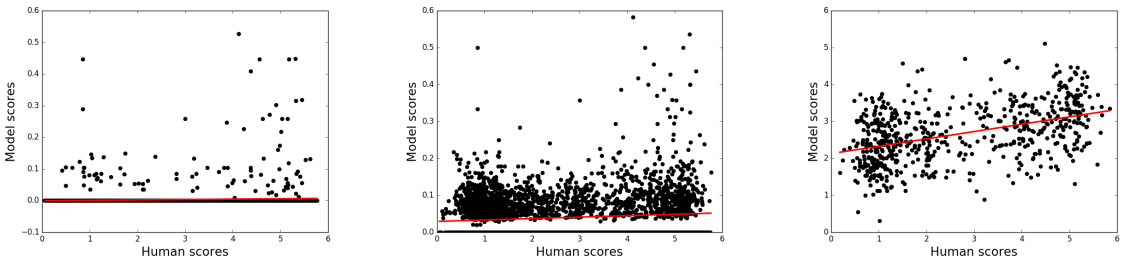
[3]We present both the Spearman correlation (computed on ranks, depicts monotonic relationships) and Pearson correlation (computed on true values, depicts linear relationships)



(a) BLEU-2 (b) ROUGE (c) ADEM

Figure 4: Scatter plot showing model against human scores, for BLEU-2 and ROUGE on the full dataset, and ADEM on the test set. We add Gaussian noise drawn from $\mathcal{N}(0, 0.3)$ to the integer human scores to better visualize the density of points, at the expense of appearing less correlated.

	Full dataset		**Test set**	
Metric	**Spearman**	**Pearson**	**Spearman**	**Pearson**
BLEU-2	0.039 (0.013)	0.081 (<0.001)	0.051 (0.254)	0.120 (<0.001)
BLEU-4	0.051 (0.001)	0.025 (0.113)	0.063 (0.156)	0.073 (0.103)
ROUGE	0.062 (<0.001)	0.114 (<0.001)	0.096 (0.031)	0.147 (<0.001)
METEOR	0.021 (0.189)	0.022 (0.165)	0.013 (0.745)	0.021 (0.601)
T2V	0.140 (<0.001)	0.141 (<0.001)	0.140 (<0.001)	0.141 (<0.001)
VHRED	-0.035 (0.062)	-0.030 (0.106)	-0.091 (0.023)	-0.010 (0.805)
	Validation set		**Test set**	
C-ADEM	0.338 (<0.001)	0.355 (<0.001)	0.366 (<0.001)	0.363 (<0.001)
R-ADEM	0.404 (<0.001)	0.404 (<0.001)	0.352 (<0.001)	0.360 (<0.001)
ADEM (T2V)	0.252 (<0.001)	0.265 (<0.001)	0.280 (<0.001)	0.287 (<0.001)
ADEM	**0.410** (<0.001)	**0.418** (<0.001)	**0.428** (<0.001)	**0.436** (<0.001)

Table 2: Correlation between metrics and human judgements, with p-values shown in brackets. 'ADEM (T2V)' indicates ADEM with tweet2vec embeddings (Dhingra et al., 2016), and 'VHRED' indicates the dot product of VHRED embeddings (i.e. ADEM at initialization). C- and R-ADEM represent the ADEM model trained to only compare the model response to the context or reference response, respectively. We compute the baseline metric scores (top) on the full dataset to provide a more accurate estimate of their scores (as they are not trained on a training set).

word-overlap metrics, in addition to results with embedding baselines and ADEM, in Table 2. The baseline metrics are evaluated on the entire dataset of 4,104 responses to provide the most accurate estimate of the score. [4] We measure the correlation for ADEM on the validation and test sets, which constitute 616 responses each.

We also conduct an analysis of the response data from (Liu et al., 2016), where the pre-processing is standardized by removing '<first_speaker>' tokens at the beginning of each utterance. The results are detailed in the supplemental material. We can observe from both this data, and the new data in Table 2, that the correlations for the word-overlap metrics are even lower than estimated in previous studies (Liu et al., 2016; Galley et al., 2015). In particular, this is the case for BLEU-4, which has frequently been used for dialogue response evaluation (Ritter et al., 2011; Sordoni et al., 2015b; Li et al., 2015; Galley et al., 2015; Li et al., 2016a).

We can see from Table 2 that ADEM correlates far better with human judgement than the word-overlap baselines. This is further illustrated by the scatterplots in Figure 4. We also compare with ADEM using tweet2vec embeddings (Dhingra et al., 2016). In this case, instead of using the VHRED pre-training method presented in Section 4, we use off-the-shelf embeddings for $\mathbf{c}$, $\mathbf{r}$, and $\hat{\mathbf{r}}$, and fine-tune M and N on our dataset. These tweet2vec embeddings are computed at the character-level with a bidirectional GRU on a Twitter dataset for hashtag prediction (Dhingra et al., 2016). We find that they obtain reasonable but inferior performance compared to using VHRED embeddings.

scores.

[4] Note that our word-overlap correlation results in Table 2 are also lower than those presented in (Galley et al., 2015). This is because Galley et al. measure corpus-level correlation, i.e. correlation averaged across different subsets (of size 100) of the data, and pre-filter for high-quality reference responses.

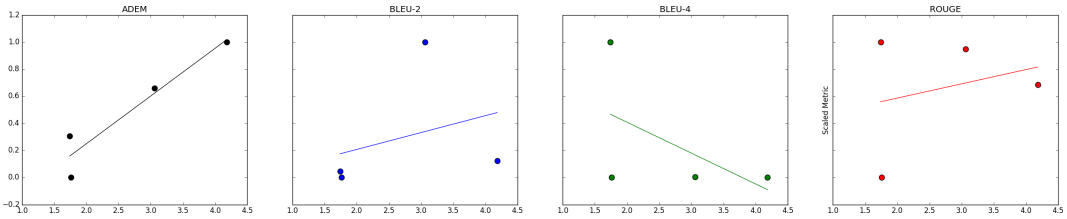


Figure 5: Scatterplots depicting the system-level correlation results for ADEM, BLEU-2, BLEU-4,and ROUGE on the test set. Each point represents the average scores for the responses from a dialogue model (TFIDF, DE, HRED, human). Human scores are shown on the horizontal axis, with normalized metric scores on the vertical axis. The ideal metric has a perfectly linear relationship.

System-level correlations We show the system-level correlations for various metrics in Table 3, and present it visually in Figure 5. Each point in the scatterplots represents a dialogue model; humans give low scores to TFIDF and DE responses, higher scores to HRED and the highest scores to other human responses. It is clear that existing word-overlap metrics are incapable of capturing this relationship for even 4 models. This renders them completely deficient for dialogue evaluation. However, ADEM produces almost the same model ranking as humans, achieving a significant Pearson correlation of 0.954.[5] Thus, ADEM correlates well with humans both at the response and system level.

Metric	Pearson
BLEU-1	-0.079 (0.921)
BLEU-2	0.308 (0.692)
BLEU-3	-0.537 (0.463)
BLEU-4	-0.536 (0.464)
ROUGE	0.268 (0.732)
ADEM	**0.954** (0.046)

Table 3: System-level correlation, with the p-value in brackets.

Generalization to previously unseen models When ADEM is used in practice, it will take as input responses from a new model that it has not seen during training. Thus, it is crucial that ADEM correlates with human judgements for new models. We test ADEM's generalization ability by performing a leave-one-out evaluation. For each dialogue model that was the source of response data for training ADEM (TF-IDF, Dual Encoder, HRED, humans), we conduct an experiment where we train on all model responses *except* those from the chosen model, and test *only* on the model that was unseen during training.

The results are given in Table 4. We observe that the ADEM model is able to generalize for all models except the Dual Encoder. This is particularly surprising for the HRED model; in this case, ADEM was trained only on responses that were written by humans (from retrieval models or human-generated), but is able to generalize to responses produced by a generative neural network model. When testing on the entire test set, the model achieves comparable correlations to the ADEM model that was trained on 25% less data selected at random.

Qualitative Analysis To illustrate some strengths and weaknesses of ADEM, we show human and ADEM scores for each of the responses to various contexts in Table 5. There are several instances where ADEM predicts accurately: in particular, ADEM is often very good at assigning low scores to poor responses. This seen in the first two contexts, where most of the responses given a score of 1 from humans are given scores less than 2 by ADEM. The single exception in response (4) for the second context seems somewhat appropriate and should perhaps have been scored higher by the human evaluator. There are also several instances where the model assigns high scores to suitable responses, as in the first two contexts.

One drawback we observed is that ADEM tends to be too conservative when predicting response scores. This is the case in the third context, where the model assigns low scores to most of the responses that a human rated highly. This behaviour is likely due to the squared error loss used to train ADEM; since the model receives a large penalty for incorrectly predicting an extreme value, it learns to predict scores closer to the average human score. We provide many more experiments, including investigation of evaluation speed, learning curves, data efficiency, a failure analysis, and the primary source of improvement over word-overlap metrics

[5] For comparison, BLEU achieves a system-level correlation of 0.99 on 5 models in the translation domain (Papineni et al., 2002).

	Test on full dataset		Test on removed model responses	
Data Removed	**Spearman**	**Pearson**	**Spearman**	**Pearson**
TF-IDF	0.406 (<0.001)	0.409 (<0.001)	0.186 (0.021)	0.196 (0.015)
Dual Encoder	0.364 (<0.001)	0.373 (<0.001)	0.026 (0.749)	0.027 (0.736)
HRED	0.393 (<0.001)	0.396 (<0.001)	0.151 (0.060)	0.148 (<0.070)
Human	0.292 (<0.001)	0.298 (<0.001)	0.216 (<0.010)	0.148 (<0.070)
Average	**0.364**	**0.369**	**0.145**	**0.130**
25% at random	0.378 (<0.001)	0.384 (<0.001)	—	—

Table 4: Correlation for ADEM when various model responses are removed from the training set. The left two columns show performance on the entire test set, and the right two columns show performance on responses only from the dialogue model not seen during training. The last row (25% at random) corresponds to the ADEM model trained on all model responses, but with the same amount of training data as the model above (i.e. 25% less data than the full training set).

6 Related Work

Related to our approach is the literature on novel methods for the evaluation of machine translation systems, especially through the WMT evaluation task (Callison-Burch et al., 2011; Macháček and Bojar, 2014; Stanojevic et al., 2015). In particular, (Albrecht and Hwa, 2007; Gupta et al., 2015) have proposed to evaluate machine translation systems using Regression and Tree-LSTMs respectively. Their approach differs from ours as, in the dialogue domain, we must additionally condition our score on the context of the conversation, which is not necessary in translation.

There has also been related work on estimating the quality of responses in chat-oriented dialogue systems. (DeVault et al., 2011) train an automatic dialogue policy evaluation metric from 19 structured role-playing sessions, enriched with paraphrases and external referee annotations. (Gandhe and Traum, 2016) propose a semi-automatic evaluation metric for dialogue coherence, similar to BLEU and ROUGE, based on 'wizard of Oz' type data.[6] (Xiang et al., 2014) propose a framework to predict utterance-level problematic situations in a dataset of Chinese dialogues using intent and sentiment factors. Finally, (Higashinaka et al., 2014) train a classifier to distinguish user utterances from system-generated utterances using various dialogue features, such as dialogue acts, question types, and predicate-argument structures.

Several recent approaches use hand-crafted reward features to train dialogue models using reinforcement learning (RL). For example, (Li et al., 2016b) use features related to ease of answering and information flow, and (Yu et al., 2016) use metrics related to turn-level appropriateness and conversational depth. These metrics are based on hand-crafted features, which only capture a small set of relevant aspects; this inevitably leads to sub-optimal performance, and it is unclear whether such objectives are preferable over retrieval-based cross-entropy or word-level maximum log-likelihood objectives. Furthermore, many of these metrics are computed at the conversation-level, and are not available for evaluating single dialogue responses.

[6] In 'wizard of Oz' scenarios, humans play the role of the dialogue system, usually unbeknown to the interlocutors.

The metrics that can be computed at the response-level could be incorporated into our framework, for example by adding a term to equation 1 consisting of a dot product between these features and a vector of learned parameters.

There has been significant work on evaluation methods for task-oriented dialogue systems, which attempt to solve a user's task such as finding a restaurant. These methods include the PARADISE framework (Walker et al., 1997) and MeMo (Möller et al., 2006), which consider a task completion signal. PARADISE in particular is perhaps the first work on learning an automatic evaluation function for dialogue, accomplished through linear regression. However, PARADISE requires that one can measure task completion and task complexity, which are not available in our setting.

7 Discussion

We use the Twitter Corpus to train our models as it contains a broad range of non-task-oriented conversations and it has been used to train many state-of-the-art models. However, our model could easily be extended to other general-purpose datasets, such as Reddit, once similar pre-trained models become publicly available. Such models are necessary even for creating a test set in a new domain, which will help us determine if ADEM generalizes to related dialogue domains. We leave investigating the domain transfer ability of ADEM for future work.

The evaluation model proposed in this paper favours dialogue models that generate responses that are rated as highly appropriate by humans. It is likely that this property does not fully capture the desired end-goal of chatbot systems. For example, one issue with building models to approximate human judgements of response quality is the problem of generic responses. Since humans often provide high scores to generic responses due to their appropriateness for many given contexts (Shang et al., 2016), a model trained to predict these scores will exhibit the same behaviour. An important direction for future work is modifying ADEM such that it is not subject to this bias. This could be done, for example, by censoring ADEM's representations (Edwards and Storkey, 2016) such that they do not contain any information about length. Alternatively, one can combine this with an *adversarial evaluation model* (Kannan and Vinyals, 2017; Li et al., 2017) that assigns a score based on how easy it is to distinguish the dialogue model responses from human responses. In this case, a model that generates generic responses will easily be distinguishable and obtain a low score.

An important direction of future research is building models that can evaluate the capability of a dialogue system to have an engaging and meaningful interaction with a human. Compared to evaluating a single response, this evaluation is arguably closer to the end-goal of chatbots. However, such an evaluation is extremely challenging to do in a completely automatic way. We view the evaluation procedure presented in this paper as an important step towards this goal; current dialogue systems are incapable of generating responses that are rated as highly appropriate by humans, and we believe our evaluation model will be useful for measuring and facilitating progress in this direction.

A Transition-Based Directed Acyclic Graph Parser for UCCA

Daniel Hershcovich[1,2] **Omri Abend**[2] **Ari Rappoport**[2]

Abstract

We present the first parser for UCCA, a cross-linguistically applicable framework for semantic representation, which builds on extensive typological work and supports rapid annotation. UCCA poses a challenge for existing parsing techniques, as it exhibits reentrancy (resulting in DAG structures), discontinuous structures and non-terminal nodes corresponding to complex semantic units. To our knowledge, the conjunction of these formal properties is not supported by any existing parser. Our transition-based parser, which uses a novel transition set and features based on bidirectional LSTMs, has value not just for UCCA parsing: its ability to handle more general graph structures can inform the development of parsers for other semantic DAG structures, and in languages that frequently use discontinuous structures.

1 Introduction

Universal Conceptual Cognitive Annotation (UCCA, Abend and Rappoport, 2013) is a cross-linguistically applicable semantic representation scheme, building on the established Basic Linguistic Theory typological framework (Dixon, 2010a,b, 2012), and Cognitive Linguistics literature (Croft and Cruse, 2004). It has demonstrated applicability to multiple languages, including English, French, German and Czech, support for rapid annotation by non-experts (assisted by an accessible annotation interface (Abend et al., 2017)), and stability under translation (Sulem et al., 2015). It has also proven useful for machine translation evaluation (Birch et al., 2016). UCCA differs from syntactic schemes in terms of content and formal structure. It exhibits reentrancy, discontinuous nodes and non-terminals, which no single existing parser supports. Lacking a parser, UCCA's applicability has been so far limited, a gap this work addresses.

We present the first UCCA parser, TUPA (Transition-based UCCA Parser), building on recent advances in discontinuous constituency and dependency graph parsing, and further introducing novel transitions and features for UCCA. Transition-based techniques are a natural starting point for UCCA parsing, given the conceptual similarity of UCCA's distinctions, centered around predicate-argument structures, to distinctions expressed by dependency schemes, and the achievements of transition-based methods in dependency parsing (Dyer et al., 2015; Andor et al., 2016; Kiperwasser and Goldberg, 2016). We are further motivated by the strength of transition-based methods in related tasks, including dependency graph parsing (Sagae and Tsujii, 2008; Ribeyre et al., 2014; Tokgöz and Eryiğit, 2015), constituency parsing (Sagae and Lavie, 2005; Zhang and Clark, 2009; Zhu et al., 2013; Maier, 2015; Maier and Lichte, 2016), AMR parsing (Wang et al., 2015a,b, 2016; Misra and Artzi, 2016; Goodman et al., 2016; Zhou et al., 2016; Damonte et al., 2017) and CCG parsing (Zhang and Clark, 2011; Ambati et al., 2015, 2016).

We evaluate TUPA on the English UCCA corpora, including in-domain and out-of-domain settings. To assess the ability of existing parsers to tackle the task, we develop a conversion procedure from UCCA to bilexical graphs and trees. Results show superior performance for TUPA, demonstrating the effectiveness of the presented approach.[1]

The rest of the paper is structured as follows:

Section 2 describes UCCA in more detail. Section 3 introduces TUPA. Section 4 discusses the data and experimental setup. Section 5 presents the experimental results. Section 6 summarizes related work, and Section 7 concludes the paper.

2 The UCCA Scheme

UCCA graphs are labeled, directed acyclic graphs (DAGs), whose leaves correspond to the tokens of the text. A node (or *unit*) corresponds to a terminal or to several terminals (not necessarily contiguous) viewed as a single entity according to semantic or cognitive considerations. Edges bear a category, indicating the role of the sub-unit in the parent relation. Figure 1 presents a few examples.

UCCA is a multi-layered representation, where each layer corresponds to a "module" of semantic distinctions. UCCA's *foundational layer*, targeted in this paper, covers the predicate-argument structure evoked by predicates of all grammatical categories (verbal, nominal, adjectival and others), the inter-relations between them, and other major linguistic phenomena such as coordination and multi-word expressions. The layer's basic notion is the *scene*, describing a state, action, movement or some other relation that evolves in time. Each scene contains one main relation (marked as either a Process or a State), as well as one or more Participants. For example, the sentence "After graduation, John moved to Paris" (Figure 1a) contains two scenes, whose main relations are "graduation" and "moved". "John" is a Participant in both scenes, while "Paris" only in the latter. Further categories account for inter-scene relations and the internal structure of complex arguments and relations (e.g. coordination, multi-word expressions and modification).

One incoming edge for each non-root node is marked as *primary*, and the rest (mostly used for implicit relations and arguments) as *remote* edges, a distinction made by the annotator. The primary edges thus form a tree structure, whereas the remote edges enable reentrancy, forming a DAG.

While parsing technology in general, and transition-based parsing in particular, is well-established for syntactic parsing, UCCA has several distinct properties that distinguish it from syntactic representations, mostly UCCA's tendency to abstract away from syntactic detail that do not affect argument structure. For instance, consider the following examples where the concept of a scene

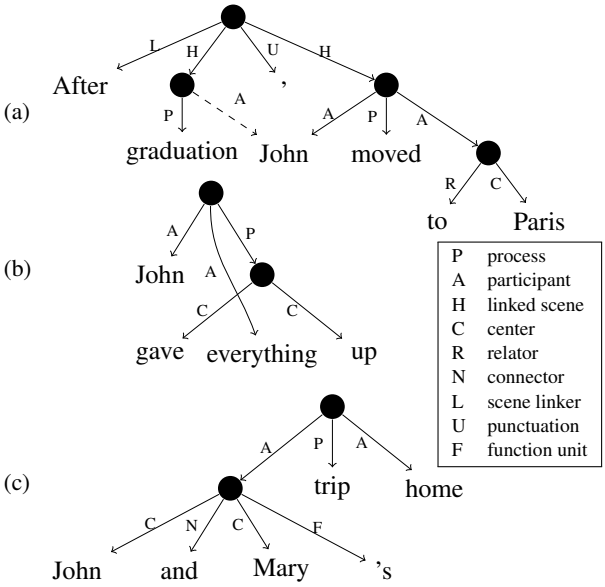

Figure 1: UCCA structures demonstrating three structural properties exhibited by the scheme. (a) includes a remote edge (dashed), resulting in "John" having two parents. (b) includes a discontinuous unit ("gave ... up"). (c) includes a coordination construction ("John and Mary"). Pre-terminal nodes are omitted for brevity. Right: legend of edge labels.

has a different rationale from the syntactic concept of a clause. First, non-verbal predicates in UCCA are represented like verbal ones, such as when they appear in copula clauses or noun phrases. Indeed, in Figure 1a, "graduation" and "moved" are considered separate events, despite appearing in the same clause. Second, in the same example, "John" is marked as a (remote) Participant in the graduation scene, despite not being overtly marked. Third, consider the possessive construction in Figure 1c. While in UCCA "trip" evokes a scene in which "John and Mary" is a Participant, a syntactic scheme would analyze this phrase similarly to "John and Mary's shoes".

These examples demonstrate that a UCCA parser, and more generally semantic parsers, face an additional level of ambiguity compared to their syntactic counterparts (e.g., "after graduation" is formally very similar to "after 2pm", which does not evoke a scene). Section 6 discusses UCCA in the context of other semantic schemes, such as AMR (Banarescu et al., 2013).

Alongside recent progress in dependency parsing into projective trees, there is increasing interest in parsing into representations with more general structural properties (see Section 6). One such property is *reentrancy*, namely the sharing of semantic units between predicates. For instance, in Figure 1a, "John" is an argument of both "gradu-

ation" and "moved", yielding a DAG rather than a tree. A second property is *discontinuity*, as in Figure 1b, where "gave up" forms a discontinuous semantic unit. Discontinuities are pervasive, e.g., with multi-word expressions (Schneider et al., 2014). Finally, unlike most dependency schemes, UCCA uses *non-terminal nodes* to represent units comprising more than one word. The use of non-terminal nodes is motivated by constructions with no clear head, including coordination structures (e.g., "John and Mary" in Figure 1c), some multi-word expressions (e.g., "The Haves and the *Have Nots*"), and prepositional phrases (either the preposition or the head noun can serve as the constituent's head). To our knowledge, no existing parser supports all structural properties required for UCCA parsing.

3 Transition-based UCCA Parsing

We now turn to presenting TUPA. Building on previous work on parsing reentrancies, discontinuities and non-terminal nodes, we define an extended set of transitions and features that supports the conjunction of these properties.

Transition-based parsers (Nivre, 2003) scan the text from start to end, and create the parse incrementally by applying a *transition* at each step to the parser's state, defined using three data structures: a buffer B of tokens and nodes to be processed, a stack S of nodes currently being processed, and a graph $G = (V, E, \ell)$ of constructed nodes and edges, where V is the set of *nodes*, E is the set of *edges*, and $\ell : E \to L$ is the *label* function, L being the set of possible labels. Some states are marked as *terminal*, meaning that G is the final output. A classifier is used at each step to select the next transition based on features encoding the parser's current state. During training, an oracle creates training instances for the classifier, based on gold-standard annotations.

Transition Set. Given a sequence of tokens $w_1, \ldots, w_n$, we predict a UCCA graph G over the sequence. Parsing starts with a single node on the stack (an artificial root node), and the input tokens in the buffer. Figure 2 shows the transition set.

In addition to the standard SHIFT and REDUCE operations, we follow previous work in transition-based constituency parsing (Sagae and Lavie, 2005), adding the NODE transition for creating new non-terminal nodes. For every $X \in L$, NODE$_X$ creates a new node on the buffer as a parent of the first element on the stack, with an X-labeled edge. LEFT-EDGE$_X$ and RIGHT-EDGE$_X$ create a new primary X-labeled edge between the first two elements on the stack, where the parent is the left or the right node, respectively. As a UCCA node may only have one incoming primary edge, EDGE transitions are disallowed if the child node already has an incoming primary edge. LEFT-REMOTE$_X$ and RIGHT-REMOTE$_X$ do not have this restriction, and the created edge is additionally marked as *remote*. We distinguish between these two pairs of transitions to allow the parser to create remote edges without the possibility of producing invalid graphs. To support the prediction of multiple parents, node and edge transitions leave the stack unchanged, as in other work on transition-based dependency graph parsing (Sagae and Tsujii, 2008; Ribeyre et al., 2014; Tokgöz and Eryiğit, 2015). REDUCE pops the stack, to allow removing a node once all its edges have been created. To handle discontinuous nodes, SWAP pops the second node on the stack and adds it to the top of the buffer, as with the similarly named transition in previous work (Nivre, 2009; Maier, 2015). Finally, FINISH pops the root node and marks the state as terminal.

Classifier. The choice of classifier and feature representation has been shown to play an important role in transition-based parsing (Chen and Manning, 2014; Andor et al., 2016; Kiperwasser and Goldberg, 2016). To investigate the impact of the type of transition classifier in UCCA parsing, we experiment with three different models.

1. Starting with a simple and common choice (e.g., Maier and Lichte, 2016), **TUPA$_{\text{Sparse}}$** uses a linear classifier with sparse features, trained with the averaged structured perceptron algorithm (Collins and Roark, 2004) and MIN-UPDATE (Goldberg and Elhadad, 2011): each feature requires a minimum number of updates in training to be included in the model.[2]

2. Changing the model to a feedforward neural network with dense embedding features, **TUPA$_{\text{MLP}}$** ("multi-layer perceptron"), uses an architecture similar to that of Chen and Manning (2014), but with two rectified linear layers

[2] We also experimented with a linear model using dense embedding features, trained with the averaged structured perceptron algorithm. It performed worse than the sparse perceptron model and was hence discarded.

Before Transition				Transition	After Transition					Condition
Stack	Buffer	Nodes	Edges		Stack	Buffer	Nodes	Edges	Terminal?	
S	$x \mid B$	V	E	SHIFT	$S \mid x$	B	V	E	$-$	
$S \mid x$	B	V	E	REDUCE	S	B	V	E	$-$	
$S \mid x$	B	V	E	NODE$_X$	$S \mid x$	$y \mid B$	$V \cup \{y\}$	$E \cup \{(y,x)_X\}$	$-$	$x \neq \text{root}$
$S \mid y, x$	B	V	E	LEFT-EDGE$_X$	$S \mid y, x$	B	V	$E \cup \{(x,y)_X\}$	$-$	$\begin{cases} x \notin w_{1:n}, \\ y \neq \text{root}, \\ y \not\rightsquigarrow_G x \end{cases}$
$S \mid x, y$	B	V	E	RIGHT-EDGE$_X$	$S \mid x, y$	B	V	$E \cup \{(x,y)_X\}$	$-$	
$S \mid y, x$	B	V	E	LEFT-REMOTE$_X$	$S \mid y, x$	B	V	$E \cup \{(x,y)^*_X\}$	$-$	
$S \mid x, y$	B	V	E	RIGHT-REMOTE$_X$	$S \mid x, y$	B	V	$E \cup \{(x,y)^*_X\}$	$-$	
$S \mid x, y$	B	V	E	SWAP	$S \mid y$	$x \mid B$	V	E	$-$	$\mathrm{i}(x) < \mathrm{i}(y)$
[root]	$\emptyset$	V	E	FINISH	$\emptyset$	$\emptyset$	V	E	$+$	

Figure 2: The transition set of TUPA. We write the stack with its top to the right and the buffer with its head to the left. $(\cdot,\cdot)_X$ denotes a primary X-labeled edge, and $(\cdot,\cdot)^*_X$ a remote X-labeled edge. $\mathrm{i}(x)$ is a running index for the created nodes. In addition to the specified conditions, the prospective child in an EDGE transition must not already have a primary parent.

instead of one layer with cube activation. The embeddings and classifier are trained jointly.

3. Finally, **TUPA$_{\text{BiLSTM}}$** uses a bidirectional LSTM for feature representation, on top of the dense embedding features, an architecture similar to Kiperwasser and Goldberg (2016). The BiLSTM runs on the input tokens in forward and backward directions, yielding a vector representation that is then concatenated with dense features representing the parser state (e.g., existing edge labels and previous parser actions; see below). This representation is then fed into a feedforward network similar to TUPA$_{\text{MLP}}$. The feedforward layers, BiLSTM and embeddings are all trained jointly.

For all classifiers, inference is performed greedily, i.e., without beam search. Hyperparameters are tuned on the development set (see Section 4).

Features. TUPA$_{\text{Sparse}}$ uses binary indicator features representing the words, POS tags, syntactic dependency labels and existing edge labels related to the top four stack elements and the next three buffer elements, in addition to their children and grandchildren in the graph. We also use bi- and trigram features based on these values (Zhang and Clark, 2009; Zhu et al., 2013), features related to discontinuous nodes (Maier, 2015, including separating punctuation and gap type), features representing existing edges and the number of parents and children, as well as the past actions taken by the parser. In addition, we use use a novel, UCCA-specific feature: number of remote children.[3]

For TUPA$_{\text{MLP}}$ and TUPA$_{\text{BiLSTM}}$, we replace all indicator features by a concatenation of the vector embeddings of all represented elements: words, POS tags, syntactic dependency labels, edge labels, punctuation, gap type and parser actions. These embeddings are initialized randomly. We additionally use external word embeddings initialized with pre-trained word2vec vectors (Mikolov et al., 2013),[4] updated during training. In addition to dropout between NN layers, we apply word dropout (Kiperwasser and Goldberg, 2016): with a certain probability, the embedding for a word is replaced with a zero vector. We do not apply word dropout to the external word embeddings.

Finally, for all classifiers we add a novel real-valued feature to the input vector, **ratio**, corresponding to the ratio between the number of terminals to number of nodes in the graph G. This feature serves as a regularizer for the creation of new nodes, and should be beneficial for other transition-based constituency parsers too.

Training. For training the transition classifiers, we use a dynamic oracle (Goldberg and Nivre, 2012), i.e., an oracle that outputs a set of optimal transitions: when applied to the current parser state, the gold standard graph is reachable from the resulting state. For example, the oracle would predict a NODE transition if the stack has on its top a parent in the gold graph that has not been created, but would predict a RIGHT-EDGE transition if the second stack element is a parent of the first element according to the gold graph and the edge between them has not been created. The transition predicted by the classifier is deemed correct and is applied to the parser state to reach the subsequent state, if the transition is included in the set of optimal transitions. Otherwise, a random optimal transition is applied, and for the perceptron-based parser, the classifier's weights are updated

[3] See Appendix A for a full list of used feature templates.

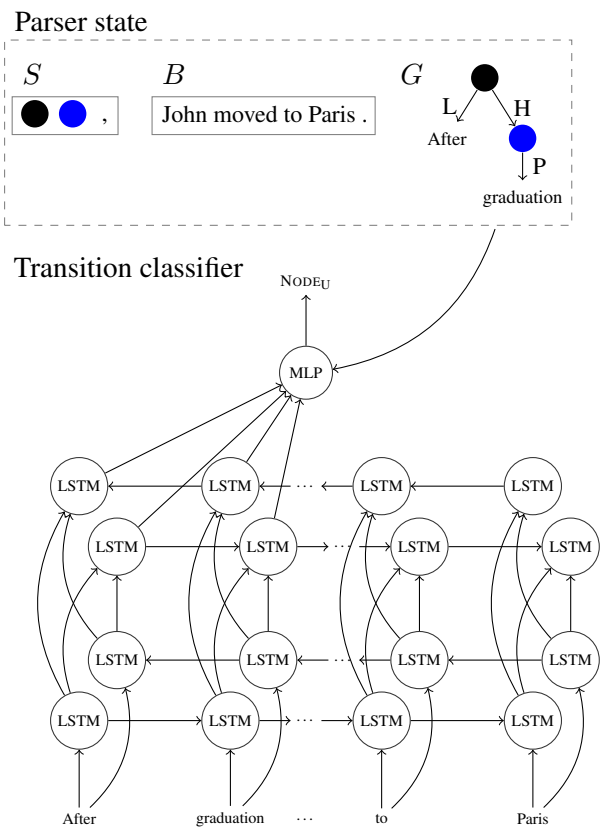

Figure 3: Illustration of the TUPA model. Top: parser state (stack, buffer and intermediate graph). Bottom: $\text{TUPA}_{\text{BiLTSM}}$ architecture. Vector representation for the input tokens is computed by two layers of bidirectional LSTMs. The vectors for specific tokens are concatenated with embedding and numeric features from the parser state (for existing edge labels, number of children, etc.), and fed into the MLP for selecting the next transition.

according to the perceptron update rule.

POS tags and syntactic dependency labels are extracted using spaCy (Honnibal and Johnson, 2015).[5] We use the categorical cross-entropy objective function and optimize the NN classifiers with the Adam optimizer (Kingma and Ba, 2014).

4 Experimental Setup

Data. We conduct our experiments on the UCCA Wikipedia corpus (henceforth, *Wiki*), and use the English part of the UCCA *Twenty Thousand Leagues Under the Sea* English-French parallel corpus (henceforth, *20K Leagues*) as out-of-domain data.[6] Table 1 presents some statistics for the two corpora. We use passages of indices up to 676 of the *Wiki* corpus as our training set, passages 688–808 as development set, and passages 942–1028 as in-domain test set. While

Table 1: Statistics of the *Wiki* and *20K Leagues* UCCA corpora. All counts exclude the root node, implicit nodes, and linkage nodes and edges.

UCCA edges can cross sentence boundaries, we adhere to the common practice in semantic parsing and train our parsers on individual sentences, discarding inter-relations between them (0.18% of the edges). We also discard linkage nodes and edges (as they often express inter-sentence relations and are thus mostly redundant when applied at the sentence level) as well as implicit nodes.[7] In the out-of-domain experiments, we apply the same parsers (trained on the *Wiki* training set) to the *20K Leagues* corpus without parameter re-tuning.

Implementation. We use the DyNet package (Neubig et al., 2017) for implementing the NN classifiers. Unless otherwise noted, we use the default values provided by the package. See Appendix C for the hyperparameter values we found by tuning on the development set.

Evaluation. We define a simple measure for comparing UCCA structures $G_p = (V_p, E_p, \ell_p)$ and $G_g = (V_g, E_g, \ell_g)$, the predicted and gold-standard graphs, respectively, over the same sequence of terminals $W = \{w_1, \ldots, w_n\}$. For an edge $e = (u, v)$ in either graph, u being the parent and v the child, its yield $y(e) \subseteq W$ is the set of terminals in W that are descendants of v. Define the set of *mutual edges* between G_p and G_g:

$$M(G_p, G_g) = \{(e_1, e_2) \in E_p \times E_g \mid y(e_1) = y(e_2) \wedge \ell_p(e_1) = \ell_g(e_2)\}$$

Labeled precision and recall are defined by dividing $|M(G_p, G_g)|$ by $|E_p|$ and $|E_g|$, respectively, and F-score by taking their harmonic mean.

[7] Appendix B further discusses linkage and implicit units.

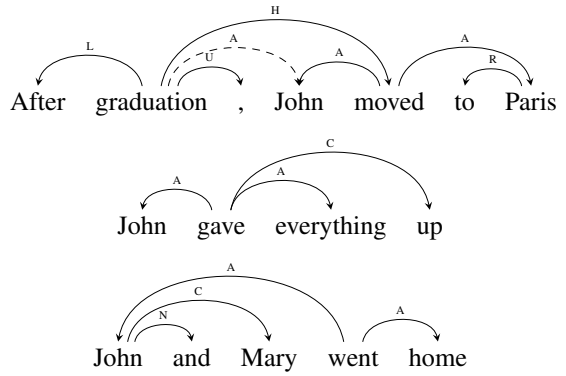

Figure 4: Bilexical graph approximation (dependency graph) for the sentences in Figure 1.

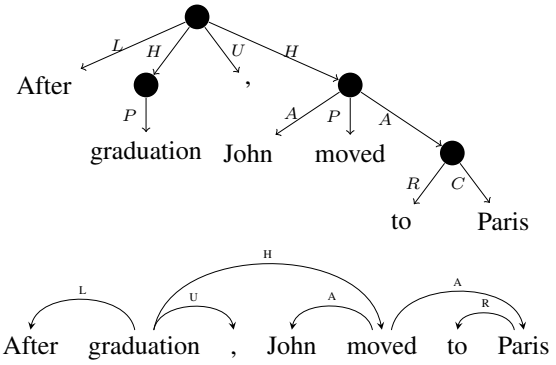

Figure 5: Tree approximation (constituency) for the sentence in Figure 1a (top), and bilexical tree approximation (dependency) for the same sentence (bottom). These are identical to the original graphs, apart from the removal of remote edges.

We report two variants of this measure: one where we consider only primary edges, and another for remote edges (see Section 2). Performance on remote edges is of pivotal importance in this investigation, which focuses on extending the class of graphs supported by statistical parsers.

We note that the measure collapses to the standard PARSEVAL constituency evaluation measure if G_p and G_g are trees. Punctuation is excluded from the evaluation, but not from the datasets.

Comparison to bilexical graph parsers. As no direct comparison with existing parsers is possible, we compare TUPA to bilexical dependency graph parsers, which support reentrancy and discontinuity but not non-terminal nodes.

To facilitate the comparison, we convert our training set into bilexical graphs (see examples in Figure 4), train each of the parsers, and evaluate them by applying them to the test set and then reconstructing UCCA graphs, which are compared with the gold standard. The conversion to bilexical graphs is done by heuristically selecting a head terminal for each non-terminal node, and attaching all terminal descendents to the head terminal. In the inverse conversion, we traverse the bilexical graph in topological order, creating non-terminal parents for all terminals, and attaching them to the previously-created non-terminals corresponding to the bilexical heads.[8]

In Section 5 we report the upper bounds on the achievable scores due to the error resulting from the removal of non-terminal nodes.

Comparison to tree parsers. For completeness, and as parsing technology is considerably more mature for tree (rather than graph) parsing, we also perform a *tree approximation* experiment, converting UCCA to (bilexical) trees and evaluating constituency and dependency tree parsers on them (see examples in Figure 5). Our approach is similar to the tree approximation approach used for dependency graph parsing (Agić et al., 2015; Fernández-González and Martins, 2015), where dependency graphs were converted into dependency trees and then parsed by dependency tree parsers. In our setting, the conversion to trees consists simply of removing remote edges from the graph, and then to bilexical trees by applying the same procedure as for bilexical graphs.

Baseline parsers. We evaluate two bilexical graph semantic dependency parsers: DAGParser (Ribeyre et al., 2014), the leading transition-based parser in SemEval 2014 (Oepen et al., 2014) and TurboParser (Almeida and Martins, 2015), a graph-based parser from SemEval 2015 (Oepen et al., 2015); UPARSE (Maier and Lichte, 2016), a transition-based constituency parser supporting discontinuous constituents; and two bilexical tree parsers: MaltParser (Nivre et al., 2007), and the stack LSTM-based parser of Dyer et al. (2015, henceforce "LSTM Parser"). Default settings are used in all cases.[9] DAGParser and UPARSE use beam search by default, with a beam size of 5 and 4 respectively. The other parsers are greedy.

5 Results

Table 2 presents our main experimental results, as well as upper bounds for the baseline parsers, re-

[8] See Appendix D for a detailed description of the conversion procedures.

[9] For MaltParser we use the ARCEAGER transition set and SVM classifier. Other configurations yielded lower scores.

Table 2: Experimental results, in percents, on the *Wiki* test set (left) and the *20K Leagues* set (right). Columns correspond to labeled precision, recall and F-score, for both primary and remote edges. F-score upper bounds are reported for the conversions. For the tree approximation experiments, only primary edges scores are reported, as they are unable to predict remote edges. $\text{TUPA}_{\text{BiLSTM}}$ obtains the highest F-scores in all metrics, surpassing the bilexical parsers, tree parsers and other classifiers.

flecting the error resulting from the conversion.[10]

DAGParser and UPARSE are most directly comparable to $\text{TUPA}_{\text{Sparse}}$, as they also use a perceptron classifier with sparse features. $\text{TUPA}_{\text{Sparse}}$ considerably outperforms both, where DAGParser does not predict any remote edges in the out-of-domain setting. TurboParser fares worse in this comparison, despite somewhat better results on remote edges. The LSTM parser of Dyer et al. (2015) obtains the highest primary F-score among the baseline parsers, with a considerable margin.

Using a feedforward NN and embedding features, TUPA_{MLP} obtains higher scores than $\text{TUPA}_{\text{Sparse}}$, but is outperformed by the LSTM parser on primary edges. However, using better input encoding allowing virtual look-ahead and look-behind in the token representation, $\text{TUPA}_{\text{BiLSTM}}$ obtains substantially higher scores than TUPA_{MLP} and all other parsers, on both primary and remote edges, both in the in-domain and out-of-domain settings. Its performance in absolute terms, of 73.5% F-score on primary edges, is encouraging in light of UCCA's inter-annotator agreement of 80–85% F-score on them (Abend and Rappoport, 2013).

The parsers resulting from tree approximation are unable to recover any remote edges, as these are removed in the conversion.[11] The bilexical DAG parsers are quite limited in this respect as well. While some of the DAG parsers' difficulty can be attributed to the conversion upper bound of 58.3%, this in itself cannot account for their poor performance on remote edges, which is an order of magnitude lower than that of $\text{TUPA}_{\text{BiLSTM}}$.

6 Related Work

While earlier work on anchored[12] semantic parsing has mostly concentrated on shallow semantic analysis, focusing on semantic role labeling of verbal argument structures, the focus has recently shifted to parsing of more elaborate representations that account for a wider range of phenomena (Abend and Rappoport, 2017).

Grammar-Based Parsing. Linguistically expressive grammars such as HPSG (Pollard and Sag, 1994), CCG (Steedman, 2000) and TAG (Joshi and Schabes, 1997) provide a theory of the syntax-semantics interface, and have been used as a basis for semantic parsers by defining com-

[10] The low upper bound for remote edges is partly due to the removal of implicit nodes (not supported in bilexical representations), where the whole sub-graph headed by such nodes, often containing remote edges, must be discarded.

[11] We also experimented with a simpler version of TUPA lacking REMOTE transitions, obtaining an increase of up to 2 labeled F-score points on primary edges, at the cost of not being able to predict remote edges.

[12] By *anchored* we mean that the semantic representation directly corresponds to the words and phrases of the text.

positional semantics on top of them (Flickinger, 2000; Bos, 2005, among others). Depending on the grammar and the implementation, such semantic parsers can support some or all of the structural properties UCCA exhibits. Nevertheless, this line of work differs from our approach in two important ways. First, the *representations* are different. UCCA does not attempt to model the syntax-semantics interface and is thus less coupled with syntax. Second, while grammar-based *parsers* explicitly model syntax, our approach directly models the relation between tokens and semantic structures, without explicit composition rules.

Broad-Coverage Semantic Parsing. Most closely related to this work is Broad-Coverage Semantic Dependency Parsing (SDP), addressed in two SemEval tasks (Oepen et al., 2014, 2015). Like UCCA parsing, SDP addresses a wide range of semantic phenomena, and supports discontinuous units and reentrancy. In SDP, however, bilexical dependencies are used, and a head must be selected for every relation—even in constructions that have no clear head, such as coordination (Ivanova et al., 2012). The use of non-terminal nodes is a simple way to avoid this liability. SDP also differs from UCCA in the type of distinctions it makes, which are more tightly coupled with syntactic considerations, where UCCA aims to capture purely semantic cross-linguistically applicable notions. For instance, the "poss" label in the DM target representation is used to annotate syntactic possessive constructions, regardless of whether they correspond to semantic ownership (e.g., "John's dog") or other semantic relations, such as marking an argument of a nominal predicate (e.g., "John's kick"). UCCA reflects the difference between these constructions.

Recent interest in SDP has yielded numerous works on graph parsing (Ribeyre et al., 2014; Thomson et al., 2014; Almeida and Martins, 2015; Du et al., 2015), including tree approximation (Agić and Koller, 2014; Schluter et al., 2014) and joint syntactic/semantic parsing (Henderson et al., 2013; Swayamdipta et al., 2016).

Abstract Meaning Representation. Another line of work addresses parsing into AMRs (Flanigan et al., 2014; Vanderwende et al., 2015; Pust et al., 2015; Artzi et al., 2015), which, like UCCA, abstract away from syntactic distinctions and represent meaning directly, using OntoNotes predicates (Weischedel et al., 2013). Events in AMR may also be evoked by non-verbal predicates, including possessive constructions.

Unlike in UCCA, the alignment between AMR concepts and the text is not explicitly marked. While sharing much of this work's motivation, not anchoring the representation in the text complicates the parsing task, as it requires the alignment to be automatically (and imprecisely) detected. Indeed, despite considerable technical effort (Flanigan et al., 2014; Pourdamghani et al., 2014; Werling et al., 2015), concept identification is only about 80%–90% accurate. Furthermore, anchoring allows breaking down sentences into semantically meaningful sub-spans, which is useful for many applications (Fernández-González and Martins, 2015; Birch et al., 2016).

Several transition-based AMR parsers have been proposed: CAMR assumes syntactically parsed input, processing dependency trees into AMR (Wang et al., 2015a,b, 2016; Goodman et al., 2016). In contrast, the parsers of Damonte et al. (2017) and Zhou et al. (2016) do not require syntactic pre-processing. Damonte et al. (2017) perform concept identification using a simple heuristic selecting the most frequent graph for each token, and Zhou et al. (2016) perform concept identification and parsing jointly. UCCA parsing does not require separately aligning the input tokens to the graph. TUPA creates non-terminal units as part of the parsing process.

Furthermore, existing transition-based AMR parsers are not general DAG parsers. They are only able to predict a subset of reentrancies and discontinuities, as they may remove nodes before their parents have been predicted (Damonte et al., 2017). They are thus limited to a sub-class of AMRs in particular, and specifically cannot produce arbitrary DAG parses. TUPA's transition set, on the other hand, allows general DAG parsing.[13]

7 Conclusion

We present TUPA, the first parser for UCCA. Evaluated in in-domain and out-of-domain settings, we show that coupled with a NN classifier and BiLSTM feature extractor, it accurately predicts UCCA graphs from text, outperforming a variety of strong baselines by a margin.

Despite the recent diversity of semantic pars-

[13] See Appendix E for a proof sketch for the completeness of TUPA's transition set.

ing work, the effectiveness of different approaches for structurally and semantically different schemes is not well-understood (Kuhlmann and Oepen, 2016). Our contribution to this literature is a general parser that supports multiple parents, discontinuous units and non-terminal nodes.

Future work will evaluate TUPA in a multilingual setting, assessing UCCA's cross-linguistic applicability. We will also apply the TUPA transition scheme to different target representations, including AMR and SDP, exploring the limits of its generality. In addition, we will explore different conversion procedures (Kong et al., 2015) to compare different representations, suggesting ways for a data-driven design of semantic annotation.

A parser for UCCA will enable using the framework for new tasks, in addition to existing applications such as machine translation evaluation (Birch et al., 2016). We believe UCCA's merits in providing a cross-linguistically applicable, broad-coverage annotation will support ongoing efforts to incorporate deeper semantic structures into various applications, such as sentence simplification (Narayan and Gardent, 2014) and summarization (Liu et al., 2015).

Abstract Syntax Networks for Code Generation and Semantic Parsing

Maxim Rabinovich* **Mitchell Stern*** **Dan Klein**
Computer Science Division
University of California, Berkeley
{rabinovich,mitchell,klein}@cs.berkeley.edu

Abstract

Tasks like code generation and semantic parsing require mapping unstructured (or partially structured) inputs to well-formed, executable outputs. We introduce abstract syntax networks, a modeling framework for these problems. The outputs are represented as abstract syntax trees (ASTs) and constructed by a decoder with a dynamically-determined modular structure paralleling the structure of the output tree. On the benchmark HEARTHSTONE dataset for code generation, our model obtains 79.2 BLEU and 22.7% exact match accuracy, compared to previous state-of-the-art values of 67.1 and 6.1%. Furthermore, we perform competitively on the ATIS, JOBS, and GEO semantic parsing datasets with no task-specific engineering.

1 Introduction

Tasks like semantic parsing and code generation are challenging in part because they are *structured* (the output must be well-formed) but not *synchronous* (the output structure diverges from the input structure).

Sequence-to-sequence models have proven effective for both tasks (Dong and Lapata, 2016; Ling et al., 2016), using encoder-decoder frameworks to exploit the sequential structure on both the input and output side. Yet these approaches do not account for much richer structural constraints on outputs—including well-formedness, well-typedness, and executability. The well-formedness case is of particular interest, since it can readily be enforced by representing outputs as abstract syntax trees (ASTs) (Aho et al., 2006), an approach that can be seen as a much lighter weight

version of CCG-based semantic parsing (Zettlemoyer and Collins, 2005).

In this work, we introduce *abstract syntax networks* (ASNs), an extension of the standard encoder-decoder framework utilizing a modular decoder whose submodels are composed to natively generate ASTs in a top-down manner. The decoding process for any given input follows a dy-

*Equal contribution.

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1139–1149
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1105

namically chosen mutual recursion between the modules, where the structure of the tree being produced mirrors the call graph of the recursion. We implement this process using a decoder model built of many submodels, each associated with a specific construct in the AST grammar and invoked when that construct is needed in the output tree. As is common with neural approaches to structured prediction (Chen and Manning, 2014; Vinyals et al., 2015), our decoder proceeds greedily and accesses not only a fixed encoding but also an attention-based representation of the input (Bahdanau et al., 2014).

Our model significantly outperforms previous architectures for code generation and obtains competitive or state-of-the-art results on a suite of semantic parsing benchmarks. On the HEARTHSTONE dataset for code generation, we achieve a token BLEU score of 79.2 and an exact match accuracy of 22.7%, greatly improving over the previous best results of 67.1 BLEU and 6.1% exact match (Ling et al., 2016).

The flexibility of ASNs makes them readily applicable to other tasks with minimal adaptation. We illustrate this point with a suite of semantic parsing experiments. On the JOBS dataset, we improve on previous state-of-the-art, achieving 92.9% exact match accuracy as compared to the previous record of 90.7%. Likewise, we perform competitively on the ATIS and GEO datasets, matching or exceeding the exact match reported by Dong and Lapata (2016), though not quite reaching the records held by the best previous semantic parsing approaches (Wang et al., 2014).

1.1 Related work

Encoder-decoder architectures, with and without attention, have been applied successfully both to sequence prediction tasks like machine translation and to tree prediction tasks like constituency parsing (Cross and Huang, 2016; Dyer et al., 2016; Vinyals et al., 2015). In the latter case, work has focused on making the task look like sequence-to-sequence prediction, either by flattening the output tree (Vinyals et al., 2015) or by representing it as a sequence of construction decisions (Cross and Huang, 2016; Dyer et al., 2016). Our work differs from both in its use of a recursive top-down generation procedure.

Dong and Lapata (2016) introduced a sequence-to-sequence approach to semantic parsing, including a limited form of top-down recursion, but without the modularity or tight coupling between output grammar and model characteristic of our approach.

Neural (and probabilistic) modeling of code, including for prediction problems, has a longer history. Allamanis et al. (2015) and Maddison and Tarlow (2014) proposed modeling code with a neural language model, generating concrete syntax trees in left-first depth-first order, focusing on metrics like perplexity and applications like code snippet retrieval. More recently, Shin et al. (2017) attacked the same problem using a grammar-based variational autoencoder with top-down generation similar to ours instead. Meanwhile, a separate line of work has focused on the problem of program induction from input-output pairs (Balog et al., 2016; Liang et al., 2010; Menon et al., 2013).

The prediction framework most similar in spirit to ours is the doubly-recurrent decoder network introduced by Alvarez-Melis and Jaakkola (2017), which propagates information down the tree using a vertical LSTM and between siblings using a horizontal LSTM. Our model differs from theirs in using a separate module for each grammar construct and learning separate vertical updates for siblings when the AST labels require all siblings to be jointly present; we do, however, use a horizontal LSTM for nodes with *variable* numbers of children. The differences between our models reflect not only design decisions, but also differences in data—since ASTs have labeled nodes and labeled edges, they come with additional structure that our model exploits.

Apart from ours, the best results on the code-generation task associated with the HEARTHSTONE dataset are based on a sequence-to-sequence approach to the problem (Ling et al., 2016). Abstract syntax networks greatly improve on those results.

Previously, Andreas et al. (2016) introduced neural module networks (NMNs) for visual question answering, with modules corresponding to linguistic substructures within the input query. The primary purpose of the modules in NMNs is to compute deep features of images in the style of convolutional neural networks (CNN). These features are then fed into a final decision layer. In contrast to the modules we describe here, NMN modules do not make decisions about what to generate or which modules to call next, nor do they

(b) Excerpt from the same AST, corresponding to the code snippet `Aura(ChangeAttack(1),MinionSelector(Adjacent()))`.

Figure 3: Fragments from the abstract syntax tree corresponding to the example code in Figure 1. Blue boxes represent composite nodes, which expand via a constructor with a prescribed set of named children. Orange boxes represent primitive nodes, with their corresponding values written underneath. Solid black squares correspond to constructor fields with `sequential` cardinality, such as the body of a class definition (Figure 3a) or the arguments of a function call (Figure 3b).

maintain recurrent state.

2 Data Representation

2.1 Abstract Syntax Trees

Our model makes use of the Abstract Syntax Description Language (ASDL) framework (Wang et al., 1997), which represents code fragments as trees with typed nodes. *Primitive types* correspond to atomic values, like integers or identifiers. Accordingly, *primitive nodes* are annotated with a primitive type and a value of that type—for instance, in Figure 3a, the `identifier` node storing `"create_minion"` represents a function of the same name.

Composite types correspond to language constructs, like expressions or statements. Each type has a collection of *constructors*, each of which specifies the particular language construct a node of that type represents. Figure 4 shows constructors for the statement (`stmt`) and expression (`expr`) types. The associated language constructs include function and class definitions, return statements, binary operations, and function calls.

Composite types enter syntax trees via *composite nodes*, annotated with a composite type and a choice of constructor specifying how the node expands. The root node in Figure 3a, for example, is

```
primitive types: identifier, object, ...

stmt
 = FunctionDef(
     identifier name, arg* args, stmt* body)
 | ClassDef(
     identifier name, expr* bases, stmt* body)
 | Return(expr? value)
 | ...

expr
 = BinOp(expr left, operator op, expr right)
 | Call(expr func, expr* args)
 | Str(string s)
 | Name(identifier id, expr_context ctx)
 | ...

...
```

Figure 4: A simplified fragment of the Python ASDL grammar.[1]

a composite node of type `stmt` that represents a class definition and therefore uses the `ClassDef` constructor. In Figure 3b, on the other hand, the root uses the `Call` constructor because it represents a function call.

Children are specified by named and typed *fields* of the constructor, which have *cardinalities* of `singular`, `optional`, or `sequential`. By default, fields have `singular` cardinality, meaning they correspond to exactly one child. For instance, the `ClassDef` constructor has a `singular` name field of type `identifier`. Fields of `optional` cardinality are associ-

[1]The full grammar can be found online on the documentation page for the Python `ast` module: https://docs.python.org/3/library/ast.html#abstract-grammar

ated with zero or one children, while fields of `sequential` cardinality are associated with zero or more children—these are designated using `?` and $\star$ suffixes in the grammar, respectively. Fields of `sequential` cardinality are often used to represent statement blocks, as in the `body` field of the `ClassDef` and `FunctionDef` constructors.

The grammars needed for semantic parsing can easily be given ASDL specifications as well, using primitive types to represent variables, predicates, and atoms and composite types for standard logical building blocks like lambdas and counting (among others). Figure 2 shows what the resulting λ-calculus trees look like. The ASDL grammars for both λ-calculus and Prolog-style logical forms are quite compact, as Figures 9 and 10 in the appendix show.

2.2 Input Representation

We represent inputs as collections of named components, each of which consists of a sequence of tokens. In the case of semantic parsing, inputs have a single component containing the query sentence. In the case of HEARTHSTONE, the card's name and description are represented as sequences of characters and tokens, respectively, while categorical attributes are represented as single-token sequences. For HEARTHSTONE, we restrict our input and output vocabularies to values that occur more than once in the training set.

3 Model Architecture

Our model uses an encoder-decoder architecture with hierarchical attention. The key idea behind our approach is to structure the decoder as a collection of mutually recursive modules. The modules correspond to elements of the AST grammar and are composed together in a manner that mirrors the structure of the tree being generated. A vertical LSTM state is passed from module to module to propagate information during the decoding process.

The encoder uses bidirectional LSTMs to embed each component and a feedforward network to combine them. Component- and token-level attention is applied over the input at each step of the decoding process.

We train our model using negative log likelihood as the loss function. The likelihood encompasses terms for all generation decisions made by the decoder.

3.1 Encoder

Each component c of the input is encoded using a component-specific bidirectional LSTM. This results in forward and backward token encodings $(\overrightarrow{\mathbf{h}^c}, \overleftarrow{\mathbf{h}^c})$ that are later used by the attention mechanism. To obtain an encoding of the input as a whole for decoder initialization, we concatenate the final forward and backward encodings of each component into a single vector and apply a linear projection.

3.2 Decoder Modules

The decoder decomposes into several classes of modules, one per construct in the grammar, which we discuss in turn. Throughout, we let $\mathbf{v}$ denote the current vertical LSTM state, and use f to represent a generic feedforward neural network. LSTM updates with hidden state $\mathbf{h}$ and input $\mathbf{x}$ are notated as $\mathrm{LSTM}(\mathbf{h}, \mathbf{x})$.

Composite type modules Each composite type `T` has a corresponding module whose role is to select among the constructors `C` for that type. As Figure 5a exhibits, a composite type module receives a vertical LSTM state $\mathbf{v}$ as input and applies a feedforward network $f_{\mathtt{T}}$ and a softmax output layer to choose a constructor:

$$p\left(\mathtt{C} \mid \mathtt{T}, \mathbf{v}\right) = \left[\mathrm{softmax}\left(f_{\mathtt{T}}\left(\mathbf{v}\right)\right)\right]_{\mathtt{C}}.$$

Control is then passed to the module associated with constructor `C`.

Constructor modules Each constructor `C` has a corresponding module whose role is to compute an intermediate vertical LSTM state $\mathbf{v}_{u,\mathtt{F}}$ for each of its fields `F` whenever `C` is chosen at a composite node u.

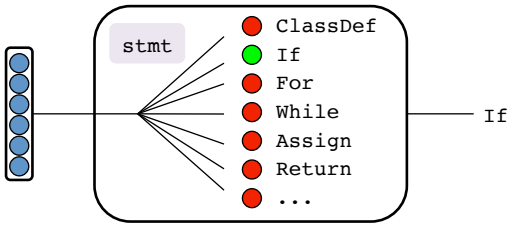
For each field `F` of the constructor, an embedding $\mathbf{e}_{\mathtt{F}}$ is concatenated with an attention-based context vector $\mathbf{c}$ and fed through a feedforward neural network $f_{\mathtt{C}}$ to obtain a context-dependent field embedding:

$$\tilde{\mathbf{e}}_{\mathtt{F}} = f_{\mathtt{C}}\left(\mathbf{e}_{\mathtt{F}},\ \mathbf{c}\right).$$

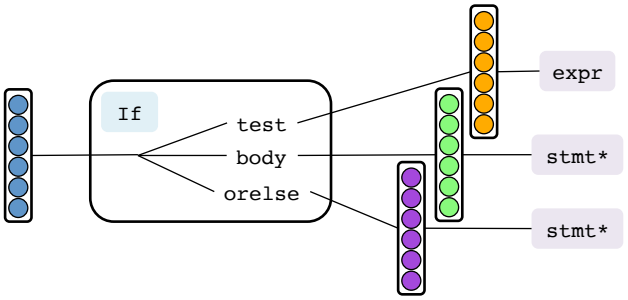
An intermediate vertical state for the field `F` at composite node u is then computed as

$$\mathbf{v}_{u,\mathtt{F}} = \mathrm{LSTM}^{v}\left(\mathbf{v}_{u},\ \tilde{\mathbf{e}}_{\mathtt{F}}\right).$$

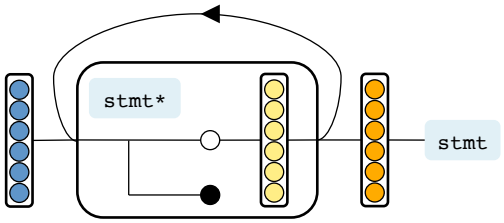
Figure 5b illustrates the process, starting with a single vertical LSTM state and ending with one updated state per field.



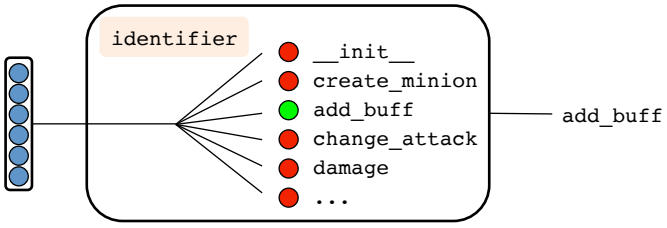
(a) A composite type module choosing a constructor for the corresponding type.



(b) A constructor module computing updated vertical LSTM states.



(c) A constructor field module (`sequential` cardinality) generating children to populate the field. At each step, the module decides whether to generate a child and continue (white circle) or stop (black circle).



(d) A primitive type module choosing a value from a closed list.

Figure 5: The module classes constituting our decoder. For brevity, we omit the cardinality modules for `singular` and `optional` cardinalities.

Constructor field modules Each field `F` of a constructor has a corresponding module whose role is to determine the number of children associated with that field and to propagate an updated vertical LSTM state to them. In the case of fields with `singular` cardinality, the decision and update are both vacuous, as exactly one child is always generated. Hence these modules forward the field vertical LSTM state $\mathbf{v}_{u,\mathtt{F}}$ unchanged to the child w corresponding to `F`:

$$\mathbf{v}_w = \mathbf{v}_{u,\mathtt{F}}. \tag{1}$$

Fields with `optional` cardinality can have either zero or one children; this choice is made using a feedforward network applied to the vertical LSTM state:

$$p(z_\mathtt{F} = 1 \mid \mathbf{v}_{u,\mathtt{F}}) = \text{sigmoid}\left(f_\mathtt{F}^{\text{gen}}(\mathbf{v}_{u,\mathtt{F}})\right). \tag{2}$$

If a child is to be generated, then as in (1), the state is propagated forward without modification.

In the case of `sequential` fields, a horizontal LSTM is employed for both child decisions and state updates. We refer to Figure 5c for an illustration of the recurrent process. After being initialized with a transformation of the vertical state, $\mathbf{s}_{\mathtt{F},0} = \mathbf{W}_\mathtt{F}\mathbf{v}_{u,\mathtt{F}}$, the horizontal LSTM iteratively decides whether to generate another child by applying a modified form of (2):

$$p\left(z_{\mathtt{F},i} = 1 \mid \mathbf{s}_{\mathtt{F},i-1},\ \mathbf{v}_{u,\mathtt{F}}\right) = \text{sigmoid}\left(f_\mathtt{F}^{\text{gen}}\left(\mathbf{s}_{\mathtt{F},i-1},\ \mathbf{v}_{u,\mathtt{F}}\right)\right).$$

If $z_{\mathtt{F},i} = 0$, generation stops and the process terminates, as represented by the solid black circle in Figure 5c. Otherwise, the process continues as represented by the white circle in Figure 5c. In that case, the horizontal state $\mathbf{s}_{u,i-1}$ is combined with the vertical state $\mathbf{v}_{u,\mathtt{F}}$ and an attention-based context vector $\mathbf{c}_{\mathtt{F},i}$ using a feedforward network $f_\mathtt{F}^{\text{update}}$ to obtain a joint context-dependent encoding of the field `F` and the position i:

$$\tilde{\mathbf{e}}_{\mathtt{F},i} = f_\mathtt{F}^{\text{update}}(\mathbf{v}_{u,\mathtt{F}},\ \mathbf{s}_{u,i-1},\ \mathbf{c}_{\mathtt{F},i}).$$

The result is used to perform a vertical LSTM update for the corresponding child w_i:

$$\mathbf{v}_{w_i} = \text{LSTM}^v(\mathbf{v}_{u,\mathtt{F}},\ \tilde{\mathbf{e}}_{\mathtt{F},i}).$$

Finally, the horizontal LSTM state is updated using the same field-position encoding, and the process continues:

$$\mathbf{s}_{u,i} = \text{LSTM}^h(\mathbf{s}_{u,i-1},\ \tilde{\mathbf{e}}_{\mathtt{F},i}).$$

Primitive type modules Each primitive type $\mathtt{T}$ has a corresponding module whose role is to select among the values $\mathtt{y}$ within the domain of that type. Figure 5d presents an example of the simplest form of this selection process, where the value $\mathtt{y}$ is obtained from a closed list via a softmax layer applied to an incoming vertical LSTM state:

$$p\left(\mathtt{y} \mid \mathtt{T}, \mathbf{v}\right) = \left[\mathrm{softmax}\left(f_{\mathtt{T}}\left(\mathbf{v}\right)\right)\right]_{\mathtt{y}}.$$

Some string-valued types are open class, however. To deal with these, we allow generation both from a closed list of previously seen values, as in Figure 5d, and synthesis of new values. Synthesis is delegated to a character-level LSTM language model (Bengio et al., 2003), and part of the role of the primitive module for open class types is to choose whether to synthesize a new value or not. During training, we allow the model to use the character LSTM only for unknown strings but include the log probability of that binary decision in the loss in order to ensure the model learns when to generate from the character LSTM.

3.3 Decoding Process

The decoding process proceeds through mutual recursion between the constituting modules, where the syntactic structure of the output tree mirrors the call graph of the generation procedure. At each step, the active decoder module either makes a generation decision, propagates state down the tree, or both.

To construct a composite node of a given type, the decoder calls the appropriate composite type module to obtain a constructor and its associated module. That module is then invoked to obtain updated vertical LSTM states for each of the constructor's fields, and the corresponding constructor field modules are invoked to advance the process to those children.

This process continues downward, stopping at each primitive node, where a value is generated but no further recursion is carried out.

3.4 Attention

Following standard practice for sequence-to-sequence models, we compute a raw bilinear attention score q_t^{raw} for each token t in the input using the decoder's current state $\mathbf{x}$ and the token's encoding $\mathbf{e}_t$:

$$q_t^{\mathrm{raw}} = \mathbf{e}_t^\top \mathbf{W} \mathbf{x}.$$

The current state $\mathbf{x}$ can be either the vertical LSTM state in isolation or a concatentation of the vertical LSTM state and either a horizontal LSTM state or a character LSTM state (for string generation). Each submodule that computes attention does so using a separate matrix $\mathbf{W}$.

A separate attention score q_c^{comp} is computed for each component of the input, independent of its content:

$$q_c^{\mathrm{comp}} = \mathbf{w}_c^\top \mathbf{x}.$$

The final token-level attention scores are the sums of the raw token-level scores and the corresponding component-level scores:

$$q_t = q_t^{\mathrm{raw}} + q_{c(t)}^{\mathrm{comp}},$$

where $c(t)$ denotes the component in which token t occurs. The attention weight vector $\mathbf{a}$ is then computed using a softmax:

$$\mathbf{a} = \mathrm{softmax}\left(\mathbf{q}\right).$$

Given the weights, the attention-based context is given by:

$$\mathbf{c} = \sum_t a_t \mathbf{e}_t.$$

Certain decision points that require attention have been highlighted in the description above; however, in our final implementation we made attention available to the decoder at all decision points.

Supervised Attention In the datasets we consider, partial or total copying of input tokens into primitive nodes is quite common. Rather than providing an explicit copying mechanism (Ling et al., 2016), we instead generate alignments where possible to define a set of tokens on which the attention at a given primitive node should be concentrated.[2] If no matches are found, the corresponding set of tokens is taken to be the whole input.

The attention supervision enters the loss through a term that encourages the final attention weights to be concentrated on the specified subset. Formally, if the matched subset of component-token pairs is S, the loss term associated with the supervision would be

$$\log \sum_t \exp\left(a_t\right) - \log \sum_{t \in S} \exp\left(a_t\right), \qquad (3)$$

[2] Alignments are generated using an exact string match heuristic that also included some limited normalization, primarily splitting of special characters, undoing camel case, and lemmatization for the semantic parsing datasets.

where a_t is the attention weight associated with token t, and the sum in the first term ranges over all tokens in the input. The loss in (3) can be interpreted as the negative log probability of attending to some token in S.

4 Experimental evaluation

4.1 Semantic parsing

Data We use three semantic parsing datasets: JOBS, GEO, and ATIS. All three consist of natural language queries paired with a logical representation of their denotations. JOBS consists of 640 such pairs, with Prolog-style logical representations, while GEO and ATIS consist of 880 and 5,410 such pairs, respectively, with λ-calculus logical forms. We use the same training-test split as Zettlemoyer and Collins (2005) for JOBS and GEO, and the standard training-development-test split for ATIS. We use the preprocessed versions of these datasets made available by Dong and Lapata (2016), where text in the input has been lowercased and stemmed using NLTK (Bird et al., 2009), and matching entities appearing in the same input-output pair have been replaced by numbered abstract identifiers of the same type.

Evaluation We compute accuracies using tree exact match for evaluation. Following the publicly released code of Dong and Lapata (2016), we canonicalize the order of the children within conjunction and disjunction nodes to avoid spurious errors, but otherwise perform no transformations before comparison.

4.2 Code generation

Data We use the HEARTHSTONE dataset introduced by Ling et al. (2016), which consists of 665 cards paired with their implementations in the open-source Hearthbreaker engine.[3] Our training-development-test split is identical to that of Ling et al. (2016), with split sizes of 533, 66, and 66, respectively.

Cards contain two kinds of components: textual components that contain the card's name and a description of its function, and categorical ones that contain numerical attributes (attack, health, cost, and durability) or enumerated attributes (rarity, type, race, and class). The name of the card is represented as a sequence of characters, while its description consists of a sequence of tokens split on whitespace and punctuation. All categorical components are represented as single-token sequences.

Evaluation For direct comparison to the results of Ling et al. (2016), we evaluate our predicted code based on exact match and token-level BLEU relative to the reference implementations from the library. We additionally compute node-based precision, recall, and F1 scores for our predicted trees compared to the reference code ASTs. Formally, these scores are obtained by defining the intersection of the predicted and gold trees as their largest common tree prefix.

4.3 Settings

For each experiment, all feedforward and LSTM hidden dimensions are set to the same value. We select the dimension from {30, 40, 50, 60, 70} for the smaller JOBS and GEO datasets, or from {50, 75, 100, 125, 150} for the larger ATIS and HEARTHSTONE datasets. The dimensionality used for the inputs to the encoder is set to 100 in all cases. We apply dropout to the non-recurrent connections of the vertical and horizontal LSTMs, selecting the noise ratio from {0.2, 0.3, 0.4, 0.5}. All parameters are randomly initialized using Glorot initialization (Glorot and Bengio, 2010).

We perform 200 passes over the data for the JOBS and GEO experiments, or 400 passes for the ATIS and HEARTHSTONE experiments. Early stopping based on exact match is used for the semantic parsing experiments, where performance is evaluated on the training set for JOBS and GEO or on the development set for ATIS. Parameters for the HEARTHSTONE experiments are selected based on development BLEU scores. In order to promote generalization, ties are broken in all cases with a preference toward higher dropout ratios and lower dimensionalities, in that order.

Our system is implemented in Python using the DyNet neural network library (Neubig et al., 2017). We use the Adam optimizer (Kingma and Ba, 2014) with its default settings for optimization, with a batch size of 20 for the semantic parsing experiments, or a batch size of 10 for the HEARTHSTONE experiments.

4.4 Results

Our results on the semantic parsing datasets are presented in Table 1. Our basic system achieves

[3] Available online at https://github.com/danielyule/hearthbreaker.

ATIS		GEO		JOBS	
System	Accuracy	System	Accuracy	System	Accuracy
ZH15	84.2	ZH15	88.9	ZH15	85.0

WKZ14	**91.3**	WKZ14	**90.4**	LJK13	90.7
DL16	84.6	DL16	87.1	DL16	90.0
ASN	85.3	ASN	85.7	ASN	**91.4**
+ SUPATT	85.9	+ SUPATT	87.1	+ SUPATT	**92.9**

Table 1: Accuracies for the semantic parsing tasks. ASN denotes our abstract syntax network framework. SUPATT refers to the supervised attention mentioned in Section 3.4.

System	Accuracy	BLEU	F1
NEAREST	3.0	65.0	65.7
LPN	6.1	67.1	–
ASN	**18.2**	**77.6**	**72.4**
+ SUPATT	**22.7**	**79.2**	**75.6**

Table 2: Results for the HEARTHSTONE task. SUPATT refers to the system with supervised attention mentioned in Section 3.4. LPN refers to the system of Ling et al. (2016). Our nearest neighbor baseline NEAREST follows that of Ling et al. (2016), though it performs somewhat better; its nonzero exact match number stems from spurious repetition in the data.

a new state-of-the-art accuracy of 91.4% on the JOBS dataset, and this number improves to 92.9% when supervised attention is added. On the ATIS and GEO datasets, we respectively exceed and match the results of Dong and Lapata (2016). However, these fall short of the previous best results of 91.3% and 90.4%, respectively, obtained by Wang et al. (2014). This difference may be partially attributable to the use of typing information or rich lexicons in most previous semantic parsing approaches (Zettlemoyer and Collins, 2007; Kwiatkowski et al., 2013; Wang et al., 2014; Zhao and Huang, 2015).

On the HEARTHSTONE dataset, we improve significantly over the initial results of Ling et al. (2016) across all evaluation metrics, as shown in Table 2. On the more stringent exact match metric, we improve from 6.1% to 18.2%, and on token-level BLEU, we improve from 67.1 to 77.6. When supervised attention is added, we obtain an additional increase of several points on each scale, achieving peak results of 22.7% accuracy and 79.2 BLEU.

```
class IronbarkProtector(MinionCard):
  def __init__(self):
    super().__init__(
      'Ironbark Protector', 8,
      CHARACTER_CLASS.DRUID,
      CARD_RARITY.COMMON)
  def create_minion(self, player):
    return Minion(
      8, 8, taunt=True)
```

Figure 6: Cards with minimal descriptions exhibit a uniform structure that our system almost always predicts correctly, as in this instance.

```
class ManaWyrm(MinionCard):
  def __init__(self):
    super().__init__(
      'Mana Wyrm', 1,
      CHARACTER_CLASS.MAGE,
      CARD_RARITY.COMMON)
  def create_minion(self, player):
    return Minion(
      1, 3, effects=[
        Effect(
          SpellCast(),
          ActionTag(
            Give(ChangeAttack(1)),
                 SelfSelector()))
      ])
```

Figure 7: For many cards with moderately complex descriptions, the implementation follows a functional style that seems to suit our modeling strategy, usually leading to correct predictions.

4.5 Error Analysis and Discussion

As the examples in Figures 6-8 show, classes in the HEARTHSTONE dataset share a great deal of common structure. As a result, in the simplest cases, such as in Figure 6, generating the code is simply a matter of matching the overall structure and plugging in the correct values in the initializer and a few other places. In such cases, our system generally predicts the correct code, with the

```
class MultiShot(SpellCard):
  def __init__(self):
    super().__init__(
      'Multi-Shot', 4,
      CHARACTER_CLASS.HUNTER,
      CARD_RARITY.FREE)
  def use(self, player, game):
    super().use(player, game)
    targets = copy.copy(
                  game.other_player.minions)
    for i in range(0, 2):
      target = game.random_choice(targets)
      targets.remove(target)
      target.damage(
        player.effective_spell_damage(3),
        self)
  def can_use(self, player, game):
    return (
      super().can_use(player, game) and
      (len(game.other_player.minions) >= 2))
```

```
class MultiShot(SpellCard):
  def __init__(self):
    super().__init__(
      'Multi-Shot', 4,
      CHARACTER_CLASS.HUNTER,
      CARD_RARITY.FREE)
  def use(self, player, game):
    super().use(player, game)
    minions = copy.copy(
                  game.other_player.minions)
    for i in range(0, 3):
      minion = game.random_choice(minions)
      minions.remove(minion)
  def can_use(self, player, game):
    return (
      super().can_use(player, game) and
      len(game.other_player.minions) >= 3)
```

Figure 8: Cards with nontrivial logic expressed in an imperative style are the most challenging for our system. In this example, our prediction comes close to the gold code, but misses an important statement in addition to making a few other minor errors. *(Left)* gold code; *(right)* predicted code.

exception of instances in which strings are incorrectly transduced. Introducing a dedicated copying mechanism like the one used by Ling et al. (2016) or more specialized machinery for string transduction may alleviate this latter problem.

The next simplest category of card-code pairs consists of those in which the card's logic is mostly implemented via nested function calls. Figure 7 illustrates a typical case, in which the card's effect is triggered by a game event (a spell being cast) and both the trigger and the effect are described by arguments to an `Effect` constructor. Our system usually also performs well on instances like these, apart from idiosyncratic errors that can take the form of under- or overgeneration or simply substitution of incorrect predicates.

Cards whose code includes complex logic expressed in an imperative style, as in Figure 8, pose the greatest challenge for our system. Factors like variable naming, nontrivial control flow, and interleaving of code predictable from the description with code required due to the conventions of the library combine to make the code for these cards difficult to generate. In some instances (as in the figure), our system is nonetheless able to synthesize a close approximation. However, in the most complex cases, the predictions deviate significantly from the correct implementation.

In addition to the specific errors our system makes, some larger issues remain unresolved. Existing evaluation metrics only approximate the actual metric of interest: functional equivalence. Modifications of BLEU, tree F1, and exact match that canonicalize the code—for example, by anonymizing all variables—may prove more meaningful. Direct evaluation of functional equivalence is of course impossible in general (Sipser, 2006), and practically challenging even for the HEARTHSTONE dataset because it requires integrating with the game engine.

Existing work also does not attempt to enforce *semantic* coherence in the output. Long-distance semantic dependencies, between occurrences of a single variable for example, in particular are not modeled. Nor is well-typedness or executability. Overcoming these evaluation and modeling issues remains an important open problem.

5 Conclusion

ASNs provide a modular encoder-decoder architecture that can readily accommodate a variety of tasks with structured output spaces. They are particularly applicable in the presence of recursive decompositions, where they can provide a simple decoding process that closely parallels the inherent structure of the outputs. Our results demonstrate their promise for tree prediction tasks, and we believe their application to more general output structures is an interesting avenue for future work.

Abstract

While neural machine translation (NMT) has made remarkable progress in recent years, it is hard to interpret its internal workings due to the continuous representations and non-linearity of neural networks. In this work, we propose to use layer-wise relevance propagation (LRP) to compute the contribution of each contextual word to arbitrary hidden states in the attention-based encoder-decoder framework. We show that visualization with LRP helps to interpret the internal workings of NMT and analyze translation errors.

1 Introduction

End-to-end neural machine translation (NMT), which leverages neural networks to directly map between natural languages, has gained increasing popularity recently (Sutskever et al., 2014; Bahdanau et al., 2015). NMT proves to outperform conventional statistical machine translation (SMT) significantly across a variety of language pairs (Junczys-Dowmunt et al., 2016) and becomes the new *de facto* method in practical MT systems (Wu et al., 2016).

However, there still remains a severe challenge: it is hard to interpret the internal workings of NMT. In SMT (Koehn et al., 2003; Chiang, 2005), the translation process can be denoted as a derivation that comprises a sequence of translation rules (e.g., phrase pairs and synchronous CFG rules). Defined on language structures with varying granularities, these translation rules are interpretable from a linguistic perspective. In contrast, NMT takes an end-to-end approach: all internal information is represented as real-valued vectors or matrices. It is challenging to associate hidden states in neural networks with interpretable language structures. As a result, the lack of interpretability makes it very difficult to understand translation process and debug NMT systems.

Therefore, it is important to develop new methods for visualizing and understanding NMT. Existing work on visualizing and interpreting neural models has been extensively investigated in computer vision (Krizhevsky et al., 2012; Mahendran and Vedaldi, 2015; Szegedy et al., 2014; Simonyan et al., 2014; Nguyen et al., 2015; Girshick et al., 2014; Bach et al., 2015). Although visualizing and interpreting neural models for natural language processing has started to attract attention recently (Karpathy et al., 2016; Li et al., 2016), to the best of our knowledge, there is no existing work on visualizing NMT models. Note that the attention mechanism (Bahdanau et al., 2015) is restricted to demonstrate the connection between words in source and target languages and unable to offer more insights in interpreting how target words are generated (see Section 4.5).

In this work, we propose to use layer-wise relevance propagation (LRP) (Bach et al., 2015) to visualize and interpret neural machine translation. Originally designed to compute the contributions of single pixels to predictions for image classifiers, LRP back-propagates relevance recursively from the output layer to the input layer. In contrast to visualization methods relying on derivatives, a major advantage of LRP is that it does not require neural activations to be differentiable or smooth (Bach et al., 2015). We adapt LRP to the attention-based encoder-decoder framework (Bahdanau et al., 2015) to calculate relevance that measures the association degree between two arbitrary neurons in neural networks. Case studies on Chinese-English translation show that visualization helps to interpret the internal workings of

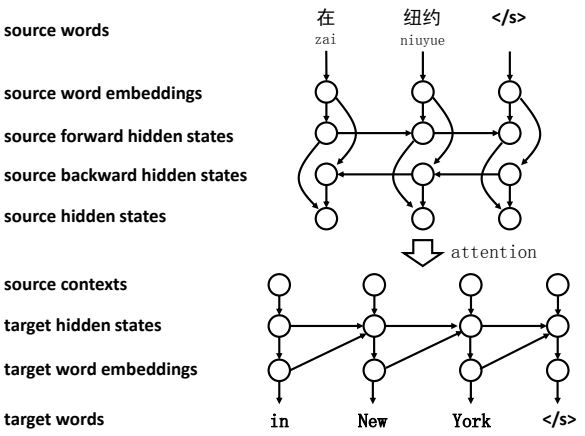

Figure 1: The attention-based encoder-decoder architecture for neural machine translation (Bahdanau et al., 2015).

NMT and analyze translation errors.

2 Background

Given a source sentence $\mathbf{x} = x_1, \ldots, x_i, \ldots, x_I$ with I source words and a target sentence $\mathbf{y} = y_1, \ldots, y_j, \ldots, y_J$ with J target words, neural machine translation (NMT) decomposes the sentence-level translation probability as a product of word-level translation probabilities:

$$P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}) = \prod_{j=1}^{J} P(y_j|\mathbf{x}, \mathbf{y}_{<j};\boldsymbol{\theta}), \quad (1)$$

where $\mathbf{y}_{<j} = y_1, \ldots, y_{j-1}$ is a partial translation.

In this work, we focus on the attention-based encoder-decoder framework (Bahdanau et al., 2015). As shown in Figure 1, given a source sentence $\mathbf{x}$, the encoder first uses source word embeddings to map each source word x_i to a real-valued vector $\boldsymbol{x}_i$.[1]

Then, a forward recurrent neural network (RNN) with GRU units (Cho et al., 2014) runs to calculate source forward hidden states:

$$\overrightarrow{\mathbf{h}}_i = f(\overrightarrow{\mathbf{h}}_{i-1}, \boldsymbol{x}_i), \quad (2)$$

where $f(\cdot)$ is a non-linear function.

Similarly, the source backward hidden states can be obtained using a backward RNN:

$$\overleftarrow{\mathbf{h}}_i = f(\overleftarrow{\mathbf{h}}_{i+1}, \boldsymbol{x}_i). \quad (3)$$

[1]Note that we use $\mathbf{x}$ to denote a source sentence and $\boldsymbol{x}$ to denote the vector representation of a single source word.

To capture global contexts, the forward and backward hidden states are concatenated as the hidden state for each source word:

$$\mathbf{h}_i = [\overrightarrow{\mathbf{h}}_i; \overleftarrow{\mathbf{h}}_i]. \quad (4)$$

Bahdanau et al. (2015) propose an attention mechanism to dynamically determine the relevant source context $\mathbf{c}_j$ for each target word:

$$\mathbf{c}_j = \sum_{i=1}^{I+1} \alpha_{j,i}\mathbf{h}_i, \quad (5)$$

where $\alpha_{j,i}$ is an attention weight that indicates how well the source word x_i and the target word y_j match. Note that an end-of-sentence token is appended to the source sentence.

In the decoder, a target hidden state for the j-th target word is calculated as

$$\mathbf{s}_j = g(\mathbf{s}_{j-1}, \boldsymbol{y}_j, \mathbf{c}_j), \quad (6)$$

where $g(\cdot)$ is a non-linear function, $\boldsymbol{y}_{j-1}$ denotes the vector representation of the $(j-1)$-th target word.

Finally, the word-level translation probability is given by

$$P(y_j|\mathbf{x}, \mathbf{y}_{<j};\boldsymbol{\theta}) = \rho(\boldsymbol{y}_{j-1}, \mathbf{s}_j, \mathbf{c}_j), \quad (7)$$

where $\rho(\cdot)$ is a non-linear function.

Although NMT proves to deliver state-of-the-art translation performance with the capability to handle long-distance dependencies due to GRU and attention, it is hard to interpret the internal information such as $\overrightarrow{\mathbf{h}}_i$, $\overleftarrow{\mathbf{h}}_i$, $\mathbf{h}_i$, $\mathbf{c}_j$, and $\mathbf{s}_j$ in the encoder-decoder framework. Though projecting word embedding space into two dimensions (Faruqui and Dyer, 2014) and the attention matrix (Bahdanau et al., 2015) shed partial light on how NMT works, how to interpret the entire network still remains a challenge.

Therefore, it is important to develop new methods for understanding the translation process and analyzing translation errors for NMT.

3 Approach

3.1 Problem Statement

Recent efforts on interpreting and visualizing neural models has focused on calculating the contribution of a unit at the input layer to the final decision at the output layer (Simonyan et al., 2014; Mahendran and Vedaldi, 2015; Nguyen et al., 2015;

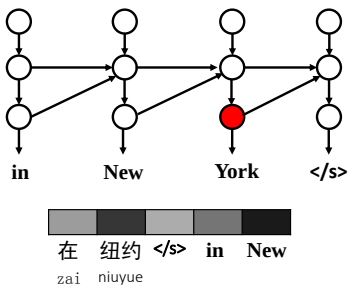

Figure 2: Visualizing the relevance between the vector representation of a target word "New York" and those of all source words and preceding target words.

Girshick et al., 2014; Bach et al., 2015; Li et al., 2016). For example, in image classification, it is important to understand the contribution of a single pixel to the prediction of classifier (Bach et al., 2015).

In this work, we are interested in calculating the contribution of source and target words to the following internal information in the attention-based encoder-decoder framework:

1. $\overrightarrow{\mathbf{h}}_i$: the i-th source forward hidden state,
2. $\overleftarrow{\mathbf{h}}_i$: the i-th source backward hidden state,
3. $\mathbf{h}_i$: the i-th source hidden state,
4. $\mathbf{c}_j$: the j-th source context vector,
5. $\mathbf{s}_j$: the j-th target hidden state,
6. $\boldsymbol{y}_j$: the j-th target word embedding.

For example, as shown in Figure 2, the generation of the third target word "York" depends on both the source context (i.e., the source sentence "zai niuyue </s>") and the target context (i.e., the partial translation "in New"). Intuitively, the source word "niuyue" and the target word "New" are more relevant to "York" and should receive higher relevance than other words. The problem is how to quantify and visualize the relevance between hidden states and contextual word vectors.

More formally, we introduce a number of definitions to facilitate the presentation.

Definition 1 *The* **contextual word set** *of a hidden state* $\mathbf{v} \in \mathbb{R}^{M\times 1}$ *is denoted as* $\mathcal{C}(\mathbf{v})$*, which is a set of source and target contextual word vectors* $\mathbf{u} \in \mathbb{R}^{N\times 1}$ *that influences the generation of* $\mathbf{v}$.

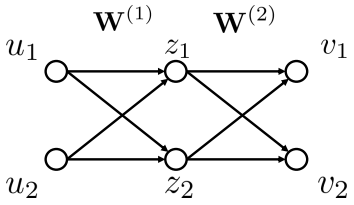

Figure 3: A simple feed-forward network for illustrating layer-wise relevance propagation (Bach et al., 2015).

For example, the context word set for $\overrightarrow{\mathbf{h}}_i$ is $\{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_i\}$, for $\overleftarrow{\mathbf{h}}_i$ is $\{\boldsymbol{x}_i, \ldots, \boldsymbol{x}_{I+1}\}$, and for $\mathbf{h}_i$ is $\{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_{I+1}\}$. The contextual word set for $\mathbf{c}_j$ is $\{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_{I+1}\}$, for $\mathbf{s}_j$ and $\boldsymbol{y}_j$ is $\{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_{I+1}, \boldsymbol{y}_1, \ldots, \boldsymbol{y}_{j-1}\}$.

As both hidden states and contextual words are represented as real-valued vectors, we need to factorize vector-level relevance at the neuron level.

Definition 2 *The* **neuron-level relevance** *between the* m*-th neuron in a hidden state* $v_m \in \mathbb{R}$ *and the* n*-th neuron in a contextual word vector* $u_n \in \mathbb{R}$ *is denoted as* $r_{u_n \leftarrow v_m} \in \mathbb{R}$*, which satisfies the following constraint:*

$$v_m = \sum_{\mathbf{u}\in\mathcal{C}(\mathbf{v})} \sum_{n=1}^{N} r_{u_n \leftarrow v_m} \tag{8}$$

Definition 3 *The* **vector-level relevance** *between a hidden state* $\mathbf{v}$ *and one contextual word vector* $\mathbf{u} \in \mathcal{C}(\mathbf{v})$ *is denoted as* $R_{\mathbf{u}\leftarrow\mathbf{v}} \in \mathbb{R}$*, which quantifies the contribution of* $\mathbf{u}$ *to the generation of* $\mathbf{v}$*. It is calculated as*

$$R_{\mathbf{u}\leftarrow\mathbf{v}} = \sum_{m=1}^{M} \sum_{n=1}^{N} r_{u_n \leftarrow v_m} \tag{9}$$

Definition 4 *The* **relevance vector** *of a hidden state* $\mathbf{v}$ *is a sequence of vector-level relevance of its contextual words:*

$$R_{\mathbf{v}} = \{R_{\mathbf{u}_1\leftarrow\mathbf{v}}, \ldots, R_{\mathbf{u}_{|\mathcal{C}(\mathbf{v})|}\leftarrow\mathbf{v}}\} \tag{10}$$

Therefore, our goal is to compute relevance vectors for hidden states in a neural network, as shown in Figure 2. The key problem is how to compute neuron-level relevance.

3.2 Layer-wise Relevance Propagation

We follow (Bach et al., 2015) to use layer-wise relevance propagation (LRP) to compute neuron-level relevance. We use a simple feed-forward network shown in Figure 3 to illustrate the central idea of LRP.

Input: A neural network G for a sentence pair and a set of hidden states to be visualized $\mathcal{V}$.
Output: Vector-level relevance set $\mathcal{R}$.

for $u \in G$ *in a forward topological order* **do**
  for $v \in \mathrm{OUT}(u)$ **do**
    calculating weight ratios $w_{u \to v}$;
  end
end
for $\mathbf{v} \in \mathcal{V}$ **do**
  for $v \in \mathbf{v}$ **do**
    $r_{v \leftarrow v} = v$; `// initializing neuron-level relevance`
  end
  for $u \in G$ *in a backward topological order* **do**
    $r_{u \leftarrow v} = \sum_{z \in \mathrm{OUT}(u)} w_{u \to z} r_{z \leftarrow v}$; `// calculating neuron-level relevance`
  end
  for $\mathbf{u} \in \mathcal{C}(\mathbf{v})$ **do**
    $R_{\mathbf{u} \leftarrow \mathbf{v}} = \sum_{u \in \mathbf{u}} \sum_{v \in \mathbf{v}} r_{u \leftarrow v}$; `// calculating vector-level relevance`
    $\mathcal{R} = \mathcal{R} \cup \{R_{\mathbf{u} \leftarrow \mathbf{v}}\}$; `// Update vector-level relevance set`
  end
end

Algorithm 1: Layer-wise relevance propagation for neural machine translation.

LRP first propagates the relevance from the output layer to the intermediate layer:

$$r_{z_1 \leftarrow v_1} = \frac{\mathbf{W}^{(2)}_{1,1} z_1}{\mathbf{W}^{(2)}_{1,1} z_1 + \mathbf{W}^{(2)}_{2,1} z_2} v_1 \quad (11)$$

$$r_{z_2 \leftarrow v_1} = \frac{\mathbf{W}^{(2)}_{2,1} z_2}{\mathbf{W}^{(2)}_{1,1} z_1 + \mathbf{W}^{(2)}_{2,1} z_2} v_1 \quad (12)$$

Note that we ignore the non-linear activation function because Bach et al. (2015) indicate that LRP is *invariant* against the choice of non-linear function.

Then, the relevance is further propagated to the input layer:

$$\begin{aligned} r_{u_1 \leftarrow v_1} = & \frac{\mathbf{W}^{(1)}_{1,1} u_1}{\mathbf{W}^{(1)}_{1,1} u_1 + \mathbf{W}^{(1)}_{2,1} u_2} r_{z_1 \leftarrow v_1} + \\ & \frac{\mathbf{W}^{(1)}_{1,2} u_1}{\mathbf{W}^{(1)}_{1,2} u_1 + \mathbf{W}^{(1)}_{2,2} u_2} r_{z_2 \leftarrow v_1} \quad (13) \\ r_{u_2 \leftarrow v_1} = & \frac{\mathbf{W}^{(1)}_{2,1} u_2}{\mathbf{W}^{(1)}_{1,1} u_1 + \mathbf{W}^{(1)}_{2,1} u_2} r_{z_1 \leftarrow v_1} + \\ & \frac{\mathbf{W}^{(1)}_{2,2} u_2}{\mathbf{W}^{(1)}_{1,2} u_1 + \mathbf{W}^{(1)}_{2,2} u_2} r_{z_2 \leftarrow v_1} \quad (14) \end{aligned}$$

Note that $r_{u_1 \leftarrow v_1} + r_{u_2 \leftarrow v_1} = v_1$.

More formally, we introduce the following definitions to ease exposition.

Definition 5 *Given a neuron u, its* **incoming neuron set** $\mathrm{IN}(u)$ *comprises all its direct connected preceding neurons in the network.*

For example, in Figure 3, the incoming neuron set of z_1 is $\mathrm{IN}(z_1) = \{u_1, u_2\}$.

Definition 6 *Given a neuron u, its* **outcoming neuron set** $\mathrm{OUT}(u)$ *comprises all its direct connected descendant neurons in the network.*

For example, in Figure 3, the incoming neuron set of z_1 is $\mathrm{OUT}(z_1) = \{v_1, v_2\}$.

Definition 7 *Given a neuron v and its incoming neurons $u \in \mathrm{IN}(v)$, the* **weight ratio** *that measures the contribution of u to v is calculated as*

$$w_{u \to v} = \frac{\mathbf{W}_{u,v} u}{\sum_{u' \in \mathrm{IN}(v)} \mathbf{W}_{u',v} u'} \quad (15)$$

Although the NMT model usually involves multiple operators such as matrix multiplication, element-wise multiplication, and maximization, they only influence the way to calculate weight ratios in Eq. (15).

For matrix multiplication such as $\mathbf{v} = \mathbf{W}\mathbf{u}$, its basic form that is calculated at the neuron level is given by $v = \sum_{u \in \mathrm{IN}(v)} \mathbf{W}_{u,v} u$. We follow Bach et al. (2015) to calculate the weight ratio using Eq. (15).

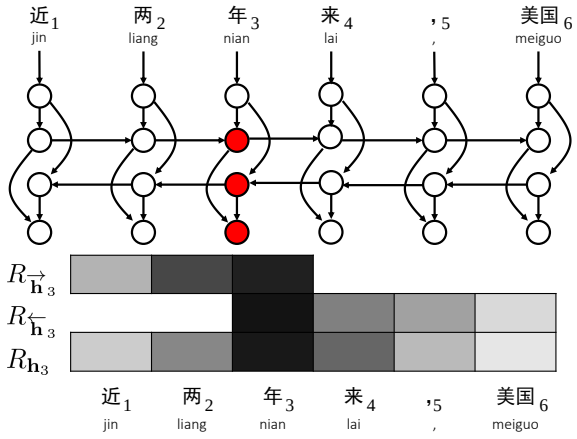

Figure 4: Visualizing source hidden states for a source content word "nian" (*years*).

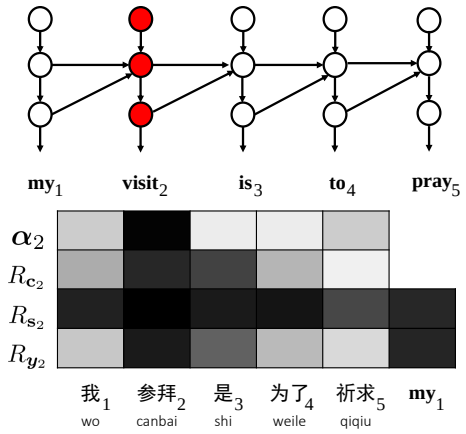

Figure 5: Visualizing target hidden states for a target content word "visit".

For element-wise multiplication such as $\mathbf{v} = \mathbf{u}_1 \circ \mathbf{u}_2$, its basic form is given by $v = \prod_{u \in \mathrm{IN}(v)} u$. We use the following method to calculate its weight ratio:

$$w_{u \to v} = \frac{u}{\sum_{u' \in \mathrm{IN}(v)} u'} \tag{16}$$

For maximization such as $v = \max\{u_1, u_2\}$, we calculate its weight ratio as follows:

$$w_{u \to v} = \begin{cases} 1 & \text{if } u = \max_{u' \in \mathrm{IN}(v)}\{u'\} \\ 0 & \text{otherwise} \end{cases} \tag{17}$$

Therefore, the general local redistribution rule for LRP is given by

$$r_{u \leftarrow v} = \sum_{z \in \mathrm{OUT}(u)} w_{u \to z} r_{z \leftarrow v} \tag{18}$$

Algorithm 1 gives the layer-wise relevance propagation algorithm for neural machine translation. The input is an attention-based encoder-decoder neural network for a sentence pair after decoding G and a set of hidden states to be visualized $\mathcal{V}$. The output is a set of vector-level relevance between intended hidden states and their contextual words $\mathcal{R}$. The algorithm first computes weight ratios for each neuron in a forward pass (lines 1-4). Then, for each hidden state to be visualized (line 6), the algorithm initializes the neuron-level relevance for itself (lines 7-9). After initialization, the neuron-level relevance is back-propagated through the network (lines 10-12). Finally, vector-level relevance is calculated based on neuron-level relevance (lines 13-16). The time complexity of Algorithm 1 is $\mathcal{O}(|G| \times |\mathcal{V}| \times O_{\max})$, where $|G|$ is the number of neuron units in the neural network G, $|\mathcal{V}|$ is the number of hidden states to be visualized and $O_{\max}$ is the maximum of out-degree for neurons in the network. Calculating relevance is more computationally expensive than computing attention as it involves all neurons in the network. Fortunately, it is possible to take advantage of parallel architectures of GPUs and relevance caching for speed-up.

4 Analysis

4.1 Data Preparation

We evaluate our approach on Chinese-English translation. The training set consists of 1.25M pairs of sentences with 27.93M Chinese words and 34.51M English words. We use the NIST 2003 dataset as the development set for model selection and the NIST 2004 dataset as test set. The BLEU score on NIST 2003 is 32.73.

We use the open-source toolkit GROUNDHOG (Bahdanau et al., 2015), which implements the attention-based encoder-decoder framework. After model training and selection on the training and development sets, we use the resulting NMT model to translate the test set. Therefore, the visualization examples in the following subsections are taken from the test set.

4.2 Visualization of Hidden States

4.2.1 Source Side

Figure 4 visualizes the source hidden states for a source content word "nian" (*years*). For each word in the source string "jin liang nian lai , meiguo" (*in recent two years, USA*), we attach a number

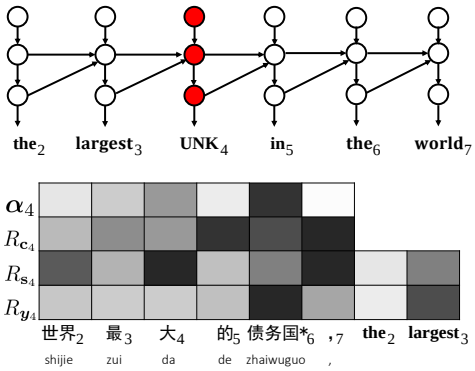

Figure 6: Visualizing target hidden states for a target UNK word.

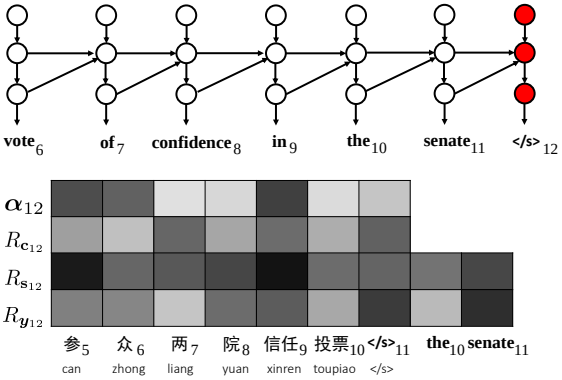

Figure 7: Analyzing translation error: word omission. The 6-th source word "zhong" is untranslated incorrectly.

to denote the position of the word in the sentence. For example, "nian" (*years*) is the third word.

We are interested in visualizing the relevance between the third source forward hidden state $\overrightarrow{\mathbf{h}}_3$ and all its contextual words "jin" (*recent*) and "liang" (*two*). We observe that the direct preceding word "liang" (*two*) contributes more to forming the forward hidden state of "nian" (*years*). For the third source backward hidden state $\overleftarrow{\mathbf{h}}_3$, the relevance of contextual words generally decreases with the increase of the distance to "nian" (*years*). Clearly, the concatenation of forward and backward hidden states $\mathbf{h}_3$ capture contexts in both directions.

The situations for function words and punctuation marks are similar but the relevance is usually more concentrated on the word itself. We omit the visualization due to space limit.

4.2.2 Target Side

Figure 5 visualizes the target-side hidden states for the second target word "visit". For comparison, we also give the attention weights $\boldsymbol{\alpha}_2$, which correctly identifies the second source word "canbai" ("visit") is most relevant to "visit".

The relevance vector of the source context $\mathbf{c}_2$ is generally consistent with the attention but reveals that the third word "shi" (*is*) also contributes to the generation of "visit".

For the target hidden state $\mathbf{s}_2$, the contextual word set includes the first target word "my". We find that most contextual words receive high values of relevance. This phenomenon has been frequently observed for most target words in other sentences. Note that relevance vector is not normalized. This is an essential difference between attention and relevance. While attention is defined to be normalized, the only constraint on relevance is that the sum of relevance of contextual words is identical to the value of intended hidden state neuron.

For the target word embedding $\mathbf{y}_2$, the relevance is generally consistent with the attention by identifying that the second source word contributes more to the generation of "visit". But $R_{\mathbf{y}_2}$ further indicates that the target word "my" is also very important for generating "visit".

Figure 6 shows the hidden states of a target UNK word, which is very common to see in NMT because of limited vocabulary. It is interesting to investigate whether the attention mechanism could put a UNK in the right place in the translation. In this example, the 6-th source word "zhaiwuguo" is a UNK. We find that the model successfully predicts the correct position of UNK by exploiting surrounding source and target contexts. But the ordering of UNK usually becomes worse if multiple UNK words exist on the source side.

4.3 Translation Error Analysis

Given the visualization of hidden states, it is possible to offer useful information for analyzing translation errors commonly observed in NMT such as word omission, word repetition, unrelated words and negation reversion.

4.3.1 Word Omission

Given a source sentence "bajisitan zongtong muxialafu yingde can zhong liang yuan xinren toupiao" (*pakistani president musharraf wins votes of confidence in senate and house*), the NMT model pro-

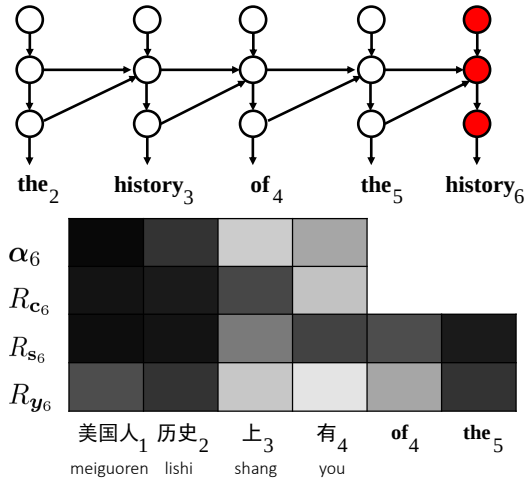

Figure 8: Analyzing translation error: word repetition. The target word "history" occurs twice in the translation incorrectly.

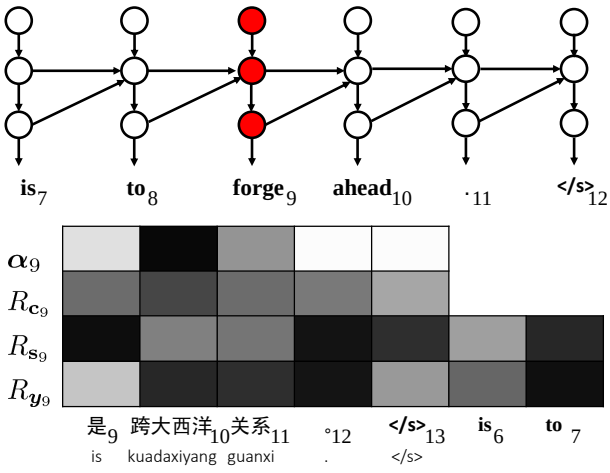

Figure 9: Analyzing translation error: unrelated words. The 9-th target word "forge" is totally unrelated to the source sentence.

duces a wrong translation "pakistani president win over democratic vote of confidence in the senate". One translation error is that the 6-th source word "zhong" (*house*) is incorrectly omitted for translation.

As the end-of-sentence token "</s>" occurs early than expected, we choose to visualize its corresponding target hidden states. Although the attention correctly identifies the 6-th source word "zhong" (*house*) to be important for generating the next target word, the relevance of source context $R_{\mathbf{c}_{12}}$ attaches more importance to the end-of-sentence token.

Finally, the relevance of target word $R_{\boldsymbol{y}_{12}}$ reveals that the end-of-sentence token and the 11-th target word "senate" become dominant in the softmax layer for generating the target word.

This example demonstrates that only using attention matrices does not suffice to analyze the internal workings of NMT. The values of relevance of contextual words might vary significantly across different layers.

4.3.2 Word Repetition

Given a source sentence "meiguoren lishi shang you jiang chengxi de chuantong , you fancuo rencuo de chuantong" (*in history , the people of america have the tradition of honesty and would not hesitate to admit their mistakes*), the NMT model produces a wrong translation "in the history of the history of the history of the americans , there is a tradition of faith in the history of mistakes". The translation error is that "history" repeats four times in the translation.

Figure 8 visualizes the target hidden states of the 6-th target word "history". According to the relevance of the target word embedding $R_{\boldsymbol{y}_6}$, the first source word "meiguoren" (*american*), the second source word "lishi" (*history*) and the 5-th target word "the" are most relevant to the generation of "history". Therefore, word repetition not only results from wrong attention but also is significantly influenced by target side context. This finding confirms the importance of controlling source and target contexts to improve fluency and adequacy (Tu et al., 2017).

4.3.3 Unrelated Words

Given a source sentence "ci ci huiyi de yi ge zhongyao yiti shi kuadaxiyang guanxi" (*one the the top agendas of the meeting is to discuss the cross-atlantic relations*), the model prediction is "a key topic of the meeting is to forge ahead". One translation error is that the 9-th English word "forge" is totally unrelated to the source sentence.

Figure 9 visualizes the hidden states of the 9-th target word "forge". We find that while the attention identifies the 10-th source word "kuadaxiyang" (*cross-atlantic*) to be most relevant, the relevance vector of the target word $R_{\boldsymbol{y}_9}$ finds that multiple source and target words should contribute to the generation of the next target word.

We observe that unrelated words are more likely to occur if multiple contextual words have high

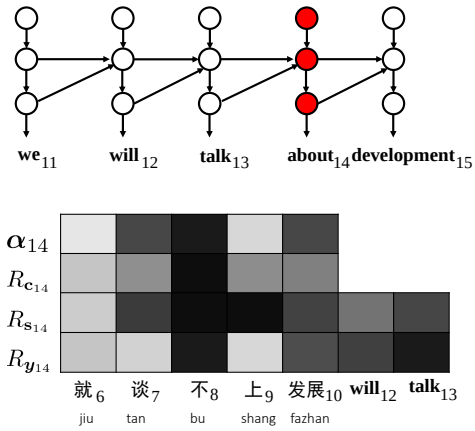

Figure 10: Analyzing translation error: negation. The 8-th negation source word "bu" (*not*) is not translated.

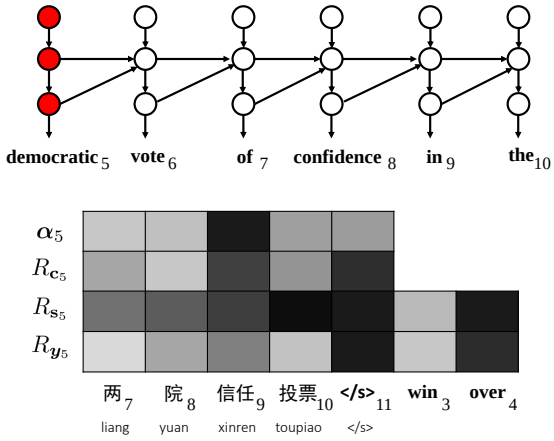

Figure 11: Analyzing translation error: extra word. The 5-th target word "democratic" is an extra word.

values in the relevance vector of the target word being generated.

4.3.4 Negation Reversion

Given a source sentence "bu jiejue shengcun wenti , jiu tan bu shang fa zhan , geng tan bu shang ke chixu fazhan" (*without solution to the issue of subsistence , there will be no development to speak of , let alone sustainable development*), the model prediction is "if we do not solve the problem of living , we will talk about development and still less can we talk about sustainable development". The translation error is that the 8-th negation source word "bu" (*not*) is untranslated. The omission of negation is a severe translation error it reverses the meaning of the source sentence.

As shown in Figure 10, while both attention and relevance correctly identify the 8-th negation word "bu" (*not*) to be most relevant, the model still generates "about" instead of a negation target word. One possible reason is that target context words "will talk" take the lead in determining the next target word.

4.4 Extra Words

Given a source sentence "bajisitan zongtong muxialafu yingde can zhong liang yuan xinren toupiao"(*pakistani president musharraf wins votes of confidence in senate and house*), the model prediction is "pakistani president win over democratic vote of confidence in the senate" The translation error is that the 5-th target word "democratic" is extra generated.

Figure 11 visualizes the hidden states of the 9-th target word "forge". We find that while the attention identifies the 9-th source word "xinren"(*confidence*) to be most relevant, the relevance vector of the target word R_{y_9} indicates that the end-of-sentence token and target words contribute more to the generation of "democratic".

4.5 Summary of Findings

We summarize the findings of visualizing and analyzing the decoding process of NMT as follows:

1. Although attention is very useful for understanding the connection between source and target words, only using attention is not sufficient for deep interpretation of target word generation (Figure 9);

2. The relevance of contextual words might vary significantly across different layers of hidden states (Figure 9);

3. Target-side context also plays a critical role in determining the next target word being generated. It is important to control both source and target contexts to produce correct translations (Figure 10);

4. Generating the end-of-sentence token too early might lead to many problems such as word omission, unrelated word generation, and truncated translation (Figures 7 and 9).

5 Related Work

Our work is closely related to previous visualization approaches that compute the contribution of a unit at the input layer to the final decision at the output layer (Simonyan et al., 2014; Mahendran and Vedaldi, 2015; Nguyen et al., 2015; Girshick et al., 2014; Bach et al., 2015; Li et al., 2016). Among them, our approach bears most resemblance to (Bach et al., 2015) since we adapt layer-wise relevance propagation to neural machine translation. The major difference is that word vectors rather than single pixels are the basic units in NMT. Therefore, we propose vector-level relevance based on neuron-level relevance for NMT. Calculating weight ratios has also been carefully designed for the operators in NMT.

The proposed approach also differs from (Li et al., 2016) in that we use relevance rather than partial derivative to quantify the contributions of contextual words. A major advantage of using relevance is that it does not require neural activations to be differentiable or smooth (Bach et al., 2015).

The relevance vector we used is significantly different from the attention matrix (Bahdanau et al., 2015). While attention only demonstrates the association degree between source and target words, relevance can be used to calculate the association degree between two arbitrary neurons in neural networks. In addition, relevance is effective in analyzing the effect of source and target contexts on generating target words.

6 Conclusion

In this work, we propose to use layer-wise relevance propagation to visualize and interpret neural machine translation. Our approach is capable of calculating the relevance between arbitrary hidden states and contextual words by back-propagating relevance along the network recursively. Analyses of the state-of-art attention-based encoder-decoder framework on Chinese-English translation show that our approach is able to offer more insights than the attention mechanism for interpreting neural machine translation.

In the future, we plan to apply our approach to more NMT approaches (Sutskever et al., 2014; Shen et al., 2016; Tu et al., 2016; Wu et al., 2016) on more language pairs to further verify its effectiveness. It is also interesting to develop relevance-based neural translation models to explicitly control relevance to produce better translations.

Detecting annotation noise in automatically labelled data

Ines Rehbein **Josef Ruppenhofer**
IDS Mannheim/University of Heidelberg, Germany
Leibniz Science Campus "Empirical Linguistics and Computational Language Modeling"
rehbein@cl.uni-heidelberg.de, ruppenhofer@ids-mannheim.de

Abstract

We introduce a method for error detection in automatically annotated text, aimed at supporting the creation of high-quality language resources at affordable cost. Our method combines an unsupervised generative model with human supervision from active learning. We test our approach on in-domain and out-of-domain data in two languages, in AL simulations and in a real world setting. For all settings, the results show that our method is able to detect annotation errors with high precision and high recall.

1 Introduction

Until recently, most of the work in Computational Linguistics has been focussed on standard written text, often from newswire. The emergence of two new research areas, Digital Humanities and Computational Sociolinguistics, have however shifted the interest towards large, noisy text collections from various sources. More and more researchers are working with social media text, historical data, or spoken language transcripts, to name but a few. Thus the need for NLP tools that are able to process this data has become more and more apparent, and has triggered a lot of work on domain adaptation and on developing more robust preprocessing tools. Studies are usually carried out on large amounts of data, and thus fully manual annotation or even error correction of automatically prelabelled text is not feasible. Given the importance of identifying noisy annotations in automatically annotated data, it is all the more surprising that up to now this area of research has been severely understudied.

This paper addresses this gap and presents a method for error detection in *automatically* labelled text. As test cases, we use POS tagging and Named Entity Recognition, both standard preprocessing steps for many NLP applications. However, our approach is general and can also be applied to other classification tasks.

Our approach is based on the work of Hovy et al. (2013) who develop a generative model for estimating the reliability of multiple annotators in a crowdsourcing setting. We adapt the generative model to the task of finding errors in *automatically* labelled data by integrating it in an active learning (AL) framework. We first show that the approach of Hovy et al. (2013) on its own is not able to beat a strong baseline. We then present our integrated model, in which we impose human supervision on the generative model through AL, and show that we are able to achieve substantial improvements in two different tasks and for two languages.

Our contributions are the following. We provide a novel approach to error detection that is able to identify errors in *automatically* labelled text with high precision *and* high recall. To the best of our knowledge, our method is the first that addresses this task in an AL framework. We show how AL can be used to guide an unsupervised generative model, and we will make our code available to the research community.[1] Our approach works particularly well in out-of-domain settings where no annotated training data is yet available.

2 Related work

Quite a bit of work has been devoted to the identifcation of errors in *manually* annotated corpora (Eskin, 2000; van Halteren, 2000; Kveton and Oliva, 2002; Dickinson and Meurers, 2003; Loftsson, 2009; Ambati et al., 2011).

[1] Our code is available at http://www.cl.uni-heidelberg.de/~rehbein/resources.

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1160–1170
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1107

Several studies have tried to identify trustworthy annotators in crowdsourcing settings (Snow et al., 2008; Bian et al., 2009), amongst them the work of Hovy et al. (2013) described in Section 3. Others have proposed selective relabelling strategies when working with non-expert annotators (Sheng et al., 2008; Zhao et al., 2011).

Manual annotations are often inconsistent and annotation errors can thus be identified by looking at the variance in the data. In contrast to this, we focus on detecting errors in *automatically* labelled data. This is a much harder problem as the annotation errors are systematic and consistent and therefore hard to detect. Only a few studies have addressed this problem. One of them is Rocio et al. (2007) who adapt a multiword unit extraction algorithm to detect automatic annotation errors in POS tagged corpora. Their semi-automatic method is geared towards finding (a small number of) high frequency errors in large datasets, often caused by tokenisation errors. Their algorithm extracts sequences that have to be manually sorted into linguistically sound patterns and erroneous patterns.

Loftsson (2009) tests several methods for error detection in POS tagged data, one of them based on the predictions of an ensemble of 5 POS taggers. Error candidates are those tokens for which the predictions of all ensemble taggers agree but that diverge from the manual annotation. This simple method yields a precision of around 16% (no. of true positives amongst the error candidates), but no information is given about the recall of the method, i.e. how many of the errors in the corpus have been identified. Rehbein (2014) extends the work of Loftsson (2009) by training a CRF classifier on the output of ensemble POS taggers. This results in a much higher precision, but with low recall (for a precision in the range of 50-60% they report a recall between 10-20%).

Also related is work that addresses the issue of learning in the presence of annotation noise (Reidsma and Carletta, 2008; Beigman and Klebanov, 2009; Bekker and Goldberger, 2016). The main difference to our work lies in its different focus. While our focus is on identifying errors with the goal of improving the quality of an existing *language resource*, their main objective is to improve the accuracy of a *machine learning system*.

In the next section we describe the approach of Hovy et al. (2013) and present our adaptation for semi-supervised error detection that combines Bayesian inference with active learning.

3 Method

3.1 Modelling human annotators

Hovy et al. (2013) develop a generative model for Multi-Annotator Competence Estimation (MACE) to determine which annotators to trust in a crowdsourcing setting (Algorithm 1, lines 2-15). MACE implements a simple graphical model where the input consists of all annotated instances I by a set of J annotators. The model generates the observed annotations A as follows. The (unobserved) "true" label T_i is sampled from a uniform prior, based on the assumption that the annotators always try to predict the correct label and thus the majority of the annotations should, more often than not, be correct. The model is unsupervised, meaning that no information on the real gold labels is available.

To model each annotator's behaviour, a binary variable S_{ij} (also unobserved) is drawn from a Bernoulli distribution that describes whether annotator j is trying to predict the correct label for instance i or whether s/he is just spamming (a behaviour not uncommon in a crowdsourcing setting). If S_{ij} is 0, the "true" label T_i is used to generate the annotation A_{ij}. If S_{ij} is 1, the predicted label A_{ij} for instance i comes from a multinomial distribution with parameter vector ξ_j.

The model parameter θ_j can be interpreted as a "trustworthiness" parameter that describes the probability that annotator j predicts the correct label. ξ_j, on the other hand, contains information about the actual behaviour of annotator j in the case that the annotator is not trying to predict the correct label.

The model parameters are learned by maximizing the marginal likelihood of the observed data, using Expectation Maximization (EM) (Dempster et al., 1977) and Bayesian variational inference. Bayesian inference is used to provide the model with priors on the annotators' behaviour and yields improved correlations over EM between the model estimates and the annotators' proficiency while keeping accuracy high. For details on the implementation and parameter settings refer to Hovy et al. (2013) and Johnson (2007).

We adapt the model of Hovy et al. (2013) and apply it to the task of error detection in *automatically* labelled text. To that end, we integrate the variational model in an active learning (AL) setting, with the goal of identifying as many errors as possible while keeping the number of instances to be checked as small as possible. The tasks we chose in our experiments are POS tagging and NER, but our approach is general and can easily be applied to other classification tasks.

3.2 Active learning

Active learning (Cohn et al., 1996) is a semi-supervised framework where a machine learner is trained on a small set of carefully selected instances that are informative for the learning process, and thus yield the same accuracy as when training the learner on a larger set of randomly chosen examples. The main objective is to save time and money by minimising the need for manual annotation. Many different measures of informativeness as well as selection strategies for AL have been proposed in the literature, amongst them *query-by-committee* learning (Seung et al., 1992).

The *query-by-committee* (QBC) approach uses a classifier ensemble (or committee) and selects the instances that show maximal disagreement between the predictions of the committee members. These instances are assumed to provide new information for the learning process, as the classifiers are most unsure about how to label them. The selected instances are then presented to the *oracle* (the human annotator), to be manually disambiguated and added to the training data. Then the classifier committee is retrained on the extended training set and the next AL iteration starts.

The query-by-committee strategy calls to mind previous work on error detection in *manually* labelled text that made use of disagreements between the predictions of a classifier ensemble and the manually assigned tag, to identify potential annotation errors in the data (Loftsson, 2009). This approach works surprisingly well, and the trade-off between precision and recall can be balanced by adding a threshold (i.e. by considering all instances where at least N of the ensemble classifiers disagree with the manually assigned label). Loftsson (2009) reports a precision of around 16% for using a committee of five POS taggers to identify annotation errors (see section 2).

Let us assume we follow this approach and apply a tagger with an average accuracy of 97% to a corpus with 100,000 tokens. We can then expect around 3,000 incorrectly tagged instances in the data. Trying to identify these with a precision of 16% means that when looking at 1,000 instances of potential errors, we can only expect to see around 160 true positive cases, and we would have to check a large amount of data in order to correct a substantial part of the annotation noise. This means that this approach is not feasible for correcting large automatically annotated data.

It is thus essential to improve precision *and* recall for error detection, and our goal is to minimise the number of instances that have to be manually checked while maximizing the number of true errors in the candidate set. In what follows we show how we can achieve this by using active learning to guide variational inference for error detection.

3.3 Guiding variational inference with AL

Variational inference is a method from calculus where the posterior distribution over a set of unobserved random variables Y is approximated by a variational distribution $Q(Y)$. We start with some observed data X (a set of predictions made by our committee of classifiers) The distribution of the true labels $Y = \{y_1, y_2, ..., y_n\}$ is unknown.

As it is too difficult to work with the posterior $p(y|x)$, we try to approximate it with a much simpler distribution $q(y)$ which models y for each observed x. To that end, we define a family Q of distributions that are computationally easy to work with, and pick the q in Q that best approximates the posterior, where $q(y)$ is called the variational approximation to the posterior $p(y|x)$.

For computing variational inference, we use the implementation of Hovy et al. (2013)[2] who jointly optimise p and q using variational EM. They alternate between adjusting q given the current p (E-step) and adjusting p given the current q (M-step). In the E-step, the objective is to find the q that minimises the divergence between the two distributions, $D(q||p)$. In the M-step, we keep q fixed and try to adjust p. The two steps are repeated until convergence.

We extend the model for use in AL as follows (Algorithm 1). We start with the predictions from a classifier ensemble and learn a variational inference model on the data (lines 2-15). We then use the posterior entropies according to the current model, and select the c instances with the highest entropies for manual validation. These instances are presented to the oracle who assigns the true label. We save the predictions made by the human annotator and, in the next iteration, use them in the variational E-step as a prior to guide the learning process. In addition, we randomly pick one of the classifiers and update its prediction by replacing the classifier's prediction with the label we obtained from the oracle.[3] In the next iteration, we train the variational model on the updated predictions. By doing this, we also gradually improve the quality of the input to the variational model.

In a typical AL approach, the main goal is to improve the *classifiers' accuracy* on new data. In contrast to that, our approach aims at increasing *precision and recall* for error detection in *automatically* labelled data, and thus at minimising the time needed for manual correction. Please note that in our model we do *not* need to retrain the classifiers used for predicting the labels but only retrain the model that determines which of the classifiers' predictions we can trust. This is crucial as it saves time and makes it easy to integrate the approach in a realistic scenario with a real human annotator in the loop.

4 Data and setup

In our first experiment (§5.1) we want to assess the benefits of our approach for finding POS errors in standard newspaper text (in-domain setting) where we have plenty of training data. For this setting, we use the English Penn Treebank, annotated with parts-of-speech, for training and testing.

In the second experiment (§5.2) we apply our method in an out-of-domain setting where we want to detect POS errors in text from new domains where no training data is yet available (out-of-domain setting). For this we use the Penn Treebank as training data, and test our models on data from the English Web treebank (Bies et al., 2012).

To test our method on a different task and a new language, we apply it to Named Entity Recognition (NER) (experiment 3, §5.3), using out-of-domain data from the Europarl corpus.[4] The data was created by Faruqui and Pado (2010) and includes the first two German Europarl session transcripts, manually annotated with NER labels according to the CoNLL 2003 annotation guidelines (Tjong Kim Sang and De Meulder, 2003).

The first three experiments are simulation studies. In our last experiment (§5.4), we show that our method also works well in a real AL scenario with a human annotator in the loop. For this we use the out-of-domain setting from the second experiment and let the annotators correct POS errors in two web genres (*answers, weblogs*) from the English Web treebank.

4.1 Tools for preprocessing

For the POS tagging experiments, we use the following taggers to predict the labels:

- bi-LSTM-aux (Plank et al., 2016)
- HunPos (Halácsy et al., 2007)
- Stanford postagger (Toutanova et al., 2003)
- SVMTool (Giménez and Màrquez, 2004)
- TreeTagger (Schmid, 1999)
- TWeb (Ma et al., 2014)
- Wapiti (Lavergne et al., 2010)

The taggers implement a range of different algorithms, including HMMs, decision trees, SVMs, maximum entropy and neural networks. We train the taggers on subsets of 20,000 sentences extracted from the standard training set of the PTB (sections 00-18)[5] and use the development and test set (sections 19-21 and 22-24) for testing. The training times of the taggers vary considerably, ranging from a few seconds (HunPos) to several

[2]MACE is available for download from http://www.isi.edu/publications/licensed-sw/mace

[3]We also experimented with updating more than one classifier, which resulted in lower precision and recall. We take this as evidence for the importance of keeping the variance in the predictions high.

[4]The NER taggers have been trained on written German data from the HGC and DeWaC corpora (see §4.1).

[5]For taggers that use a development set during training, we also extract the dev data from sections 00-18 of the PTB.

hours. This is a problem for the typical AL setting where it is crucial not to keep the human annotators waiting for the next instance while the system retrains. A major advantage of our setup is that we do not need to retrain the baseline classifiers as we only use them once, for preprocessing, before the actual error detection starts.

For the NER experiment, we use tools for which pretrained models for German are available, namely GermaNER (Benikova et al., 2015), and the StanfordNER system (Finkel and Manning, 2009) with models trained on the HGC and the DeWaC corpus (Baroni et al., 2009; Faruqui and Padó, 2010).[6]

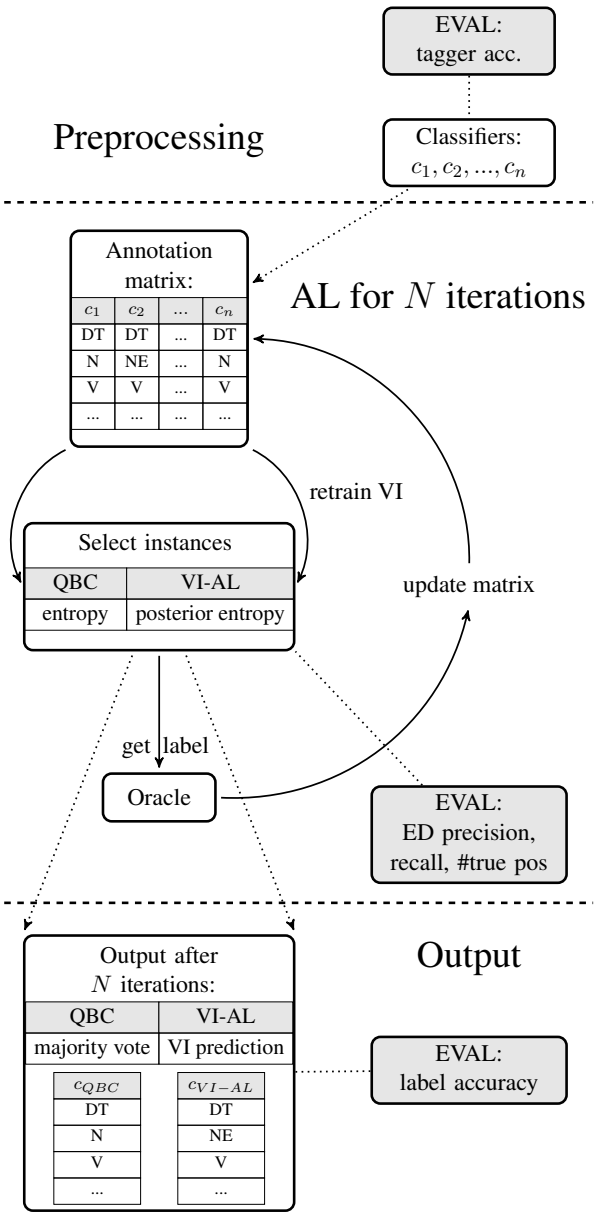
4.2 Evaluation measures

We report results for different evaluation measures to asses the usefulness of our method. First, we report **tagger accuracy** on the data, obtained during preprocessing (figure 1). This corresponds to the accuracy of the labels in the corpus *before* error correction (baseline accuracy). **Label accuracy** measures the accuracy of the labels in the corpus *after* N iterations of error correction. Please note that we do not retrain the tools used for preprocessing, but assess the quality of the data after N iterations of manual inspection and correction.

We also report precision and recall for the error detection itself. **True positives (tp)** refers to the number of instances selected for correction during AL that were actual annotation errors. We compute **Error detection (ED) precision** as the number of true positives divided by the number of all instances selected for error correction during N iterations of AL, and **recall** as the ratio of correctly identified errors to all errors in the data.

4.3 Baseline accuracies

Table 1 shows the accuracies for the individual POS taggers used in experiments 1, 2 and 4. Please note that this is not a fair comparison as each tagger was trained on a *different* randomly sampled subset of the data and, crucially, we did not optimise any of the taggers but used default settings in all experiments.[7] The accuracies of the



EVAL	*Evaluation measures used in the experiments*
tagger acc	Accuracy of preprocessing classifiers on the data.
label acc	Label accuracy in the corpus after N iterations of AL.
true pos	No. of instances selected for correction that are true errors.
ED prec	No. of true pos. / all instances selected for error correction.
recall	Correctly identified errors / all errors in the corpus.

Figure 1: Error detection procedure and overview over different evaluation measures for assessing the quality of error identification.

baseline taggers vary between 94-97%, with an average accuracy of 95.8%. The majority baseline yields better results than the best individual tagger, with an accuracy of 97.3%. Importantly, the predictions made by the variational inference model (MACE) are in the same range as the majority baseline and thus *do not improve over the*

[6]To increase the number of annotators we use an older version of the StanfordNER (2009-01-16) and a newer version (2015-12-09), with both the DeWaC and HGC models, resulting in a total of 5 annotators for the NER task.

[7]Please note that the success of our method relies on the variation in the ensemble predictions, and thus improving the accuracies for preprocessing is not guaranteed to improve precision for the error detection task.

Tagger	Acc.
bilstm	97.00
hunpos	96.18
stanford	96.93

majority vote on the *automatically* labelled data.

To be able to run the variational inference model in an AL setting, we limit the size of the test data (the size of the pre-annotated data to be corrected) to batches of 5,000 tokens. This allows us to reduce the training time of the variational model and avoid unnecessary waiting times for the oracle.

For NER (experiment 3), in contrast to POS tagging, we have a much smaller label set with only 5 labels (PER, ORG, LOC, MISC, O), and a highly skewed distribution where most of the instances belong to the negative class (O). To ensure a sufficient number of NEs in the data, we increase the batch size and use the whole out-of-domain testset with 4,395 sentences in the experiment.[8] The overall accuracies of the different NER models are all in the range of 97.7-98.6%. Results for individual classes, however, vary considerably between the different models.

5 Results

5.1 Experiment 1: In-domain setting

In our first experiment, we explore the benefits of our AL approach to error detection in a setting where we have a reasonably large amount of training data, and where training and test data come from the same domain (in-domain setting).

We implement two selection strategies. The first one is a *Query-by-Committee* approach (QBC) where we use the disagreements in the predictions of our tagger ensemble to identify potential errors. For each instance i, we compute the entropy over the predicted labels M by the 7 taggers and select the N instances with the highest entropy (Equation 1).

$$H = -\sum_{m=1}^{M} P(y_i = m) \log P(y_i = m) \quad (1)$$

For each selected instance, we then replace the label predicted by majority vote with the gold label. Please note that the selected instances might already have the correct label, and thus the replacement does not necessarily increase accuracy but only does so when the algorithm selects a true error. We then evaluate the accuracy of the majority predictions after updating the N instances ranked highest for entropy[9] (figure 1).

We compare the QBC setting to our integrated approach where we guide the generative model with human supervision. Here the instances are selected according to their posterior entropy as assigned by the variational model, and after being disambiguated by the oracle, the predictions of a randomly selected classifier are updated with the oracle tags. We run the AL simulation for 500 iterations[10] and select one new instance in each iteration. After replacing the predicted label for this instance by the gold label, we retrain the variational model and select the next instance, based on the new posterior probabilities learned on the modified dataset. We refer to this setting as VI-AL.

	QBC		VI-AL	
N	**label acc**	**ED prec**	**label acc**	**ED prec**
0	97.58	-	97.56	-
100	97.84	13.0	98.42	**41.0**
200	97.86	7.0	98.90	**33.0**
300	97.90	5.3	99.16	**26.3**
400	97.82	3.0	99.26	**21.0**
500	97.92	3.4	99.34	**17.6**

Table 2: **Label accuracies** on 5,000 tokens of WSJ text after N iterations, and precision for error detection (ED prec).

Table 2 shows POS tag accuracies (lab-acc) *after* N iterations of active learning. For the QBC setting, we see a slight increase in label accuracy of 0.3% (from 97.6 to 97.9) after manually validating 10% of the instances in the data. For the first 100 instances, we see a precision of 13% for error

[8] This is possible because, given the lower number of class labels, the training time for the VI-AL model for NER is much shorter than for the POS data.

[9] Please recall that, in contrast to a traditional QBC active learning approach, we do not retrain the classifiers but only update the labels predicted by the classifiers.

[10] We stopped after 500 iterations as this was enough to detect nearly all errors in the WSJ data.

Table 4: Increase in POS **label accuracy** on the web genres (5,000 tokens) after N iterations of error correction with VI-AL.

detection. In the succeeding iterations, the precision slowly decreases as it gets harder to identify new errors. We even observe a slight decrease in label accuracy after 400 iterations that is due to the fact that ties are broken randomly and thus the vote for the same instance can vary between iterations.

Looking at the AL setting with variational inference, we also see the highest precision for identifying errors during the first 100 iterations. However, the precision for error dection is more than 3 times as high as for QBC (41% vs. 13%), and we are still able to detect new errors during the last 100 iterations. This results in an increase in POS label accuracy in the corpus from 97.56% to 99.34%, a near perfect result.

To find out what error types we were not able to identify, we manually checked the remaining 33 errors that we failed to detect in the first 500 iterations. Most of those are cases where an adjective (JJ) was mistaken for a past participle (VBN).

(2) Companies were **closed**$_{JJ/VBN}$ yesterday

Manning (2011), who presents a categorization of the type of errors made by a state-of-the-art POS tagger on the PTB, refers to the error type in example (2) as *underspecified/unclear*, a category that he applies to instances where "the tag is underspecified, ambiguous, or unclear in the context". These cases are also hard to disambiguate for human annotators, so it is not surprising that our system failed to detect them.

5.2 Experiment 2: Out-of-domain setting

In the second experiment, we test how our approach performs in an out-of-domain setting. For this, we use the English Web treebank (Bies et al., 2012), a corpus of over 250,000 words of English weblogs, newsgroups, email, reviews and question-answers manually annotated for parts-of-speech and syntax. Our objective is to develop and test a method for error detection that can also be applied to out-of-domain scenarios for creating and improving language resources when *no in-domain training data is available*. We thus abstain from retraining the taggers on the web data and use the tools and models from experiment 1 (§5.1) as is, trained on the WSJ. As the English Web treebank uses an extended tagset with additional tags for URLs and email addresses etc., we allow the oracle to assign new tags unknown to the preprocessing classifiers. In a traditional AL setting, this would not be possible, as all class labels have to be known from the start. In our setting, however, this can be easily implemented.

For each web genre, we extract samples of 5,000 tokens and run an active learning simulation with 500 iterations, where in each iteration one new instance is selected and disambiguated. After each iteration, we update the variational model and the predictions of a randomly selected classifier, as described in Section 5.1.

Table 3 shows the performance of the WSJ-trained taggers on the web data. As expected, the results are much lower than the ones from the in-domain setting. This allows us to explore the behaviour of our error detection approach under different conditions, in particular to test our approach on tag predictions of a lower quality. The last three rows in Table 3 give the average tagger accuracy, the accuracy for the majority vote for the ensemble (not to be confused with QBC), and the accuracy we get when using the predictions from the variational model *without AL* (MACE).

	QBC			VI-AL

Table 5: No. of true positives (# tp), precision (ED prec) and recall for error detection on 5,000 tokens from the *answers* set after N iterations.

We can see that the majority baseline often, but not always succeeds in beating the best individual tagger. Results for MACE are more or less in the same range as the majority vote, same as in experiment 1, but *do not improve over the baseline*.

Next, we employ AL in the out-of-domain setting (Tables 4, 5 and 6). Table 4 shows the increase in POS label accuracy for the five web genres after running N iterations of AL with variational inference (VI-AL). Table 5 compares the results of the two selection strategies, QBC and VI-AL, on the *answers* subcorpus after an increasing number of AL iterations.[11] Table 6 completes the picture by showing results for error detection for all web genres, for QBC and VI-AL, after inspecting 10% of the data (500 iterations).

Table 4 shows that using VI-AL for error detection results in a substantial increase in POS label accuracy for all genres. VI-AL still detects new errors after a high number of iterations, without retraining the ensemble taggers. This is especially useful in a setting where no labelled target domain data is yet available.

Table 5 shows the number of true positives amongst the selected error candidates as well as precision and recall for error detection for different stages of AL on the *answers* genre. We can see that during the early learning stages, both selection strategies have a high precision and QBC beats VI-AL. After 200 iterations it becomes more difficult to detect new errors, and the precision for both methods decreases. The decrease, however, is much slower for VI-AL, leading to higher precision after the initial rounds of training, and the gap in results becomes more and more pronounced.

[11] Due to space restrictions, we can only report detailed results for one web genre. Results for the other web genres follow the same trend (see Tables 4 and 6).

	QBC			VI-AL

Table 6: No. of true positives (# tp), precision (ED prec) and recall for error detection on 5,000 tokens after 500 iterations on all web genres.

After 600 iterations, VI-AL beats QBC by more than 10%, thus resulting in a lower number of instances that have to be checked to obtain the same POS accuracy in the final dataset. Looking at recall, we see that by manually inspecting 10% of the data VI-AL manages to detect more than 50% of all errors, and after validating 20% of the data, we are able to eliminate 75% of all errors in the corpus. In contrast, QBC detects less than 60% of the annotation errors in the dataset.

In the out-of-domain setting where we start with low-quality POS predictions, we are able to detect errors in the data with a much higher precision than in the in-domain setting, where the number of errors in the dataset is much lower. Even after 1,000 iterations, the precision for error detection is close to 50% in the answers data.

Table 6 shows that the same trend appears for the other web genres, where we observe a substantially higher precision and recall when guiding AL with variational inference (VI-AL). Only on the email data are the results below the ones for QBC, but the gap is small.

5.3 Experiment 3: A new task (and language)

We now want to test if the approach generalises well to other classification tasks, and also to new languages. To that end, we apply our approach to the task of Named Entity Recognition (NER) on German data (§4).

Table 7 shows results for error detection for NER. In comparison to the POS experiments, we observe a much lower recall, for both QBC and VI-AL. This is due to the larger size of the NER testset which results in a higher absolute number of errors in the data. Please bear in mind that recall is computed as the ratio of correctly identified errors to all errors in the testset (here we have a total of 110,405 tokens in the test set which means that we identified >35% of all errors by querying *less than 1% of the data*). Also note that the overall number of errors is higher in the QBC setting (1,756

	QBC			VI-AL

900	551	**61.2**	31.4	512	56.9	**31.9**
1000	617	**61.7**	35.1	585	58.5	**35.8**
1000	remaining errors:1,139			remaining errors:1,043		

Table 7: Error detection results on the GermEval 2014 NER testset after N iterations (true positives, ED precision and recall).

errors) than in the VI-AL setting (1,628 errors), as in the first setting we used a majority vote for generating the data pool while in the second setting we relied on the predictions of MACE. For POS tagging, we did not observe a difference between the initial data pools (Table 3). For NER, however, the initial predictions of MACE are better than the majority vote.

During the first 800 iterations, precision for VI-AL is much higher than for QBC, but then slowly decreases. For QBC, however, we see the opposite trend. Here precision stays in the range of 52-56% for the first 600 iterations. After that, it slowly increases, and during the last iterations QBC precision outperforms VI-AL.

Recall, however, is higher for the VI-AL model, for *all* iterations. This means that even if precision is slightly lower than in the QBC setting after 800 iterations, it is still better to use the VI-AL model. For comparison, in the QBC setting we still have 1,139 errors left in the corpus after 1,000 iterations, while for VI-AL the number of errors remaining in the data is much lower (1,043).

5.4 Experiment 4: A real-world scenario

In our final experiment, we test our approach in a real-world scenario with a human annotator in the loop. To that end, we let two linguistically trained human annotators correct POS errors identified by AL. We use the out-of-domain data from experiment 2 (§5.2), specifically the *answers* and *weblog* subcorpora.

We run two VI-AL experiments where the oracle is presented with new error candidates for 500 iterations. The time needed for correction was 135 minutes (annotator 1, answers) and 157 minutes (annotator 2, weblog) for correcting 500 instances each. This includes the time needed to consult the annotation guidelines, as both annotators had no prior experience with the extended English Web treebank guidelines. We expect that the amount of time needed for correction will decrease when the annotators become more familiar with the annotation scheme. Results are shown in Table 8.

	VI-AL *with human annotator*					
	answers			*weblog*		
N	**# tp**	**ED prec**	**rec**	**# tp**	**ED prec**	**rec**
100	71	68.0	10.8	62	62.0	20.3
200	103	63.5	20.2	112	56.0	36.7
300	177	58.0	27.6	156	52.0	51.1
400	224	55.3	35.1	170	42.5	55.7
500	259	51.2	40.6	180	36.0	59.0

Table 8: POS results for VI-AL with a **human annotator** on 2 web genres (true positives, precision and recall for error detection on 5,000 tokens)

As expected, precision as well as recall are lower for the human annotators as compared to the simulation study (Table 6). However, even with some annotation noise we were able to detect more than 40% of all errors in the *answers* data and close to 60% of all errors in the *weblog* corpus, by manually inspecting only 10% of the data. This results in an increase in POS label accuracy from 88.8 to 92.5% for the *answers* corpus and from 93.9 to 97.5% for the *weblogs*, which is very close to the 97.8% we obtained in the simulation study (Table 4).

6 Conclusions

In the paper, we addressed a severely understudied problem, namely the detection of errors in *automatically* annotated language resources. We present an approach that combines an unsupervised generative model with human supervision in an AL framework. Using POS tagging and NER as test cases, we showed that our model can detect errors with high precision *and* recall, and works especially well in an out-of-domain setting. Our approach is language-agnostic and can be used without retraining the classifiers, which saves time and is of great practical use in an AL setting. We also showed that combining an unsupervised generative model with human supervision is superior to using a query-by-committee strategy for AL.

Our system architecture is generic and can be applied to any classification task, and we expect it to be of use in many annotation projects, especially when dealing with non-standard data or in out-of-domain settings.

Abstract

Abstractive summarization is the ultimate goal of document summarization research, but previously it is less investigated due to the immaturity of text generation techniques. Recently impressive progress has been made to abstractive sentence summarization using neural models. Unfortunately, attempts on abstractive document summarization are still in a primitive stage, and the evaluation results are worse than extractive methods on benchmark datasets. In this paper, we review the difficulties of neural abstractive document summarization, and propose a novel graph-based attention mechanism in the sequence-to-sequence framework. The intuition is to address the saliency factor of summarization, which has been overlooked by prior works. Experimental results demonstrate our model is able to achieve considerable improvement over previous neural abstractive models. The data-driven neural abstractive method is also competitive with state-of-the-art extractive methods.

1 Introduction

Document summarization is a task to generate a fluent, condensed summary for a document, and keep important information. As a useful technique to alleviate the information overload people are facing today, document summarization has been extensively investigated. Efforts on document summarization can be categorized to extractive and abstractive methods. Extractive methods produce the summary of a document by extracting sentences from the original document. They have the advantage of producing fluent sentences and preserving the meaning of original documents, but also inevitably face the drawbacks of information redundancy and incoherence between sentences. Moreover, extraction is far from the way humans write summaries.

On the contrary, abstractive methods are able to generate better summaries with the use of arbitrary words and expressions, but generating abstractive summaries is much more difficult in practice. Abstractive summarization involves sophisticated techniques including meaning representation, content organization, and surface realization. Each of these techniques has large space to be improved (Yao et al., 2017). Due to the immaturity of natural language generation techniques, fully abstractive approaches are still at the beginning and cannot always ensure grammatical abstracts.

Recent neural networks enable an end-to-end framework for natural language generation. Success has been witnessed on tasks like machine translation and image captioning, together with the abstractive sentence summarization (Rush et al., 2015). Unfortunately, the extension of sentence abstractive methods to the document summarization task is not straightforward. Encoding and decoding for a long sequence of multiple sentences, currently still lack satisfactory solutions (Yao et al., 2017). Recent abstractive document summarization models are yet not able to achieve convincing performance, with a considerable gap from extractive methods.

In this paper, we review the key factors of document summarization, i.e., the saliency, fluency, coherence, and novelty requirements of the generated summary. Fluency is what neural generation models are naturally good at, but the other factors are less considered in previous neural abstractive models. A recent study (Chen et al., 2016) starts to consider the factor of novelty, using a distraction mechanism to avoid redundancy. As far as we

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1171–1181
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1108

know, however, saliency has not been addressed by existing neural abstractive models, despite its importance for summary generation.

In this work, we study how neural summarization models can discover the salient information of a document. Inspired by the graph-based extractive summarization methods, we introduce a novel graph-based attention mechanism in the encoder-decoder framework. Moreover, we investigate the challenges of accepting and generating long sequences for sequence-to-sequence (seq2seq) models, and propose a new hierarchical decoding algorithm with a reference mechanism to generate the abstractive summaries. The proposed method is able to tackle the constraints of saliency, non-redundancy, information correctness, and fluency under a unified framework.

We conduct experiments on two large-scale corpora with human generated summaries. Experimental results demonstrate that our approach consistently outperforms previous neural abstractive summarization models, and is also competitive with state-of-the-art extractive methods.

We organize the paper as follows. Section 2 introduces related work. Section 3 describes our method. In Section 4 we present the experiments and have discussion. Finally in Section 5 we conclude this paper.

2 Related Work

2.1 Extractive Summarization Methods

Document summarization can be categorized to extractive methods and abstractive methods. Extractive methods extract sentences from the original document to form the summary. Notable early works include (Edmundson, 1969; Carbonell and Goldstein, 1998; McDonald, 2007). In recent years much progress has also been made under traditional extractive frameworks (Li et al., 2013; Dasgupta et al., 2013; Nishikawa et al., 2014).

Neural networks have also been widely investigated on the extractive summarization task. Earlier works explore to use deep learning techniques in the traditional framework (Kobayashi et al., 2015; Yin and Pei, 2015; Cao et al., 2015a,b). More recent works predict the extraction of sentences in a more data-driven way. Cheng and Lapata (2016) propose an encoder-decoder approach where the encoder learns the representation of sentences and documents while the decoder classifies each sentence using an attention mechanism. Nallapati et al. (2017) propose a recurrent neural network (RNN)-based sequence model for extractive summarization of documents. Neural sentence extractive models are able to leverage large-scale training data and achieve performance better than traditional extractive summarization methods.

2.2 Abstractive Summarization Methods

Abstractive summarization aims at generating the summary based on understanding the input text. It involves multiple subproblems like simplification, paraphrasing, and fusion. Previous research is mostly restricted in one or a few of the subproblems or specific domains (Woodsend and Lapata, 2012; Thadani and McKeown, 2013; Cheung and Penn, 2014; Pighin et al., 2014; Sun et al., 2015).

As for neural network models, success is achieved on sentence abstractive summarization. Rush et al. (2015) train a neural attention model on a large corpus of news documents and their headlines, and later Chopra et al. (2016) extend their work with an attentive recurrent neural network framework. Nallapati et al. (2016) introduce various effective techniques in the RNN seq2seq framework. These neural sentence abstraction models are able to achieve state-of-the-art results on the DUC competition of generating headline-level summaries for news documents.

Some recent works investigate neural abstractive models on the document summarization task. Cheng and Lapata (2016) also adopt a word extraction model, which is restricted to use the words of the source document to generate a summary, although the performance is much worse than the sentence extractive model. Nallapati et al. (2016) extend the sentence summarization model by trying a hierarchical attention architecture and a limited vocabulary during the decoding phase. However these models still investigate few properties of the document summarization task. Chen et al. (2016) first attempt to explore the novelty factor of summarization, and propose a distraction-based attentional model. Unfortunately these state-of-the-art neural abstractive summarization models are still not competitive to extractive methods, and there are several problems remain to be solved.

3 Our Method

3.1 Overview

In this section we introduce our method. We adopt an encoder-decoder framework, which is

widely used in machine translation (Bahdanau et al., 2014) and dialog systems (Mou et al., 2016), etc. In particular, we use a hierarchical encoder-decoder framework similar to (Li et al., 2015), as shown in Figure 1. The main distinction of this work is that we introduce a graph-based attention mechanism which is illustrated in Figure 1b, and we propose a hierarchical decoding algorithm with a reference mechanism to tackle the difficulty of abstractive summary generation. In the following parts, we will first introduce the encoder-decoder framework, and then describe the graph-based attention and the hierarchical decoding algorithm.

3.2 Encoder

The goal of the encoder is to map the input document to a vector representation. A document d is a sequence of sentences $d = \{s_i\}$, and a sentence s_i is a sequence of words $s_i = \{w_{i,k}\}$. Each word $w_{i,k}$ is represented by its distributed representation $\mathbf{e}_{i,k}$, which is mapped by a word embedding matrix E_v. We adopt a hierarchical encoder framework, where we use a word encoder enc_{word} to encode the words of a sentence s_i into the sentence representation, and use a sentence encoder enc_{sent} to encode the sentences of a document d into the document representation. The input to the word encoder is the word sequence of a sentence, appended with an "<eos>" token indicating the end of a sentence. The word encoder sequentially updates its hidden state after receiving each word, as $\mathbf{h}_{i,k} = enc_{\text{word}}(\mathbf{h}_{i,k-1}, \mathbf{e}_{i,k})$. The last hidden state (after the word encoder receives "<eos>") is denoted as $\mathbf{h}_{i,-1}$, and used as the embedding representation of the sentence s_i, denoted as $\mathbf{x}_i$. A sentence encoder is used to sequentially receive the embeddings of the sentences, given by $\mathbf{h}_i = enc_{\text{sent}}(\mathbf{h}_{i-1}, \mathbf{x}_i)$. A pseudo sentence of an "<eod>" token is appended at the end of the document to indicate the end of the whole document. The hidden state after the sentence encoder receives "<eod>" is treated as the representation of the input document $\mathbf{c} = \mathbf{h}_{-1}$.

We use the Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) as both the word encoder enc_{word} and sentence encoder enc_{sent}. In particular, we adopt the variant of LSTM structure in (Graves, 2013).

3.3 Decoder with Attention

The decoder is used to generate output sentences $\{s'_j\}$ according to the representation of the input sentences. We also use an LSTM-based hierarchical decoder framework to generate the summary, because the summary typically comprises several sentences. The sentence decoder dec_{sent} receives the document representation $\mathbf{c}$ as the initial state $\mathbf{h}'_0 = \mathbf{c}$, and predicts the sentence representations sequentially, by $\mathbf{h}'_j = dec_{\text{sent}}(\mathbf{h}'_{j-1}, \mathbf{x}'_{j-1})$, where $\mathbf{x}'_{j-1}$ is the encoded representation of the previously generated sentence s'_{j-1}. The word decoder dec_{word} receives a sentence representation $\mathbf{h}'_j$ as the initial state $\mathbf{h}'_{j,0} = \mathbf{h}'_j$, and predicts the word representations sequentially, by $\mathbf{h}'_{j,k} = dec_{\text{word}}(\mathbf{h}'_{j,k-1}, \mathbf{e}_{j,k-1})$, where $\mathbf{e}_{j,k-1}$ is the embedding of the previously generated word. The predicted word representations are mapped to vectors of the vocabulary size dimension, and then normalized by a softmax layer as the probability distribution of generating the words in the vocabulary. A word decoder stops when it generates the "<eos>" token and similarly the sentence decoder stops when it generates the "<eod>" token.

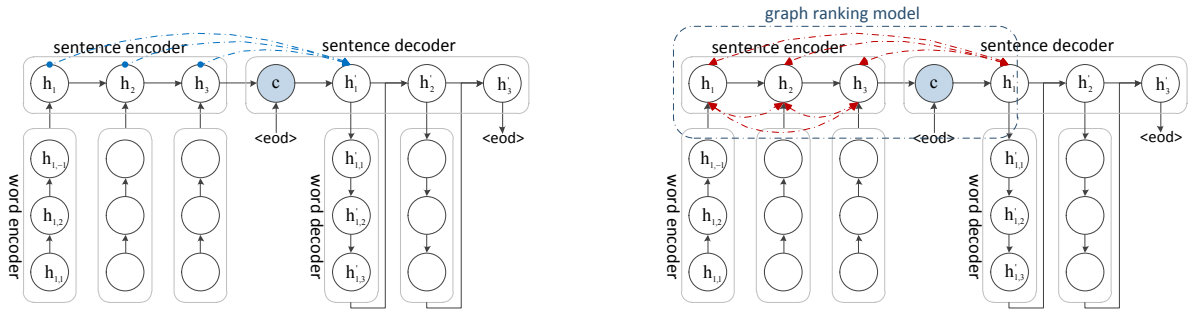
In primitive decoder models, $\mathbf{c}$ is the same for generating all the output words, which requires $\mathbf{c}$ to be a sufficient representation for the whole input sequence. The attention mechanism (Bahdanau et al., 2014) is usually introduced to alleviate the burden of remembering the whole input sequence, and to allow the decoder to pay different attention to different parts of input at different generation states. The attention mechanism sets a different $\mathbf{c}_j$ when generating sentence j, by $\mathbf{c}_j = \sum_i \alpha_i^j \mathbf{h}_i$. α_i^j indicates how much the i-th original sentence s_i contributes to generating the j-th sentence. α_i^j is usually computed as:

$$\alpha_i^j = \frac{e^{\eta\left(\mathbf{h}_i, \mathbf{h}'_j\right)}}{\sum_l e^{\eta\left(\mathbf{h}_l, \mathbf{h}'_j\right)}} \tag{1}$$

where η is the function modeling the relation between $\mathbf{h}_i$ and $\mathbf{h}'_j$. η can be defined using various functions including $\eta(\mathbf{a}, \mathbf{b}) = \mathbf{a}^T\mathbf{b}$, $\eta(\mathbf{a}, \mathbf{b}) = \mathbf{a}^T M \mathbf{b}$, and even a non-linear function achieved by a multi-layer neural network. In this paper we use $\eta(\mathbf{a}, \mathbf{b}) = \mathbf{a}^T M \mathbf{b}$ where M is a parameter matrix.

3.4 Graph-based Attention Mechanism

Traditional attention computes the importance score of a sentence s_i, when generating sentence s'_j, according to the relation between the hidden state $\mathbf{h}_i$ and current decoding state $\mathbf{h}'_j$, as shown



(a) Traditional attention.

(b) Graph-based attention.

Figure 1: Hierarchical encoder-decoder framework and comparison of the attention mechanisms.

in Figure 1a. This attention mechanism is useful in scenarios like machine translation and image captioning, because the model is able to learn a relevance mapping between the input and output. However, for document summarization, it is not easy for the model to learn how to summarize the salient information of a document, i.e., which sentences are more important to a document.

To tackle this challenge, we learn from graph-based extractive summarization models TextRank (Mihalcea and Tarau, 2004) and LexRank (Erkan and Radev, 2004), which are based on the PageRank (Page et al., 1999) algorithm. These unsupervised graph-based models show good ability to identify important sentences in a document. The underlying idea is that a sentence is important in a document if it is heavily linked with many important sentences (Wan, 2010).

In graph-based extractive summarization, a graph G is constructed to rank the original sentences. The vertices V are the set of n sentences to be considered, and the edges E are the relations between the sentences, which are typically modeled by the similarity of sentences. Let $W \in \mathcal{R}^{n\times n}$ be the adjacent matrix. Then the saliency scores of the sentences are determined by making use of the global information on the graph recursively, as:

$$\mathbf{f}(t+1) = \lambda W D^{-1}\mathbf{f}(t) + (1-\lambda)\mathbf{y} \quad (2)$$

where $\mathbf{f} = [f_1, \ldots, f_n] \in \mathcal{R}^n$ denotes the rank scores of the n sentences. $\mathbf{f}(t)$ denotes the rank scores at the t-th iteration. D is a diagonal matrix with its (i,i)-element equal to the sum of the i-th column of W. Assume we use $\mathbf{h}_i$ as the representation of s_i, and $W(i,j) = \mathbf{h}_i^T M \mathbf{h}_j$, where M is a parameter matrix to be learned. λ is a damping factor. $\mathbf{y} \in \mathcal{R}^n$ with all elements equal to $1/n$. The solution of $\mathbf{f}$ can be calculated using the closed-form:

$$\mathbf{f} = (1-\lambda)(I - \lambda W D^{-1})^{-1}\mathbf{y} \quad (3)$$

In the graph model, the importance score of a sentence s_i is determined by the relation between $\mathbf{h}_i$ and the $\{\mathbf{h}_l\}$ of all other sentences. Relatively, in traditional attention mechanisms, the importance (attention) score α_i^j is determined by the relation between $\mathbf{h}_i$ and $\mathbf{h}_j^{'}$, regardless of other original sentences. In our model we hope to combine the two effects, and compute the rank scores of the original sentences regarding $\mathbf{h}_j^{'}$, so that the importance scores of original sentences are different when decoding different state $\mathbf{h}_j^{'}$, denoted by $\mathbf{f}^j$. In our model we use the scores $\mathbf{f}^j$ to compute the attention. Therefore, $\mathbf{h}_j^{'}$ should be considered in the graph model. Inspired by the query-focused graph-based extractive summarization model (Wan et al., 2007), we realize this by applying the idea of topic-sensitive PageRank (Haveliwala, 2002), which is to rank the sentences with the concern of their relevance to the topic. We treat the current decoding state $\mathbf{h}_j^{'}$ as the topic and add it into the graph as the 0-th pseudo-sentence. Given a topic T, the topic-sensitive PageRank is similar to Eq. 3 except that $\mathbf{y}$ becomes:

$$\mathbf{y}_T = \begin{cases} \frac{1}{|T|} & i \in T \\ 0 & i \notin T \end{cases} \quad (4)$$

Therefore $\mathbf{y}_T$ is always a one hot vector and only $y_0 = 1$, indicating the 0-th sentence is $s_j^{'}$. Denote W^j as the new adjacent matrix added with $\mathbf{h}_j^{'}$, and D^j as the new diagonal matrix corresponding to W^j. Then the convergence score vector $\mathbf{f}^j$ contains the importance scores for all the

input sentences when generating sentence $s_j^{'}$, as:

$$\mathbf{f}^j = (1-\lambda)(I - \lambda W^j D^{j^{-1}})^{-1}\mathbf{y}_T \quad (5)$$

The new scores $\mathbf{f}^j$ can be used to compute the graph-based attention when decoding $\mathbf{h}_j^{'}$, to find the sentences which are both globally important and relevant to current decoding state $\mathbf{h}_j^{'}$. Inspired by (Chen et al., 2016) we adopt a distraction mechanism to compute the final attention value α_i^j, which subtracts the rank scores of the previous step, to penalize the model from attending to previously attended sentences, and also help to normalize the ranked scores $\mathbf{f}^j$. The graph-based attention is finally computed as:

$$\alpha_i^j = \frac{\max(f_i^j - f_i^{j-1}, 0)}{\sum_l \left(\max(f_l^j - f_l^{j-1}, 0)\right)} \quad (6)$$

where $\mathbf{f}^0$ is initialized with all elements equal to $1/n$. The graph-based attention will only focus on those sentences ranked higher over the previous decoding step, so that it concentrates more on the sentences which are both salient and novel. Both Eq. 5 and Eq. 6 are differentiable; thus we can use the graph-based attention function Eq. 6 to replace the traditional attention function Eq. 1, and the neural model using the graph-based attention can also be trained using traditional gradient-based methods.

3.5 Model Training

The loss function $\mathcal{L}$ of the model is the negative log likelihood of generating summaries over the training set $\mathcal{D}$:

$$\mathcal{L} = \sum_{(Y,X)\in\mathcal{D}} -\log p(Y|X;\theta) \quad (7)$$

where $X = \{x_1, \ldots, x_{|X|}\}$ and $Y = \{y_1, \ldots, y_{|Y|}\}$ denote the word sequences of a document and its summary respectively, including the "<eos>" and "<eod>" tokens for structure information. Then

$$\log p(Y|X;\theta) = \sum_{\tau=1}^{|Y|} \log p\left(y_\tau | \{y_1, \ldots, y_{\tau-1}\}, \mathbf{c}; \theta\right) \quad (8)$$

and $\log p\left(y_\tau | \{y_1, \ldots, y_{\tau-1}\}, \mathbf{c}; \theta\right)$ is modeled by the LSTM encoder and decoder. We use the Adamax (Kingma and Ba, 2014) gradient-based optimization method to optimize the model parameters θ.

3.6 Decoding Algorithm

We find there are several problems during the generation of summary, including out-of-vocabulary (OOV) words, information incorrectness, error accumulation and repetition. These problems make the generated abstractive summaries far from satisfactory. In this work, we propose a hierarchical decoding algorithm with a reference mechanism to tackle these difficulties, which effectively improves the quality of generated summaries.

As OOV words frequently occur in name entities, we can first identify the entities of a document using NLP toolkit like Stanford CoreNLP[1]. Then we prefix every entity with an "@entity" token and a number indicating how many words the entity has. We hope the entity prefixes can help better deal with entities which have more than one word, and help improve the accuracy of recovering OOV words in entities. After decoding we recover the OOV words by matching entities in the original document according to the contexts.

For the hierarchical decoder, a major challenge is that same sentences or phrases are often repeated in the output. A beam search strategy may help to alleviate the repetition in a sentence, but the repetition in the whole generated summary is remained a problem. The word-level beam search is not easy to be extended to the sentence level. The reason is that the K-best sentences generated by a word decoder will mostly be similar to each other, which is also noticed by Li et al. (2016).

In this paper we propose a hierarchical beam search algorithm with a reference mechanism. The hierarchical algorithm comprises K-best word-level beam search and N-best sentence-level beam search. At the word level, the only difference to vanilla beam search is that we add an additional term to the score $\tilde{p}(y_\tau)$ of generating word y_τ, and now $score(y_\tau) = \tilde{p}(y_\tau) + \gamma\left(ref(Y_{\tau-1} + y_\tau, s_*) - ref(Y_{\tau-1}, s_*)\right)$, where $Y_{\tau-1} = \{y_1, \ldots, y_{\tau-1}\}$ and $\tilde{p}(y_\tau) = \log p\left(y_\tau | Y_{\tau-1}, \mathbf{c}; \theta\right)$. s_* is an original sentence to refer to. ref is a function which calculates the ratio of bigram overlap between two texts. The added term aims to favor the generated word y_τ with improving the bigram overlap between current generated summary $Y_{\tau-1}$ and the target orig-

Table 1: The statistics of the two datasets. D.L. and S.L. indicate the average number of sentences in the document and summary, respectively.

inal sentence s_*. At the word decoder level, the reference mechanism helps to both improve the information correctness and avoid redundancy. Because the reference score is based on the bigram overlap improvement to the whole generated summary $Y_{\tau-1}$, the awareness of previously generated sentences also helps alleviate sentence-level redundancy. A factor γ is introduced to control the influence of the reference mechanism. Note that because of the non-optimal search, the generated sentence will still be different to the original sentence even with an extremely large γ.

At the sentence level, N-best sentence beam is to keep the N generated sentences by referring to N different original sentences, which have the highest attention scores and have not been used as a reference. With referring to N different sentences, the N candidate sentences are guaranteed diverse. Sentence-level beam search is realized by maximizing the accumulated score of all the sentences generated.

4 Experiments

4.1 Dataset

We conduct experiments on two large-scale corpora of CNN and DailyMail, which have been widely used in neural document summarization tasks. The corpora are originally constructed in (Hermann et al., 2015) by collecting human generated abstractive highlights from the news stories in the CNN and DailyMail website. The statistics and split of the two datasets are listed in Table 1.

4.2 Implementation

We use the corpora which are already provided with labeled entities (Nallapati et al., 2016). The documents and summaries are first lowercased and tokenized, and all digit characters are replaced with the "#" symbol, similar to (Nallapati et al., 2016, 2017). We keep the 40,000 most frequently occurring words and other words are replaced with the "<OOV>" token.

We use Theano[2] for implementation. For the word encoder and decoder we use three layers of LSTM, and for the sentence encoder and decoder we use one layer of LSTM. The dimension of hidden vectors are all 512. We use pre-trained GloVe (Pennington et al., 2014) vectors[3] for the initialization of word vectors, which will be further trained in the model. The dimension of word vectors is 100. λ is set to 0.9. The parameters of Adamax are set to those provided in (Kingma and Ba, 2014). The batch size is set to 8 documents, and an epoch is set containing 10,000 randomly sampled documents. Convergence is reached within 200 epochs on the DailyMail dataset and 120 epochs on the CNN dataset. It takes about one day for every 30 epochs on a GTX-1080 GPU card. γ is tuned on the validation set and the best choice is 300. The beam sizes for word decoder and sentence decoder are 15 and 2, respectively.

4.3 Evaluation

We adopt the widely used ROUGE (Lin, 2004) toolkit for evaluation. We first compare with the reported results in (Chen et al., 2016) including various traditional extractive methods and a state-of-the-art abstractive model (Distraction-M3) on the CNN dataset, as shown in Table 2. Uni-GRU is a non-hierarchical seq2seq baseline model. In Table 3 we compare our method with the results of state-of-the-art neural summarization methods reported in recent papers. Extractive models include NN-SE (Cheng and Lapata, 2016) and SummaRuNNer (Nallapati et al., 2017), while SummaRuNNer-abs is also an extractive model similar to SummaRuNNer but is trained directly on the abstractive summaries. Moreover, we include several baselines for comparison, including the baselines reported in (Cheng and Lapata, 2016) although they are tested on 500 samples of the test set. LREG is a feature based method using linear regression. NN-ABS is a neural abstractive baseline which is a simple hierarchical extension of (Rush et al., 2015). NN-WE is the abstractive model which restricts the generation of words from the original document. Lead-3 is a strong extractive baseline that uses the lead three sentences as the summary.

In Table 4 we compare our model with the abstractive attentional encoder-decoder models in

(Nallapati et al., 2016), which leverage several effective techniques and achieve state-of-the-art performance on sentence abstractive summarization tasks. The words-lvt2k and words-lvt2k-ptr are flat models and words-lvt2k-hieratt is a hierarchical extension.

Results in Table 2 show our abstractive method is able to outperform traditional extractive methods and the distraction-based abstractive model. The results in Tables 3 and 4 show that our method has considerable improvement over neural abstractive baselines, and is able to outperform state-of-the-art neural extractive methods. An interesting observation is the results of the hierarchical model in Table 4 are lower than the flat models, which may demonstrate the difficulty for a traditional attention model to identify the important information in a document.

We also conducted human evaluation on 20 random samples from the DailyMail test set and compared the summaries generated by our method with the outputs of Lead-3, NN-SE (Cheng and Lapata, 2016) and Distraction (Chen et al., 2016). The output summaries of NN-SE are provided by the authors, and the output summaries of Distraction are achieved by running the code provided by the authors on the DailyMail dataset. Three participants were asked to compare the generated summaries with the human summaries, and assess each summary from four independent perspectives: (1) How informative the summary is? (2) How concise the summary is? (3) How coherent (between sentences) the summary is? (4) How fluent, grammatical the sentences of a summary are? Each property is assessed with a score from 1 (worst) to 5 (best). The average results are presented in Table 5.

Method	Rouge-1	Rouge-2	Rouge-L
words-lvt2k	32.5	11.8	29.5
words-lvt2k-ptr	32.1	11.7	29.2
words-lvt2k-hieratt	31.8	11.6	28.7
Our Method	**38.1**	**13.9**	**34.0**

Table 4: Comparison results on the **merged CNN/DailyMail test set** using **full-length F1** metric.

Method	Informative	Concise	Coherent	Fluent
Lead-3	3.60	3.75	4.16	3.85
NN-SE	3.85	3.70	3.48	3.78
Distraction	3.03	3.25	2.93	3.65
Our Method	3.93	3.82	3.53	3.80

Table 5: Human evaluation results.

As shown in Table 5, our method consistently outperforms the previous state-of-the-art abstractive method Distraction. Compared with extractive methods, our method is able to generate more informative and concise summaries, which shows the advantage of abstractive methods. The Distraction method in fact usually produces the shortest summaries, but the conciseness score is low mainly because sometimes it generates repeated sentences. The repetition also causes Distraction to achieve a low coherence score. Concerning coherence and fluency, our abstractive method achieves slightly better scores than NN-SE, while not surprisingly Lead-3 gets the best scores. The fluency scores show the good ability of the abstractive model to generate fluent and grammatical sentences.

4.4 Model Validation

We conduct experiments to see how the model's performance is affected by the choice of the hyperparameters. For efficiency we test on 500 random samples from the DailyMail test set. Figure 2a shows the maximum average Rouge-2 F1-score achieved when the model is trained using different λ values within 200 and 300 epochs. When using a larger λ, the performance is better and the convergence is faster. When $\lambda = 1.0$ the model fails to train because of running into a singular matrix.

Figure 2b shows the results achieved when using different γ values in the hierarchical decoding algorithm. $\gamma = 0$ is the baseline of the traditional decoding algorithm which does not refer to the original document. The poor results indicate that even the model is able to learn to identify the salient information in the original document, the performance is limited by the model's ability of generating a long output sequence. That may be a reason why simple extensions of seq2seq models fail on the abstractive document summarization task. The performance is significantly improved using a reasonable γ, and the optimal γ value is consistent with the one chosen on the validation set. When using an extremely large γ, the permanence begins to decrease, because the model will copy too much from the original document, and at this time the generated text also becomes less fluent. Results show that introducing the reference mechanism in the hierarchical beam search is very effective. The γ factor significantly affects the results, but the optimal value is easy to be decided on a validation set.

We also conduct ablation experiments on the CNN dataset to verify the effectiveness of the proposed model. Results on the CNN test set are shown in Table 6. "*w/o GraphAtt*" is to replace the graph-based attention by a traditional attention function. "*w/o SentenceBeam*" is to remove the sentence-level beam search. "*w/o BeamSearch*" is to remove both the sentence-level and word-level beam search, and use a greedy decoding algorithm with the reference mechanism. As seen from Table 6, the graph-based attention mechanism is significantly better than traditional attention mechanism for the document summarization task. Beam search helps significantly improve the generated summaries. Our proposed decoding algorithm enables a sentence-level beam search, which helps improve the generated summaries with multiple sentences.

4.5 Case Study

We show the case study of a sample[4] from the DailyMail test set in Figure 3. We show the "@entity" and number here although they are removed in the evaluation. We compare our result with the output by a model using traditional attention as *Baseline Attention*. We also show the output generated by a *Baseline Decoder*, which sets $\gamma = 0$ and does not use the sentence-level beam search, to study the difficulty for a traditional decoder to generate multiple sentences. Many observations can be found in Figure 3. The lead three sentences mainly focus on the money information and are not sufficient. As for the *Baseline Decoder*, first it usually ends the generation too early. The "<eod>" token indicates where the original output stops. When we force the decoder not to end here, the model shows the ability to continue producing the important information. However, two flaws are presented. First is the repetition of "## - year -

[4]The original story and highlights can be found at http://www.dailymail.co.uk/news/article-3041766/Benefits-cheat-pocketed-17-000-taxpayers-money.html

Gold Summary:
@entity 2 mary day , ## , claimed over £ ##,### in benefits despite not being eligible .
she had £ ##,### savings in the bank which meant she was not entitled .
day used taxpayers ' money to go on luxury holidays to @entity 1 indian resort of @entity 1 goa .
pleaded guilty to dishonestly claiming benefits and has paid back money .

Lead3:
a benefits cheat who pocketed almost £ ##,### of taxpayers ' money and spent it on a string of luxury holidays despite having £ ##,### in the bank has avoided jail .
@entity 2 mary day , ## , of @entity 1 swanage in @entity 1 dorset , used taxpayers ' money to go on luxury holidays to the @entity 1 indian resort of @entity 1 goa for up to a month each time .
day fraudulently claimed £ ##,### of income support and disability allowance despite having £ ##,### of her own savings in the bank .

Baseline Decoder:
- month - old @entity 2 mary day , ## , was given £ ##,### in money .
the ## - year - old claimed £ ##,### in disability allowance . <*eod*>
the ## - year - old was given a six - month prison sentence .
- year - old pleaded guilty to two counts of fraud .

Baseline Attention:
@entity 2 mary day , ## , used taxpayers ' money to go on luxury holidays .
claimed £ ##,### of income support and disability allowance despite having savings in the bank . <*eod*>
benefits of taxpayers £ ##,### in disability handouts .

Our Method:
@entity 2 mary day , ## , used taxpayers ' money to go on luxury holidays to the @entity 1 indian resort of @entity 1 goa .
despite having £ ##,### of her own savings in the bank , she claimed £ ##,### of income support and disability allowance .
she pleaded guilty and had given the sentence for three months in prison , but suspended the sentence for ## months .

Figure 3: Examples of generated summaries.

old". Because the word decoder is unaware of the history generated sentences, it repeats generating the sequence as the subject all the time. Second, more importantly, is the information incorrectness. The "## - month - old" is not appropriate to describe the heroine, and the "six - month prison sentence" is in fact "three months". Information incorrectness occurs because, for a decoder, it aims at generating a fluent sentence according to the input representation. However, no favor of consistent with the original input is concerned. The proposed hierarchical decoding algorithm helps to alleviate the two problems. The awareness of all the generated sentences helps prevent from always generating some important information. The favor of bigram overlapping with the original sentences helps generate more correct sentences. For example the model is able to correctly distinguish between the "three-month sentence" and the "##-month suspend". In conclusion, our method is able to identify the most important information in the original document, and the decoding algorithm we propose is able to generate a more discourse-fluent and information-correct abstractive summary.

The visualization of the graph-based attention when our method generates the presented example

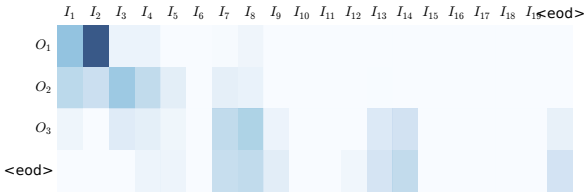

Figure 4: Attention heatmap when generating the example summary. I_i and O_i indicate the i-th sentence of the input and output, respectively.

is shown in Figure 4. It seems that the graph-based attention mechanism is able to find the important sentences in the input document, and the distraction mechanism makes the decoder focus on different sentences during decoding. Gradually the decoder attends to "<eod>" until it stops.

5 Conclusion and Future Work

In this paper we tackle the challenging task of abstractive document summarization, which is still less investigated to date. We study the difficulty of the abstractive document summarization task, and address the need of finding salient content from the original document, which is overlooked by previous studies. We propose a novel graph-based attention mechanism in a hierarchical encoder-decoder framework, and propose a hierarchical beam search algorithm to generate multi-sentence summary. Extensive experiments verify the effectiveness of the proposed method. Experimental results on two large-scale datasets demonstrate our method achieves state-of-the-art abstractive document summarization performance. It is also able to achieve competitive results with state-of-the-art neural extractive summarization models.

There is lots of future work we can do. An appealing direction is to investigate the neural abstractive method on the multi-document summarization task, which is more challenging and lacks training data. Further endeavor may be needed.

Probabilistic Typology: Deep Generative Models of Vowel Inventories

Ryan Cotterell and **Jason Eisner**
Department of Computer Science
Johns Hopkins University
{ryan.cotterell,eisner}@jhu.edu

Abstract

Linguistic typology studies the range of structures present in human language. The main goal of the field is to discover which sets of possible phenomena are universal, and which are merely frequent. For example, all languages have vowels, while most—but not all—languages have an [u] sound. In this paper we present the first probabilistic treatment of a basic question in phonological typology: What makes a natural vowel inventory? We introduce a series of deep stochastic point processes, and contrast them with previous computational, simulation-based approaches. We provide a comprehensive suite of experiments on over 200 distinct languages.

1 Introduction

Human languages exhibit a wide range of phenomena, within some limits. However, some structures seem to occur or co-occur more frequently than others. Linguistic typology attempts to describe the range of natural variation and seeks to organize and quantify linguistic universals, such as patterns of co-occurrence. Perhaps one of the simplest typological questions comes from phonology: which vowels tend to occur and co-occur within the phoneme inventories of different languages? Drawing inspiration from the linguistic literature, we propose models of the probability distribution from which the attested vowel inventories have been drawn.

It is a typological universal that every language contains both vowels and consonants (Velupillai, 2012). But which vowels a language contains is guided by softer constraints, in that certain configurations are more widely attested than others. For instance, in a typical phoneme inventory, there tend to be far fewer vowels than consonants. Likewise, all languages contrast vowels based on height, although which contrast is made is language-dependent (Ladefoged and Maddieson, 1996). Moreover, while over 600 unique vowel phonemes have been attested cross-linguistically (Moran et al., 2014), certain regions of acoustic space are used much more often than others, e.g., the regions conventionally transcribed as [a], [i], and [u]. Human language also seems to prefer inventories where phonologically distinct vowels are spread out in acoustic space ("dispersion") so that they can be easily distinguished by a listener. We depict the acoustic space for English in Figure 2.

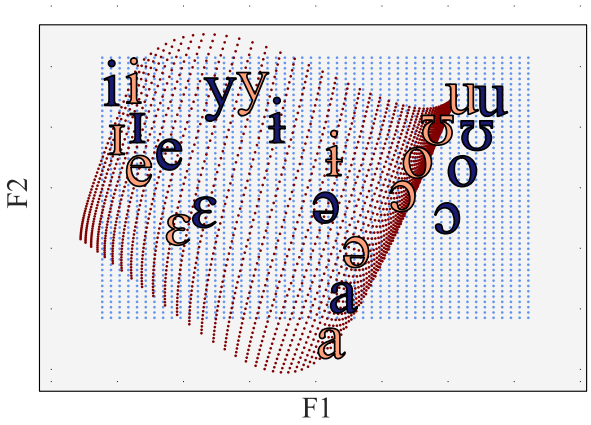

Figure 1: The transformed vowel space that is constructed within one of our deep generative models (see §7.1). A deep network nonlinearly maps the blue grid ("formant space") to the red grid ("metric space"), with individual vowels mapped from blue to red position as shown. Vowel pairs such as [ə]–[ɔ] that are brought close together are anti-correlated in the point process. Other pairs such as [y]–[i] are driven apart. For purposes of the visualization, we have transformed the red coordinate system to place red vowels near their blue positions—while preserving distances up to a constant factor (a "Procrustes transformation").

In this work, we regard the proper goal of linguistic typology as the construction of a universal prior distribution from which linguistic systems are drawn. For vowel system typology, we propose three formal probability models based on stochastic point processes. We estimate the parameters of the model on one set of languages and evaluate performance on a held-out set. We explore three questions: (i) How well do the properties of our proposed probability models line up experimentally with linguistic theory? (ii) How well can our models predict held-out vowel systems? (iii) Do our models benefit from a "deep" transformation from formant space to metric space?

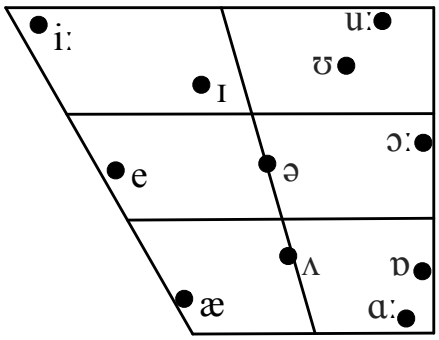

Figure 2: The standard vowel table in IPA for the RP accent of English. The x-axis indicates the front-back spectrum and the y-axis indicates the high-low distinction.

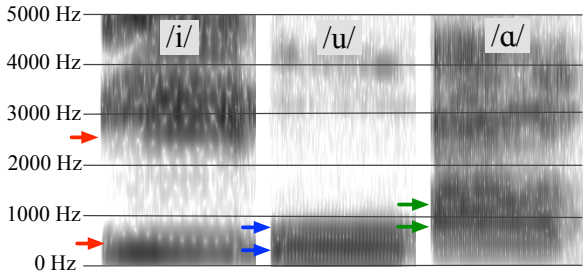

Figure 3: Example spectrogram of the three English vowels: [i], [u] and [ɑ]. The x-axis is time and y-axis is frequency. The first two formants F_1 and F_2 are marked in with colored arrows for each vowel. We used the Praat toolkit to generate the spectrogram and find the formants (Boersma et al., 2002).

2 Vowel Inventories and their Typology

Vowel inventories are a simple entry point into the study of linguistic typology. Every spoken language chooses a discrete set of vowels, and the number of vowel phonemes ranges from 3 to 46, with a mean of 8.7 (Gordon, 2016). Nevertheless, the empirical distribution over vowel inventories is remarkably peaked. The majority of languages have 5–7 vowels, and there are only a handful of distinct 4-vowel systems attested despite many possibilities. Reigning linguistic theory (Becker-Kristal, 2010) has proposed that vowel inventories are shaped by the principles discussed below.

2.1 Acoustic Phonetics

One way to describe the sound of a vowel is through its acoustic energy at different frequencies. A spectrogram (Figure 3) is a visualization of the energy at various frequencies over time. Consider the "peak" frequencies $F_0 < F_1 < F_2 < \ldots$ that have a greater energy than their neighboring frequencies. F_0 is called the fundamental frequency or pitch. The other qualities of the vowel are largely determined by $F_1, F_2, \ldots$, which are known as formants (Ladefoged and Johnson, 2014). In many languages, the first two formants F_1 and F_2 contain enough information to identify a vowel: Figure 3 shows how these differ across three English vowels. We consider each vowel listed in the International Phonetic Alphabet (IPA) to be *cross-linguistically* characterized by some (F_1, F_2) pair.

2.2 Dispersion

The dispersion criterion (Liljencrants and Lindblom, 1972; Lindblom, 1986) states that the phonemes of a language must be "spread out" so that they are easily discriminated by a listener. A language seeks phonemes that are sufficiently "distant" from one another to avoid confusion. Distances between phonemes are defined in some latent "metric space." We use this term rather than "perceptual space" because the confusability of two vowels may reflect not just their perceptual similarity, but also their common distortions by imprecise articulation or background noise.[1]

2.3 Focalization

The dispersion criterion alone does not seem to capture the whole story. Certain vowels are simply more popular cross-linguistically. A commonly accepted explanation is the *quantal theory of speech* (Stevens, 1972, 1989). The quantal theory states that certain sounds are easier to articulate and to perceive than others. These vowels may be characterized as those where F_1 and F_2 have frequencies that are close to one another. On the production side, these vowels are easier to pronounce since they allow for greater articulatory imprecision. On the perception side, they are more salient since the two spectral peaks aggregate and act as one, larger peak to a certain degree. In general, languages will prefer these vowels.

2.4 Dispersion-Focalization Theory

The dispersion-focalization theory (DFT) combines both of the above notions. A good vowel system now consists of vowels that contrast with each other *and* are individually desirable (Schwartz et al., 1997). This paper provides the first probabilistic treatment of DFT, and new evaluation metrics for future probabilistic and non-probabilistic treatments of vowel inventory typology.

[1] We assume in this paper that the metric space is universal—although it would not be unreasonable to suppose that each language's vowel system has adapted to avoid confusion in the *specific* communicative environment of its speakers.

3 Point Process Models

Given a base set $\mathcal{V}$, a point process is a distribution over its subsets.[2] In this paper, we take $\mathcal{V}$ to be the set of all IPA symbols corresponding to vowels. Thus a draw from a point process is a vowel inventory $V \subseteq \mathcal{V}$, and the point process itself is a distribution over such inventories. We will consider three basic point process models for vowel systems: the Bernoulli Point Process, the Markov Point Process and the Determinantal Point Process. In this section, we review the relevant theory of point processes, highlighting aspects related to §2.

3.1 Bernoulli Point Processes

Taking $\mathcal{V} = \{v_1, \ldots, v_N\}$, a Bernoulli point process (BPP) makes an *independent* decision about whether to include each vowel in the subset. The probability of a vowel system $V \subseteq \mathcal{V}$ is thus

$$p(V) \propto \prod_{v_i \in V} \phi(v_i), \tag{1}$$

where ϕ is a unary potential function, i.e., $\phi(v_i) \geq 0$. Qualitatively, this means that $\phi(v_i)$ should be large if the i^{th} vowel is good in the sense of §2.3. Marginal inference in a BPP is computationally trivial. The probability that the inventory V contains v_i is $\phi(v_i)/(1 + \phi(v_i))$, independent of the other vowels in V. Since a BPP predicts each vowel independently, it only models focalization. Thus, the model provides an appropriate baseline that will let us measure the importance of the dispersion principle—how far can we get with just focalization? A BPP may still tend to generate well-dispersed sets if it defines ϕ to be large only on certain vowels in $\mathcal{V}$ and these are well-dispersed (e.g., [i], [u], [a]). More precisely, it can define ϕ so that $\phi(v_i)\phi(v_j)$ is small whenever v_i, v_j are similar.[3] But it cannot actively encourage dispersion: including v_i does not lower the probability of also including v_j.

3.2 Markov Point Processes

A Markov Point Process (MPP) (Van Lieshout, 2000)—also known as a Boltzmann machine (Ackley et al., 1985; Hinton and Sejnowski, 1986)—generalizes the BPP by adding pairwise interactions between vowels. The probability of a vowel system $V \subseteq \mathcal{V}$ is now

$$p(V) \propto \prod_{v_i \in V} \phi(v_i) \prod_{v_i, v_j \in V} \psi(v_i, v_j), \tag{2}$$

where each $\phi(v_i) \geq 0$ is, again, a unary potential that scores the quality of the i^{th} vowel, and each $\psi(v_i, v_j) \geq 0$ is a binary potential that scores the combination of the i^{th} and j^{th} vowels. Roughly speaking, the potential $\psi(v_i, v_j)$ should be large if the i^{th} and j^{th} vowel often co-occur. Recall that under the principle of dispersion, the vowels that often co-occur are easily distinguishable. Thus, confusable vowel pairs should tend to have potential $\psi(v_i, v_j) < 1$.

Unlike the BPP, the MPP can capture both focalization *and* dispersion. In this work, we will consider a fully connected MPP, i.e., there is a potential function for each pair of vowels in $\mathcal{V}$. MPPs closely resemble Ising models (Ising, 1925), but with the difference that Ising models are typically lattice-structured, rather than fully connected.

Inference in MPPs. Inference in fully connected MPPs, just as in general Markov Random Fields (MRFs), is intractable (Cooper, 1990) and we must rely on approximation. In this work, we estimate any needed properties of the MPP distribution by (approximately) drawing vowel inventories from it via Gibbs sampling (Geman and Geman, 1984; Robert and Casella, 2005). Gibbs sampling simulates a discrete-time Markov chain whose stationary distribution is the desired MPP distribution. At each time step, for some random $v_i \in \mathcal{V}$, it stochastically decides whether to replace the current inventory V with $\bar{V}$, where $\bar{V}$ is a copy of V with v_i added (if $v_i \notin V$) or removed (if $v_i \in V$). The probability of replacement is $\frac{p(\bar{V})}{p(V)+p(\bar{V})}$.

3.3 Determinantal Point Processes

A determinantal point process (DPP) (Macchi, 1975) provides an elegant alternative to an MPP, and one that is directly suited to modeling both focalization and dispersion. Inference requires only

[2] A point process is a specific kind of stochastic process, which is the technical term for a distribution over *functions*. Under this view, drawing some subset of $\mathcal{V}$ from the point process is regarded as drawing some *indicator function* on $\mathcal{V}$.

[3] We point out that such a scheme would break down if we extended our work to cover fine-grained phonetic modeling of the vowel inventory. In that setting, we ask not just whether the inventory includes /i/ but exactly which pronunciation of /i/ it contains. In the limit, ϕ becomes a function over a *continuous* vowel space $\mathcal{V} = \mathbb{R}^2$, turning the BPP into an inhomogeneous spatial Poisson process. A continuous ϕ function implies that the model places similar probability on similar vowels. Then if most vowel inventories contain some version of /i/, then many of them will contain several closely related variants of /i/ (independently chosen). By contrast, the other methods in this paper do extend nicely to fine-grained phonetic modeling.

a few matrix computations and runs tractably in $O(|\mathcal{V}|^3)$ time, even though the model may encode a rich set of multi-way interactions. We focus on the L-ensemble parameterization of the DPP, due to Borodin and Rains (2005).[4] This type of DPP defines the probability of an inventory $V \subseteq \mathcal{V}$ as

$$p(V) \propto \det L_V, \tag{3}$$

where $L \in \mathbb{R}^{N \times N}$ (for $N = |\mathcal{V}|$) is a symmetric positive semidefinite matrix, and L_V refers to the submatrix of L with only those rows and columns corresponding to those elements in the subset V.

Although MAP inference remains NP-hard in DPPs (just as in MPPs), marginal inference becomes tractable. We may compute the normalizing constant in closed form as follows:

$$\sum_{V \in 2^{\mathcal{V}}} \det L_V = \det (L + I). \tag{4}$$

How does a DPP ensure focalization and dispersion? L is positive semidefinite iff it can be written as $E^\top E$ for some matrix $E \in \mathbb{R}^{N \times N}$. It is possible to express $p(V)$ in terms of the column vectors of E, which we call $\mathbf{e}_1, \ldots, \mathbf{e}_N$:

- For inventories of size 2, $p(\{v_i, v_j\}) \propto (\phi(v_i)\phi(v_j)\sin\theta)^2$, where $\phi(v_i), \phi(v_j)$ represent the *quality* of vowels v_i, v_j (as in the BPP) while $\sin\theta \in [0, 1]$ represents their *dissimilarity*. More precisely, $\phi(v_i), \phi(v_j)$ are the lengths of vectors $\mathbf{e}_i, \mathbf{e}_j$ while θ is the angle between them. Thus, we should choose the columns of E so that focal vowels get *long* vectors and similar vowels get vectors *of similar direction*.
- Generalizing beyond inventories of size 2, $p(V)$ is proportional to the square of the volume of the parallelepiped whose sides are given by $\{\mathbf{e}_i : v_i \in V\}$. This volume can be regarded as $\prod_{v_i \in V} \phi(v_i)$ times a term that ranges from 1 for an orthogonal set of vowels to 0 for a linearly dependent set of vowels.
- The events $v_i \in V$ and $v_j \in V$ are anti-correlated (when not independent). That is, while both vowels may individually have high probabilities (focalization), having either one in the inventory lowers the probability of the other (dispersion).

[4] Most DPPs are L-ensembles (Kulesza and Taskar, 2012).

4 Dataset

At this point it is helpful to introduce the empirical dataset we will model. For each of 223 languages,[5] Becker-Kristal (2010) provides the vowel inventory as a set of IPA symbols, listing the first 5 formants for each vowel (or fewer when not available in the original source). Some corpus statistics are shown in Figs. 4 and 5.[6] For the present paper, we take $\mathcal{V}$ to be the set of all 53 IPA symbols that appear in the corpus. We treat these IPA labels as meaningful, in that we consider two vowels in different languages to be the *same* vowel in $\mathcal{V}$ if (for example) they are both annotated as [ɔ]. We characterize that vowel by its *average* formant vector across all languages in the corpus that contain the vowel: e.g., $(F_1, F_2, \ldots) = (500, 700, \ldots)$ for [ɔ]. In future work, we plan to relax this idealization (see footnote 3), allowing us to investigate natural questions such as whether [u] is pronounced higher (smaller F_1) in languages that also contain [o] (to achieve better dispersion).

5 Model Parameterization

The BPP, MPP, and DPP models (§3) require us to specify parameters for each vowel in $\mathcal{V}$. In §5.1, we will accomplish this by deriving the parameters for each vowel v_i from a possibly high-dimensional embedding of that vowel, $\boldsymbol{e}(v_i) \in \mathbb{R}^r$.

In §5.2, $\boldsymbol{e}(v_i) \in \mathbb{R}^r$ will in turn be defined as some learned function of $\boldsymbol{f}(v_i) \in \mathbb{R}^k$, where $\boldsymbol{f} : \mathcal{V} \mapsto \mathbb{R}^k$ is the function that maps a vowel to a k-vector of its measurable acoustic properties. This approach allows us to determine reasonable parameters even for rare vowels, based on their measurable properties. It will even enable us in

[5] Becker-Kristal lists some languages multiple times with different measurements. When a language had multiple listings, we selected one randomly for our experiments.

[6] Caveat: The corpus is a curation of information from various phonetics papers into a common electronic format. No standard procedure was followed across all languages: it was up to individual phoneticists to determine the size of each vowel inventory, the choice of IPA symbols to describe it, and the procedure for measuring the formants. Moreover, it is an idealization to provide a single vector of formants for each vowel *type* in the language. In real speech, different *tokens* of the same vowel are pronounced differently, because of coarticulation with the vowel context, allophony, interspeaker variation, and stochastic intraspeaker variation. Even within a token, the formants change during the duration of the vowel. Thus, one might do better to represent a vowel's pronunciation not by a formant vector, but by a conditional probability distribution over its formant trajectories given its context, or by a parameter vector that characterizes such a conditional distribution. This setting would require richer data than we present here.

future to generalize to vowels that were unseen in the training set, letting us scale to very large or infinite $\mathcal{V}$ (footnote 3).

5.1 Deep Point Processes

We consider deep versions of all three processes.

Deep Bernoulli Point Process. We define

$$\phi(v_i) = ||\boldsymbol{e}(v_i)|| \geq 0 \tag{5}$$

Deep Markov Point Process. The MPP employs the same unary potential as the BPP, as well as the binary potential

$$\psi(v_i, v_j) = \exp -\frac{1}{T \cdot ||\boldsymbol{e}(v_i) - \boldsymbol{e}(v_j)||^2} < 1 \tag{6}$$

where the learned temperature $T > 0$ controls the relative strength of the unary and binary potentials.

This formula is inspired by Coulomb's law for describing the repulsion of static electrically charged particles. Just as the repulsive force between two particles approaches ∞ as they approach each other, the probability of finding two vowels in the same inventory approaches $\exp -\infty = 0$ as they approach each other. The formula is also reminiscent of Shepard (1987)'s "universal law of generalization," which says here that the probability of responding to v_i as if it were v_j should fall off exponentially with their distance in some "psychological space" (here, embedding space).

Deep Determinantal Point Process. For the DPP, we simply define the vector $\mathbf{e}_i$ to be $\boldsymbol{e}(v_i)$, and proceed as before.

Summary. In the deep BPP, the probability of a set of vowels is proportional to the product of the lengths of their embedding vectors. The deep MPP modifies this by multiplying in *pairwise* repulsion terms in $(0, 1)$ that increase as the vectors' endpoints move apart in Euclidean space (or as $T \to \infty$). The deep DPP instead modifies it by multiplying in a single *setwise* repulsion term in $(0, 1)$ that increases as the embedding vectors become more mutually orthogonal. In the limit, then, the MPP and DPP both approach the BPP.

5.2 Embeddings

Throughout this work, we simply have $\boldsymbol{f}$ extract the first $k = 2$ formants, since our dataset does not provide higher formants for all languages.[7] For example, we have $\boldsymbol{f}([\text{ɔ}]) = (500, 700)$. We now describe three possible methods for mapping $\boldsymbol{f}(v_i)$ to an embedding $\boldsymbol{e}(v_i)$. Each of these maps has learnable parameters.

Neural Embedding. We first consider directly embedding each vowel v_i into a vector space $\mathbb{R}^r$. We achieve this through a feed-forward neural net

$$\boldsymbol{e}(v_i) = W_1 \tanh\left(W_0 \boldsymbol{f}(v_i) + \mathbf{b}_0\right) + \mathbf{b}_1, \tag{7}$$

Equation (7) gives an architecture with 1 layer of nonlinearity; in general we consider stacking $d \geq 0$ layers. Here $W_0 \in \mathbb{R}^{r \times k}, W_1 \in \mathbb{R}^{r \times r}, \ldots W_d \in \mathbb{R}^{r \times r}$ are weight matrices, $\mathbf{b}_0, \ldots \mathbf{b}_d \in \mathbb{R}^r$ are bias vectors, and $\tanh$ could be replaced by any pointwise nonlinearity. We treat both the depth d and the embedding size r as hyperparameters, and select the optimal values on a development set.

Interpretable Neural Embedding. We are interested in the special case of neural embeddings when $r = k$ since then (for any d) the mapping $\boldsymbol{f}(v_i) \mapsto \boldsymbol{e}(v_i)$ is a diffeomorphism:[8] a smooth invertible function of $\mathbb{R}^k$. An example of such a diffeomorphism is shown in Figure 1.

There is a long history in cognitive psychology of mapping stimuli into some psychological space. The distances in this psychological space may be predictive of generalization (Shepard, 1987) or of perception. Due to the anatomy of the ear, the mapping of vowels from acoustic space to perceptual space is often presumed to be nonlinear (Rosner and Pickering, 1994; Nearey and Kiefte, 2003), and there are many perceptually-oriented phonetic scales, e.g., Bark and Mel, that carry out such nonlinear transformations while preserving the dimensionality k, as we do here. As discussed in §2.2, vowel system typology is similarly believed to be influenced by distances between the vowels in a latent metric space. We are interested in whether a constrained k-dimensional model of these distances can do well in our experiments.

Prototype-Based Embedding. Unfortunately, our interpretable neural embedding is unfortunately incompatible with the DPP. The DPP assigns probability 0 to any vowel inventory V whose $\boldsymbol{e}$ vectors are linearly dependent. If the vectors are in $\mathbb{R}^k$, then this means that $p(V) = 0$ whenever $|V| > k$. In our setting, this would limit vowel inventories to size 2.

[7] In lieu of higher formants, we could have extended the vector $\boldsymbol{f}(v_i)$ to encode the binary distinctive features of the IPA vowel v_i: round, tense, long, nasal, creaky, etc.

[8] Provided that our nonlinearity in (7) is a differentiable invertible function like $\tanh$ rather than relu.

Our solution to this problem is to still construct our interpretable metric space $\mathbb{R}^k$, but then map that nonlinearly to $\mathbb{R}^r$ for some large r. This latter map is constrained. Specifically, we choose "prototype" points $\boldsymbol{\mu}_1, \ldots, \boldsymbol{\mu}_r \in \mathbb{R}^k$. These prototype points are parameters of the model: their coordinates are learned and do not necessarily correspond to any actual vowel. We then construct $\boldsymbol{e}(v_i) \in \mathbb{R}^r$ as a "response vector" of similarities of our vowel v_i to these prototypes. Crucially, the responses depend on distances measured in the interpretable metric space $\mathbb{R}^k$. We use a Gaussian-density response function, where $\mathbf{x}(v_i)$ denotes the representation of our vowel v_i in the interpretable space:

$$\begin{aligned} \boldsymbol{e}(v_i)_\ell &= w_\ell \; p(\mathbf{x}(v_i); \boldsymbol{\mu}_\ell, \sigma^2 I) \\ &= w_\ell \; (2\pi\sigma^2)^{-\left(\frac{k}{2}\right)} \exp\left(\frac{-||\mathbf{x} - \boldsymbol{\mu}_\ell||^2}{2\sigma^2}\right). \end{aligned} \tag{8}$$

for $\ell = 1, 2, \ldots, r$. We additionally impose the constraints that each $w_\ell \geq 0$ and $\sum_{\ell=1}^{r} w_\ell = 1$.

Notice that the sum $\sum_{\ell=1}^{r} \boldsymbol{e}(v_i)$ may be viewed as the density at $\mathbf{x}(v_i)$ under a Gaussian mixture model. We use this fact to construct a prototype-based MPP as well: we redefine $\phi(v_i)$ to equal this positive density, while still defining ψ via equation (6). The idea is that dispersion is measured in the interpretable space $\mathbb{R}^k$, and focalization is defined by certain "good" regions in that space that are centered at the r prototypes.

6 Evaluation Metrics

Fundamentally, we are interested in whether our model has abstracted the core principles of what makes a *good* vowel system. Our choice of a probabilistic model provides a natural test: how surprised is our model by held-out languages? In other words, how likely does our model think unobserved, but attested vowel systems are? While this is a natural evaluation paradigm in NLP, it has not—to the best of our knowledge—been applied to a quantitative investigation of linguistic typology.

As a second evaluation, we introduce a *vowel system cloze task* that could also be used to evaluate non-probabilistic models. This task is defined by analogy to the traditional semantic cloze task (Taylor, 1953), where the reader is asked to fill in a missing word in the sentence from the context. In our vowel system cloze task, we present a learner with a subset of the vowels in a held-out vowel system and ask them to predict the remaining vowels. Consider, as a concrete example, the general American English vowel system (excluding long vowels) {[i], [ɪ], [u], [ʊ], [ɛ], [æ], [ɔ], [ɑ], [ə]}. One potential cloze task would be to predict {[i], [u]} given {[ɪ], [ʊ], [ɛ], [æ], [ɔ], [ɑ], [ə]} and the fact that two vowels are missing from the inventory. Within the cloze task, we report accuracy, i.e., did we guess the missing vowel right? We consider three versions of the cloze tasks. First, we predict *one* missing vowel in a setting where exactly one vowel was deleted. Second, we predict *up to one* missing vowel where a vowel *may* have been deleted. Third, we predict *up to two* missing vowels, where one or two vowels may be deleted.

7 Experiments

We evaluate our models using 10-fold cross-validation over the 223 languages. We report the mean performance over the 10 folds. The performance on each fold ("test") was obtained by training many models on 8 of the other 9 folds ("train"), selecting the model that obtained the best task-specific performance on the remaining fold ("development"), and assessing it on the test fold. Minimization of the parameters is performed with the L-BFGS algorithm (Liu and Nocedal, 1989). As a preprocessing step, the first two formants values F_1 and F_2 are centered around zero and scaled down by a factor of 1000 since the formant values themselves may be quite large.

Specifically, we use the development fold to select among the following combinations of hyperparameters. For neural embeddings, we tried $r \in \{2, 10, 50, 100, 150, 200\}$. For prototype embeddings, we took the number of components $r \in \{20, 30, 40, 50\}$. We tried network depths $d \in \{0, 1, 2, 3\}$. We sweep the coefficient for an L_2 regularizer on the neural network parameters.

7.1 Results and Discussion

Figure 1 visualizes the diffeomorphism from formant space to metric space for one of our DPP models (depth $d = 3$ with $r = 20$ prototypes). Similar figures can be generated for all of the interpretable models.

We report results for cross-entropy and the cloze evaluation in Table 1.[9] Under both metrics, we see that the DPP is slightly better than the MPP; both are better than the BPP. This ranking holds for

[9] Computing cross-entropy exactly is intractable with the MPP, so we resort to an unbiased importance sampling scheme where we draw samples from the BPP and reweight according to the MPP (Liu et al., 2015).

	BPP	uBPP	uMPP	uDPP	iBPP	iMPP	iDPP	pBPP	pMPP	pDPP
x-ent	8.24	8.28	8.08	8.00	13.01	11.50	✗	12.83	10.95	10.29
cloze-1	69.55%	69.55%	72.05%	73.18%	64.13%	67.02%	✗	65.13%	68.18%	68.18%
cloze-01	60.00%	60.00%	61.01%	62.27%	61.78%	61.04%	✗	61.02%	63.04%	63.63%
cloze-012	53.18%	53.18%	57.92%	58.18%	39.04%	43.02%	✗	40.56%	45.01%	45.46%

Table 1: Cross-entropy in nats (lower is better) and cloze prediction accuracy (higher is better). "BPP" is a simple BPP with one parameter for each of the 53 vowels in $\mathcal{V}$. This model does artificially well by modeling an "accidental" feature of our data: it is able to learn not only which vowels are popular among languages, but also which IPA symbols are popular or conventional among the descriptive phoneticists who created our dataset (see footnote 6), something that would become irrelevant if we upgraded our task to predict actual formant vectors rather than IPA symbols (see footnote 3). Our point processes, by contrast, are appropriately allowed to consider a vowel only through its formant vector. The "*u*-" versions of the models use the uninterpretable neural embedding of the formant vector into $\mathbb{R}^r$: by taking r to be large, they are still able to learn special treatment for each vowel in $\mathcal{V}$ (which is why uBPP performs identically to BPP, before being beaten by uMPP and uDPP). The "*i*-" versions limit themselves to an interpretable neural embedding into $\mathbb{R}^k$, giving a more realistic description that does not perform as well. The "*p*-"versions lift that $\mathbb{R}^k$ embedding into $\mathbb{R}^r$ by measuring similarities to r prototypes; they thereby improve on the corresponding *i*- versions. For each result shown, the depth d of our neural network was tuned on a development set (typically $d = 2$). r was also tuned when applicable (typically $r > 100$ dimensions for the *u*- models and $r \approx 30$ prototypes for the *p*- models).

each of the 3 embedding schemes. The embedding schemes themselves are compared in the caption.

Within each embedding scheme, the BPP performs several points worse on the cloze tasks, confirming that dispersion is needed to model vowel inventories well. Still, the BPP's respectable performance shows that much of the structure can be capture by focalization. As §3 noted, the BPP may generate well-dispersed sets, as the common vowels tend to be dispersed already (see Figure 4). In this capacity, however, the BPP is not explanatory as it cannot actually tell us why *these* vowels should be frequent.

We mention that depth in the neural network is helpful, with deeper embedding networks performing slightly better than depth $d = 0$.

Finally, we identified each model's favorite complete vowel system of size n (Table 2). For the BPP, this is simply the n most probable vowels. Decoding the DPP and MPP is NP-hard, but we found the best system by brute force (for small n). The dispersion in these models predicts different systems than the BPP.

8 Discussion: Probabilistic Typology

Typology as Density Estimation? Our goal is to define a *universal* distribution over all possible vowel inventories. Is this appropriate? We regard this as a natural approach to typology, because it directly describes which kinds of linguistic systems are more or less common. Traditional implicational universals ("all languages with v_i have v_j") are softened, in our approach, into conditional probabilities such as "$p(v_j \in V \mid v_i \in V) \approx 0.9$." Here the 0.9 is not merely an empirical ratio, but a smoothed probability derived from the complete estimated distribution. It is meant to make predictions about unseen languages.

Whether human language learners exploit any properties of this distribution[10] is a separate question that goes beyond typology. Jakobson (1941) did find that children acquired phoneme inventories in an order that reflected principles similar to dispersion ("maximum contrast") and focalization.

At any rate, we estimate the distribution given some set of attested systems that are assumed to have been drawn IID from it. One might object that this IID assumption ignores evolutionary relationships among the attested systems, causing our estimated distribution to favor systems that are coincidentally frequent among current human languages, rather than being natural in some timeless sense. We reply that our approach is then appropriate when the goal of typology is to estimate the distribution of *actual* human languages—a distribution that can be utilized in principle (and also in practice, as we show) to predict properties of *actual* languages from outside the training set.

A different possible goal of typology is a theory of *natural* human languages. This goal would require a more complex approach. One should not imagine that natural languages are drawn in a vacuum from some single, stationary distribution. Rather, each language is drawn *conditionally* on its parent language. Thus, one should estimate a stochastic model of the evolution of linguistic systems through time, and identify "naturalness" with

[10] This could happen because learners have evolved to expect the languages (the Baldwin effect), or because the languages have evolved to be easily learned (universal grammar).

	BPP			MPP			DPP		
		changes from $n-1$			changes from $n-1$			changes from $n-1$	
n	MAP inventory	additions	deletions	MAP inventory	additions	deletions	MAP inventory	additions	deletions
1	i	i		ə	ə		ə	ə	
2	i, u	u		i, u	i, u	ə	i, u	i, u	ə
3	i, u, a	a		i, u, a	a		i, u, a	a	
4	i, u, a, o	o		i, u, a, e	e		i, u, a, o	o	
5	i, u, a, o, e	e		i, u, a, e, ə	ə		i, u, a, o, ə	o	

Table 2: Highest-probability inventory of each size according to our three models (prototype-based embeddings and $d = 3$). The MAP configuration is computed by brute-force enumeration for small n.

the directions in which this system tends to evolve.

Energy Minimization Approaches. The traditional energy-based approach (Liljencrants and Lindblom, 1972) to vowel simulation minimizes the following objective (written in our notation):

$$\mathcal{E}(m) = \sum_{1 \leq i < j \leq m} \frac{1}{||\boldsymbol{e}(v_i) - \boldsymbol{e}(v_j)||^2}, \quad (9)$$

where the vectors $\boldsymbol{e}(v_i) \in \mathbb{R}^r$ are not spit out of a deep network, as in our case, but rather directly optimized. Liljencrants and Lindblom (1972) propose a coordinate descent algorithm to optimize $\mathcal{E}(m)$. While this is not in itself a probabilistic model, they generate diverse vowel systems through random restarts that find different local optima (a kind of *deterministic* evolutionary mechanism). We note that equation (9) assumes that the number of vowels m is given, and only encodes a notion of dispersion. Roark (2001) subsequently extended equation (9) to include the notion of focalization.

Vowel Inventory Size. A fatal flaw of the traditional energy minimization paradigm is that it has no clear way to compare vowel inventories of different sizes. The problem is quite crippling since, in general, inventories with fewer vowels will have lower energy. This does not match reality—the empirical distribution over inventory sizes (shown in Figure 5) shows that the mode is actually 5 and small inventories are uncommon: no 1-vowel inventory is attested and only one 2-vowel inventory is known. A probabilistic model over *all* vowel systems must implicitly model the size of the system. Indeed, our models pit all potential inventories against each other, bestowing the extra burden to match the empirical distribution over size.

Frequency of Inventories. Another problem is the inability to model frequency. While for inventories of a modest size (3-5 vowels) there are very few unique attested systems, there is a plethora of attested larger vowel systems. The energy minimization paradigm has no principled manner to tell the scientist how likely a novel system may be. Appealing again to the empirical distribution over attested vowel systems, we consider the relative diversity of systems of each size. We graph this in Figure 5. Consider all vowel systems of size 7. There are $\binom{|\mathcal{V}|}{7}$ potential inventories, yet the empirical distribution is remarkably peaked. Our probabilistic models have the advantage in this context as well, as they naturally quantify the likelihood of an individual inventory.

Typology is a Small-Data Problem. In contrast to many common problems in applied NLP, e.g., part-of-speech tagging, parsing and machine translation, the modeling of linguistic typology is fundamentally a "small-data" problem. Out of the 7105 languages on earth, we only have linguistic annotation for 2600 of them (Comrie et al., 2013). Moreover, we only have *phonetic and phonological annotation* for a much smaller set of languages—between 300-500 (Maddieson, 2013). Given the paucity of data, overfitting on only those attested languages is a dangerous possibility—just because a certain inventory has never been attested, it is probably wrong to conclude that it is impossible—or even improbable—on that basis alone. By analogy to language modeling, almost all sentences observed in practice are novel with respect to the training data, but we still must employ a principled manner to discriminate high-probability sentences (which are syntactically and semantically coherent) from low-probability ones. Probabilistic modeling provides a natural paradigm for this sort of investigation—machine learning has developed well-understood smoothing techniques, e.g., regularization with tuning on a held-out dev set, to avoid overfitting in a small-data scenario.

Related Work in NLP. Various point processes have been previously applied to potpourri of tasks

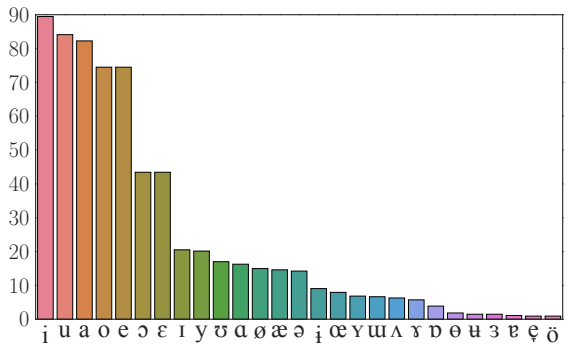

Figure 4: Percentage of the vowel inventories (y-axis) in the Becker-Kristal corpus (Becker-Kristal, 2010) that have a given vowel (shown in IPA along the x-axis).

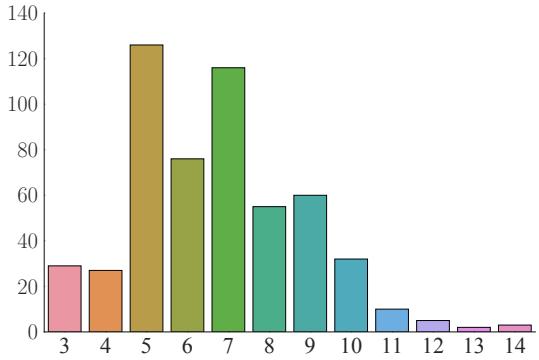

Figure 5: Histogram of the sizes of different vowel inventories in the corpus. The x-axis is the size of the vowel inventory and the y-axis is the number of inventories with that size.

in NLP. Determinantal point processes have found a home in the literature in tasks that require diversity. E.g., DPPs have achieved state-of-the-art results on multi-document document summarization (Kulesza and Taskar, 2011), news article selection (Affandi et al., 2012) recommender systems (Gartrell et al., 2017), joint clustering of verbal lexical semantic properties (Reichart and Korhonen, 2013), *inter alia*. Poisson point processes have also been applied to NLP problems: Yee et al. (2015) model the emerging topic on social media using a homogeneous point process and Lukasik et al. (2015) apply a log-Gaussian point process, a variant of the Poisson point process, to rumor detection in Twitter. We are unaware of previous attempts to probabilistically model vowel inventory typology.

Future Work. This work lends itself to several technical extensions. One could expand the function $\boldsymbol{f}$ to more completely characterize each vowel's acoustic properties, perceptual properties, or distinctive features (footnote 7). One could generalize our point process models to sample finite subsets from the *continuous* space of vowels (footnote 3). One could consider augmenting the MPP with a new factor that explicitly controls the size of the vowel inventory. Richer families of point processes might also be worth exploring. For example, perhaps the vowel inventory is generated by some temporal mechanism with latent intermediate steps, such as sequential selection of the vowels or evolutionary drift of the inventory. Another possibility is that vowel systems tend to reuse distinctive features or even follow factorial designs, so that an inventory with creaky front vowels also tends to have creaky back vowels.

9 Conclusions

We have presented a series of point process models for the modeling of vowel system inventory typology with the goal of a mathematical grounding for research in phonological typology. All models were additionally given a deep parameterization to learn representations similar to perceptual space in cognitive science. Also, we motivated our preference for *probabilistic* modeling in linguistic typology over previously proposed computational approaches and argued it is a more natural research paradigm. Additionally, we have introduced several novel evaluation metrics for research in vowel-system typology, which we hope will spark further interest in the area. Their performance was empirically validated on the Becker-Kristal corpus, which includes data from over 200 languages.

Abstract

Different linguistic perspectives causes many diverse segmentation criteria for Chinese word segmentation (CWS). Most existing methods focus on improve the performance for each single criterion. However, it is interesting to exploit these different criteria and mining their common underlying knowledge. In this paper, we propose adversarial multi-criteria learning for CWS by integrating shared knowledge from multiple heterogeneous segmentation criteria. Experiments on eight corpora with heterogeneous segmentation criteria show that the performance of each corpus obtains a significant improvement, compared to single-criterion learning. Source codes of this paper are available on Github[1].

1 Introduction

Chinese word segmentation (CWS) is a preliminary and important task for Chinese natural language processing (NLP). Currently, the state-of-the-art methods are based on statistical supervised learning algorithms, and rely on a large-scale annotated corpus whose cost is extremely expensive. Although there have been great achievements in building CWS corpora, they are somewhat incompatible due to different segmentation criteria. As shown in Table 1, given a sentence "姚明进入总决赛 (YaoMing reaches the final)", the two commonly-used corpora, PKU's People's Daily (PKU) (Yu et al., 2001) and Penn Chinese Treebank (CTB) (Fei, 2000), use different segmentation criteria. In a sense, it is a waste of resources if we fail to fully exploit these corpora.

Corpora	Yao	Ming	reaches	the final	
CTB	姚明		进入	总决赛	
PKU	姚	明	进入	总	决赛

Table 1: Illustration of the different segmentation criteria.

Recently, some efforts have been made to exploit heterogeneous annotation data for Chinese word segmentation or part-of-speech tagging (Jiang et al., 2009; Sun and Wan, 2012; Qiu et al., 2013; Li et al., 2015, 2016). These methods adopted stacking or multi-task architectures and showed that heterogeneous corpora can help each other. However, most of these model adopt the shallow linear classifier with discrete features, which makes it difficult to design the shared feature spaces, usually resulting in a complex model. Fortunately, recent deep neural models provide a convenient way to share information among multiple tasks (Collobert and Weston, 2008; Luong et al., 2015; Chen et al., 2016).

In this paper, we propose an adversarial multi-criteria learning for CWS by integrating shared knowledge from multiple segmentation criteria. Specifically, we regard each segmentation criterion as a single task and propose three different shared-private models under the framework of multi-task learning (Caruana, 1997; Ben-David and Schuller, 2003), where a shared layer is used to extract the criteria-invariant features, and a private layer is used to extract the criteria-specific features. Inspired by the success of adversarial strategy on domain adaption (Ajakan et al., 2014; Ganin et al., 2016; Bousmalis et al., 2016), we further utilize adversarial strategy to make sure the shared layer can extract the common underlying and criteria-invariant features, which are suitable for all the criteria. Finally, we exploit the eight segmentation criteria on the five simplified Chi-

nese and three traditional Chinese corpora. Experiments show that our models are effective to improve the performance for CWS. We also observe that traditional Chinese could benefit from incorporating knowledge from simplified Chinese.

The contributions of this paper could be summarized as follows.

- Multi-criteria learning is first introduced for CWS, in which we propose three shared-private models to integrate multiple segmentation criteria.
- An adversarial strategy is used to force the shared layer to learn criteria-invariant features, in which an new objective function is also proposed instead of the original cross-entropy loss.
- We conduct extensive experiments on eight CWS corpora with different segmentation criteria, which is by far the largest number of datasets used simultaneously.

2 General Neural Model for Chinese Word Segmentation

Chinese word segmentation task is usually regarded as a character based sequence labeling problem. Specifically, each character in a sentence is labeled as one of $\mathcal{L} = \{B, M, E, S\}$, indicating the begin, middle, end of a word, or a word with single character. There are lots of prevalent methods to solve sequence labeling problem such as maximum entropy Markov model (MEMM), conditional random fields (CRF), etc. Recently, neural networks are widely applied to Chinese word segmentation task for their ability to minimize the effort in feature engineering (Zheng et al., 2013; Pei et al., 2014; Chen et al., 2015a,b).

Specifically, given a sequence with n characters $X = \{x_1, \ldots, x_n\}$, the aim of CWS task is to figure out the ground truth of labels $Y^* = \{y_1^*, \ldots, y_n^*\}$:

$$Y^* = \arg\max_{Y \in \mathcal{L}^n} p(Y|X), \quad (1)$$

where $\mathcal{L} = \{B, M, E, S\}$.

The general architecture of neural CWS could be characterized by three components: (1) a character embedding layer; (2) feature layers consisting of several classical neural networks and (3) a tag inference layer. The role of feature layers is to extract features, which could be either convolution neural network or recurrent neural network. In this paper, we adopt the bi-directional long short-term memory neural networks followed by CRF as the tag inference layer. Figure 1 illustrates the general architecture of CWS.

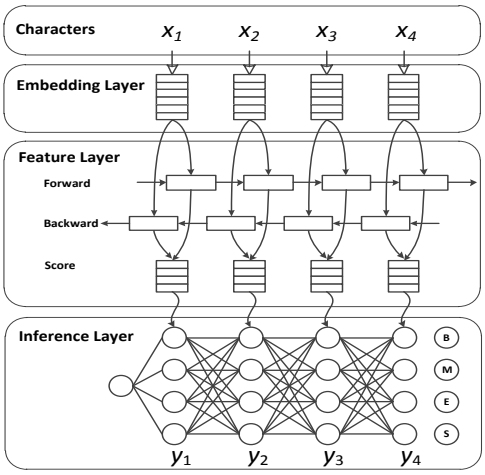

Figure 1: General neural architecture for Chinese word segmentation.

2.1 Embedding layer

In neural models, the first step usually is to map discrete language symbols to distributed embedding vectors. Formally, we lookup embedding vector from embedding matrix for each character x_i as $\mathbf{e}_{x_i} \in \mathbb{R}^{d_e}$, where d_e is a hyper-parameter indicating the size of character embedding.

2.2 Feature layers

We adopt bi-directional long short-term memory (Bi-LSTM) as feature layers. While there are numerous LSTM variants, here we use the LSTM architecture used by (Jozefowicz et al., 2015), which is similar to the architecture of (Graves, 2013) but without peep-hole connections.

LSTM LSTM introduces gate mechanism and memory cell to maintain long dependency information and avoid gradient vanishing. Formally, LSTM, with input gate $\mathbf{i}$, output gate $\mathbf{o}$, forget gate $\mathbf{f}$ and memory cell $\mathbf{c}$, could be expressed as:

$$\begin{bmatrix} \mathbf{i}_i \\ \mathbf{o}_i \\ \mathbf{f}_i \\ \tilde{\mathbf{c}}_i \end{bmatrix} = \begin{bmatrix} \sigma \\ \sigma \\ \sigma \\ \phi \end{bmatrix} \left(\mathbf{W}_g{}^{\mathsf{T}} \begin{bmatrix} \mathbf{e}_{x_i} \\ \mathbf{h}_{i-1} \end{bmatrix} + \mathbf{b}_g \right), \quad (2)$$

$$\mathbf{c}_i = \mathbf{c}_{i-1} \odot \mathbf{f}_i + \tilde{\mathbf{c}}_i \odot \mathbf{i}_i, \quad (3)$$

$$\mathbf{h}_i = \mathbf{o}_i \odot \phi(\mathbf{c}_i), \quad (4)$$

where $\mathbf{W}_g \in \mathbb{R}^{(d_e+d_h)\times 4d_h}$ and $\mathbf{b}_g \in \mathbb{R}^{4d_h}$ are trainable parameters. d_h is a hyper-parameter, in-

dicating the hidden state size. Function $\sigma(\cdot)$ and $\phi(\cdot)$ are sigmoid and tanh functions respectively.

Bi-LSTM In order to incorporate information from both sides of sequence, we use bi-directional LSTM (Bi-LSTM) with forward and backward directions. The update of each Bi-LSTM unit can be written precisely as follows:

$$\mathbf{h}_i = \overrightarrow{\mathbf{h}}_i \oplus \overleftarrow{\mathbf{h}}_i, \quad (5)$$

$$= \text{Bi-LSTM}(\mathbf{e}_{x_i}, \overrightarrow{\mathbf{h}}_{i-1}, \overleftarrow{\mathbf{h}}_{i+1}, \theta), \quad (6)$$

where $\overrightarrow{\mathbf{h}}_i$ and $\overleftarrow{\mathbf{h}}_i$ are the hidden states at position i of the forward and backward LSTMs respectively; $\oplus$ is concatenation operation; θ denotes all parameters in Bi-LSTM model.

2.3 Inference Layer

After extracting features, we employ conditional random fields (CRF) (Lafferty et al., 2001) layer to inference tags. In CRF layer, $p(Y|X)$ in Eq (1) could be formalized as:

$$p(Y|X) = \frac{\Psi(Y|X)}{\sum_{Y' \in \mathcal{L}^n} \Psi(Y'|X)}. \quad (7)$$

Here, $\Psi(Y|X)$ is the potential function, and we only consider interactions between two successive labels (first order linear chain CRFs):

$$\Psi(Y|X) = \prod_{i=2}^{n} \psi(X, i, y_{i-1}, y_i), \quad (8)$$

$$\psi(\mathbf{x}, i, y', y) = \exp(s(X, i)_y + \mathbf{b}_{y'y}), \quad (9)$$

where $\mathbf{b}_{y'y} \in \mathbf{R}$ is trainable parameters respective to label pair (y', y). Score function $s(X, i) \in \mathbb{R}^{|\mathcal{L}|}$ assigns score for each label on tagging the i-th character:

$$s(X, i) = \mathbf{W}_s^\top \mathbf{h}_i + \mathbf{b}_s, \quad (10)$$

where $\mathbf{h}_i$ is the hidden state of Bi-LSTM at position i; $\mathbf{W}_s \in \mathbb{R}^{d_h \times |\mathcal{L}|}$ and $\mathbf{b}_s \in \mathbb{R}^{|\mathcal{L}|}$ are trainable parameters.

3 Multi-Criteria Learning for Chinese Word Segmentation

Although neural models are widely used on CWS, most of them cannot deal with incompatible criteria with heterogonous segmentation criteria simultaneously.

Inspired by the success of multi-task learning (Caruana, 1997; Ben-David and Schuller, 2003; Liu et al., 2016a,b), we regard the heterogenous criteria as multiple "related" tasks, which could improve the performance of each other simultaneously with shared information.

Formally, assume that there are M corpora with heterogeneous segmentation criteria. We refer $\mathcal{D}_m$ as corpus m with N_m samples:

$$\mathcal{D}_m = \{(X_i^{(m)}, Y_i^{(m)})\}_{i=1}^{N_m}, \quad (11)$$

where X_i^m and Y_i^m denote the i-th sentence and the corresponding label in corpus m.

To exploit the shared information between these different criteria, we propose three sharing models for CWS task as shown in Figure 2. The feature layers of these three models consist of a private (criterion-specific) layer and a shared (criterion-invariant) layer. The difference between three models is the information flow between the task layer and the shared layer. Besides, all of these three models also share the embedding layer.

3.1 Model-I: Parallel Shared-Private Model

In the feature layer of Model-I, we regard the private layer and shared layer as two parallel layers. For corpus m, the hidden states of shared layer and private layer are:

$$\mathbf{h}_i^{(s)} = \text{Bi-LSTM}(\mathbf{e}_{x_i}, \overrightarrow{\mathbf{h}}_{i-1}^{(s)}, \overleftarrow{\mathbf{h}}_{i+1}^{(s)}, \theta_s), \quad (12)$$

$$\mathbf{h}_i^{(m)} = \text{Bi-LSTM}(\mathbf{e}_{x_i}, \overrightarrow{\mathbf{h}}_{i-1}^{(m)}, \overleftarrow{\mathbf{h}}_{i+1}^{(m)}, \theta_m), \quad (13)$$

and the score function in the CRF layer is computed as:

$$s^{(m)}(X, i) = {\mathbf{W}_s^{(m)}}^\top \begin{bmatrix} \mathbf{h}_i^{(s)} \\ \mathbf{h}_i^{(m)} \end{bmatrix} + \mathbf{b}_s^{(m)}, \quad (14)$$

where $\mathbf{W}_s^{(m)} \in \mathbb{R}^{2d_h \times |\mathcal{L}|}$ and $\mathbf{b}_s^{(m)} \in \mathbb{R}^{|\mathcal{L}|}$ are criterion-specific parameters for corpus m.

3.2 Model-II: Stacked Shared-Private Model

In the feature layer of Model-II, we arrange the shared layer and private layer in stacked manner. The private layer takes output of shared layer as input. For corpus m, the hidden states of shared layer and private layer are:

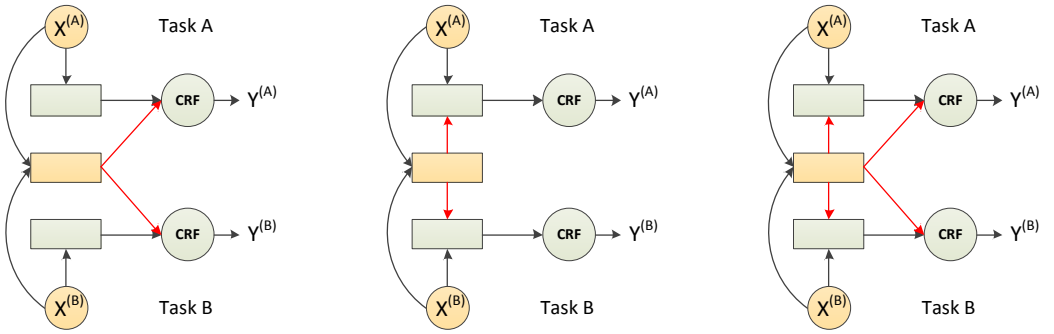
$$\mathbf{h}_i^{(s)} = \text{Bi-LSTM}(\mathbf{e}_{x_i}, \overrightarrow{\mathbf{h}}_{i-1}^{(s)}, \overleftarrow{\mathbf{h}}_{i+1}^{(s)}, \theta_s), \quad (15)$$

$$\mathbf{h}_i^{(m)} = \text{Bi-LSTM}(\begin{bmatrix} \mathbf{e}_{x_i} \\ \mathbf{h}_i^{(s)} \end{bmatrix}, \overrightarrow{\mathbf{h}}_{i-1}^{(m)}, \overleftarrow{\mathbf{h}}_{i+1}^{(m)}, \theta_m) \quad (16)$$

and the score function in the CRF layer is computed as:

$$s^{(m)}(X, i) = {\mathbf{W}_s^{(m)}}^\top \mathbf{h}_i^{(m)} + \mathbf{b}_s^{(m)}, \quad (17)$$

where $\mathbf{W}_s^{(m)} \in \mathbb{R}^{2d_h \times |\mathcal{L}|}$ and $\mathbf{b}_s^{(m)} \in \mathbb{R}^{|\mathcal{L}|}$ are criterion-specific parameters for corpus m.



(a) Model-I (b) Model-II (c) Model-III

Figure 2: Three shared-private models for multi-criteria learning. The yellow blocks are the shared Bi-LSTM layer, while the gray block are the private Bi-LSTM layer. The yellow circles denote the shared embedding layer. The red information flow indicates the difference between three models.

3.3 Model-III: Skip-Layer Shared-Private Model

In the feature layer of Model-III, the shared layer and private layer are in stacked manner as Model-II. Additionally, we send the outputs of shared layer to CRF layer directly.

The Model III can be regarded as a combination of Model-I and Model-II. For corpus m, the hidden states of shared layer and private layer are the same with Eq (15) and (16), and the score function in CRF layer is computed as the same as Eq (14).

3.4 Objective function

The parameters of the network are trained to maximize the log conditional likelihood of true labels on all the corpora. The objective function $\mathcal{J}_{seg}$ can be computed as:

$$\mathcal{J}_{seg}(\Theta^m, \Theta^s) = \sum_{m=1}^{M} \sum_{i=1}^{N_m} \log p(Y_i^{(m)} | X_i^{(m)}; \Theta^m, \Theta^s), \tag{18}$$

where Θ^m and Θ^s denote all the parameters in private and shared layers respectively.

4 Incorporating Adversarial Training for Shared Layer

Although the shared-private model separates the feature space into shared and private spaces, there is no guarantee that sharable features do not exist in private feature space, or vice versa. Inspired by the work on domain adaptation (Ajakan et al., 2014; Ganin et al., 2016; Bousmalis et al., 2016), we hope that the features extracted by shared layer is invariant across the heterogonous segmentation criteria. Therefore, we jointly optimize the shared layer via adversarial training (Goodfellow et al., 2014).

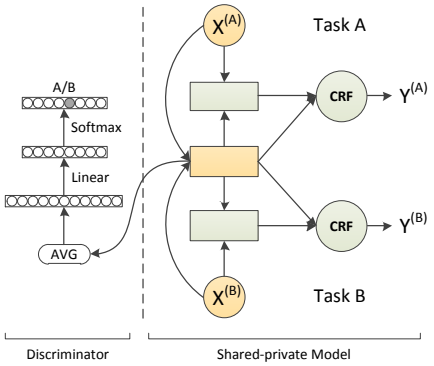


Figure 3: Architecture of Model-III with adversarial training strategy for shared layer. The discriminator firstly averages the hidden states of shared layer, then derives probability over all possible criteria by applying softmax operation after a linear transformation.

Therefore, besides the task loss for CWS, we additionally introduce an adversarial loss to prevent criterion-specific feature from creeping into shared space as shown in Figure 3. We use a criterion discriminator which aims to recognize which criterion the sentence is annotated by using the shared features.

Specifically, given a sentence X with length n, we refer to $\mathbf{h}_X^{(s)}$ as shared features for X in one of the sharing models. Here, we compute $\mathbf{h}_X^{(s)}$ by simply averaging the hidden states of shared layer $\mathbf{h}_X^{(s)} = \frac{1}{n}\sum_i^n \mathbf{h}_{x_i}^{(s)}$. The criterion discriminator computes the probability $p(\cdot|X)$ over all criteria as:

$$p(\cdot|X; \Theta^d, \Theta^s) = \text{softmax}(\mathbf{W}_d^\top \mathbf{h}_X^{(s)} + \mathbf{b}_d), \tag{19}$$

where Θ^d indicates the parameters of criterion discriminator $\mathbf{W}_d \in \mathbb{R}^{d_h \times M}$ and $\mathbf{b}_d \in \mathbb{R}^M$; Θ^s denotes the parameters of shared layers.

4.1 Adversarial loss function

The criterion discriminator maximizes the cross entropy of predicted criterion distribution $p(\cdot|X)$ and true criterion.

$$\max_{\Theta^d} \mathcal{J}^1_{adv}(\Theta^d) = \sum_{m=1}^{M} \sum_{i=1}^{N_m} \log p(m|X_i^{(m)}; \Theta^d, \Theta^s). \quad (20)$$

An adversarial loss aims to produce shared features, such that a criterion discriminator cannot reliably predict the criterion by using these shared features. Therefore, we maximize the entropy of predicted criterion distribution when training shared parameters.

$$\max_{\Theta^s} \mathcal{J}^2_{adv}(\Theta^s) = \sum_{m=1}^{M} \sum_{i=1}^{N_m} \mathrm{H}\left(p(m|X_i^{(m)}; \Theta^d, \Theta^s)\right), \quad (21)$$

where $\mathrm{H}(p) = -\sum_i p_i \log p_i$ is an entropy of distribution p.

Unlike (Ganin et al., 2016), we use entropy term instead of negative cross-entropy.

5 Training

Finally, we combine the task and adversarial objective functions.

$$\mathcal{J}(\Theta; \mathcal{D}) = \mathcal{J}_{seg}(\Theta^m, \Theta^s) + \mathcal{J}^1_{adv}(\Theta^d) + \lambda \mathcal{J}^2_{adv}(\Theta^s), \quad (22)$$

where λ is the weight that controls the interaction of the loss terms and $\mathcal{D}$ is the training corpora.

The training procedure is to optimize two discriminative classifiers alternately as shown in Algorithm 1. We use Adam (Kingma and Ba, 2014) with minibatchs to maximize the objectives.

Notably, when using adversarial strategy, we firstly train 2400 epochs (each epoch only trains on eight batches from different corpora), then we only optimize $\mathcal{J}_{seg}(\Theta^m, \Theta^s)$ with Θ^s fixed until convergence (early stop strategy).

6 Experiments

6.1 Datasets

To evaluate our proposed architecture, we experiment on eight prevalent CWS datasets from SIGHAN2005 (Emerson, 2005) and SIGHAN2008 (Jin and Chen, 2008). Table 2 gives the details of the eight datasets. Among these datasets, AS, CITYU and CKIP are traditional Chinese, while the remains, MSRA, PKU, CTB, NCC and SXU, are simplified Chinese. We use 10% data of shuffled train set as development set for all datasets.

6.2 Experimental Configurations

For hyper-parameter configurations, we set both the character embedding size d_e and the dimensionality of LSTM hidden states d_h to 100. The initial learning rate α is set to 0.01. The loss weight coefficient λ is set to 0.05. Since the scale of each dataset varies, we use different training batch sizes for datasets. Specifically, we set batch sizes of AS and MSR datasets as 512 and 256 respectively, and 128 for remains. We employ dropout strategy on embedding layer, keeping 80% inputs (20% dropout rate).

For initialization, we randomize all parameters following uniform distribution at $(-0.05, 0.05)$. We simply map traditional Chinese characters to simplified Chinese, and optimize on the same character embedding matrix across datasets, which is pre-trained on Chinese Wikipedia corpus, using word2vec toolkit (Mikolov et al., 2013). Following previous work (Chen et al., 2015b; Pei et al., 2014), all experiments including baseline results are using pre-trained character embedding with bigram feature.

6.3 Overall Results

Table 3 shows the experiment results of the proposed models on test sets of eight CWS datasets, which has three blocks.

(1) In the first block, we can see that the performance is boosted by using Bi-LSTM, and the

		Test	0.1M	0.2M	17.5K	3.6K	3.6K	4.74%
	SXU	Train	0.5M	0.9M	32.5K	4.2K	17.1K	-
		Test	0.1M	0.2M	12.4K	2.8K	3.7K	5.12%

Table 2: Details of the eight datasets.

performance of Bi-LSTM cannot be improved by merely increasing the depth of networks. In addition, although the F value of LSTM model in (Chen et al., 2015b) is 97.4%, they additionally incorporate an external idiom dictionary.

(2) In the second block, our proposed three models based on multi-criteria learning boost performance. Model-I gains 0.75% improvement on averaging F-measure score compared with Bi-LSTM result (94.14%). Only the performance on MSRA drops slightly. Compared to the baseline results (Bi-LSTM and stacked Bi-LSTM), the proposed models boost the performance with the help of exploiting information across these heterogeneous segmentation criteria. Although various criteria have different segmentation granularities, there are still some underlying information shared. For instance, MSRA and CTB treat family name and last name as one token "宁泽涛 (NingZeTao)", whereas some other datasets, like PKU, regard them as two tokens, "宁 (Ning)" and "泽涛 (ZeTao)". The partial boundaries (before "宁 (Ning)" or after "涛 (Tao)") can be shared.

(3) In the third block, we introduce adversarial training. By introducing adversarial training, the performances are further boosted, and Model-I is slightly better than Model-II and Model-III. The adversarial training tries to make shared layer keep criteria-invariant features. For instance, as shown in Table 3, when we use shared information, the performance on MSRA drops (worse than baseline result). The reason may be that the shared parameters bias to other segmentation criteria and introduce noisy features into shared parameters. When we additionally incorporate the adversarial strategy, we observe that the performance on MSRA is improved and outperforms the baseline results. We could also observe the improvements on other datasets. However, the boost from the adversarial strategy is not significant. The main reason might be that the proposed three sharing models implicitly attempt to keep invariant features by shared parameters and learn discrepancies by the task layer.

6.4 Speed

To further explore the convergence speed, we plot the results on development sets through epochs. Figure 4 shows the learning curve of Model-I without incorporating adversarial strategy. As shown in Figure 4, the proposed model makes progress gradually on all datasets. After about 1000 epochs, the performance becomes stable and convergent.

We also test the decoding speed, and our models process 441.38 sentences per second averagely. As the proposed models and the baseline models (Bi-LSTM and stacked Bi-LSTM) are nearly in the same complexity, all models are nearly the same efficient. However, the time consumption of training process varies from model to model. For the models without adversarial training, it costs about 10 hours for training (the same for stacked Bi-LSTM to train eight datasets), whereas it takes about 16 hours for the models with adversarial training. All the experiments are conducted on the hardware with Intel(R) Xeon(R) CPU E5-2643 v3 @ 3.40GHz and NVIDIA GeForce GTX TITAN X.

Table 3: Results of proposed models on test sets of eight CWS datasets. There are three blocks. The first block consists of two baseline models: Bi-LSTM and stacked Bi-LSTM. The second block consists of our proposed three models without adversarial training. The third block consists of our proposed three models with adversarial training. Here, P, R, F, OOV indicate the precision, recall, F value and OOV recall rate respectively. The maximum F values in each block are highlighted for each dataset.

6.5 Error Analysis

We further investigate the benefits of the proposed models by comparing the error distributions between the single-criterion learning (baseline model Bi-LSTM) and multi-criteria learning (Model-I and Model-I with adversarial training) as shown in Figure 5. According to the results, we could observe that a large proportion of points lie above diagonal lines in Figure 5a and Figure 5b, which implies that performance benefit from integrating knowledge and complementary information from other corpora. As shown in Table 3, on the test set of CITYU, the performance of Model-I and its adversarial version (Model-I+ADV) boost from 92.17% to 95.59% and 95.42% respectively.

In addition, we observe that adversarial strategy is effective to prevent criterion specific features from creeping into shared space. For instance, the segmentation granularity of personal name is often different according to heterogenous criteria. With the help of adversarial strategy, our models could correct a large proportion of mistakes on personal name. Table 4 lists the examples from 2333-th and 89-th sentences in test sets of PKU and MSRA datasets respectively.

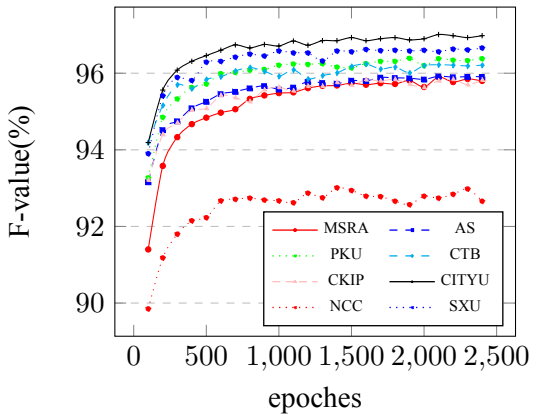

Figure 4: Convergence speed of Model-I without adversarial training on development sets of eight datasets.

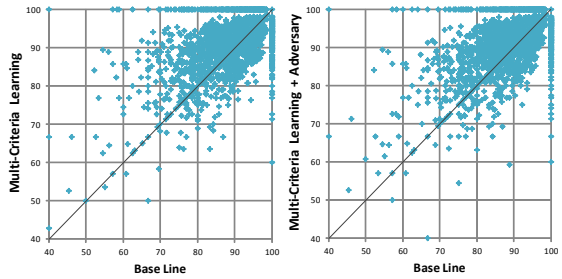

(a) (b)

Figure 5: F-measure scores on test set of CITYU dataset. Each point denotes a sentence, with the (x, y) values of each point denoting the F-measure scores of the two models, respectively. (a) is comparison between Bi-LSTM and Model-I. (b) is comparison between Bi-LSTM and Model-I with adversarial training.

7 Knowledge Transfer

We also conduct experiments of whether the shared layers can be transferred to the other related tasks or domains. In this section, we investigate the ability of knowledge transfer on two experiments: (1) simplified Chinese to traditional Chinese and (2) formal texts to informal texts.

7.1 Simplified Chinese to Traditional Chinese

Traditional Chinese and simplified Chinese are two similar languages with slightly difference on character forms (e.g. multiple traditional characters might map to one simplified character). We investigate that if datasets in traditional Chinese and simplified Chinese could help each other. Table 5 gives the results of Model-I on 3 traditional Chinese datasets under the help of 5 simplified Chinese datasets. Specifically, we firstly train the model on simplified Chinese datasets, then we train traditional Chinese datasets independently with shared parameters fixed.

Models	PKU-2333		MSRA-89	
Golds	Roh 卢	Moo-hyun 武铉	Mu Ling Ying 穆玲英	
Base Line	卢武铉		穆	玲英
Model-I	卢武铉		穆	玲英
Modell-I+ADV	卢	武铉	穆玲英	

Table 4: Segmentation cases of personal names.

Models	AS	CKIP	CITYU	Avg.
Baseline(Bi-LSTM)	**94.20**	93.06	94.07	93.78
Model-I*	94.12	**93.24**	**95.20**	**94.19**

Table 5: Performance on 3 traditional Chinese datasets. Model-I* means that the shared parameters are trained on 5 simplified Chinese datasets and are fixed for traditional Chinese datasets. Here, we conduct Model-I without incorporating adversarial training strategy.

As we can see, the average performance is boosted by 0.41% on F-measure score (from 93.78% to 94.19%), which indicates that shared features learned from simplified Chinese segmentation criteria can help to improve performance on traditional Chinese. Like MSRA, as AS dataset is relatively large (train set of 5.4M tokens), the features learned by shared parameters might bias to other datasets and thus hurt performance on such large dataset AS.

7.2 Formal Texts to Informal Texts

7.2.1 Dataset

We use the NLPCC 2016 dataset[2] (Qiu et al., 2016) to evaluate our model on micro-blog texts. The NLPCC 2016 data are provided by the shared task in the 5th CCF Conference on Natural Language Processing & Chinese Computing (NLPCC 2016): Chinese Word Segmentation and POS Tagging for micro-blog Text. Unlike the popular used newswire dataset, the NLPCC 2016 dataset is collected from Sina Weibo[3], which consists of the informal texts from micro-blog with the various topics, such as finance, sports, entertainment, and so on. The information of the dataset is shown in Table 6.

[2] https://github.com/FudanNLP/NLPCC-WordSeg-Weibo

[3] http://www.weibo.com/

Dataset	Words	Chars	Word Types	Char Types	Sents	OOV Rate
Train	421,166	688,743	43,331	4,502	20,135	-
Dev	43,697	73,246	11,187	2,879	2,052	6.82%
Test	187,877	315,865	27,804	3,911	8,592	6.98%

Table 6: Statistical information of NLPCC 2016 dataset.

Models	P	R	F	OOV
Baseline(Bi-LSTM)	93.56	94.33	93.94	70.75
Model-I*	**93.65**	**94.83**	**94.24**	**74.72**

Table 7: Performances on the test set of NLPCC 2016 dataset. Model-I* means that the shared parameters are trained on 8 Chinese datasets (Table 2) and are fixed for NLPCC dataset. Here, we conduct Model-I without incorporating adversarial training strategy.

7.2.2 Results

Formal documents (like the eight datasets in Table 2) and micro-blog texts are dissimilar in many aspects. Thus, we further investigate that if the formal texts could help to improve the performance of micro-blog texts. Table 7 gives the results of Model-I on the NLPCC 2016 dataset under the help of the eight datasets in Table 2. Specifically, we firstly train the model on the eight datasets, then we train on the NLPCC 2016 dataset alone with shared parameters fixed. The baseline model is Bi-LSTM which is trained on the NLPCC 2016 dataset alone.

As we can see, the performance is boosted by 0.30% on F-measure score (from 93.94% to 94.24%), and we could also observe that the OOV recall rate is boosted by 3.97%. It shows that the shared features learned from formal texts can help to improve the performance on of micro-blog texts.

8 Related Works

There are many works on exploiting heterogeneous annotation data to improve various NLP tasks. Jiang et al. (2009) proposed a stacking-based model which could train a model for one specific desired annotation criterion by utilizing knowledge from corpora with other heterogeneous annotations. Sun and Wan (2012) proposed a structure-based stacking model to reduce the approximation error, which makes use of structured features such as sub-words. These models are unidirectional aid and also suffer from error propagation problem.

Qiu et al. (2013) used multi-tasks learning framework to improve the performance of POS tagging on two heterogeneous datasets. Li et al. (2015) proposed a coupled sequence labeling model which could directly learn and infer two heterogeneous annotations. Chao et al. (2015) also utilize multiple corpora using coupled sequence labeling model. These methods adopt the shallow classifiers, therefore suffering from the problem of defining shared features.

Our proposed models use deep neural networks, which can easily share information with hidden shared layers. Chen et al. (2016) also adopted neural network models for exploiting heterogeneous annotations based on neural multi-view model, which can be regarded as a simplified version of our proposed models by removing private hidden layers.

Unlike the above models, we design three sharing-private architectures and keep shared layer to extract criterion-invariance features by introducing adversarial training. Moreover, we fully exploit eight corpora with heterogeneous segmentation criteria to model the underlying shared information.

9 Conclusions & Future Works

In this paper, we propose adversarial multi-criteria learning for CWS by fully exploiting the underlying shared knowledge across multiple heterogeneous criteria. Experiments show that our proposed three shared-private models are effective to extract the shared information, and achieve significant improvements over the single-criterion methods.

Abstract

We present neural network-based joint models for Chinese word segmentation, POS tagging and dependency parsing. Our models are the first neural approaches for fully joint Chinese analysis that is known to prevent the error propagation problem of pipeline models. Although word embeddings play a key role in dependency parsing, they cannot be applied directly to the joint task in the previous work. To address this problem, we propose embeddings of character strings, in addition to words. Experiments show that our models outperform existing systems in Chinese word segmentation and POS tagging, and perform preferable accuracies in dependency parsing. We also explore bi-LSTM models with fewer features.

1 Introduction

Dependency parsers have been enhanced by the use of neural networks and embedding vectors (Chen and Manning, 2014; Weiss et al., 2015; Zhou et al., 2015; Alberti et al., 2015; Andor et al., 2016; Dyer et al., 2015). When these dependency parsers process sentences in English and other languages that use symbols for word separations, they can be very accurate. However, for languages that do not contain word separation symbols, dependency parsers are used in pipeline processes with word segmentation and POS tagging models, and encounter serious problems because of error propagations. In particular, Chinese word segmentation is notoriously difficult because sentences are written without word dividers and Chinese words are not clearly defined. Hence, the pipeline of word segmentation, POS tagging and dependency parsing always suffers from word segmentation errors. Once words have been wrongly-segmented, word embeddings and traditional one-hot word features, used in dependency parsers, will mistake the precise meanings of the original sentences. As a result, pipeline models achieve dependency scores of around 80% for Chinese.

A traditional solution to this error propagation problem is to use joint models. Many Chinese words play multiple grammatical roles with only one grammatical form. Therefore, determining the word boundaries and the subsequent tagging and dependency parsing are closely correlated. Transition-based joint models for Chinese word segmentation, POS tagging and dependency parsing are proposed by Hatori et al. (2012) and Zhang et al. (2014). Hatori et al. (2012) state that dependency information improves the performances of word segmentation and POS tagging, and develop the first transition-based joint word segmentation, POS tagging and dependency parsing model. Zhang et al. (2014) expand this and find that both the inter-word dependencies and intra-word dependencies are helpful in word segmentation and POS tagging.

Although the models of Hatori et al. (2012) and Zhang et al. (2014) perform better than pipeline models, they rely on the one-hot representation of characters and words, and do not assume the similarities among characters and words. In addition, not only words and characters but also many incomplete tokens appear in the transition-based joint parsing process. Such incomplete or unknown words (UNK) could become important cues for parsing, but they are not listed in dictionaries or pre-trained word embeddings. Some recent studies show that character-based embeddings are effective in neural parsing (Ballesteros et al., 2015; Zheng et al., 2015), but their models could not be directly applied to joint models because they use given word segmentations. To solve

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1204–1214
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1111

these problems, we propose neural network-based joint models for word segmentation, POS tagging and dependency parsing. We use both character and word embeddings for known tokens and apply character string embeddings for unknown tokens.

Another problem in the models of Hatori et al. (2012) and Zhang et al. (2014) is that they rely on detailed feature engineering. Recently, bidirectional LSTM (bi-LSTM) based neural network models with very few feature extraction are proposed (Kiperwasser and Goldberg, 2016; Cross and Huang, 2016). In their models, the bi-LSTM is used to represent the tokens including their context. Indeed, such neural networks can observe whole sentence through the bi-LSTM. This bi-LSTM is similar to that of neural machine translation models of Bahdanau et al. (2014). As a result, Kiperwasser and Goldberg (2016) achieve competitive scores with the previous state-of-the-art models. We also develop joint models with n-gram character string bi-LSTM.

In the experiments, we obtain state-of-the-art Chinese word segmentation and POS tagging scores, and the pipeline of the dependency model achieves the better dependency scores than the previous joint models. To the best of our knowledge, this is the first model to use embeddings and neural networks for Chinese full joint parsing.

Our contributions are summarized as follows: (1) we propose the first embedding-based fully joint parsing model, (2) we use character string embeddings for UNK and incomplete tokens. (3) we also explore bi-LSTM models to avoid the detailed feature engineering in previous approaches. (4) in experiments using Chinese corpus, we achieve state-of-the-art scores in word segmentation, POS tagging and dependency parsing.

2 Model

All full joint parsing models we present in this paper use the transition-based algorithm in Section 2.1 and the embeddings of character strings in Section 2.2. We present two neural networks: the feed-forward neural network models in Section 2.3 and the bi-LSTM models in Section 2.4.

2.1 Transition-based Algorithm for Joint Segmentation, POS Tagging, and Dependency Parsing

Based on Hatori et al. (2012), we use a modified arc-standard algorithm for character transitions (Figure 1). The model consists of one buffer and one stack. The buffer contains characters in the input sentence, and the stack contains words shifted from the buffer. The stack words may have their child nodes. The words in the stack are formed by the following transition operations.

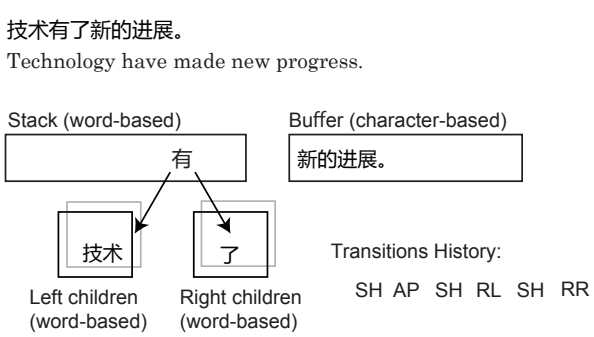

Figure 1: Transition-based Chinese joint model for word segmentation, POS tagging and dependency parsing.

- `SH(t)` (*shift*): Shift the first character of the buffer to the top of the stack as a new word.
- `AP` (*append*): Append the first character of the buffer to the end of the top word of the stack.
- `RR` (*reduce-right*): Reduce the right word of the top two words of the stack, and make the right child node of the left word.
- `RL` (*reduce-left*): Reduce the left word of the top two words of the stack, and make the left child node of the right word.

The `RR` and `RL` operations are the same as those of the arc-standard algorithm (Nivre, 2004a). `SH` makes a new word whereas `AP` makes the current word longer by adding one character. The POS tags are attached with the `SH(t)` transition.

In this paper, we explore both greedy models and beam decoding models. This parsing algorithm works in both types. We also develop a joint model of word segmentation and POS tagging, along with a dependency parsing model. The joint model of word segmentation and POS tagging does not have `RR` and `RL` transitions.

2.2 Embeddings of Character Strings

First, we explain the embeddings used in the neural networks. Later, we explain details of the neural networks in Section 2.3 and 2.4.

Both meaningful words and incomplete tokens appear during transition-based joint parsing. Although embeddings of incomplete tokens are not used in previous work, they could become useful features in several cases. For example, "南京东路" (Nanjing East Road, the famous shopping street of Shanghai) is treated as a single Chinese word in the Penn Chinese Treebank (CTB) corpus. There are other named entities of this form in CTB, e.g, "北京西路" (Beijing West Road) and "湘西路" (Hunan West Road). In these cases, "南京" (Nanjing) and "北京" (Beijing) are location words, while "东路" (East Road) and "西路" (West Road) are sub-words. "东路" and "西路" are similar in terms of their character composition and usage, which is not sufficiently considered in the previous work. Moreover, representations of incomplete tokens are helpful for compensating the segmentation ambiguity. Suppose that the parser makes over-segmentation errors and segments "南京东路" to "南京" and "东路". In this case, "东路" becomes UNK. However, the models could infer that "东路" is also a location, from its character composition and neighboring words. This could give models robustness of segmentation errors. In our models, we prepare the word and character embeddings in the pre-training. We also use the embeddings of character strings for sub-words and UNK which are not in the pre-trained embeddings.

The characters and words are embedded in the same vector space during pre-training. We prepare the same training corpus with the segmented word files and the segmented character files. Both files are concatenated and learned by word2vec (Mikolov et al., 2013). We use the embeddings of 1M frequent words and characters. Words and characters that are in the training set and do not have pre-trained embeddings are given randomly initialized embeddings. The development set and the test set have out-of-vocabulary (OOV) tokens for these embeddings.

The embeddings of the unknown character strings are generated in the neural computation graph when they are required. Consider a character string $c_1 c_2 \cdots c_n$ consisting of characters c_i. When this character string is not in the pre-trained embeddings, the model obtains the embeddings $\mathbf{v}(c_1 c_2 \cdots c_n)$ by the mean of each character embeddings $\sum_{i=1}^{n} \mathbf{v}(c_i)$. Embeddings of words, characters and character strings have the same dimension and are chosen in the neural computation graph. We avoid using the "UNK" vector as far as possible, because this degenerates the information about unknown tokens. However, models use the "UNK" vector if the parser encounters characters that are not in the pre-trained embeddings, though this is quite uncommon.

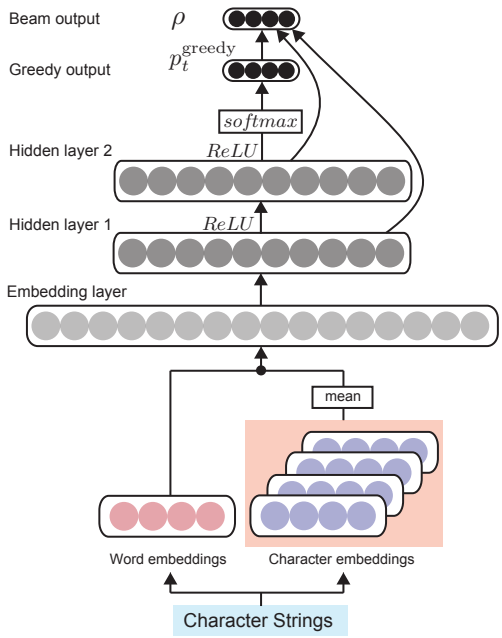

Figure 2: The feed-forward neural network model. The greedy output is obtained at the second top layer, while the beam decoding output is obtained at the top layer. The input character strings are translated into word embeddings if the embeddings of the character strings are available. Otherwise, the embeddings of the character strings are used.

2.3 Feed-forward Neural Network

2.3.1 Neural Network

We present a feed-forward neural network model in Figure 2. The neural network for greedy training is based on the neural networks of Chen and Manning (2014) and Weiss et al. (2015). We add the dynamic generation of the embeddings of character strings for unknown tokens, as described in Section 2.2. This neural network has two hidden layers with 8,000 dimensions. This is larger than Chen and Manning (2014) (200 dimensions) or Weiss et al. (2015) (1,024 or 2,048 dimensions). We use the ReLU for the activation function of the hidden layers (Nair and Hinton, 2010) and the softmax function for the output layer of the greedy

Type	Value
Size of $\mathbf{h_1}$,$\mathbf{h_2}$	8,000
Initial learning rate	0.01
Initial learning rate of beam decoding	0.001
Embedding vocabulary size	1M
Embedding vector size	200
Small embedding vector size	20
Minibatch size	200

Table 1: Parameters for neural network structure and training.

neural network. There are three randomly initialized weight matrices between the embedding layers and the softmax function. The loss function $L(\theta)$ for the greedy training is

$$L(\theta) = -\sum_{s,t} \log p_{s,t}^{\text{greedy}} + \frac{\lambda}{2}||\theta||^2,$$

$$p_{s,t}^{\text{greedy}}(\boldsymbol{\beta}) \propto \exp\left(\sum_j w_{tj}\beta_j + b_t\right),$$

where t denotes one transition among the transition set $\mathcal{T}$ ($t \in \mathcal{T}$). s denotes one element of the single mini-batch. $\boldsymbol{\beta}$ denotes the output of the previous layer. $\mathbf{w}$ and $\mathbf{b}$ denote the weight matrix and the bias term. θ contains all parameters. We use the $L2$ penalty term and the Dropout. The backprop is performed including the word and character embeddings. We use Adagrad (Duchi et al., 2010) to optimize learning rate. We also consider Adam (Kingma and Ba, 2015) and SGD, but find that Adagrad performs better in this model. The other learning parameters are summarized in Table 1.

In our model implementation, we divide all sentences into training batches. Sentences in the same training batches are simultaneously processed by the neural mini-batches. By doing so, the model can parse all sentences of the training batch in the number of transitions required to parse the longest sentence in the batch. This allows the model to parse more sentences at once, as long as the neural mini-batch can be allocated to the GPU memory. This can be applied to beam decoding.

2.3.2 Features

The features of this neural network are listed in Table 2. We use three kinds of features: (1) features obtained from Hatori et al. (2012) by removing combinations of features, (2) features obtained from Chen and Manning (2014), (3) original features related to character strings. In particular, the original features include sub-words, character strings across the buffer and the stack, and character strings in the buffer. Character strings across the buffer and stack could capture the currently-segmented word. To avoid using character strings that are too long, we restrict the length of character string to a maximum of four characters. Unlike Hatori et al. (2012), we use sequential characters of sentences for features, and avoid hand-engineered combinations among one-hot features, because such combinations could be automatically generated in the neural hidden layers as distributed representations (Hinton et al., 1986).

Type	Features
Stack word and tags	s0w, s1w, s2w
	s0p, s1p, s2p
Stack 1 children and tags	s0l0w, s0r0w, s0l1w, s0r1w
	s0l0p, s0r0p, s0l1p, s0r1p
Stack 2 children	s1l0w, s1r0w, s1l1w, s1r1w
Children of children	s0l0lw, s0r0rw, s1l0lw, s1r0rw
Buffer characters	b0c, b1c, b2c, b3c
Previously shifted words	q0w, q1w
Previously shifted tags	q0p, q1p
Character of q0	q0e
Parts of q0 word	q0f1, q0f2, q0f3
Strings across q0 and buf.	q0b1, q0b2, q0b3
Strings of buffer characters	b0-2, b0-3, b0-4
	b1-3, b1-4, b1-5
	b2-4, b2-5, b2-6
	b3-5, b3-6
	b4-6
Length of q0	lenq0

Table 2: Features for the joint model. "q0" denotes the last shifted word and "q1" denotes the word shifted before "q0". In "part of q0 word", "f1", "f2" and "f3" denote sub-words of "q0", which are 1, 2 and 3 sequential characters including the last character of "q0" respectively. In "strings across q0 and buf.", "q0bX" denotes "q0" and X sequential characters of the buffer. This feature could capture words that boundaries have not determined yet. In "strings of buffer characters", "bX-Y" denotes sequential characters from the X-th to Y-th character of the buffer. The suffix "e" denotes the end character of the word. The dimension of the embedding of "length of q0" is 20.

In the later section, we evaluate a joint model for word segmentation and POS tagging. This model does not use the children and children-of-children of stack words as features.

2.3.3 Beam Search

Structured learning plays an important role in previous joint parsing models for Chinese.[1] In this paper, we use the structured learning model proposed by Weiss et al. (2015) and Andor et al. (2016).

In Figure 2, the output layer for the beam decoding is at the top of the network. There are a perceptron layer which has inputs from the two hidden layers and the greedy output layer: $[\mathbf{h}_1, \mathbf{h}_2, \mathbf{p}^{\text{greedy}}(\mathbf{y})]$. This layer is learned by the following cost function (Andor et al., 2016):

$$L(d^*_{1:j};\theta) = -\sum_{i=1}^{j}\rho(d^*_{1:i-1}, d^*_i;\theta) + \ln \sum_{d'_{1:j}\in\mathcal{B}_{1:j}} \exp \sum_{i=1}^{j}\rho(d'_{1:i-1}, d'_i;\theta),$$

where $d_{1:j}$ denotes the transition path and $d^*_{1:j}$ denotes the gold transition path. $\mathcal{B}_{1:j}$ is the set of transition paths from 1 to j step in beam. ρ is the value of the top layer in Figure 2. This training can be applied throughout the network. However, we separately train the last beam layer and the previous greedy network in practice, as in Andor et al. (2016). First, we train the last perceptron layer using the beam cost function freezing the previous greedy-trained layers. After the last layer has been well trained, backprop is performed including the previous layers. We notice that training the embedding layer at this stage could make the results worse, and thus we exclude it. Note that this whole network backprop requires considerable GPU memory. Hence, we exclude particularly large batches from the training, because they cannot be on GPU memory. We use multiple beam sizes for training because models can be trained faster with small beam sizes. After the small beam size training, we use larger beam sizes. The test of this fully joint model takes place with a beam size of 16.

Hatori et al. (2012) use special alignment steps in beam decoding. The `AP` transition has size-2 steps, whereas the other transitions have a size-1 step. Using this alignment, the total number of steps for an N-character sentence is guaranteed to be $2N-1$ (excluding the root arc) for any transition path. This can be interpreted as the `AP` transition doing two things: appending characters and resolving intra-word dependencies. This alignment stepping assumes that the intra-word dependencies of characters to the right of the characters exist in each Chinese word.

[1] Hatori et al. (2012) report that structured learning with a beam size of 64 is optimal.

2.4 Bi-LSTM Model

In Section 2.3, we describe a neural network model with feature extraction. Unfortunately, although this model is fast and very accurate, it has two problems: (1) the neural network cannot see the whole sentence information. (2) it relies on feature engineering. To solve these problems, Kiperwasser and Goldberg (2016) propose a bi-LSTM neural network parsing model. Surprisingly, their model uses very few features, and bi-LSTM is applied to represent the context of the features. Their neural network consists of three parts: bi-LSTM, a feature extraction function and a multilayer perceptron (MLP). First, all tokens in the sentences are converted to embeddings. Second, the bi-LSTM reads all embeddings of the sentence. Third, the feature function extracts the feature representations of tokens from the bi-LSTM layer. Finally, an MLP with one hidden layer outputs the transition scores of the transition-based parser.

In this paper, we propose a Chinese joint parsing model with simple and global features using n-gram bi-LSTM and a simple feature extraction function. The model is described in Figure 3. We consider that Chinese sentences consist of tokens, including words, UNKs and incomplete tokens, which can have some meanings and are useful for parsing. Such tokens appear in many parts of the sentence and have arbitrary lengths. To capture them, we propose the n-gram bi-LSTM. The n-gram bi-LSTM read through characters $c_i \cdots c_{i+n-1}$ of the sentence (c_i is the i-th character). For example, the 1-gram bi-LSTM reads each character, and the 2-gram bi-LSTM reads two consecutive characters $c_i c_{i+1}$. After the n-gram forward LSTM reads character string $c_i \cdots c_{i+n-1}$, it next reads $c_{i+1} \cdots c_{i+n}$. The backward LSTM reads from $c_{i+1} \cdots c_{i+n}$ toward $c_i \cdots c_{i+n-1}$. This allows models to capture any n-gram character strings in the input sentence.[2] All n-gram inputs to bi-LSTM are given by the embeddings of words and characters or the dynamically generated embeddings of character strings, as described in

[2] At the end of the sentence of length N, character strings $c_i \cdots c_N (N < i+n-1)$, which are shorter than n characters, are used.

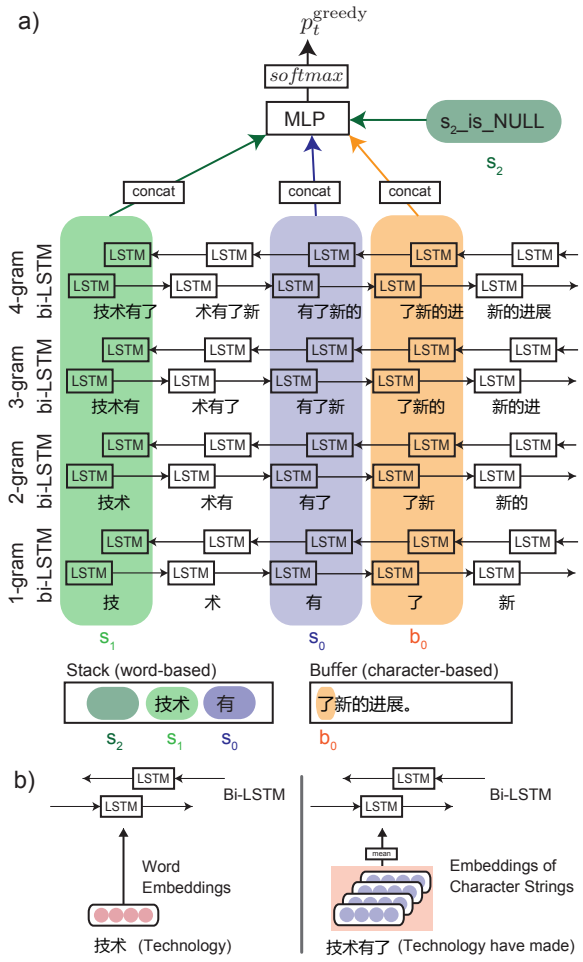

Figure 3: The bi-LSTM model. (a): The Chinese sentence "技术有了新的进展。" has been processed. (b): Similar to the feed-forward neural network model, the embeddings of words, characters and character strings are used. In this figure, a word "技术"(technology) has its embedding, while a token "技术有了"(technology have made) does not.

Section 2.2. Although these arbitrary n-gram tokens produce UNKs, character string embeddings can capture similarities among them. Following the bi-LSTM layer, the feature function extracts the corresponding outputs of the bi-LSTM layer. We summarize the features in Table 3. Finally, MLP and the softmax function outputs the transition probability. We use an MLP with three hidden layers as for the model in Section 2.3. We train this neural network with the loss function for the greedy training.

Model	Features
4 features	s0w, s1w, s2w, b0c
8 features	s0w, s1w, s2w, b0c s0r0w, s0l0w, s1r0w, s1l0w

Table 3: Features for the bi-LSTM models. All features are words and characters. We experiment both four and eight features models.

	Test	10k	13k

Table 4: Summary of datasets.

3 Experiments

3.1 Experimental Settings

We use the Penn Chinese Treebank 5.1 (CTB-5) and 7 (CTB-7) datasets to evaluate our models, following the splitting of Jiang et al. (2008) for CTB-5 and Wang et al. (2011) for CTB-7. The statistics of datasets are presented in Table 4. We use the Chinese Gigaword Corpus for embedding pre-training. Our model is developed for unlabeled dependencies. The development set is used for parameter tuning. Following Hatori et al. (2012) and Zhang et al. (2014), we use the standard word-level evaluation with F1-measure. The POS tags and dependencies cannot be correct unless the corresponding words are correctly segmented.

We trained three models: SegTag, SegTagDep and Dep. SegTag is the joint word segmentation and POS tagging model. SegTagDep is the full joint segmentation, tagging and dependency parsing model. Dep is the dependency parsing model which is similar to Weiss et al. (2015) and Andor et al. (2016), but uses the embeddings of character strings. Dep compensates for UNKs and segmentation errors caused by previous word segmentation using embeddings of character strings. We will examine this effect later.

Most experiments are conducted on GPUs, but some of beam decoding processes are performed on CPUs because of the large mini-batch size. The neural network is implemented with Theano.

Model	Seg	POS
Hatori+12 SegTag	97.66	93.61
Hatori+12 SegTag(d)	98.18	94.08
Hatori+12 SegTagDep	97.73	94.46
Hatori+12 SegTagDep(d)	98.26	94.64
M. Zhang+14 EAG	97.76	94.36
Y. Zhang+15	98.04	94.47
SegTag(g)	98.41	**94.84**
SegTag	**98.60**	94.76

Table 5: Joint segmentation and POS tagging scores. Both scores are in F-measure. In Hatori et al. (2012), (d) denotes the use of dictionaries. (g) denotes greedy trained models. All scores for previous models are taken from Hatori et al. (2012), Zhang et al. (2014) and Zhang et al. (2015).

3.2 Results

3.2.1 Joint Segmentation and POS Tagging

First, we evaluate the joint segmentation and POS tagging model (SegTag). Table 5 compares the performance of segmentation and POS tagging using the CTB-5 dataset. We train two modles: a greedy-trained model and a model trained with beams of size 4. We compare our model to three previous approaches: Hatori et al. (2012), Zhang et al. (2014) and Zhang et al. (2015). Our SegTag joint model is superior to these previous models, including Hatori et al. (2012)'s model with rich dictionary information, in terms of both segmentation and POS tagging accuracy.

3.2.2 Joint Segmentation, POS Tagging and Dependency Parsing

Table 6 presents the results of our full joint model. We employ the greedy trained full joint model SegTagDep(g) and the beam decoding model SegTagDep. All scores for the existing models in this table are taken from Zhang et al. (2014). Though our model surpasses the previous best end-to-end joint models in terms of segmentation and POS tagging, the dependency score is slightly lower than the previous models. The greedy model SegTagDep(g) achieves slightly lower scores than beam models, although this model works considerably fast because it does not use beam decoding.

Model	Seg	POS	Dep
Hatori+12	97.75	94.33	81.56
M. Zhang+14 EAG	97.76	94.36	**81.70**

Y. Zhang+15	98.04	94.47	82.01
SegTagDep(g)	98.24	94.49	80.15
SegTagDep	98.37	**94.83**‡	81.42‡
SegTag+Dep	**98.60**‡	94.76‡	**82.60**‡

Table 7: The SegTag+Dep model. Note that the model of Zhang et al. (2015) requires other base parsers. ‡ denotes that the improvement is statistically siginificant at $p < 0.01$ compared with SegTagDep(g) using paired t-test.

3.2.3 Pipeline of Our Joint SegTag and Dep Model

We use our joint SegTag model for the pipeline input of the Dep model (SegTag+Dep). Both SegTag and Dep models are trained and tested by the beam cost function with beams of size 4. Table 7 presents the results. Our SegTag+Dep model performs best in terms of the dependency and word segmentation. The SegTag+Dep model is better than the full joint model. This is because most segmentation errors of these models occur around named entities. Hatori et al. (2012)'s alignment step assumes the intra-word dependencies in words, while named entities do not always have them. For example, SegTag+Dep model treats named entity "海赛克", a company name, as one word, while the SegTagDep model divides this to "海" (sea) and "赛克", where "赛克" could be used for foreigner's name. For such words, SegTagDep prefers `SH` because `AP` has size-2 step of the character appending and intra-word dependency resolution, which does not exist for named entities. This problem could be solved by adding a special transition `AP_named_entity` which is similar to `AP` but with size-1 step and used

Model	Dep
Dep(g)-cs	80.51
Dep(g)	80.98

Table 8: SegTag+Dep(g) model with and without character strings (cs) representations. Note that we compare these models with greedy training for simplicity's sake.

Model	Seg	POS	Dep
SegTagDep(g) -q0bX	97.81	93.79	79.16
SegTagDep(g)	98.24	94.49	80.15

M. Zhang+14 STD	95.53	90.75	**75.63**
SegTagDep(g)	96.06	90.28	73.98
SegTagDep	95.86	90.91‡	74.04
SegTag+Dep	**96.23**‡	**91.25**‡	75.28‡

Table 10: Results from SegTag+Dep and SegTagDep applied to the CTB-7 corpus. (g) denotes greedy trained models. ‡ denotes that the improvement is statistically siginificant at $p < 0.01$ compared with SegTagDep(g) using paired t-test.

only for named entities. Additionally, Zhang et al. (2014)'s STD (arc-standard) model works slightly better than Hatori et al. (2012)'s fully joint model in terms of the dependency score. Zhang et al. (2014)'s STD model is similar to our SegTag+Dep because they combine a word segmentator and a dependency parser using "deque" of words.

3.2.4 Effect of Character String Embeddings

Finally, we compare the two pipeline models of SegTag+Dep to show the effectiveness of using character string representations instead of "UNK" embeddings. We use two dependency models with greedy training: Dep(g) for dependency model and Dep(g)-cs for dependency model without the character string embeddings . In the Dep(g)-cs model, we use the "UNK" embedding when the embeddings of the input features are unavailable, whereas we use the character string embeddings in model Dep(g). The results are presented in Table 8. When the models encounter unknown tokens, using the embeddings of character strings is better than using the "UNK" embedding.

3.2.5 Effect of Features across the Buffer and Stack

We test the effect of special features: q0bX in Table 2. The q0bX features capture the tokens across the buffer and stack. Joint transition-based parsing models by Hatori et al. (2012) and Chen and Manning (2014) decide POS tags of words before corresponding word segmentations are determined. In our model, the q0bX features capture words even if their segmentations are not determined. We examine the effectiveness of these features by training greedy full joint models with and without them. The results are shown in Table 9. The q0bX features boost not only POS tagging scores but also word segmentation scores.

3.2.6 CTB-7 Experiments

We also test the SegTagDep and SegTag+Dep models on CTB-7. In these experiments, we notice that the MLP with four hidden layers performs better than the MLP with three hidden layers, but we could not find definite differences in the experiments in CTB-5. We speculate that this is caused by the difference in the training set size. We present the final results with four hidden layers in Table 10.

3.2.7 Bi-LSTM Model

We experiment the n-gram bi-LSTMs models with four and eight features listed in Table 3. We summarize the result in Table 11. The greedy bi-LSTM models perform slightly worse than the previous models, but they do not rely on feature engineering.

4 Related Work

Zhang and Clark (2008) propose an incremental joint word segmentation and POS tagging model driven by a single perceptron. Zhang and Clark (2010) improve this model by using both character and word-based decoding. Hatori et al. (2011) propose a transition-based joint POS tagging and dependency parsing model. Zhang et al. (2013) propose a joint model using character structures of words for constituency parsing. Wang et al. (2013) also propose a lattice-based joint model for constituency parsing. Zhang et al. (2015) propose joint segmentation, POS tagging and dependency re-ranking system. This system requires

Model	Seg	POS	Dep
Hatori+12	97.75	94.33	81.56
M. Zhang+14 EAG	97.76	94.36	81.70
SegTagDep (g)	98.24	94.49	80.15
Bi-LSTM 4feat.(g)	97.72	93.12	79.03
Bi-LSTM 8feat.(g)	97.70	93.37	79.38

Table 11: Bi-LSTM feature extraction model. "4feat." and "8feat." denote the use of four and eight features.

base parsers. In neural joint models, Zheng et al. (2013) propose a neural network-based Chinese word segmentation model based on tag inferences. They extend their models for joint segmentation and POS tagging. Zhu et al. (2015) propose the re-ranking system of parsing results with recursive convolutional neural network.

5 Conclusion

We propose the joint parsing models by the feed-forward and bi-LSTM neural networks. Both of them use the character string embeddings. The character string embeddings help to capture the similarities of incomplete tokens. We also explore the neural network with few features using n-gram bi-LSTMs. Our SegTagDep joint model achieves better scores of Chinese word segmentation and POS tagging than previous joint models, and our SegTag and Dep pipeline model achieves state-of-the-art score of dependency parsing. The bi-LSTM models reduce the cost of feature engineering.

Robust Incremental Neural Semantic Graph Parsing

Jan Buys[1] **and Phil Blunsom**[1,2]

Abstract

Parsing sentences to linguistically-expressive semantic representations is a key goal of Natural Language Processing. Yet statistical parsing has focussed almost exclusively on bilexical dependencies or domain-specific logical forms. We propose a neural encoder-decoder transition-based parser which is the first full-coverage semantic graph parser for Minimal Recursion Semantics (MRS). The model architecture uses stack-based embedding features, predicting graphs jointly with unlexicalized predicates and their token alignments. Our parser is more accurate than attention-based baselines on MRS, and on an additional Abstract Meaning Representation (AMR) benchmark, and GPU batch processing makes it an order of magnitude faster than a high-precision grammar-based parser. Further, the 86.69% Smatch score of our MRS parser is higher than the upper-bound on AMR parsing, making MRS an attractive choice as a semantic representation.

1 Introduction

An important goal of Natural Language Understanding (NLU) is to parse sentences to structured, interpretable meaning representations that can be used for query execution, inference and reasoning. Recently end-to-end models have outperformed traditional pipeline approaches, predicting syntactic or semantic structure as intermediate steps, on NLU tasks such as sentiment analysis and semantic relatedness (Le and Mikolov, 2014; Kiros et al., 2015), question answering (Hermann et al., 2015) and textual entailment (Rocktäschel et al., 2015). However the linguistic structure used in applications has predominantly been shallow, restricted to bilexical dependencies or trees.

In this paper we focus on robust parsing into linguistically deep representations. The main representation that we use is Minimal Recursion Semantics (MRS) (Copestake et al., 1995, 2005), which serves as the semantic representation of the English Resource Grammar (ERG) (Flickinger, 2000). Existing parsers for full MRS (as opposed to bilexical semantic graphs derived from, but simplifying MRS) are grammar-based, performing disambiguation with a maximum entropy model (Toutanova et al., 2005; Zhang et al., 2007); this approach has high precision but incomplete coverage.

Our main contribution is to develop a fast and robust parser for full MRS-based semantic graphs. We exploit the power of global conditioning enabled by deep learning to predict linguistically deep graphs incrementally. The model does not have access to the underlying ERG or syntactic structures from which the MRS analyses were originally derived. We develop parsers for two graph-based conversions of MRS, Elementary Dependency Structure (EDS) (Oepen and Lønning, 2006) and Dependency MRS (DMRS) (Copestake, 2009), of which the latter is inter-convertible with MRS.

Abstract Meaning Representation (AMR) (Banarescu et al., 2013) is a graph-based semantic representation that shares the goals of MRS. Aside from differences in the choice of which linguistic phenomena are annotated, MRS is a compositional representation explicitly coupled with the syntactic structure of the sentence, while AMR does not assume compositionality or alignment with the sentence structure. Recently a number of AMR parsers have been developed (Flanigan et al., 2014; Wang et al., 2015b; Artzi et al., 2015;

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1215–1226
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1112

Damonte et al., 2017), but corpora are still under active development and low inter-annotator agreement places on upper bound of 83% F1 on expected parser performance (Banarescu et al., 2013). We apply our model to AMR parsing by introducing structure that is present explicitly in MRS but not in AMR (Buys and Blunsom, 2017).

Parsers based on RNNs have achieved state-of-the-art performance for dependency parsing (Dyer et al., 2015; Kiperwasser and Goldberg, 2016) and constituency parsing (Vinyals et al., 2015b; Dyer et al., 2016; Cross and Huang, 2016b). One of the main reasons for the prevalence of bilexical dependencies and tree-based representations is that they can be parsed with efficient and well-understood algorithms. However, one of the key advantages of deep learning is the ability to make predictions conditioned on unbounded contexts encoded with RNNs; this enables us to predict more complex structures without increasing algorithmic complexity. In this paper we show how to perform linguistically deep parsing with RNNs.

Our parser is based on a transition system for semantic graphs. However, instead of generating arcs over an ordered, fixed set of nodes (the words in the sentence), we generate the nodes and their alignments jointly with the transition actions. We use a graph-based variant of the arc-eager transition-system. The sentence is encoded with a bidirectional RNN. The transition sequence, seen as a graph linearization, can be predicted with any encoder-decoder model, but we show that using hard attention, predicting the alignments with a pointer network and conditioning explicitly on stack-based features improves performance. In order to deal with data sparsity candidate lemmas are predicted as a pre-processing step, so that the RNN decoder predicts unlexicalized node labels.

We evaluate our parser on DMRS, EDS and AMR graphs. We show that our model architecture improves performance from 79.68% to 84.16% F1 over an attention-based encoder-decoder baseline. Although our parser is less accurate that a high-precision grammar-based parser on a test set of sentences parsable by that grammar, incremental prediction and GPU batch processing enables it to parse 529 tokens per second, against 7 tokens per second for the grammar-based parser. On AMR parsing our model obtains 60.11% Smatch, an improvement of 8% over an existing neural AMR parser.

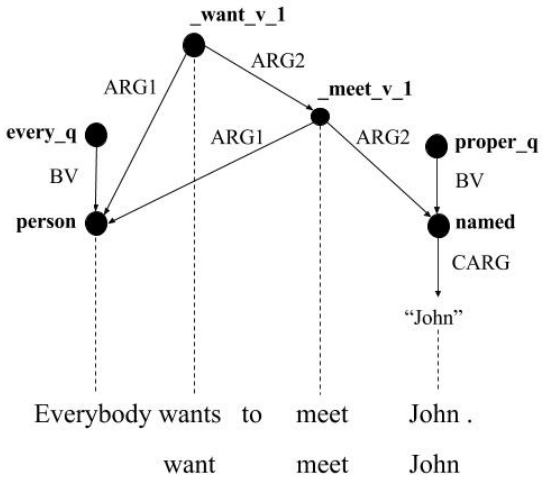

Figure 1: Semantic representation of the sentence "Everybody wants to meet John." The graph is based on the Elementary Dependency Structure (EDS) representation of Minimal Recursion Semantics (MRS). The alignments are given together with the corresponding tokens, and lemmas of surface predicates and constants.

2 Meaning Representations

We define a common framework for semantic graphs in which we can place both MRS-based graph representations (DMRS and EDS) and AMR. Sentence meaning is represented with rooted, labelled, connected, directed graphs (Kuhlmann and Oepen, 2016). An example graph is visualized in Figure 1. representations. Node labels are referred to as *predicates* (*concepts* in AMR) and edge labels as *arguments* (AMR *relations*). In addition *constants*, a special type of node modifiers, are used to denote the string values of named entities and numbers (including date and time expressions). Every node is aligned to a token or a continuous span of tokens in the sentence the graph corresponds to.

Minimal Recursion Semantics (MRS) is a framework for computational semantics that can be used for parsing or generation (Copestake et al., 2005). Instances and eventualities are represented with logical variables. Predicates take arguments with labels from a small, fixed set of roles. Arguments are either logical variables or handles, designated formalism-internal variables. Handle equality constraints support scope underspecification; multiple scope-resolved logical representations can be derived from one MRS structure. A predicate corresponds to its intrinsic argument

and is aligned to a character span of the (untokenized) input sentence. Predicates representing named entities or numbers are parameterized by strings. Quantification is expressed through predicates that bound instance variables, rather than through logical operators such as ∃ or ∀. MRS was designed to be integrated with feature-based grammars such as Head-driven Phrase Structure Grammar (HPSG) (Pollard and Sag, 1994) or Lexical Functional Grammar (LFG) (Kaplan and Bresnan, 1982). MRS has been implement the English Resource Grammar (ERG) (Flickinger, 2000), a broad-coverage high-precision HPSG grammar.

Oepen and Lønning (2006) proposed Elementary Dependency Structure (EDS), a conversion of MRS to variable-free dependency graphs which drops scope underspecification. Copestake (2009) extended this conversion to avoid information loss, primarily through richer edge labels. The resulting representation, Dependency MRS (DMRS), can be converted back to the original MRS, or used directly in MRS-based applications (Copestake et al., 2016). We are interested in the empirical performance of parsers for both of these representations: while EDS is more interpretable as an independent semantic graph representation, DMRS can be related back to underspecified logical forms. A bilexical simplification of EDS has previously been used for semantic dependency parsing (Oepen et al., 2014, 2015). Figure 1 illustrates an EDS graph.

MRS makes an explicit distinction between surface and abstract predicates (by convention surface predicates are prefixed by an underscore). Surface predicates consist of a lemma followed by a coarse part-of-speech tag and an optional sense label. Predicates absent from the ERG lexicon are represented by their surface forms and POS tags. We convert the character-level predicate spans given by MRS to token-level spans for parsing purposes, but the representation does not require gold tokenization. Surface predicates usually align with the span of the token(s) they represent, while abstract predicates can span longer segments. In full MRS every predicate is annotated with a set of morphosyntactic features, encoding for example tense, aspect and number information; we do not currently model these features.

AMR (Banarescu et al., 2013) graphs can be represented in the same framework, despite a number of linguistic differences with MRS. Some information annotated explicitly in MRS is latent in AMR, including alignments and the distinction between surface (lexical) and abstract concepts. AMR predicates are based on PropBank (Palmer et al., 2005), annotated as lemmas plus sense labels, but they form only a subset of concepts. Other concepts are either English words or special keywords, corresponding to overt lexemes in some cases but not others.

      :BV-of ( <5> proper_q ) ) )
```

Figure 2: A top-down linearization of the EDS graph in Figure 1, using unlexicalized predicates.

3 Incremental Graph Parsing

We parse sentences to their meaning representations by incrementally predicting semantic graphs together with their alignments. Let $\mathbf{e} = e_1, e_2, \ldots, e_I$ be a tokenized English sentence, $\mathbf{t} = t_1, t_2, \ldots, t_J$ a sequential representation of its graph derivation and $\mathbf{a} = a_1, a_2, \ldots, a_J$ an alignment sequence consisting of integers in the range $1, \ldots, I$. We model the conditional distribution $p(\mathbf{t}, \mathbf{a}|\mathbf{e})$ which decomposes as

$$\prod_{j=1}^{J} p(a_j|(\mathbf{a}, \mathbf{t})_{1:j-1}, \mathbf{e}) p(t_j|\mathbf{a}_{1:j}, \mathbf{t}_{1:j-1}, \mathbf{e}).$$

We also predict the end-of-span alignments as a seperate sequence $\mathbf{a}^{(\mathbf{e})}$.

3.1 Top-down linearization

We now consider how to linearize the semantic graphs, before defining the neural models to parameterize the parser in section 4. The first approach is to linearize a graph as the pre-order traversal of its spanning tree, starting at a designated root node (see Figure 2). Variants of this approach have been proposed for neural constituency parsing (Vinyals et al., 2015b), logical form prediction (Dong and Lapata, 2016; Jia and Liang, 2016) and AMR parsing (Barzdins and Gosko, 2016; Peng et al., 2017).

In the linearization, labels of edges whose direction are reversed in the spanning tree are marked

by adding `-of`. Edges not included in the spanning tree, referred to as *reentrancies*, are represented with special edges whose dependents are dummy nodes pointing back to the original nodes. Our potentially lossy representation represents these edges by repeating the dependent node labels and alignments, which are recovered heuristically. The alignment does not influence the linearized node ordering.

3.2 Transition-based parsing

Figure 1 shows that the semantic graphs we work with can also be interpreted as dependency graphs, as nodes are aligned to sentence tokens. Transition-based parsing (Nivre, 2008) has been used extensively to predict dependency graphs incrementally. We apply a variant of the arc-eager transition system that has been proposed for graph (as opposed to tree) parsing (Sagae and Tsujii, 2008; Titov et al., 2009; Gómez-Rodríguez and Nivre, 2010) to derive a transition-based parser for deep semantic graphs. In dependency parsing the sentence tokens also act as nodes in the graph, but here we need to generate the nodes incrementally as the transition-system proceeds, conditioning the generation on the given sentence. Damonte et al. (2017) proposed an arc-eager AMR parser, but their transition system is more narrowly restricted to AMR graphs.

The transition system consists of a *stack* of graph nodes being processed and a *buffer*, holding a single node at a time. The main transition actions are *shift*, *reduce*, *left-arc*, *right-arc*. Figure 3 shows an example transition sequence together with the stack and buffer after each step. The shift transition moves the element on the buffer to the top of the stack, and generates a predicate and its alignment as the next node on the buffer. Left-arc and right-arc actions add labeled arcs between the buffer and stack top (for DMRS a transition for undirected arcs is included), but do not change the state of the stack or buffer. Finally, reduce pops the top element from the stack, and predicts its end-of-span alignment (if included in the representation). To predict non-planar arcs, we add another transition, which we call *cross-arc*, which first predicts the stack index of a node which is not on top of the stack, adding an arc between the head of the buffer and that node. Another special transition designates the buffer node as the root.

To derive an oracle for this transition system, it is necessary to determine the order in which the nodes are generated. We consider two approaches. The first ordering is obtained by performing an in-order traversal of the spanning tree, where the node order is determined by the alignment. In the resulting linearization the only non-planar arcs are reentrancies. The second approach lets the ordering be monotone (non-decreasing) with respect to the alignments, while respecting the in-order ordering for nodes with the same alignment. In an arc-eager oracle arcs are added greedily, while a reduce action can either be performed as soon as the stack top node has been connected to all its dependents, or delayed until it has to reduce to allow the correct parse tree to be formed. In our model the oracle delays reduce, where possible, until the end alignment of the stack top node spans the node on the buffer. As the span end alignments often cover phrases that they head (e.g. for quantifiers) this gives a natural interpretation to predicting the span end together with the reduce action.

3.3 Delexicalization and lemma prediction

Each token in MRS annotations is aligned to at most one surface predicate. We decompose surface predicate prediction by predicting candidate lemmas for input tokens, and delexicalized predicates consisting only of sense labels. The full surface predicates are then recovered through the predicted alignments.

We extract a dictionary mapping words to lemmas from the ERG lexicon. Candidate lemmas are predicted using this dictionary, and where no dictionary entry is available with a lemmatizer. The same approach is applied to predict constants, along with additional normalizations such as mapping numbers to digit strings.

We use the Stanford CoreNLP toolkit (Manning et al., 2014) to tokenize and lemmatize sentences, and tag tokens with the Stanford Named Entity Recognizer (Finkel et al., 2005). The tokenization is customized to correspond closely to the ERG tokenization; hyphens are removed pre-processing step. For AMR we use automatic alignments and the graph topology to classify concepts as surface or abstract (Buys and Blunsom, 2017). The lexicon is restricted to Propbank (Palmer et al., 2005) predicates; for other concepts we extract a lexicon from the training data.

Action	Stack	Buffer	Arc added
init(1, person)	[ ]	(1, 1, person)	-
sh(1, every_q)	[(1, 1, person)]	(2, 1, every_q)	-
la(BV)	[(1, 1, person)]	(2, 1, every_q)	(2, BV, 1)
sh(2, _v_1)	[(1, 1, person), (2, 1, every_q)]	(2, 1, _v_1)	-
re	[(1, 1, person)]	(3, 2, _v_1)	-
la(ARG1)	[(1, 1, person)]	(3, 2, _v_1)	(3, ARG1, 1)

Figure 3: Start of the transition sequence for parsing the graph in Figure 1. The transitions are shift (`sh`), reduce (`re`), left arc (`la`) and right arc (`ra`). The action taken at each step is given, along with the state of the stack and buffer after the action is applied, and any arcs added. Shift transitions generate the alignments and predicates of the nodes placed on the buffer. Items on the stack and buffer have the form (*node index, alignment, predicate label*), and arcs are of the form (*head index, argument label, dependent index*).

4 Encoder-Decoder Models

4.1 Sentence encoder

The sentence $\mathbf{e}$ is encoded with a bidirectional RNN. We use a standard LSTM architecture without peephole connections (Jozefowicz et al., 2015). For every token e we embed its word, POS tag and named entity (NE) tag as vectors x_w, x_t and x_n, respectively.

The embeddings are concatenated and passed through a linear transformation

$$g(e) = W^{(x)}[x_w; x_t; x_n] + b^x,$$

such that $g(e)$ has the same dimension as the LSTM. Each input position i is represented by a hidden state h_i, which is the concatenation of its forward and backward LSTM state vectors.

4.2 Hard attention decoder

We model the alignment of graph nodes to sentence tokens, $\mathbf{a}$, as a random variable. For the arc-eager model, a_j corresponds to the alignment of the node of the buffer after action t_j is executed. The distribution of t_j is over all transitions and predicates (corresponding to shift transitions), predicted with a single softmax.

The parser output is predicted by an RNN decoder. Let s_j be the decoder hidden state at output position j. We initialize s_0 with the final state of the backward encoder. The alignment is predicted with a pointer network (Vinyals et al., 2015a).

The logits are computed with an MLP scoring the decoder hidden state against each of the encoder hidden states (for $i = 1, \ldots, I$),

$$u_j^i = w^T \tanh(W^{(1)}h_i + W^{(2)}s_j).$$

The alignment distribution is then estimated by

$$p(a_j = i|\mathbf{a}_{1:j-1}, \mathbf{t}_{1:j-1}, \mathbf{e}) = \text{softmax}(u_j^i).$$

To predict the next transition t_i, the output vector is conditioned on the encoder state vector h_{a_j}, corresponding to the alignment:

$$o_j = W^{(3)}s_j + W^{(4)}h_{a_j}$$
$$v_j = R^{(d)}o_j + b^{(d)},$$

where $R^{(d)}$ and $b^{(d)}$ are the output representation matrix and bias vector, respectively.

The transition distribution is then given by

$$p(t_j|\mathbf{a}_{1:j}, \mathbf{t}_{1:j-1}, \mathbf{e}) = \text{softmax}(v_j).$$

Let $e(t)$ be the embedding of decoder symbol t. The RNN state at the next time-step is computed as

$$d_{j+1} = W^{(5)}e(t_j) + W^{(6)}h_{a_j}$$
$$s_{j+1} = RNN(d_{j+1}, s_j).$$

The end-of-span alignment $a_j^{(e)}$ for MRS-based graphs is predicted with another pointer network. The end alignment of a token is predicted only when a node is reduced from the stack, therefore this alignment is not observed at each time-step; it is also not fed back into the model.

The hard attention approach, based on supervised alignments, can be contrasted to soft attention, which learns to attend over the input without supervision. The attention is computed as with hard attention, as $\alpha_j^i = \text{softmax}(u_j^i)$. However instead of making a hard selection, a weighted average over the encoder vectors is computed as $q_j = \sum_{i=1}^{i=I} \alpha_j^i h_i$. This vector is used instead of h_{a_j} for prediction and feeding to the next time-step.

4.3 Stack-based model

We extend the hard attention model to include features based on the transition system stack. These features are embeddings from the bidirectional RNN encoder, corresponding to the alignments of the nodes on the buffer and on top of the stack. This approach is similar to the features proposed by Kiperwasser and Goldberg (2016) and Cross and Huang (2016a) for dependency parsing, although they do not use RNN decoders.

To implement these features the layer that computes the output vector is extended to

$$o_j = W^{(3)} s_j + W^{(4)} h_{a_j} + W^{(7)} h_{\mathtt{st}_0},$$

where $\mathtt{st}_0$ is the sentence alignment index of the element on top of the stack. The input layer to the next RNN time-step is similarly extended to

$$d_{j+1} = W^{(5)} e(t_j) + W^{(6)} h_{\mathtt{buf}} + W^{(8)} h_{\mathtt{st}_0},$$

where `buf` is the buffer alignment after t_j is executed.

Our implementation of the stack-based model enables batch processing in static computation graphs, similar to Bowman et al. (2016). We maintain a stack of alignment indexes for each element in the batch, which is updated inside the computation graph after each parsing action. This enables minibatch SGD during training as well as efficient batch decoding.

We perform greedy decoding. For the stack-based model we ensure that if the stack is empty, the next transition predicted has to be shift. For the other models we ensure that the output is well-formed during post-processing by robustly skipping over out-of-place symbols or inserting missing ones.

5 Related Work

Prior work for MRS parsing predominantly predicts structures in the context of grammar-based parsing, where sentences are parsed to HPSG derivations consistent with the grammar, in this case the ERG (Flickinger, 2000). The nodes in the derivation trees are feature structures, from which MRS is extracted through unification. This approach fails to parse sentences for which no valid derivation is found. Maximum entropy models are used to score the derivations in order to find the most likely parse (Toutanova et al., 2005). This approach is implemented in the PET (Callmeier, 2000) and ACE[1] parsers.

There have also been some efforts to develop robust MRS parsers. One proposed approach learns a PCFG grammar to approximate the HPSG derivations (Zhang and Krieger, 2011; Zhang et al., 2014). MRS is then extracted with robust unification to compose potentially incompatible feature structures, although that still fails for a small proportion of sentences. The model is trained on a large corpus of Wikipedia text parsed with the grammar-based parser. Ytrestøl (2012) proposed a transition-based approach to HPSG parsing that produces derivations from which both syntactic and semantic (MRS) parses can be extracted. The parser has an option not to be restricted by the ERG. However, neither of these approaches have results available that can be compared directly to our setup, or generally available implementations.

Although AMR parsers produce graphs that are similar in structure to MRS-based graphs, most of them make assumptions that are invalid for MRS, and rely on extensive external AMR-specific resources. Flanigan et al. (2014) proposed a two-stage parser that first predicts concepts or subgraphs corresponding to sentence segments, and then parses these concepts into a graph structure. However MRS has a large proportion of abstract nodes that cannot be predicted from short segments, and interact closely with the graph structure. Wang et al. (2015b,a) proposed a custom transition-system for AMR parsing that converts dependency trees to AMR graphs, relying on assumptions on the relationship between these. Pust et al. (2015) proposed a parser based on syntax-based machine translation (MT), while AMR has also been integrated into CCG Semantic Parsing (Artzi et al., 2015; Misra and Artzi, 2016). Recently Damonte et al. (2017) and Peng et al. (2017) proposed AMR parsers based on neural networks.

6 Experiments

6.1 Data

DeepBank (Flickinger et al., 2012) is an HPSG and MRS annotation of the Penn Treebank Wall Street Journal (WSJ) corpus. It was developed following an approach known as dynamic treebanking (Oepen et al., 2004) that couples treebank annotation with grammar development, in this case

[1] http://sweaglesw.org/linguistics/ace/

of the ERG. This approach has been shown to lead to high inter-annotator agreement: 0.94 against 0.71 for AMR (Bender et al., 2015). Parses are only provided for sentences for which the ERG has an analysis acceptable to the annotator – this means that we cannot evaluate parsing accuracy for sentences which the ERG cannot parse (approximately 15% of the original corpus).

We use Deepbank version 1.1, corresponding to ERG 1214[2], following the suggested split of sections 0 to 19 as training data data, 20 for development and 21 for testing. The gold-annotated training data consists of 35,315 sentences. We use the LOGON environment[3] and the pyDelphin library[4] to extract DMRS and EDS graphs.

For AMR parsing we use LDC2015E86, the dataset released for the SemEval 2016 AMR parsing Shared Task (May, 2016). This data includes newswire, weblog and discussion forum text. The training set has 16,144 sentences. We obtain alignments using the rule-based JAMR aligner (Flanigan et al., 2014).

6.2 Evaluation

Dridan and Oepen (2011) proposed an evaluation metric called Elementary Dependency Matching (EDM) for MRS-based graphs. EDM computes the F1-score of tuples of predicates and arguments. A predicate tuple consists of the label and character span of a predicate, while an argument tuple consists of the character spans of the head and dependent nodes of the relation, together with the argument label. In order to tolerate subtle tokenization differences with respect to punctuation, we allow span pairs whose ends differ by one character to be matched.

The Smatch metric (Cai and Knight, 2013), proposed for evaluating AMR graphs, also measures graph overlap, but does not rely on sentence alignments to determine the correspondences between graph nodes. Smatch is instead computed by performing inference over graph alignments to estimate the maximum F1-score obtainable from a one-to-one matching between the predicted and gold graph nodes.

Table 1: DMRS development set results for attention-based encoder-decoder models with alignments encoded in the linearization, for top-down (TD) and arc-eager (AE) linearizations, and lexicalized and unlexicalized predicate prediction.

6.3 Model setup

Our parser[5] is implemented in TensorFlow (Abadi et al., 2015). For training we use Adam (Kingma and Ba, 2015) with learning rate 0.01 and batch-size 64. Gradients norms are clipped to 5.0 (Pascanu et al., 2013). We use single-layer LSTMs with dropout of 0.3 (tuned on the development set) on input and output connections. We use encoder and decoder embeddings of size 256, and POS and NE tag embeddings of size 32, For DMRS and EDS graphs the hidden units size is set to 256, for AMR it is 128. This configuration, found using grid search and heuristic search within the range of models that fit into a single GPU, gave the best performance on the development set under multiple graph linearizations. Encoder word embeddings are initialized (in the first 100 dimensions) with pre-trained order-sensitive embeddings (Ling et al., 2015). Singletons in the encoder input are replaced with an unknown word symbol with probability 0.5 for each iteration.

6.4 MRS parsing results

We compare different linearizations and model architectures for parsing DMRS on the development data, showing that our approach is more accurate than baseline neural approaches. We report EDM scores, including scores for predicate (EDM$_P$) and argument (EDM$_A$) prediction.

First we report results using standard attention-based encoder-decoders, with the alignments encoded as token strings in the linearization. (Table 1). We compare the top-down (TD) and arc-eager (AE) linearizations, as well as the effect of delexicalizing the predicates (factorizing lemmas out of the linearization and predicting them sepa-

Model	EDM	EDM_P	EDM_A
TD soft	81.53	85.32	76.94
TD hard	82.75	86.37	78.37
AE hard	84.65	87.77	80.85
AE stack	85.28	88.38	81.51

Table 2: DMRS development set results of encoder-decoder models with pointer-based alignment prediction, delexicalized predicates and hard or soft attention.

rately.) In both cases constants are predicted with a dictionary lookup based on the predicted spans. A special label is predicted for predicates not in the ERG lexicon – the words and POS tags that make up those predicates are recovered through the alignments during post-processing.

The arc-eager unlexicalized representation gives the best performance, even though the model has to learn to model the transition system stack through the recurrent hidden states without any supervision of the transition semantics. The unlexicalized models are more accurate, mostly due to their ability to generalize to sparse or unseen predicates occurring in the lexicon. For the arc-eager representation, the oracle EDM is 99% for the lexicalized representation and 98.06% for the delexicalized representation. The remaining errors are mostly due to discrepancies between the tokenization used by our system and the ERG tokenization. The unlexicalized models are also faster to train, as the decoder's output vocabulary is much smaller, reducing the expense of computing softmaxes over large vocabularies.

Next we consider models with delexicalized linearizations that predict the alignments with pointer networks, contrasting soft and hard attention models (Table 2). The results show that the arc-eager models performs better than those based on top-down representation. For the arc-eager model we use hard attention, due to the natural interpretation of the alignment prediction corresponding to the transition system. The stack-based architecture gives further improvements.

When comparing the effect of different predicate orderings for the arc-eager model, we find that the monotone ordering performs 0.44 EDM better than the in-order ordering, despite having to parse more non-planar dependencies.

We also trained models that only predict predicates (in monotone order) together with their start spans. The hard attention model obtains 91.36% F1 on predicates together with their start spans with the unlexicalized model, compared to 88.22% for lexicalized predicates and 91.65% for the full parsing model.

Model	TD RNN	AE RNN	ACE
EDM	79.68	84.16	89.64
EDM_P	83.36	87.54	92.08
EDM_A	75.16	80.10	86.77
Start EDM	84.44	87.81	91.91
Start EDM_A	80.93	85.61	89.28
Smatch	85.28	86.69	93.50

Table 3: DMRS parsing test set results, comparing the standard top-down attention-based and arc-eager stack-based RNN models to the grammar-based ACE parser.

Table 3 reports test set results for various evaluation metrics. Start EDM is calculated by requiring only the start of the alignment spans to match, not the ends. We compare the performance of our baseline and stack-based models against ACE, the ERG-based parser.

Despite the promising performance of the model a gap remains between the accuracy of our parser and ACE. One reason for this is that the test set sentences will arguably be easier for ACE to parse as their choice was restricted by the same grammar that ACE uses. EDM metrics excluding end-span prediction (Start EDM) show that our parser has relatively more difficulty in parsing end-span predictions than the grammar-based parser.

We also evaluate the speed of our model compared with ACE. For the unbatched version of our model, the stack-based parser parses 41.63 tokens per second, while the batched implementation parses 529.42 tokens per second using a batch size of 128. In comparison, the setting of ACE for which we report accuracies parses 7.47 tokens per second. By restricting the memory usage of ACE, which restricts its coverage, we see that ACE can parse 11.07 tokens per second at 87.7% coverage, and 15.11 tokens per second at 77.8% coverage.

Finally we report results for parsing EDS (Table 4). The EDS parsing task is slightly simpler than DMRS, due to the absence of rich argument labels and additional graph edges that allow the recovery of full MRS. We see that for ACE the accuracies are very similar, while for our model EDS

Model	AE RNN	ACE

AE hard unlex	76.83	59.83
AE stack unlex	77.93	61.21

Table 5: Development set results for AMR parsing. All the models except the first predict alignments with pointer networks.

parsing is more accurate on the EDM metrics. We hypothesize that most of the extra information in DMRS can be obtained through the ERG, to which ACE has access but our model doesn't.

An EDS corpus which consists of about 95% of the DeepBank data has also been released[6], with the goal of enabling comparison with other semantic graph parsing formalisms, including CCG dependencies and Prague Semantic Dependencies, on the same data set (Kuhlmann and Oepen, 2016). On this corpus our model obtains 85.87 EDM and 85.49 Smatch.

6.5 AMR parsing

We apply the same approach to AMR parsing. Results on the development set are given in Table 5. The arc-eager-based models again give better performance, mainly due to improved concept prediction accuracy. However, concept prediction remains the most important weakness of the model; Damonte et al. (2017) reports that state-of-the-art AMR parsers score 83% on concept prediction.

We report test set results in Table 6. Our best neural model outperforms the baseline JAMR parser (Flanigan et al., 2014), but still lags behind the performance of state-of-the-art AMR parsers such as CAMR (Wang et al., 2016) and AMR Eager (Damonte et al., 2017). These models make extensive use of external resources, including syntactic parsers and semantic role labellers. Our attention-based encoder-decoder model already outperforms previous sequence-to-sequence

AMR parsers (Barzdins and Gosko, 2016; Peng et al., 2017), and the arc-eager model boosts accuracy further. Our model also outperforms a Synchronous Hyperedge Replacement Grammar model (Peng and Gildea, 2016) which is comparable as it does not make extensive use of external resources.

7 Conclusion

In this paper we advance the state of parsing by employing deep learning techniques to parse sentence to linguistically expressive semantic representations that have not previously been parsed in an end-to-end fashion. We presented a robust, wide-coverage parser for MRS that is faster than existing parsers and amenable to batch processing. We believe that there are many future avenues to explore to further increase the accuracy of such parsers, including different training objectives, more structured architectures and semi-supervised learning.

Abstract

Joint extraction of entities and relations is an important task in information extraction. To tackle this problem, we firstly propose a novel tagging scheme that can convert the joint extraction task to a tagging problem. Then, based on our tagging scheme, we study different end-to-end models to extract entities and their relations directly, without identifying entities and relations separately. We conduct experiments on a public dataset produced by distant supervision method and the experimental results show that the tagging based methods are better than most of the existing pipelined and joint learning methods. What's more, the end-to-end model proposed in this paper, achieves the best results on the public dataset.

1 Introduction

Joint extraction of entities and relations is to detect entity mentions and recognize their semantic relations simultaneously from unstructured text, as Figure 1 shows. Different from open information extraction (Open IE) (Banko et al., 2007) whose relation words are extracted from the given sentence, in this task, relation words are extracted from a predefined relation set which may not appear in the given sentence. It is an important issue in knowledge extraction and automatic construction of knowledge base.

Traditional methods handle this task in a pipelined manner, i.e., extracting the entities (Nadeau and Sekine, 2007) first and then recognizing their relations (Rink, 2010). This separated framework makes the task easy to deal with, and each component can be more flexible. But it neglects the relevance between these two sub-tasks and each subtask is an independent model. The results of entity recognition may affect the performance of relation classification and lead to erroneous delivery (Li and Ji, 2014).

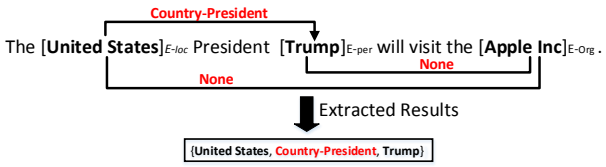

Figure 1: A standard example sentence for the task. "Country-President" is a relation in the predefined relation set.

Different from the pipelined methods, joint learning framework is to extract entities together with relations using a single model. It can effectively integrate the information of entities and relations, and it has been shown to achieve better results in this task. However, most existing joint methods are feature-based structured systems (Li and Ji, 2014; Miwa and Sasaki, 2014; Yu and Lam, 2010; Ren et al., 2017). They need complicated feature engineering and heavily rely on the other NLP toolkits, which might also lead to error propagation. In order to reduce the manual work in feature extraction, recently, (Miwa and Bansal, 2016) presents a neural network-based method for the end-to-end entities and relations extraction. Although the joint models can represent both entities and relations with shared parameters in a single model, they also extract the entities and relations separately and produce redundant information. For instance, the sentence in Figure 1 contains three entities: "United States", "Trump" and "Apple Inc". But only "United States" and "Trump" hold a fix relation "Country-President". Entity "Apple Inc" has no obvious relationship with the other entities in this sen-

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1227–1236
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1113

tence. Hence, the extracted result from this sentence is {**United States**$_{e1}$, **Country-President**$_{r}$, **Trump**$_{e2}$}, which called triplet here.

In this paper, we focus on the extraction of triplets that are composed of two entities and one relation between these two entities. Therefore, we can model the triplets directly, rather than extracting the entities and relations separately. Based on the motivations, we propose a tagging scheme accompanied with the end-to-end model to settle this problem. We design a kind of novel tags which contain the information of entities and the relationships they hold. Based on this tagging scheme, the joint extraction of entities and relations can be transformed into a tagging problem. In this way, we can also easily use neural networks to model the task without complicated feature engineering.

Recently, end-to-end models based on LSTM (Hochreiter and Schmidhuber, 1997) have been successfully applied to various tagging tasks: Named Entity Recognition (Lample et al., 2016), CCG Supertagging (Vaswani et al., 2016), Chunking (Zhai et al., 2017) et al. LSTM is capable of learning long-term dependencies, which is beneficial to sequence modeling tasks. Therefore, based on our tagging scheme, we investigate different kinds of LSTM-based end-to-end models to jointly extract the entities and relations. We also modify the decoding method by adding a biased loss to make it more suitable for our special tags.

The method we proposed is a supervised learning algorithm. In reality, however, the process of manually labeling a training set with a large number of entity and relation is too expensive and error-prone. Therefore, we conduct experiments on a public dataset[1] which is produced by distant supervision method (Ren et al., 2017) to validate our approach. The experimental results show that our tagging scheme is effective in this task. In addition, our end-to-end model can achieve the best results on the public dataset.

The major contributions of this paper are: (1) A novel tagging scheme is proposed to jointly extract entities and relations, which can easily transform the extraction problem into a tagging task. (2) Based on our tagging scheme, we study different kinds of end-to-end models to settle the problem. The tagging-based methods are better than most of the existing pipelined and joint learning methods. (3) Furthermore, we also develop an end-to-end model with biased loss function to suit for the novel tags. It can enhance the association between related entities.

2 Related Works

Entities and relations extraction is an important step to construct a knowledge base, which can be benefit for many NLP tasks. Two main frameworks have been widely used to solve the problem of extracting entity and their relationships. One is the pipelined method and the other is the joint learning method.

The pipelined method treats this task as two separated tasks, i.e., named entity recognition (NER) (Nadeau and Sekine, 2007) and relation classification (RC) (Rink, 2010). Classical NER models are linear statistical models, such as Hidden Markov Models (HMM) and Conditional Random Fields (CRF) (Passos et al., 2014; Luo et al., 2015). Recently, several neural network architectures (Chiu and Nichols, 2015; Huang et al., 2015; Lample et al., 2016) have been successfully applied to NER, which is regarded as a sequential token tagging task. Existing methods for relation classification can also be divided into handcrafted feature based methods (Rink, 2010; Kambhatla, 2004) and neural network based methods (Xu, 2015a; Zheng et al., 2016; Zeng, 2014; Xu, 2015b; dos Santos, 2015).

While joint models extract entities and relations using a single model. Most of the joint methods are feature-based structured systems (Ren et al., 2017; Yang and Cardie, 2013; Singh et al., 2013; Miwa and Sasaki, 2014; Li and Ji, 2014). Recently, (Miwa and Bansal, 2016) uses a LSTM-based model to extract entities and relations, which can reduce the manual work.

Different from the above methods, the method proposed in this paper is based on a special tagging manner, so that we can easily use end-to-end model to extract results without NER and RC. end-to-end method is to map the input sentence into meaningful vectors and then back to produce a sequence. It is widely used in machine translation (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014) and sequence tagging tasks (Lample et al., 2016; Vaswani et al., 2016). Most methods apply bidirectional LSTM to encode the input sentences, but the decoding methods are always different. For examples, (Lample et al., 2016) use a CRF layers to decode the tag sequence, while

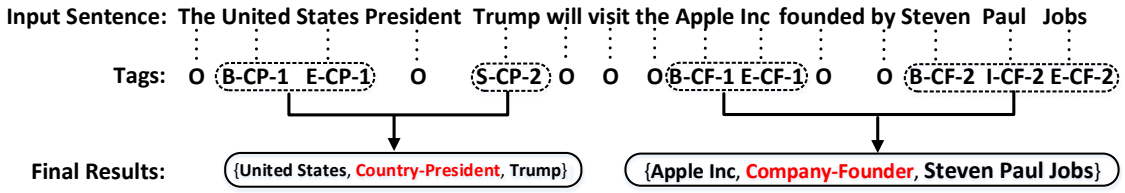

Figure 2: Gold standard annotation for an example sentence based on our tagging scheme, where "CP" is short for "Country-President" and "CF" is short for "Company-Founder".

(Vaswani et al., 2016; Katiyar and Cardie, 2016) apply LSTM layer to produce the tag sequence.

3 Method

We propose a novel tagging scheme and an end-to-end model with biased objective function to jointly extract entities and their relations. In this section, we firstly introduce how to change the extraction problem to a tagging problem based on our tagging method. Then we detail the model we used to extract results.

3.1 The Tagging Scheme

Figure 2 is an example of how the results are tagged. Each word is assigned a label that contributes to extract the results. Tag "O" represents the "Other" tag, which means that the corresponding word is independent of the extracted results. In addition to "O", the other tags consist of three parts: the word position in the entity, the relation type, and the relation role. We use the "BIES" (Begin, Inside, End,Single) signs to represent the position information of a word in the entity. The relation type information is obtained from a predefined set of relations and the relation role information is represented by the numbers "1" and "2". An extracted result is represented by a triplet: $(Entity_1, RelationType, Entity_2)$. "1" means that the word belongs to the first entity in the triplet, while "2" belongs to second entity that behind the relation type. Thus, the total number of tags is $N_t = 2 * 4 * |R| + 1$, where $|R|$ is the size of the predefined relation set.

Figure 2 is an example illustrating our tagging method. The input sentence contains two triplets: {**United States, Country-President, Trump**} and {**Apple Inc, Company-Founder, Steven Paul Jobs**}, where "Country-President" and "Company-Founder" are the predefined relation types. The words "United","States"," Trump","Apple","Inc" ,"Steven", "Paul" and "Jobs" are all related to the final extracted results. Thus they are tagged based on our special tags. For example, the word of "United" is the first word of entity "United States" and is related to the relation "Country-President", so its tag is "B-CP-1". The other entity " Trump", which is corresponding to "United States", is labeled as "S-CP-2". Besides, the other words irrelevant to the final result are labeled as "O".

3.2 From Tag Sequence To Extracted Results

From the tag sequence in Figure 2, we know that " Trump" and "United States" share the same relation type "Country-President", "Apple Inc" and "Steven Paul Jobs" share the same relation type "Company-Founder". We combine entities with the same relation type into a triplet to get the final result. Accordingly, " Trump" and "United States" can be combined into a triplet whose relation type is "Country-President". Because, the relation role of " Trump" is "2" and "United States" is "1", the final result is {**United States, Country-President, Trump**}. The same applies to {**Apple Inc, Company-Founder, Steven Paul Jobs**}.

Besides, if a sentence contains two or more triplets with the same relation type, we combine every two entities into a triplet based on the nearest principle. For example, if the relation type "Country-President" in Figure 2 is "Company-Founder", then there will be four entities in the given sentence with the same relation type. "United States" is closest to entity " Trump" and the "Apple Inc" is closest to "Jobs", so the results will be {**United States, Company-Founder, Trump**} and {**Apple Inc, Company-Founder, Steven Paul Jobs**}.

In this paper, we only consider the situation where an entity belongs to a triplet, and we leave identification of overlapping relations for future work.

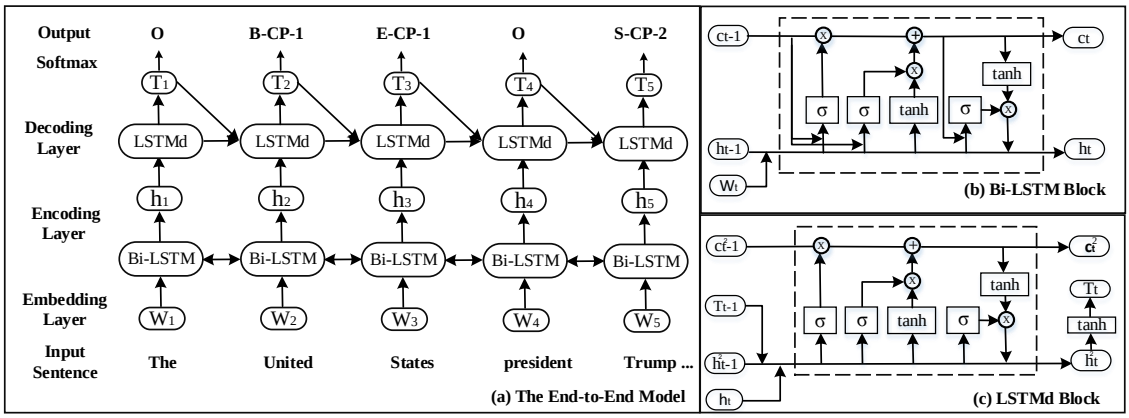

Figure 3: An illustration of our model. (a): The architecture of the end-to-end model, (b): The LSTM memory block in Bi-LSTM encoding layer, (c): The LSTM memory block in LSTM$_d$ decoding layer.

3.3 The End-to-end Model

In recent years, end-to-end model based on neural network is been widely used in sequence tagging task. In this paper, we investigate an end-to-end model to produce the tags sequence as Figure 3 shows. It contains a bi-directional Long Short Term Memory (Bi-LSTM) layer to encode the input sentence and a LSTM-based decoding layer with biased loss. The biased loss can enhance the relevance of entity tags.

The Bi-LSTM Encoding Layer. In sequence tagging problems, the Bi-LSTM encoding layer has been shown the effectiveness to capture the semantic information of each word. It contains forward lstm layer, backward lstm layer and the concatenate layer. The word embedding layer converts the word with 1-hot representation to an embedding vector. Hence, a sequence of words can be represented as $W = \{w_1, ...w_t, w_{t+1}...w_n\}$, where $w_t \in \mathbb{R}^d$ is the d-dimensional word vector corresponding to the t-th word in the sentence and n is the length of the given sentence. After word embedding layer, there are two parallel LSTM layers: forward LSTM layer and backward LSTM layer. The LSTM architecture consists of a set of recurrently connected subnets, known as memory blocks. Each time-step is a LSTM memory block. The LSTM memory block in Bi-LSTM encoding layer is used to compute current hidden vector h_t based on the previous hidden vector h_{t-1}, the previous cell vector c_{t-1} and the current input word embedding w_t. Its structure diagram is shown in Figure 3 (b), and detail operations are defined as follows:

$$i_t = \delta(W_{wi}w_t + W_{hi}h_{t-1} + W_{ci}c_{t-1} + b_i), \quad (1)$$

$$f_t = \delta(W_{wf}w_t + W_{hf}h_{t-1} + W_{cf}c_{t-1} + b_f), \quad (2)$$

$$z_t = tanh(W_{wc}w_t + W_{hc}h_{t-1} + b_c), \quad (3)$$

$$c_t = f_t c_{t-1} + i_t z_t, \quad (4)$$

$$o_t = \delta(W_{wo}w_t + W_{ho}h_{t-1} + W_{co}c_t + b_o), \quad (5)$$

$$h_t = o_t tanh(c_t), \quad (6)$$

where i, f and o are the input gate, forget gate and output gate respectively, b is the bias term, c is the cell memory, and $W_{(.)}$ are the parameters. For each word w_t, the forward LSTM layer will encode w_t by considering the contextual information from word w_1 to w_t, which is marked as $\overrightarrow{h_t}$. In the similar way, the backward LSTM layer will encode w_t based on the contextual information from w_n to w_t, which is marked as $\overleftarrow{h_t}$. Finally, we concatenate $\overleftarrow{h_t}$ and $\overrightarrow{h_t}$ to represent word t's encoding information, denoted as $h_t = [\overrightarrow{h_t}, \overleftarrow{h_t}]$.

The LSTM Decoding Layer. We also adopt a LSTM structure to produce the tag sequence. When detecting the tag of word w_t, the inputs of decoding layer are: h_t obtained from Bi-LSTM encoding layer, former predicted tag embedding T_{t-1}, former cell value $c^{(2)}_{t-1}$, and the former hidden vector in decoding layer $h^{(2)}_{t-1}$. The structure diagram of the memory block in LSTM$_d$ is shown in Figure 3 (c), and detail operations are defined as follows:

$$i^{(2)}_t = \delta(W^{(2)}_{wi}h_t + W^{(2)}_{hi}h^{(2)}_{t-1} + W_{ti}T_{t-1} + b^{(2)}_i), \quad (7)$$

$$f_t^{(2)} = \delta(W_{wf}^{(2)} h_t + W_{hf}^{(2)} h_{t-1}^{(2)} + W_{tf} T_{t-1} + b_f^{(2)}), \tag{8}$$

$$z_t^{(2)} = tanh(W_{wc}^{(2)} h_t + W_{hc}^{(2)} h_{t-1}^{(2)} + W_{tc} T_{t-1} + b_c^{(2)}), \tag{9}$$

$$c_t^{(2)} = f_t^{(2)} c_{t-1}^{(2)} + i_t^{(2)} z_t^{(2)}, \tag{10}$$

$$o_t^{(2)} = \delta(W_{wo}^{(2)} h_t + W_{ho}^{(2)} h_{t-1}^{(2)} + W_{co}^{(2)} c_t + b_o^{(2)}), \tag{11}$$

$$h_t^{(2)} = o_t^{(2)} tanh(c_t^{(2)}), \tag{12}$$

$$T_t = W_{ts} h_t^{(2)} + b_{ts}. \tag{13}$$

The final softmax layer computes normalized entity tag probabilities based on the tag predicted vector T_t:

$$y_t = W_y T_t + b_y, \tag{14}$$

$$p_t^i = \frac{exp(y_t^i)}{\sum_{j=1}^{N_t} exp(y_t^j)}, \tag{15}$$

where W_y is the softmax matrix, N_t is the total number of tags. Because T is similar to tag embedding and LSTM is capable of learning long-term dependencies, the decoding manner can model tag interactions.

The Bias Objective Function. We train our model to maximize the log-likelihood of the data and the optimization method we used is RMSprop proposed by Hinton in (Tieleman and Hinton, 2012). The objective function can be defined as:

$$L = max \sum_{j=1}^{|\mathbb{D}|} \sum_{t=1}^{L_j} (log(p_t^{(j)} = y_t^{(j)} | x_j, \Theta) \cdot I(O) + \alpha \cdot log(p_t^{(j)} = y_t^{(j)} | x_j, \Theta) \cdot (1 - I(O))),$$

where $|\mathbb{D}|$ is the size of training set, L_j is the length of sentence x_j, $y_t^{(j)}$ is the label of word t in sentence x_j and $p_t^{(j)}$ is the normalized probabilities of tags which defined in Formula 15. Besides, $I(O)$ is a switching function to distinguish the loss of tag 'O' and relational tags that can indicate the results. It is defined as follows:

$$I(O) = \begin{cases} 1, & if \quad tag = 'O' \\ 0, & if \quad tag \neq 'O'. \end{cases}$$

α is the bias weight. The larger α is, the greater influence of relational tags on the model.

4 Experiments

4.1 Experimental setting

Dataset To evaluate the performance of our methods, we use the public dataset NYT [2] which is produced by distant supervision method (Ren et al., 2017). A large amount of training data can be obtained by means of distant supervision methods without manually labeling. While the test set is manually labeled to ensure its quality. In total, the training data contains $353k$ triplets, and the test set contains $3,880$ triplets. Besides, the size of relation set is 24.

Evaluation We adopt standard Precision (Prec), Recall (Rec) and F1 score to evaluate the results. Different from classical methods, our method can extract triplets without knowing the information of entity types. In other words, we did not use the label of entity types to train the model, therefore we do not need to consider the entity types in the evaluation. A triplet is regarded as correct when its relation type and the head offsets of two corresponding entities are both correct. Besides, the ground-truth relation mentions are given and "None" label is excluded as (Ren et al., 2017; Li and Ji, 2014; Miwa and Bansal, 2016) did. We create a validation set by randomly sampling 10% data from test set and use the remaining data as evaluation based on (Ren et al., 2017)'s suggestion. We run 10 times for each experiment then report the average results and their standard deviation as Table 1 shows.

Hyperparameters Our model consists of a Bi-LSTM encoding layer and a LSTM decoding layer with bias objective function. The word embeddings used in the encoding part are initialed by running word2vec[3] (Mikolov et al., 2013) on NYT training corpus. The dimension of the word embeddings is $d = 300$. We regularize our network using dropout on embedding layer and the dropout ratio is 0.5. The number of lstm units in encoding layer is 300 and the number in decoding layer is 600. The bias parameter α corresponding to the results in Table 1 is 10.

[2]The dataset can be downloaded at: https://github.com/shanzhenren/CoType. There are three data sets in the public resource and we only use the NYT dataset. Because more than 50% of the data in BioInfer has overlapping relations which is beyond the scope of this paper. As for dataset Wiki-KBP, the number of relation type in the test set is more than that of the train set, which is also not suitable for a supervised training method. Details of the data can be found in Ren's(Ren et al., 2017) paper.

Table 1: The predicted results of different methods on extracting both entities and their relations. The first part (from row 1 to row 3) is the pipelined methods and the second part (row 4 to 6) is the jointly extracting methods. Our tagging methods are shown in part three (row 7 to 9). In this part, we not only report the results of precision, recall and F1, we also compute their standard deviation.

Baselines We compare our method with several classical triplet extraction methods, which can be divided into the following categories: the pipelined methods, the jointly extracting methods and the end-to-end methods based our tagging scheme.

For the pipelined methods, we follow (Ren et al., 2017)'s settings: The NER results are obtained by CoType (Ren et al., 2017) then several classical relation classification methods are applied to detect the relations. These methods are: (1) DS-logistic (Mintz et al., 2009) is a distant supervised and feature based method, which combines the advantages of supervised IE and unsupervised IE features; (2) LINE (Tang et al., 2015) is a network embedding method, which is suitable for arbitrary types of information networks; (3) FCM (Gormley et al., 2015) is a compositional model that combines lexicalized linguistic context and word embeddings for relation extraction.

The jointly extracting methods used in this paper are listed as follows: (4) DS-Joint (Li and Ji, 2014) is a supervised method, which jointly extracts entities and relations using structured perceptron on human-annotated dataset; (5) MultiR (Hoffmann et al., 2011) is a typical distant supervised method based on multi-instance learning algorithms to combat the noisy training data; (6) CoType (Ren et al., 2017) is a domain independent framework by jointly embedding entity mentions, relation mentions, text features and type labels into meaningful representations.

In addition, we also compare our method with two classical end-to-end tagging models: LSTM-CRF (Lample et al., 2016) and LSTM-LSTM (Vaswani et al., 2016). LSTM-CRF is proposed for entity recognition by using a bidirectional LSTM to encode input sentence and a conditional random fields to predict the entity tag sequence. Different from LSTM-CRF, LSTM-LSTM uses a LSTM layer to decode the tag sequence instead of CRF. They are used for the first time to jointly extract entities and relations based on our tagging scheme.

4.2 Experimental Results

We report the results of different methods as shown in Table 1. It can be seen that our method, LSTM-LSTM-Bias, outperforms all other methods in F1 score and achieves a 3% improvement in $F1$ over the best method CoType (Ren et al., 2017). It shows the effectiveness of our proposed method. Furthermore, from Table 1, we also can see that the jointly extracting methods are better than pipelined methods, and the tagging methods are better than most of the jointly extracting methods. It also validates the validity of our tagging scheme for the task of jointly extracting entities and relations.

When compared with the traditional methods, the precisions of the end-to-end models are significantly improved. But only LSTM-LSTM-Bias can be better to balance the precision and recall. The reason may be that these end-to-end models all use a Bi-LSTM encoding input sentence and different neural networks to decode the results. The methods based on neural networks can well fit the data. Therefore, they can learn the common features of the training set well and may lead to the lower expansibility. We also find that the LSTM-LSTM

Elements	E1			E2			(E1,E2)		
PRF	*Prec.*	*Rec.*	*F1*	*Prec.*	*Rec.*	*F1*	*Prec.*	*Rec.*	*F1*
LSTM-CRF	**0.596**	0.325	0.420	0.605	0.325	0.423	**0.724**	0.341	0.465
LSTM-LSTM	0.593	0.342	0.434	**0.619**	0.334	0.434	0.705	0.340	0.458
LSTM-LSTM-Bias	0.590	**0.479**	**0.529**	0.597	**0.451**	**0.514**	0.645	**0.437**	**0.520**

Table 2: The predicted results of triplet's elements based on our tagging scheme.

model is better than LSTM-CRF model based on our tagging scheme. Because, LSTM is capable of learning long-term dependencies and CRF (Lafferty et al., 2001) is good at capturing the joint probability of the entire sequence of labels. The related tags may have a long distance from each other. Hence, LSTM decoding manner is a little better than CRF. LSTM-LSTM-Bias adds a bias weight to enhance the effect of entity tags and weaken the effect of invalid tag. Therefore, in this tagging scheme, our method can be better than the common LSTM-decoding methods.

5 Analysis and Discussion

5.1 Error Analysis

In this paper, we focus on extracting triplets composed of two entities and a relation. Table 1 has shown the predict results of the task. It treats an triplet is correct only when the relation type and the head offsets of two corresponding entities are both correct. In order to find out the factors that affect the results of end-to-end models, we analyze the performance on predicting each element in the triplet as Table 2 shows. $E1$ and $E2$ represent the performance on predicting each entity, respectively. If the head offset of the first entity is correct, then the instance of $E1$ is correct, the same to $E2$. Regardless of relation type, if the head offsets of two corresponding entities are both correct, the instance of $(E1, E2)$ is correct.

As shown in Table 2, $(E1, E2)$ has higher precision when compared with $E1$ and $E2$. But its recall result is lower than $E1$ and $E2$. It means that some of the predicted entities do not form a pair. They only obtain $E1$ and do not find its corresponding $E2$, or obtain $E2$ and do not find its corresponding $E1$. Thus it leads to the prediction of more single E and less $(E1, E2)$ pairs. Therefore, entity pair $(E1, E2)$ has higher precision and lower recall than single E. Besides, the predicted results of $(E1, E2)$ in Table 2 have about 3% improvement when compared predicted results in Table 1, which means that 3% of the test data is predicted to be wrong because the relation type is predicted to be wrong.

5.2 Analysis of Biased Loss

Different from LSTM-CRF and LSTM-LSTM, our approach is biased towards relational labels to enhance links between entities. In order to further analyze the effect of the bias objective function, we visualize the ratio of predicted single entities for each end-to-end method as Figure 4. The single entities refer to those who cannot find their corresponding entities. Figure 4 shows whether it is E1 or E2, our method can get a relatively low ratio on the single entities. It means that our method can effectively associate two entities when compared LSTM-CRF and LSTM-LSTM which pay little attention to the relational tags.

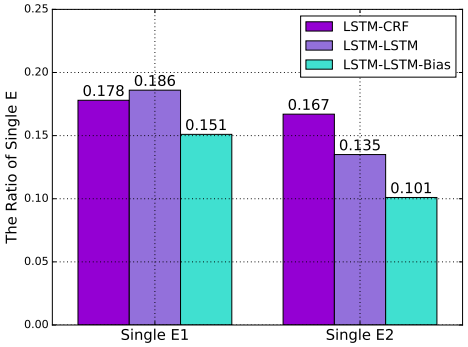

Figure 4: The ratio of predicted single entities for each method. The higher of the ratio the more entities are left.

Besides, we also change the Bias Parameter α from 1 to 20, and the predicted results are shown in Figure 5. If α is too large, it will affect the accuracy of prediction and if α is too small, the recall will decline. When $\alpha = 10$, LSTM-LSTM-Bias can balance the precision and recall, and can achieve the best F1 scores.

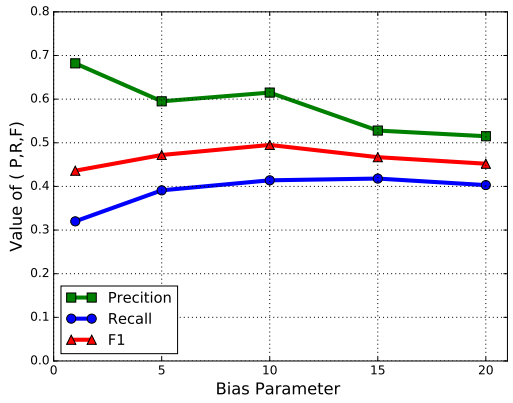

Figure 5: The results predicted by LSTM-LSTM-Bias on different bias parameter α.

5.3 Case Study

In this section, we observe the prediction results of end-to-end methods, and then select several representative examples to illustrate the advantages and disadvantages of the methods as Table 3 shows. Each example contains three row, the first row is the gold standard, the second and the third rows are the extracted results of model LSTM-LSTM and LSTM-LSTM-Bias respectively.

$S1$ represents the situation that the distance between the two interrelated entities is far away from each other, which is more difficult to detect their relationships. When compared with LSTM-LSTM, LSTM-LSTM-Bias uses a bias objective function which enhance the relevance between entities. Therefore, in this example, LSTM-LSTM-Bias can extract two related entities, while LSTM-LSTM can only extract one entity of "Florida" and can not detect entity "Panama City Beach".

$S2$ is a negative example that shows these methods may mistakenly predict one of the entity. There are no indicative words between entities $Nuremberg$ and $Germany$. Besides, the patten "a * of *" between $Germany$ and $MiddleAges$ may be easy to mislead the models that there exists a relation of "Contains" between them. The problem can be solved by adding some samples of this kind of expression patterns to the training data.

$S3$ is a case that models can predict the entities' head offset right, but the relational role is wrong. LSTM-LSTM treats both "Stephen A. Schwarzman" and "Blackstone Group" as entity $E1$, and can not find its corresponding $E2$. Although, LSTM-LSMT–Bias can find the entities pair $(E1, E2)$, it reverses the roles of "Stephen A. Schwarzman" and "Blackstone Group". It shows that LSTM-LSTM-Bias is able to better on pre-

dicting entities pair, but it remains to be improved in distinguishing the relationship between the two entities.

6 Conclusion

In this paper, we propose a novel tagging scheme and investigate the end-to-end models to jointly extract entities and relations. The experimental results show the effectiveness of our proposed method. But it still has shortcoming on the identification of the overlapping relations. In the future work, we will replace the softmax function in the output layer with multiple classifier, so that a word can has multiple tags. In this way, a word can appear in multiple triplet results, which can solve the problem of overlapping relations. Although, our model can enhance the effect of entity tags, the association between two corresponding entities still requires refinement in next works.

Abstract

In this paper, we study a novel approach for named entity recognition (NER) and mention detection (MD) in natural language processing. Instead of treating NER as a sequence labeling problem, we propose a new local detection approach, which relies on the recent fixed-size ordinally forgetting encoding (FOFE) method to fully encode each sentence fragment and its left/right contexts into a fixed-size representation. Subsequently, a simple feedforward neural network (FFNN) is learned to either reject or predict entity label for each individual text fragment. The proposed method has been evaluated in several popular NER and MD tasks, including CoNLL 2003 NER task and TAC-KBP2015 and TAC-KBP2016 Tri-lingual Entity Discovery and Linking (EDL) tasks. Our method has yielded pretty strong performance in all of these examined tasks. This local detection approach has shown many advantages over the traditional sequence labeling methods.

1 Introduction

Natural language processing (NLP) plays an important role in artificial intelligence, which has been extensively studied for many decades. Conventional NLP techniques include the rule-based symbolic approaches widely used about two decades ago, and the more recent statistical approaches relying on feature engineering and statistical models. In the recent years, deep learning approach has achieved huge successes in many applications, ranging from speech recognition to image classification. It is drawing increasing attention in the NLP community.

In this paper, we are interested in a fundamental problem in NLP, namely named entity recognition (NER) and mention detection (MD). NER and MD are very challenging tasks in NLP, laying the foundation of almost every NLP application. NER and MD are tasks of identifying entities (named and/or nominal) from raw text, and classifying the detected entities into one of the pre-defined categories such as person (PER), organization (ORG), location (LOC), etc. Some tasks focus on named entities only, while the others also detect nominal mentions. Moreover, nested mentions may need to be extracted too. For example,

$$[Sue]_{PER} \text{ and her } [brother]_{PER\_N} \text{ studied in } [University\ of\ [Toronto]_{LOC}]_{ORG}.$$

where *Toronto* is a LOC entity, embedded in another longer ORG entity *University of Toronto*.

Similar to many other NLP problems, NER and MD is formulated as a sequence labeling problem, where a tag is sequentially assigned to each word in the input sentence. It has been extensively studied in the NLP community (Borthwick et al., 1998). The core problem is to model the conditional probability of an output sequence given an arbitrary input sequence. Many hand-crafted features are combined with statistical models, such as conditional random fields (CRFs) (Nguyen et al., 2010), to compute conditional probabilities. More recently, some popular neural networks, including convolutional neural networks (CNNs) and recurrent neural networks (RNNs), are proposed to solve sequence labelling problems. In the inference stage, the learned models compute the conditional probabilities and the output sequence is generated by the Viterbi decoding algorithm (Viterbi, 1967).

In this paper, we propose a novel local detection approach for solving NER and MD problems. The idea can be easily extended to many other se-

quence labeling problems, such as chunking, part-of-speech tagging (POS). Instead of globally modeling the whole sequence in training and jointly decode the entire output sequence in test, our method examines all word segments (up to a certain length) in a sentence. A word segment will be examined individually based on the underlying segment itself and its left and right contexts in the sentence so as to determine whether this word segment is a valid named entity and the corresponding label if it is. This approach conforms to the way human resolves an NER problem. Given any word fragment and its contexts in a sentence or paragraph, people accurately determine whether this word segment is a named entity or not. People rarely conduct a global decoding over the entire sentence to make such a decision. The key to making an accurate local decision for each individual fragment is to have full access to the fragment itself as well as its complete contextual information. The main pitfall to implement this idea is that we can not easily encode the segment and its contexts in models since they are of varying lengths in natural languages. Many feature engineering techniques have been proposed but all of these methods will inevitably lead to information loss. In this work, we propose to use a recent fixed-size encoding method, namely fixed-size ordinally forgetting encoding (FOFE) (Zhang et al., 2015a,b), to solve this problem. The FOFE method is a simple recursive encoding method. FOFE theoretically guarantees (almost) unique and lossless encoding of any variable-length sequence. The left and the right contexts for each word segment are encoded by FOFE method, and then a simple neural network can be trained to make a precise recognition for each individual word segment based on the fixed-size presentation of the contextual information. This FOFE-based local detection approach is more appealing to NER and MD. Firstly, feature engineering is almost eliminated. Secondly, under this local detection framework, nested mention is handled with little modification. Next, it makes better use of partially-labeled data available from many application scenarios. Sequence labeling model requires all entities in a sentence to be labeled. If only some (not all) entities are labeled, it is not effective to learn a sequence labeling model. However, every single labeled entity, along with its contexts, may be used to learn the proposed model. At last, due to the simplicity of FOFE, simple neural networks, such as multilayer perceptrons, are sufficient for recognition. These models are much faster to train and easier to tune. In the test stage, all possible word segments from a sentence may be packed into a mini-batch, jointly recognized in parallel on GPUs. This leads to a very fast decoding process as well.

In this paper, we have applied this FOFE-based local detection approach to several popular NER and MD tasks, including the CoNLL 2003 NER task and TAC-KBP2015 and TAC-KBP2016 Tri-lingual Entity Discovery and Linking (EDL) tasks. Our proposed method has yielded strong performance in all of these examined tasks.

2 Related Work

It has been a long history of research involving neural networks (NN). In this section, we briefly review some recent NN-related research work in NLP, which may be relevant to our work.

The success of word embedding (Mikolov et al., 2013; Liu et al., 2015) encourages researchers to focus on machine-learned representation instead of heavy feature engineering in NLP. Using word embedding as the typical feature representation for words, NNs become competitive to traditional approaches in NER. Many NLP tasks, such as NER, chunking and part-of-speech (POS) tagging can be formulated as sequence labeling tasks. In (Collobert et al., 2011), deep convolutional neural networks (CNN) and conditional random fields (CRF) are used to infer NER labels at a sentence level, where they still use many hand-crafted features to improve performance, such as capitalization features explicitly defined based on first-letter capital, non-initial capital and so on.

Recently, recurrent neural networks (RNNs) have demonstrated the ability in modeling sequences (Graves, 2012). Huang et al. (2015) built on the previous CNN-CRF approach by replacing CNNs with bidirectional Long Short-Term Memory (B-LSTM). Though they have reported improved performance, they employ heavy feature engineering in that work, most of which is language-specific. There is a similar attempt in (Rondeau and Su, 2016) with full-rank CRF. CNNs are used to extract character-level features automatically in (dos Santos et al., 2015).

Gazetteer is a list of names grouped by the predefined categories. Gazetteer is shown to be one of the most effective external knowledge sources

to improve NER performance (Sang and Meulder, 2003). Thus, gazetteer is widely used in many NER systems. In (Chiu and Nichols, 2016), state-of-the-art performance on a popular NER task, i.e., CoNLL2003, is achieved by incorporating a large gazetteer. Different from previous ways to use a set of bits to indicate whether a word is in gazetteer or not, they have encoded a match in BIOES (Begin, Inside, Outside, End, Single) annotation, which captures positional information.

Interestingly enough, none of these recent successes in NER was achieved by a vanilla RNN. Rather, these successes are often established by sophisticated models combining CNNs, LSTMs and CRFs in certain ways. In this paper, based on recent work in (Zhang et al., 2015a,b) and (Zhang et al., 2016), we propose a novel but simple solution to NER by applying DNN on top of FOFE-based features. This simpler approach can achieve performance very close to state-of-the-art on various NER and MD tasks, without using any external knowledge or feature engineering.

3 Preliminary

In this section, we will briefly review some background techniques, which are important to our proposed NER and mention detection approach.

3.1 Deep Feedforward Neural Networks

It is well known that neural network is a universal approximator under certain conditions (Hornik, 1991). A feedforward neural network (FFNN) is a weighted graph with a layered architecture. Each layer is composed of several nodes. Successive layers are fully connected. Each node applies a function on the weighted sum of the lower layer. An NN can learn by adjusting its weights in a process called back-propagation. The learned NN may be used to generalize and extrapolate to new inputs that have not been seen during training.

3.2 Fixed-size Ordinally Forgetting Encoding

FFNN is a powerful computation model. However, it requires fixed-size inputs and lacks the ability of capturing long-term dependency. Because most NLP problems involves variable-length sequences of words, RNNs/LSTMs are more popular than FFNNs in dealing with these problems. The Fixed-size Ordinally Forgetting Encoding (FOFE), originally proposed in (Zhang et al., 2015a,b), nicely overcomes the limitations of FFNNs because it can uniquely and losslessly encode a variable-length sequence of words into a fixed-size representation.

Give a vocabulary V, each word can be represented by a one-hot vector. FOFE mimics bag-of-words (BOW) but incorporates a forgetting factor to capture positional information. It encodes any sequence of variable length composed by words in V. Let $S = w_1, w_2, w_3, ..., w_T$ denote a sequence of T words from V, and $\boldsymbol{e_t}$ be the one-hot vector of the t-th word in S, where $1 \leq t \leq T$. The FOFE of each partial sequence $\boldsymbol{z_t}$ from the first word to the t-th word is recursively defined as:

$$\boldsymbol{z_t} = \begin{cases} \mathbf{0}, & \text{if } t = 0 \\ \alpha \cdot \boldsymbol{z_{t-1}} + \boldsymbol{e_t}, & \text{otherwise} \end{cases} \quad (1)$$

where the constant α is called forgetting factor, and it is picked between 0 and 1 exclusively. Obviously, the size of $\boldsymbol{z_t}$ is $|V|$, and it is irrelevant to the length of original sequence, T.

Here's an example. Assume that we have three words in our vocabulary, e.g. A, B, C, whose one-hot representations are $[1, 0, 0]$, $[0, 1, 0]$ and $[0, 0, 1]$ respectively. When calculating from left to right, the FOFE for the sequence "ABC" is $[\alpha^2, \alpha, 1]$ and that of "ABCBC" is $[\alpha^4, \alpha+\alpha^3, 1+\alpha^2]$.

The word sequences can be unequivocally recovered from their FOFE representations (Zhang et al., 2015a,b). The uniqueness of FOFE representation is theoretically guaranteed by the following two theorems:

Theorem 1. *If the forgetting factor α satisfies $0 < \alpha \leq 0.5$, FOFE is unique for any countable vocabulary V and any finite value T.*

Theorem 2. *For $0.5 < \alpha < 1$, given any finite value T and any countable vocabulary V, FOFE is almost unique everywhere, except only a finite set of countable choices of α.*

Though in theory uniqueness is not guaranteed when α is chosen from 0.5 to 1, in practice the chance of hitting such scenarios is extremely slim, almost impossible due to quantization errors in the system. Furthermore, in natural languages, normally a word does not appear repeatedly within a near context. Simply put, FOFE is capable of uniquely encoding any sequence of arbitrary length, serving as a fixed-size but theoretically lossless representation for any sequence.

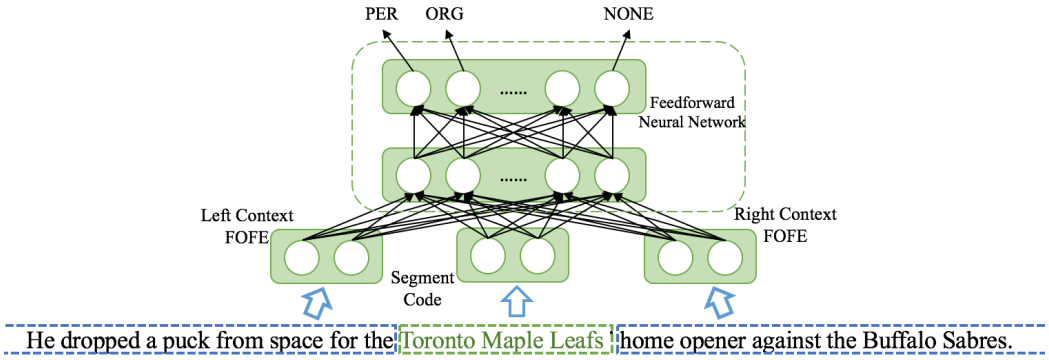

Figure 1: Illustration of the local detection approach for NER using FOFE codes as input and an FFNN as model. The window currently examines the fragment of *Toronto Maple Leafs*. The window will scan and scrutinize all fragments up to K words.

3.3 Character-level Models in NLP

Kim et al. (2016) model morphology in the character level since this may provide some additional advantages in dealing with unknown or out-of-vocabulary (OOVs) words in a language. In the literature, convolutional neural networks (CNNs) have been widely used as character-level models in NLP (Kim et al., 2016). A trainable character embedding is initialized based on a set of possible characters. When a word fragment comes, character vectors are retrieved according to its spelling to construct a matrix. This matrix can be viewed as a single-channel image. CNN is applied to generate a more abstract representation of the word fragment.

The above FOFE method can be easily extended to model character-level feature in NLP. Any word, phrase or fragment can be viewed as a sequence of characters. Based on a pre-defined set of all possible characters, we apply the same FOFE method to encode the sequence of characters. This always leads to a fixed-size representation, irrelevant to the number of characters in question. For example, a word fragment of "Walmart" may be viewed as a sequence of seven characters: 'W', 'a', 'l', 'm', 'a', 'r', 't'. The FOFE codes of character sequences are always fixed-sized and they can be directly fed to an FFNN for morphology modeling.

4 FOFE-based Local Detection for NER

As described above, our FOFE-based local detection approach for NER, called **FOFE-NER** hereafter, is motivated by the way how human actually infers whether a word segment in text is an entity or mention, where the entity types of the other entities in the same sentence is not a must. Particularly, the dependency between adjacent entities is fairly weak in NER. Whether a fragment is an entity or not, and what class it may belong to, largely depend on the internal structure of the fragment itself as well as the left and right contexts in which it appears. To a large extent, the meaning and spelling of the underlying fragment are informative to distinguish named entities from the rest of the text. Contexts play a very important role in NER or MD when it involves multi-sense words/phrases or out-of-vocabulary (OOV) words.

As shown in Figure 1, our proposed **FOFE-NER** method will examine all possible fragments in text (up to a certain length) one by one. For each fragment, it uses the FOFE method to fully encode the underlying fragment itself, its left context and right context into some fixed-size representations, which are in turn fed to an FFNN to predict whether the current fragment is NOT a valid entity mention (*NONE*), or its correct entity type (*PER*, *LOC*, *ORG* and so on) if it is a valid mention. This method is appealing because the FOFE codes serves as a theoretically lossless representation of the hypothesis and its full contexts. FFNN is used as a universal approximator to map from text to the entity labels.

In this work, we use FOFE to explore both word-level and character-level features for each fragment and its contexts.

4.1 Word-level Features

FOFE-NER generates several word-level features for each fragment hypothesis and its left and right contexts as follows:

- Bag-of-word (BoW) of the fragment, e.g.

bag-of-word vector of 'Toronto', 'Maple' and 'Leafs' in Figure 1.

- FOFE code for left context including the fragment, e.g. FOFE code of the word sequence of "... *puck from space for the Toronto Maple Leafs*" in Figure 1.
- FOFE code for left context excluding the fragment, e.g. the FOFE code of the word sequence of "... *puck from space for the*" in Figure 1..
- FOFE code for right context including the fragment, e.g. the FOFE code of the word sequence of "... *against opener home ' Leafs Maple Toronto*" in Figure 1.
- FOFE code for right context excluding the fragment, e.g. the FOFE code of the word sequence of "... *against opener home* " in Figure 1.

Moreover, all of the above word features are computed for both case-sensitive words in raw text as well as case-insensitive words in normalized lower-case text. These FOFE codes are projected to lower-dimension dense vectors based on two projection matrices, $\mathbf{W}_s$ and $\mathbf{W}_i$, for case-sensitive and case-insensitive FOFE codes respectively. These two projection matrices are initialized by word embeddings trained by *word2vec*, and fine-tuned during the learning of the neural networks.

Due to the recursive computation of FOFE codes in eq.(1), all of the above FOFE codes can be jointly computed for one sentence or document in a very efficient manner.

4.2 Character-level Features

On top of the above word-level features, we also augment character-level features for the underlying segment hypothesis to further model its morphological structure. For the example in Figure 1, the current fragment, *Toronto Maple Leafs*, is considered as a sequence of case-sensitive characters, i.e. "{'T', 'o', ..., 'f' , 's' }", we then add the following character-level features for this fragment:

- Left-to-right FOFE code of the character sequence of the underlying fragment. That is the FOFE code of the sequence, "*'T', 'o', ..., 'f' , 's'* ".
- Right-to-left FOFE code of the character sequence of the underlying fragment. That is the FOFE code of the sequence, "*'s' , 'f' , ..., 'o', 'T'* ".

These case-sensitive character FOFE codes are also projected by another character embedding matrix, which is randomly initialized and fine-tuned during model training.

Alternatively, we may use the character CNNs, as described in Section 3.3, to generate character-level features for each fragment hypothesis as well.

5 Training and Decoding Algorithm

Obviously, the above **FOFE-NER** model will take each sentence of words, $S = [w_1, w_2, w_3, ..., w_m]$, as input, and examine all continuous sub-sequences $[w_i, w_{i+1}, w_{i+2}, ..., w_j]$ up to n words in S for possible entity types. All sub-sequences longer than n words are considered as non-entities in this work.

When we train the model, based on the entity labels of all sentences in the training set, we will generate many sentence fragments up to n words. These fragments fall into three categories:

- Exact-match with an entity label, e.g., the fragment "*Toronto Maple Leafs*" in the previous example.
- Partial-overlap with an entity label, e.g., "*for the Toronto*".
- Disjoint with all entity label, e.g. "*from space for*".

For all exact-matched fragments, we generate the corresponding outputs based on the types of the matched entities in the training set. For both partial-overlap and disjoint fragments, we introduce a new output label, **NONE**, to indicate that these fragments are not a valid entity. Therefore, the output nodes in the neural networks contains all entity types plus a rejection option denoted as **NONE**.

During training, we implement a producer-consumer software design such that a thread fetches training examples, computes all FOFE codes and packs them as a mini-batch while the other thread feeds the mini-batches to neural networks and adjusts the model parameters and all projection matrices. Since "partial-overlap" and "disjoint" significantly outnumber "exact-match", they are down-sampled so as to balance the data set.

During inference, all fragments not longer than

n words are all fed to **FOFE-NER** to compute their scores over all entity types. In practice, these fragments can be packed as one mini-batch so that we can compute them in parallel on GPUs. As the NER result, the **FOFE-NER** model will return a subset of fragments only if: i) they are recognized as a valid entity type (not **NONE**); AND ii) their NN scores exceed a global pruning threshold.

Occasionally, some partially-overlapped or nested fragments may occur in the above pruned prediction results. We can use one of the following simple post-processing methods to remove overlappings from the final results:

1. *highest-first*: We check every word in a sentence. If it is contained by more than one fragment in the pruned results, we only keep the one with the maximum NN score and discard the rest.

2. *longest-first*: We check every word in a sentence. If it is contained by more than one fragment in the pruned results, we only keep the longest fragment and discard the rest.

Either of these strategies leads to a collection of non-nested, non-overlapping, non-NONE entity labels.

In some tasks, it may require to label all nested entities. This has imposed a big challenge to the sequence labeling methods. However, the above post-processing can be slightly modified to generate nested entities' labels. In this case, we first run either *highest-first* or *longest-first* to generate the first round result. For every entity survived in this round, we will recursively run either *highest-first* or *longest-first* on all entities in the original set, which are completely contained by it. This will generate more prediction results. This process may continue to allow any levels of nesting. For example, for a sentence of "w_1 w_2 w_3 w_4 w_5", if the model first generates the prediction results after the global pruning, as ["w_2w_3", PER, 0.7], ["w_3w_4", LOC, 0.8], ["$w_1w_2w_3w_4$", ORG, 0.9], if we choose to run *highest-first*, it will generate the first entity label as ["$w_1w_2w_3w_4$", ORG, 0.9]. Secondly, we will run *highest-first* on the two fragments that are completely contained by the first one, i.e., ["w_2w_3", PER, 0.7], ["w_3w_4", LOC, 0.8], then we will generate the second nested entity label as ["w_3w_4", LOC, 0.8]. Fortunately, in any real NER and MD tasks, it is pretty rare to have overlapped predictions in the NN outputs. Therefore, the extra expense to run this recursive post-processing method is minimal.

6 Second-Pass Augmentation

As we know, CRF brings marginal performance gain to all taggers (but not limited to NER) because of the dependancies (though fairly weak) between entity types. We may easily add this level of information to our model by introducing another pass of **FOFE-NER**. We call it *2nd-pass FOFE-NER*.

In 2nd-pass FOFE-NER, another set of model is trained on outputs from the first-pass **FOFE-NER**, including all predicted entities. For example, given a sentence

$$S = [w_1, w_2, ...w_i, ...w_j, ...w_n]$$

and an underlying word segment $[w_i, ..., w_j]$ in the second pass, every predicted entity outside this segment is substituted by its entity type predicted from the first pass. For example, in the first pass, a sentence like *"Google has also recruited Fei-Fei Li, director of the AI lab at Stanford University."* is predicted as: *"<ORG> has also recruited Fei-Fei Li, director of the AI lab at <ORG>."* In 2nd-pass FOFE-NER, when examining the segment "*Fei-Fei Li*", the predicted entity types *<ORG>* are used to replace the actual named entities. The 2nd-pass FOFE-NER model is trained on the outputs of the first pass, where all detected entities are replaced by their predicted types as above.

During inference, the results returned by the 1st-pass model are substituted in the same way. The scores for each hypothesis from 1st-pass model and 2nd-pass model are linear interpolated and then decoded by either *highest-first* or *longest-first* to generate the final results of 2nd-pass FOFE-NER.

Obviously, 2nd-pass FOFE-NER may capture the semantic roles of other entities while filtering out unwanted constructs and sparse combonations. On the other hand, it enables longer context expansion, since FOFE memorizes contextual information in an unselective decaying fashion.

7 Experiments

In this section, we evaluate the effectiveness of our proposed methods on several popular NER and MD tasks, including CoNLL 2003 NER task and TAC-KBP2015 and TAC-KBP2016 Trilingual Entity Discovery and Linking (EDL) tasks.

We have made our codes available at https://github.com/xmb-cipher/fofe-ner for readers to reproduce the results in this paper.

7.1 CoNLL 2003 NER task

The CoNLL-2003 dataset (Sang and Meulder, 2003) consists of newswire from the Reuters RCV1 corpus tagged with four types of non-nested named entities: location (LOC), organization (ORG), person (PER), and miscellaneous (MISC).

The top 100,000 words, are kept as vocabulary, including punctuations. For the case-sensitive embedding, an OOV is mapped to <unk> if it contains no upper-case letter and <UNK> otherwise. We perform grid search on several hyper-parameters using a held-out dev set. Here we summarize the set of hyper-parameters used in our experiments: i) *Learning rate*: initially set to 0.128 and is multiplied by a decay factor each epoch so that it reaches 1/16 of the initial value at the end of the training; ii) *Network structure*: 3 fully-connected layers of 512 nodes with ReLU activation, randomly initialized based on a uniform distribution between $-\sqrt{\frac{6}{N_i+N_o}}$ and $\sqrt{\frac{6}{N_i+N_o}}$ (Glorot et al., 2011); iii) *Character embeddings*: 64 dimensions, randomly initialized. iv) *mini-batch*: 512; v) *Dropout rate*: initially set to 0.4, slowly decreased during training until it reaches 0.1 at the end. vi) *Number of epochs*: 128; vii)*Embedding matrices* case-sensitive and case-insensitive word embeddings of 256 dimensions, trained from Reuters RCV1; viii) We stick to the official data train-dev-test partition. ix) *Forgetting factor* $\alpha = 0.5$. [1]

We have investigated the performance of our method on the CoNLL-2003 dataset by using different combinations of the FOFE features (both word-level and character-level). The detailed comparison results are shown in Table 1. In Table 2, we have compared our best performance with some top-performing neural network systems on this task. As we can see from Table 2, our system (highest-first decoding) yields very strong performance (90.85 in F_1 score) in this task, outperforming most of neural network models reported on this dataset. More importantly, we have not used any hand-crafted features in our systems, and all features (either word or char level) are automatically derived from the data. Highest-first and longest-first perform similarly. In (Chiu and Nichols, 2016)[2], a slightly better performance (91.62 in F_1 score) is reported but a customized gazetteer is used in theirs.

7.2 KBP2015 EDL Task

Given a document collection in three languages (English, Chinese and Spanish), the KBP2015 trilingual EDL task (Ji et al., 2015) requires to automatically identify entities **(including nested entities)** from a source collection of textual documents in multiple languages as in Table 3, and classify them into one of the following pre-defined five types: Person (PER), Geo-political Entity (GPE), Organization (ORG), Location (LOC) and Facility (FAC). The corpus consists of news articles and discussion forum posts published in recent years, related but non-parallel across languages.

Three models are trained and evaluated independently. Unless explicitly listed, hyperparameters follow those used for CoNLL2003 as described in section 7.1 and 2nd-pass model is not used. Three sets of word embeddings of 128 dimensions are derived from English Gigaword (Parker et al., 2011), Chinese Gigaword (Graff and Chen, 2005) and Spanish Gigaword (Mendonca et al., 2009) respectively. Some language-specific modifications are made:

- **Chinese**: Because Chinese segmentation is not reliable, we label Chinese at character level. The analogous roles of case-sensitive word-embedding and case-sensitive word-embedding are played by character embedding and word-embedding in which the character appears. Neither Char FOFE features nor Char CNN features are used for Chinese.
- **Spanish**: Character set of Spanish is a super set of that of English. When building character-level features, we use the mod function to hash each character's UTF8 encoding into a number between 0 (inclusive) and 128 (exclusive).

As shown in Table 4, our FOFE-based local detection method has obtained fairly strong perfor-

[1] The choice of the forgetting factor α is empirical. We've evaluated $\alpha = 0.5, 0.6, 0.7, 0.8$ on a development set in some early experiments. It turns out that $\alpha = 0.5$ is the best. As a result, $\alpha = 0.5$ is used for all NER/MD tasks throughout this paper.

[2] In their work, they have used a combination of training-set and dev-set to train the model, differing from all other systems (including ours) in Table 2.

FEATURE			P	R	F1
word-level	case-insensitive	context FOFE incl. word fragment	86.64	77.04	81.56
		context FOFE excl. word fragment	53.98	42.17	47.35

Table 4: Entity Discovery Performance of our method on the KBP2015 EDL evaluation data, with comparison to the best systems in KBP2015 official evaluation.

mance in the KBP2015 dataset. The overall trilingual entity discovery performance is slightly better than the best systems participated in the official KBP2015 evaluation, with 73.9 vs. 72.4 as measured by F_1 scores. Outer and inner decodings are *longest-first* and *highest-first* respectively.

7.3 KBP2016 EDL task

In KBP2016, the trilingual EDL task is extended to detect nominal mentions of all 5 entity types for all three languages. In our experiments, for simplicity, we treat nominal mention types as some extra entity types and detect them along with named entities together with a single model.

7.3.1 Data Description

No official training set is provided in KBP2016. We make use of three sets of training data:

- **Training and evaluation data in KBP2015**: as described in 7.2

LANG	NAME			NOMINAL			OVERALL			2016 BEST		
	P	R	F1	P	R	F1	P	R	F1	P	R	F1
ENG	0.898	0.789	0.840	0.554	0.336	0.418	0.836	0.680	0.750	0.846	0.710	0.772
CMN	0.848	0.702	0.768	0.414	0.258	0.318	0.789	0.625	0.698	0.789	0.737	0.762
SPA	0.835	0.778	0.806	0.000	0.000	0.000	0.835	0.602	0.700	0.839	0.656	0.736
ALL	0.893	0.759	0.821	0.541	0.315	0.398	0.819	0.639	**0.718**	0.802	0.704	0.756

Table 5: Official entity discovery performance of our methods on KBP2016 trilingual EDL track. Neither KBP2015 nor in-house data labels nominal mentions. Nominal mentions in Spanish are totally ignored since no training data is found for them.

training data	P	R	F_1
KBP2015	0.836	0.598	0.697
KBP2015 + WIKI	0.837	0.628	**0.718**
KBP2015 + in-house	0.836	0.680	**0.750**

Table 6: Our entity discovery official performance (English only) in KBP2016 is shown as a comparison of three models trained by different combinations of training data sets.

- **Machine-labeled Wikipedia (WIKI)**: When terms or names are first mentioned in a Wikipedia article they are often linked to the corresponding Wikipedia page by hyperlinks, which clearly highlights the possible named entities with well-defined boundary in the text. We have developed a program to automatically map these hyperlinks into KBP annotations by exploring the infobox (if existing) of the destination page and/or examining the corresponding Freebase types. In this way, we have created a fairly large amount of weakly-supervised trilingual training data for the KBP2016 EDL task. Meanwhile, a gazeteer is created and used in KBP2016.
- **In-house dataset**: A set of 10,000 English and Chinese documents is manually labeled using some annotation rules similar to the KBP 2016 guidelines.

We split the available data into training, validation and evaluation sets in a ratio of 90:5:5. The models are trained for 256 epochs if the in-house data is not used, and 64 epochs otherwise.

7.3.2 Effect of various training data

In our first set of experiments, we investigate the effect of using different training data sets on the final entity discovery performance. Different training runs are conducted on different combinations of the aforementioned data sources. In Table 6, we have summarized the official English entity discovery results from several systems we submitted to KBP2016 EDL evaluation round I and II. The first system, using only the KBP2015 data to train the model, has achieved 0.697 in F_1 score in the official KBP2016 English evaluation data. After adding the weakly labeled data, WIKI, we can see the entity discovery performance is improved to 0.718 in F_1 score. Moreover, we can see that it yields even better performance by using the KBP2015 data and the in-house data sets to train our models, giving 0.750 in F_1 score.

7.3.3 The official trilingual EDL performance in KBP2016

The official best results of our system are summarized in Table 5. We have broken down the system performance according to different languages and categories of entities (named or nominal). Our system, achieving 0.718 in F_1 score in the KBP2016 trilingual EDL track, ranks second among all participants. Note that our result is produced by a single system while the top system is a combination of two different models, each of which is based on 5-fold cross-validation (Liu et al., 2016).

8 Conclusion

In this paper, we propose a novel solution to NER and MD by applying FFNN on top of FOFE features. This simple local-detection based approach has achieved almost state-of-the-art performance on various NER and MD tasks, without using any external knowledge or feature engineering.

Abstract

Named entities are frequently used in a metonymic manner. They serve as references to related entities such as people and organisations. Accurate identification and interpretation of metonymy can be directly beneficial to various NLP applications, such as Named Entity Recognition and Geographical Parsing. Until now, metonymy resolution (MR) methods mainly relied on parsers, taggers, dictionaries, external word lists and other handcrafted lexical resources. We show how a minimalist neural approach combined with a novel predicate window method can achieve competitive results on the SemEval 2007 task on Metonymy Resolution. Additionally, we contribute with a new Wikipedia-based MR dataset called *RelocaR*, which is tailored towards locations as well as improving previous deficiencies in annotation guidelines.

1 Introduction

In everyday language, we come across many types of figurative speech. These irregular expressions are understood with little difficulty by humans but require special attention in NLP. One of these is metonymy, a type of common figurative language, which stands for the substitution of the concept, phrase or word being meant with a semantically related one. For example, in "**Moscow** traded gas and aluminium with **Beijing**.", both location names were substituted in place of governments.

Named Entity Recognition (NER) taggers have no provision for handling metonymy, meaning that this frequent linguistic phenomenon goes largely undetected within current NLP. Classification decisions presently focus on the entity using features such as orthography to infer its word sense, largely ignoring the context, which provides the strongest clue about whether a word is used metonymically. A common classification approach is choosing the N words to the immediate left and right of the entity or the whole paragraph as input to the model. However, this "greedy" approach also processes input that should in practice be ignored.

Metonymy is problematic for applications such as Geographical Parsing (Monteiro et al., 2016; Gritta et al., 2017, GP) and other information extraction tasks in NLP. In order to accurately identify and ground location entities, for example, we must recognise that metonymic entities constitute false positives and should not be treated the same way as regular locations. For example, in "**London** voted for the change.", London refers to the concept of "people" and should not be classified as a location. There are many types of metonymy (Shutova et al., 2013), however, in this paper, we primarily address metonymic location mentions with reference to GP and NER.

Contributions: (1) We investigate how to improve classification tasks by introducing a novel minimalist method called Predicate Window (PreWin), which outperforms common feature selection baselines. Our final minimalist classifier is comparable to systems which use many external features and tools. (2) We improve the annotation guidelines in MR and contribute with a new Wikipedia-based MR dataset called ReLocaR to address the training data shortage. (3) We make an annotated subset of the CoNLL 2003 (NER) Shared Task available for extra MR training data, alongside models, tools and other data.

2 Related Work

Some of the earliest work on MR that used an approach similar to our method (machine learning and dependency parsing) was by Nissim and Markert (2003a). The decision list classifier with backoff was evaluated using syntactic head-modifier relations, grammatical roles and a thesaurus to overcome data sparseness and generalisation problems. However, the method was still limited for classifying unseen data. Our method uses the same paradigm but adds more features, a different machine learning architecture and a better usage of the parse tree structure.

Much of the later work on MR comes from the SemEval 2007 Shared Task 8 (Markert and Nissim, 2007) and later by Markert and Nissim (2009). The feature set of Nissim and Markert (2003a) was updated to include: grammatical role of the potentially metonymic word (PMW) (such as subj, obj), lemmatised head/modifier of PMW, determiner of PMW, grammatical number of PMW (singular, plural), number of words in PMW and number of grammatical roles of PMW in current context. The winning system by Farkas et al. (2007) used these features and a maximum entropy classifier to achieve 85.2% accuracy. This was also the "leanest" system but still made use of feature engineering and some external tools. Brun et al. (2007) achieved 85.1% accuracy using local syntactical and global distributional features generated with an adapted, proprietary Xerox deep parser. This was the only unsupervised approach, based on using syntactic context similarities calculated on large corpora such as the the British National Corpus (BNC) with 100M tokens.

Nastase and Strube (2009) used a Support Vector Machine (SVM) with handcrafted features (in addition to the features provided by Markert and Nissim (2007)) including grammatical collocations extracted from the BNC to learn selectional preferences, WordNet 3.0, Wikipedia's category network, whether the entity "has-a-product" such as Suzuki and whether the entity "has-an-event" such as Vietnam (both obtained from Wikipedia). The bigger set of around 60 features and leveraging global (paragraph) context enabled them to achieve 86.1% accuracy. Once again, we draw attention to the extra training, external tools and additional feature generation.

Similar recent work by Nastase and Strube (2013) which extends that of Nastase et al. (2012) involved transforming Wikipedia into a large-scale multilingual concept network called WikiNet. By building on Wikipedia's existing network of categories and articles, their method automatically discovers new relations and their instances. As one of their extrinsic evaluations, metonymy resolution was tested. Global context (whole paragraph) was used to interpret the target word. Using an SVM and a powerful knowledge base built from Wikipedia, the highest performance to date (a 0.1% improvement from Nastase and Strube (2009)) was achieved at 86.2%, which has remained the SOTA until now.

The related work on MR so far has made limited use of dependency trees. Typical features came in the form of a head dependency of the target entity, its dependency label and its role (subj-of-win, dobj-of-visit, etc). However, other classification tasks made good use of dependency trees. Liu et al. (2015) used the shortest dependency path and dependency sub-trees successfully to improve relation classification (new SOTA on SemEval 2010 Shared Task). Bunescu and Mooney (2005) show that using dependency trees to generate the input sequence to a model performs well in relation extraction tasks. Dong et al. (2014) used dependency parsing for Twitter sentiment classification to find the words syntactically connected to the target of interest. Joshi and Penstein-Rosé (2009) used dependency parsing to explore how features based on syntactic dependency relations can be used to improve performance on opinion mining. In unsupervised lymphoma (type of cancer) classification, Luo et al. (2014) constructed a sentence graph from the results of a two-phase dependency parse to mine pathology reports for the relationships between medical concepts. Our methods also exploit the versatility of dependency parsing to leverage information about the sentence structure.

2.1 SemEval 2007 Dataset

Our main standard for performance evaluation is the SemEval 2007 Shared Task 8 (Markert and Nissim, 2007) dataset first introduced in Nissim and Markert (2003b). Two types of entities were evaluated, organisations and locations, randomly retrieved from the British National Corpus (BNC).

We only use the locations dataset, which comprises a train (925 samples) and a test (908 samples) partition. For *medium* evaluation, the classes are **literal** (geographical territories and political entities), **metonymic** (place-for-people, place-for-product, place-for-event, capital-for-government or place-for-organisation) and **mixed** (metonymic and literal frames invoked simultaneously or unable to distinguish). The metonymic class further breaks down into two levels of subclasses allowing for *fine* evaluation. The class distribution within SemEval is approx 80% literal, 18% metonymic and 2% mixed. This seems to be the approximate natural distribution of the classes for location metonymy, which we have also observed while sampling Wikipedia for our new dataset.

3 Our Approach

Our contribution broadly divides into two main parts, data and methodology. Section 3 introduces our new dataset, Section 4 introduces our new feature extraction method.

3.1 Design and Motivation

As part of our contribution, we created a new MR dataset called ReLocaR (Real Location Retrieval), partly due to the lack of quality annotated train/test data and partly because of the shortcomings with the SemEval 2007 dataset (see Section 3.2). Our corpus is designed to evaluate the capability of a classifier to distinguish **literal**, **metonymic** and **mixed** location mentions. In terms of dataset size, ReLocaR contains 1,026 training and 1,000 test instances. The data was sampled using Wikipedia's Random Article API[1]. We kept the sentences, which contained at least one of the places from a manually compiled list[2] of countries and capitals of the world. The natural distribution of literal versus metonymic examples is approximately 80/20 so we had to discard the excess literal examples during sampling to balance the classes.

3.2 ReLocaR - Improvements over SemEval

1. We do not break down the metonymic class further as the distinction between the subclasses is subtle and hard to agree on.

2. The distribution of the three classes in ReLocaR (literal, metonymic, mixed) is approximately (49%, 49%, 2%) eliminating the high bias (80%, 18%, 2%) of SemEval. We will show how such a high bias transpires in the test results (Section 5).

3. We have reviewed the annotation of the test partition and found that we disagreed with up to 11% of the annotations. Zhang and Gelernter (2015) disagreed with the annotation 8% of the time. Poibeau (2007) also challenged some annotation decisions. ReLocaR was annotated by 4 trained linguists (undergraduate and graduate) and 2 computational linguists (authors). Linguists were independently instructed (see section 3.3) to assign one of the two classes to each example with little guidance. We leveraged their linguistic training and expertise to make decisions rather than imposing some specific scheme. Unresolved sentences would receive the mixed class label.

4. The most prominent difference is a small change in the annotation scheme (after independent linguistic advice). The SemEval 2007 Task 8 annotation scheme (Markert and Nissim, 2007) considers the political entity interpretation a literal reading. It suggests that in "**Britain**'s current account deficit...", Britain refers to a literal location, rather than a government (which is an organisation). This is despite acknowledging that "The locative and the political sense is often distinguished in dictionaries as well as in the ACE annotation scheme...". In ReLocaR datasets, we consider a political entity a metonymic reading.

3.2.1 Why government is not a location

A government/nation/political entity is semantically much closer to Organisation/Person than a Location. "**Moscow** talks to **Beijing**." does not tell us *where* this is happening. It most likely means a politician is talking to another politician. These are not places but people and/or groups. It is paramount to separate references to "inanimate" places from references to "animate" entities.

3.3 Annotation Guidelines (Summary)

ReLocaR has three classes, **literal**, **metonymic** and **mixed**. Literal reading comprises territorial interpretations (the geographical territory, the land, soil and physical location) i.e. inanimate places that serve to point to a set of coordinates (where something might be located and/or happening) such as "The treaty was signed in **Italy**.", "Peter comes from **Russia**.", "**Britain**'s

[1] https://www.mediawiki.org/wiki/API:Random
[2] https://github.com/milangritta/Minimalist-Location-Metonymy-Resolution/data/locations.txt

Andy Murray won the Grand Slam today.", "**US** companies increased exports by 50%.", "**China**'s artists are among the best in the world." or "The reach of the transmission is as far as **Brazil**.".

A metonymic reading is any location occurrence that expresses animacy (Coulson and Oakley, 2003) such as "**Jamaica**'s indifference will not improve the negotiations.", "**Sweden**'s budget deficit may rise next year.". The following are other metonymic scenarios: a location name, which stands for any persons or organisations associated with it such as "We will give aid to **Afghanistan**.", a location as a product such as "I really enjoyed that delicious **Bordeaux**.", a location posing as a sports team "**India** beat **Pakistan** in the playoffs.", a governmental or other legal entity posing as a location "**Zambia** passed a new justice law today.", events acting as locations "**Vietnam** was a bad experience for me".

The mixed reading is assigned in two cases: either both readings are invoked at the same time such as in "The Central European country of **Slovakia** recently joined the EU." or there is not enough context to ascertain the reading i.e. both are plausible such as in "We marvelled at the art of ancient **Mexico**.". In difficult cases such as these, the mixed class is assigned.

3.4 Inter-Annotator Agreement

We give the IAA for the test partition only. The whole dataset was annotated by the first author as the main annotator. Two pairs of annotators (4 linguists) then labelled 25% of the dataset each for a 3-way agreement. The agreement before adjudication was 91% and 93%, 97.2% and 99.2% after adjudication (for pair one and two respectively). The other 50% of sentences were then once again labelled by the main annotator with a 97% agreement with self. The remainder of the sentences (unable to agree on among annotators even after adjudication) were labelled as a mixed class (1.8% of all sentences).

3.5 CoNLL 2003 and MR

We have also annotated a small subset of the CoNLL 2003 NER Shared Task data for metonymy resolution (locations only). Respecting the Reuters RCV1 Corpus (Lewis et al., 2004) distribution permissions[3], we make only a heavily processed subset available on GitHub[4]. There are 4,089 positive (literal) and 2,126 negative (metonymic) sentences to assist with algorithm experimentation and model prototyping. Due to the lack of annotated training data for MR, this is a valuable resource. The data was annotated by the first author, there are no IAA figures.

4 Methodology

4.1 Predicate Window (PreWin)

Through extensive experimentation and observation, we arrived at the intuition behind PreWin, our novel feature extraction method. The classification decision of the class of the target entity is mostly informed not by the whole sentence (or paragraph), rather it is a small and focused "predicate window" pointed to by the entity's head dependency. In other words, most of the sentence is not only superfluous for the task, it actually lowers the accuracy of the model due to irrelevant input. This is particularly important in metonymy resolution as the entity's surface form is not taken into consideration, only its context.

In Figure 1, we show the process of extracting the Predicate Window from a sample sentence (more examples are available in the Appendix). We start by using the SpaCy dependency parser by Honnibal and Johnson (2015), which is the fastest in the world, open source and highly customisable. Each dependency tree provides the following features: dependency labels and entity head dependency. Rather than using most of the tree, we only use a single local head dependency relationship to point to the predicate. Leveraging a dependency parser helps PreWin with selecting the minimum relevant input to the model while discarding irrelevant input, which may cause the neural model to behave unpredictably. Finally, the entity itself is never used as input in any of our methods, we only rely on context.

PreWin then extracts up to 5 words and their dependency labels starting at the **head** of the entity (see the next paragraph for exceptions), going in the away (from the entity) direction. The method always skips the **conjunct** ("and", "or")

[3]http://trec.nist.gov/data/reuters/reuters.html
[4]https://github.com/milangritta/Minimalist-Location-Metonymy-Resolution

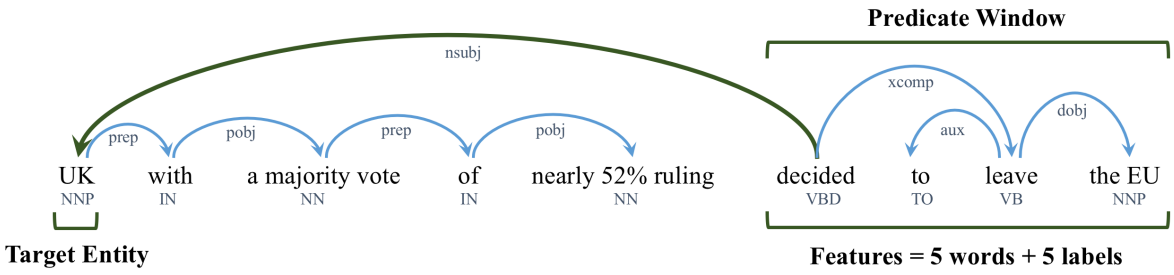

Figure 1: The predicate window starts at the head of the target entity and ends up to 4 words further, going away from the entity. The "conj" relations are always skipped. In the above example, the head of "UK" is "decided" so PreWin takes 5 words plus dependency labels as the input to the model. The left-hand side input to the model is empty and is set to zeroes (see Figure 2 for a full model diagram).

relationships in order to find the predicate (see Figure 3 in the Appendix for a visual example of why this is important). The reason for the choice of 5 words is the balance between too much input, feeding the model with less relevant context and just enough context to capture the necessary semantics. We have experimented with lengths of 3-10 words, however 5 words typically achieved the best results.

The following are the three types of exceptions when the output will not start with the head of the entity. In these cases, PreWin will include the neighbouring word as well. In a sentence "The pub is located in southern **Zambia**.", the head of the entity is "in", however in this case PreWin will include "southern" (*adjectival modifier*) as this carries important semantics for the classification. Similarly, PreWin will also include the neighbouring *compound noun* as in: "Lead coffins were very rare in colonial **America**.", the output will include "colonial" as a feature plus the next four words. In another sentence: "**Vancouver**'s security is the best in the world.', PreWin will include the "**'s**" (*case*) plus the next four words continuing from the head of the entity (the word "security").

4.2 Neural Network Architecture

The output of PreWin is used to train the following machine learning model. We decided to use the Long Short Term Memory (LSTM) architecture by Keras[5] (Chollet, 2015). Two LSTMs are used, one for the left and right side (up to 5 words each). Two fully connected (dense) layers are used for the left and right dependency relation labels (up to 5 labels each, encoded as one-hot). The full architecture is available in the Appendix, please see Figure 2. You can download the models and data from GitHub[6]. LSTMs are excellent at processing language sequences (Hochreiter and Schmidhuber, 1997; Sak et al., 2014; Graves et al., 2013), which is why we use this architecture. It allows the model to encode the word sequences, preserve important word order and provide superior classification performance. Both the Multilayer Perceptron and the Convolutional Neural Network were consistently inferior (typically 5% - 10% lower accuracy) in our earlier performance comparisons. For all experiments, we used a vocabulary of the first (most frequent) 100,000 word vectors in GloVe[7] (Pennington et al., 2014). Finally, unless explicitly stated otherwise, the standard dimension of word embeddings was 50, which we found to work best.

4.3 "Immediate" Baseline

A common approach in lexical classification tasks is choosing the 5 to 10 words to the immediate right and left of the entity as input to a model (Mikolov et al., 2013; Mesnil et al., 2013; Baroni et al., 2014; Collobert et al., 2011). We evaluate this method (its 5 and 10-word variant) alongside PreWin and Paragraph.

4.4 Paragraph Baseline

The paragraph baseline method extends the "immediate" one by taking 50 words from each side of the entity as the input to the classifier. In practice, this extends the feature window to include extra-sentential evidence in the paragraph. This ap-

[5]https://keras.io/

[6]https://github.com/milangritta/Minimalist-Location-Metonymy-Resolution

[7]http://nlp.stanford.edu/projects/glove/

proach is also popular in machine learning (Melamud et al., 2016; Zhang et al., 2016).

4.5 Ensemble of Models

In addition to a single best performing model, we have combined several models trained on different data and/or using different model configurations. For the SemEval test, we combined three separate models trained on the newly annotated CoNLL dataset and the training data for SemEval. For the ReLocaR test, we once again let three models vote, trained on CooNLL and ReLocaR data.

5 Results

We evaluate all methods using three datasets for **training** (ReLocaR, SemEval, CoNLL) and two for **testing** (ReLocaR, SemEval). Due to inherent randomness in the deep learning libraries, we performed 10 runs for each setup and averaged the figures (we also report standard deviation).

5.1 Metrics and Significance

Following the SemEval 2007 convention, we use two metrics to evaluate performance, accuracy and f-scores (for each class). We only evaluate at the **coarse level**, which means literal versus non-literal (metonymic and mixed are merged into one class). In terms of statistical significance, our best score on the SemEval dataset (908 samples) is not significant at the 95% confidence level. However, the accuracy improvements of PreWin over the common baselines are highly statistically significant with 99.9%+ confidence.

5.2 Predicate Window

Tables 1 and 2 show PreWin performing consistently better than other baselines, in many instances, significantly better and with fewer words (smaller input). The standard deviation is also lower for PreWin meaning more stable test runs. Compared with the 5 and 10 window "immediate" baseline, which is the common approach in classification, PreWin is more discriminating with its input. Due to the linguistic variety and the myriad of ways the target word sense can be triggered in a sentence, it is not always the case that the 5 or 10 nearest words inform us of the target entity's meaning/type. We ought to ask what else is being expressed in the same 5 to 10-word window?

Conventional classification methods (Immediate, Paragraph) can also be seen as prioritising either feature precision or feature recall. **Paragraph** maximises the input sequence size, which maximises recall at the expense of including features that are either irrelevant or mislead the model, lowering precision. **Immediate** baseline maximises precision by using features close to the target entity at the expense of missing important features positioned outside of its small window, lowering recall. PreWin can be understood as an integration of both approaches. It retains high precision by limiting the size of the feature window to 5 while maximising recall by searching anywhere in the sentence, frequently outside of a limited "immediate" window.

Perhaps we can also caution against a simple adherence to Firth (1957) *"You shall know a word by the company it keeps"*. This does not appear to be the case in our experiments as PreWin regularly performs better than the "immediate" baseline. Further prototypical examples of the method can be viewed in the Appendix. Our intuition that most words in the sentence, indeed in the paragraph do not carry the semantic information required to classify the target entity is ultimately based on evidence. The model uses only a small window, linked to the entity via a head dependency relationship for the final classification decision.

5.3 Common Errors

Most of the time (typically 85% for the two datasets), PreWin is sufficient for an accurate classification. However, it does not work well in some cases. The typical 15% error rate breaks down as follows (percentages were estimated based on extensive experimentation and observation):

Discarding important context (3%): Sometimes the 5 or 10 word "immediate" baseline method would actually have been preferred such as in the sentence "...REF in 2014 ranked **Essex** in the top 20 universities...". PreWin discards the right-hand side input, which is required in this case for a correct classification. Since "ranked" is the head of "Essex", the rest of the sentence gets ignored and the valuable context gets lost.

More complex semantic patterns (11%): Many common mistakes were due to the lack

of the model's understanding of more complex predicates such as in the following sentences: " ...of military presence of **Germany**.", "**Houston** also served as a member and treasurer of the..." or "...invitations were extended to **Yugoslavia** ...". We think this is due to a lack of training data (around 1,000 sentences per dataset). Additional examples such as "...days after the tour had exited **Belgium**." expose some of the limitations of the neural model to recognise uncommon ways of expressing a reference to a literal place. Recall that no external resources or tools were used to supplement the training/features, the model had to learn to generalise from what it has seen during training, which was limited in our experiments.

Parsing mistakes (1%): were less common though still present. It is important to choose the right dependency parser for the task since different parsers will often generate slightly different parse trees. We have used SpaCy[8] for all our experiments, which is a Python-based industrial strength NLP library. Sometimes, tokenisation errors for acronyms like "U.S.A." and wrongly hyphenated words may also cause parsing errors, however, this was infrequent.

Method	Training (Size)	Acc (STD)
PreWin	SemEval (925)	**62.4** (2.30)
Immediate 5	SemEval (925)	60.6 (2.34)
Immediate 10	SemEval (925)	59.2 (2.26)
Paragraph	SemEval (925)	58.0 (2.49)
PreWin	CoNLL (6,215)	**82.8** (0.46)
Immediate 5	CoNLL (6,215)	78.2 (0.61)
Immediate 10	CoNLL (6,215)	79.1 (0.76)
Paragraph	CoNLL (6,215)	79.5 (1.50)
PreWin	ReLocaR (1,026)	**83.6** (0.71)
Immediate 5	ReLocaR (1,026)	81.4 (1.34)
Immediate 10	ReLocaR (1,026)	81.3 (1.44)
Paragraph	ReLocaR (1,026)	80.0 (2.25)
Ensemble	ReLocaR/CoNLL	**84.8** (0.34)

Table 1: Results for ReLocaR data. Figures are averaged over 10 runs. STD - Standard deviation.

5.4 Flexibility of Neural Model

The top accuracy figures for ReLocaR are almost identical to SemEval. The highest single model accuracy for ReLocaR was 83.6% (84.8% with Ensemble), which was within 0.5% of the equivalent methods for SemEval (83.1%, 84.6% for Ensemble). Both were achieved using the same methods (PreWin or Ensemble), neural architecture and size of corpora. When the models were trained on the CoNLL data, the accuracies were 82.8% and 79.5%. However, when the models trained on ReLocaR and tested on SemEval (and vice versa), accuracy dropped to between 62.4% and 69% showing that what was learnt does not seem to transfer well to another dataset. We think the reason for this is the difference in annotation guidelines; the government is a **metonymic** reading, not a literal one. This causes the model to make more mistakes.

Method	Training (Size)	Acc (STD)
PreWin	SemEval (925)	**83.1** (0.64)
Immediate 5	SemEval (925)	81.3 (1.11)
Immediate 10	SemEval (925)	81.9 (0.89)
Paragraph	SemEval (925)	81.3 (0.88)
PreWin	CoNLL (6,215)	**79.5** (0.34)
Immediate 5	CoNLL (6,215)	77.8 (1.47)
Immediate 10	CoNLL (6,215)	77.8 (1.22)
Paragraph	CoNLL (6,215)	77.2 (2.10)
PreWin	ReLocaR (1,026)	**69.0** (3.13)
Immediate 5	ReLocaR (1,026)	63.6 (5.42)
Immediate 10	ReLocaR (1,026)	64.2 (4.12)
Paragraph	ReLocaR (1,026)	64.4 (7.76)
Nastase et al.	SemEval (925)	**86.2** (N/A)
Ensemble	SemEval/CoNLL	84.6 (0.43)

Table 2: Results for SemEval data. Figures are averaged over 10 runs. STD - standard deviation.

5.5 Ensemble Method

The highest accuracy and f-scores were achieved with the ensemble method for both datasets. We combined three models (previously described in section 4.5) for SemEval to achieve 84.6% accuracy and three models for ReLocaR to achieve 84.8% for the new dataset. Training separate models with different parameters and/or on different datasets does increase classification capability as various models learn distinct aspects of the task, enabling the 1.2 - 1.5% improvement.

5.6 Dimensionality of Word Embeddings

We found that increasing dimension size (up to 300) did not materially improve performance.

[8] https://spacy.io/

The neural network tended to overfit, even with fewer epochs, the results were comparable to our default 50-dimensional embeddings. We posit that fewer dimensions of the distributed word representations force the abstraction level higher as the meaning of words must be expressed more succinctly. We think this helps the model generalise better, particularly for smaller datasets. Lastly, learning word embeddings from scratch on datasets this small (around 1,000 samples) is possible but impractical, the performance typically decreases by around 5% if word embeddings are not initialised first.

Dataset / Method	Literal	Non-Literal
SemEval / PreWin	90.6	57.3
SemEval / SOTA	**91.6**	**59.1**
ReLocaR / PreWin	84.4	84.8

Table 3: Per class f-scores - all figures obtained using the Ensemble method, averaged over 10 runs. Note the model class bias for SemEval.

5.7 F-Scores and Class Imbalance

Table 3 shows the SOTA f-scores, our best results for SemEval 2007 and the best f-scores for ReLocaR. The class imbalance inside SemEval (80% literal, 18% metonymic, 2% mixed) is reflected as a high bias in the final model. This is not the case with ReLocaR and its 49% literal, 49% metonymic and 2% mixed ratio of 3 classes. The model was equally capable of distinguishing between literal and non-literal cases.

5.8 Another baseline

There was another baseline we tested, however, it was not covered anywhere so far because of its low performance. It was a type of extreme parse tree pruning, during which most of the sentence gets discarded and we only retain 3 to 4 content words. The method uses non-local (long range) dependencies to construct a short input sequence. However, the method was a case of ignoring too many relevant words and accuracy was fluctuating in the mid-60% range, which is why we did not report the results. However, it serves to further justify the choice of 5 words as the predicate window as fewer words caused the model to underperform.

6 Discussion

6.1 NER, GP and Metonymy

We think the next frontier is a NER tagger, which actively handles metonymy. The task of labelling entities should be mainly driven by context rather than the word's surface form. If the target entity looks like "**London**", this should not mean the entity is automatically a location. Metonymy is a frequent linguistic phenomenon (around 20% of location mentions are metonymic, see section 3.1) and could be handled by NER taggers to enable many innovative downstream NLP applications.

Geographical Parsing is a pertinent use case. In order to monitor/mine text documents for geographical information only, the current NER technology does not have a solution. We think it is incorrect for any NER tagger to label "Vancouver" as a location in "*Vancouver welcomes you!*". A better output might be something like the following: *Vancouver = location AND metonymy = True*. This means Vancouver is usually a location but is used metonymically in this case. How this information is used will be up to the developer. Organisations behaving as persons, share prices or products are but a few other examples of metonymy.

6.2 Simplicity and Minimalism

Previous work in MR such as most of the SemEval 2007 participants (Farkas et al., 2007; Nicolae et al., 2007; Leveling, 2007; Brun et al., 2007; Poibeau, 2007) and the more recent contributions used a selection of many of the following features/tools for classification: handmade trigger word lists, WordNet, VerbNet, FrameNet, extra features generated/learnt from parsing Wikipedia (approx 3B words) and BNC (approx 100M words), custom databases, handcrafted features, multiple (sometimes proprietary) parsers, Levin's verb classes, 3,000 extra training instances from a corpus called MAScARA[9] by Markert and Nissim (2002) and other extra resources including the SemEval Task 8 features. We managed to achieve comparable performance with a small neural network typically trained in no more than 5 epochs, minimal training data, a basic dependency parser and the new PreWin method by being highly discriminating in choosing signal over noise.

[9] http://homepages.inf.ed.ac.uk/mnissim/mascara/

7 Conclusions and Future Work

We showed how a minimalist neural approach can replace substantial external resources, handcrafted features and how the PreWin method can even ignore most of the paragraph where the entity is positioned and still achieve competitive performance in metonymy resolution. The pressing new question is: "How much better the performance could have been if our method availed itself of the extra training data and resources used by previous works?" Indeed this may be the next research chapter for PreWin.

We discussed how tasks such as Geographical Parsing can benefit from "metonymy-enhanced" NER tagging. We have also presented a case for better annotation guidelines for MR (after consulting with a number of linguists), which now means that a government is not a literal class, rather it is a metonymic one. We fully agreed with the rest of the previous annotation guidelines. We also introduced ReLocaR, a new corpus for (location) metonymy resolution and encourage researchers to make effective use of it (including the additional CoNLL 2003 subset we annotated for metonymy).

Future work may involve testing PreWin on an NER task to see if and how it can generalise to a different classification task and how the results compare to the SOTA and similar methods such as that of Collobert et al. (2011) using the CoNLL 2003 NER datasets. Word Sense Disambiguation (Yarowsky, 2010; Pilehvar and Navigli, 2014) with neural networks (Melamud et al., 2016) is another related classification task suitable for testing PreWin. If it does perform better, this will be of considerable interest to classification research (and beyond) in NLP.

Abstract

We propose a novel geolocation prediction model using a complex neural network. Our model unifies text, metadata, and user network representations with an attention mechanism to overcome previous ensemble approaches. In an evaluation using two open datasets, the proposed model exhibited a maximum 3.8% increase in accuracy and a maximum of 6.6% increase in accuracy@161 against previous models. We further analyzed several intermediate layers of our model, which revealed that their states capture some statistical characteristics of the datasets.

1 Introduction

Social media sites have become a popular source of information to analyze current opinions of numerous people. Many researchers have worked to realize various automated analytical methods for social media because manual analysis of such vast amounts of data is difficult. Geolocation prediction is one such analytical method that has been studied widely to predict a user location or a document location. Location information is crucially important information for analyses such as disaster analysis (Sakaki et al., 2010), disease analysis (Culotta, 2010), and political analysis (Tumasjan et al., 2010). Such information is also useful for analyses such as sentiment analysis (Martínez-Cámara et al., 2014) and user attribute analysis (Rao et al., 2010) to undertake detailed region-specific analyses.

Geolocation prediction has been performed for Wikipedia (Overell, 2009), Flickr (Serdyukov et al., 2009; Crandall et al., 2009), Facebook (Backstrom et al., 2010), and Twitter (Cheng et al., 2010; Eisenstein et al., 2010). Among these sources, Twitter is often preferred because of its characteristics, which are suited for geolocation prediction. First, some tweets include geotags, which are useful as ground truth locations. Secondly, tweets include *metadata* such as timezones and self-declared locations that can facilitate geolocation prediction. Thirdly, a user network is obtainable by consideration of the interaction between two users as a network link.

Herein, we propose a neural network model to tackle geolocation prediction in Twitter. Past studies have combined text, metadata, and user network information with ensemble approaches (Han et al., 2013, 2014; Rahimi et al., 2015a; Jayasinghe et al., 2016) to achieve state-of-the-art performance. Our model combines text, metadata, and user network information using a complex neural network. Neural networks have recently shown effectiveness to capture complex representations combining simpler representations from large-scale datasets (Goodfellow et al., 2016). We intend to obtain unified text, metadata, and user network representations with an attention mechanism (Bahdanau et al., 2014) that is superior to the earlier ensemble approaches. The contributions of this paper are the following:

1. We propose a neural network model that learns unified text, metadata, and user network representations with an attention mechanism.
2. We show that the proposed model outperforms the previous ensemble approaches in two open datasets.
3. We analyze some components of the proposed model to gain insight into the unification processes of the model.

Our model specifically emphasizes geolocation prediction in Twitter to use benefits derived from the characteristics described above. However, our

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1260–1272
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1116

model can be readily extended to other social media analyses such as user attribute analysis and political analysis, which can benefit from metadata and user network information.

In subsequent sections of this paper, we explain the related works in four perspectives in Section 2. The proposed neural network model is described in Section 3 along with two open datasets that we used for evaluations in Section 4. Details of an evaluation are reported in Section 5 with discussions in Section 6. Finally, Section 7 concludes the paper with some future directions.

2 Related Works

2.1 Text-based Approach

Probability distributions of words over locations have been used to estimate the geolocations of users. Maximum likelihood estimation approaches (Cheng et al., 2010, 2013) and language modeling approaches minimizing KL-divergence (Wing and Baldridge, 2011; Kinsella et al., 2011; Roller et al., 2012) have succeeded in predicting user locations using word distributions. Topic modeling approaches to extract latent topics with geographical regions (Eisenstein et al., 2010, 2011; Hong et al., 2012; Ahmed et al., 2013) have also been explored considering word distributions.

Supervised machine learning methods with word features are also popular in text-based geolocation prediction. Multinomial Naive Bayes (Han et al., 2012, 2014; Wing and Baldridge, 2011), logistic regression (Wing and Baldridge, 2014; Han et al., 2014), hierarchical logistic regression (Wing and Baldridge, 2014), and a multilayer neural network with stacked denoising autoencoder (Liu and Inkpen, 2015) have realized geolocation prediction from text. A semi-supervised machine learning approach by Cha et al. (2015) has also been produced using a sparse-coding and dictionary learning.

2.2 User-network-based Approach

Social media often include interactions of several kinds among users. These interactions can be regarded as links that form a network among users. Several studies have used such user network information to predict geolocation. Backstrom et al. (2010) introduced a probabilistic model to predict the location of a user using friendship information in Facebook. Friend and follower information in Twitter were used to predict user locations with a most frequent friend algorithm (Davis Jr. et al., 2011), a unified descriptive model (Li et al., 2012b), location-based generative models (Li et al., 2012a), dynamic Bayesian networks (Sadilek et al., 2012), a support vector machine (Rout et al., 2013), and maximum likelihood estimation (McGee et al., 2013). Mention information in Twitter is also used with label propagation models (Jurgens, 2013; Compton et al., 2014) and an energy and social local coefficient model (Kong et al., 2014). Jurgens et al. (2015) compared nine user-network-based approaches targeting Twitter, controlling data conditions.

2.3 Metadata-based Approach

Metadata such as location fields are useful as effective clues to predict geolocation. Hecht et al. (2011) reported that decent accuracy of geolocation prediction can be achieved using location fields. Approaches to combine metadata with texts are also proposed to extend text-based approaches. Combinatory approaches such as a dynamically weighted ensemble method (Mahmud et al., 2012), polygon stacking (Schulz et al., 2013), stacking (Han et al., 2013, 2014), and average pooling with a neural network (Miura et al., 2016) have strengthened geolocation prediction.

2.4 Combinatory Approach Extending User-network-based Approach

Several attempts have been made to combine user-network-based approaches with other approaches. A text-based approach with logistic regression was combined with label propagation approaches to enhance geolocation prediction (Rahimi et al., 2015a,b, 2016). Jayasinghe et al. (2016) combined nine components including text-based approaches, metadata-based approaches, and a user-network-based approach with a cascade ensemble method.

2.5 Comparisons with Proposed Model

A model we propose in Section 3 which combines text, metadata, and user network information with a neural network, can be regarded as an alternative to approaches using text and metadata (Mahmud et al., 2012; Schulz et al., 2013; Han et al., 2013, 2014; Miura et al., 2016), approaches with text and user network information (Rahimi et al., 2015a,b), and an approach with text, metadata, and user network information (Jayasinghe et al., 2016). In Section 5, we demonstrate that our model outperforms earlier models.

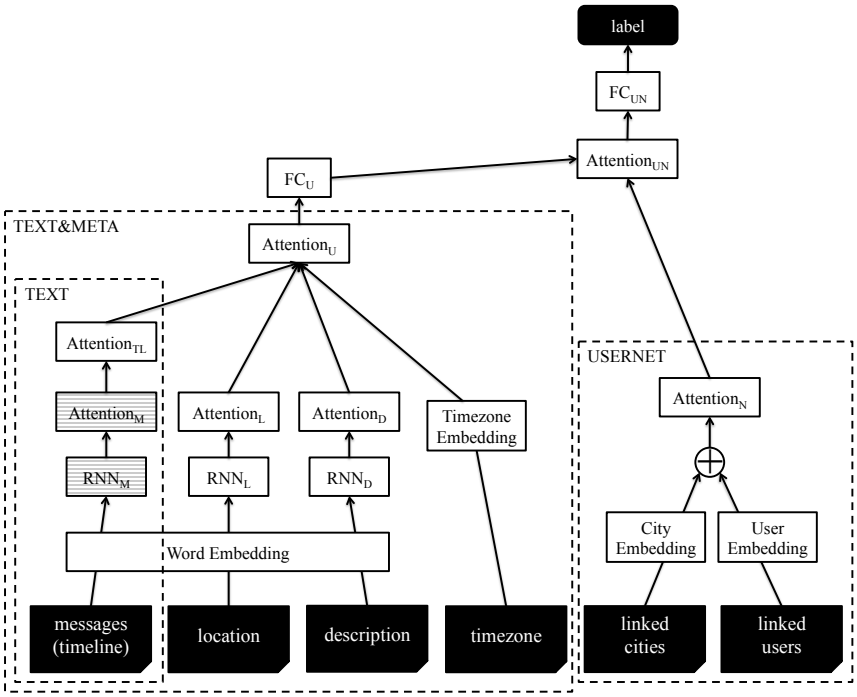

Figure 1: Overview of the proposed model. RNN denotes a recurrent neural network layer. FC denotes a fully connected layer. The striped layers are message-level processes. $\oplus$ represents element-wise addition.

In terms of machine learning methods, our model is a neural network model that shares some similarity with previous neural network models (Liu and Inkpen, 2015; Miura et al., 2016). Our model and these previous models have two key differences. First, our model integrates user network information along with other information. Secondly, our model combines text and metadata with an attention mechanism (Bahdanau et al., 2014).

3 Model

3.1 Proposed Model

Figure 1 presents an overview of our model: a complex neural network for classification with a city as a label. For each user, the model accepts inputs of messages, a location field, a description field, a timezone, linked users, and the cities of linked users.

User network information is incorporated by city embeddings and user embeddings of linked users. User embeddings are introduced along with city embeddings because linked users with city information[1] are limited. We chose to let the model learn geolocation representations of linked users directly via user embeddings. The model can be broken down to several components, details of which are described in Section 3.1.1–3.1.4.

3.1.1 Text Component

We describe the text component of the model, which is the "TEXT" section in Figure 1. Figure 2 presents an overview of the text component. The component consists of a recurrent neural network (RNN) (Graves, 2012) layer and attention layers. An input of the component is a *timeline* of a user, which consists of messages in a time sequence.

As an implementation of RNN, we used Gated Recurrent Unit (GRU) (Cho et al., 2014) with a bi-directional setting. In the RNN layer, word embeddings $\boldsymbol{x}$ of a message are processed with the following transition functions:

$$\boldsymbol{z}_t = \sigma\left(\boldsymbol{W}_z \boldsymbol{x}_t + \boldsymbol{U}_z \boldsymbol{h}_{t-1} + \boldsymbol{b}_z\right) \quad (1)$$

$$\boldsymbol{r}_t = \sigma\left(\boldsymbol{W}_r \boldsymbol{x}_t + \boldsymbol{U}_r \boldsymbol{h}_{t-1} + \boldsymbol{b}_r\right) \quad (2)$$

$$\tilde{\boldsymbol{h}}_t = \tanh\left(\boldsymbol{W}_h \boldsymbol{x}_t + \boldsymbol{U}_h \left(\boldsymbol{r}_t \odot \boldsymbol{h}_{t-1}\right) + \boldsymbol{b}_h\right) \quad (3)$$

$$\boldsymbol{h}_t = \left(\boldsymbol{1} - \boldsymbol{z}_t\right) \odot \boldsymbol{h}_{t-1} + \boldsymbol{z}_t \odot \tilde{\boldsymbol{h}}_t \quad (4)$$

where $\boldsymbol{z}_t$ is an update gate, $\boldsymbol{r}_t$ is a reset gate, $\tilde{\boldsymbol{h}}_t$ is a candidate state, $\boldsymbol{h}_t$ is a state, $\boldsymbol{W}_z, \boldsymbol{W}_r, \boldsymbol{W}_h, \boldsymbol{U}_z, \boldsymbol{U}_r, \boldsymbol{U}_h$ are weight matrices, $\boldsymbol{b}_z, \boldsymbol{b}_r, \boldsymbol{b}_h$ are bias vectors, σ is a logistic sigmoid function, and $\odot$ is an element-wise multiplication operator. The bi-directional GRU outputs $\overrightarrow{\boldsymbol{h}}$

[1] City information are provided by a dataset. The detail of the city information is explained in Section 4.

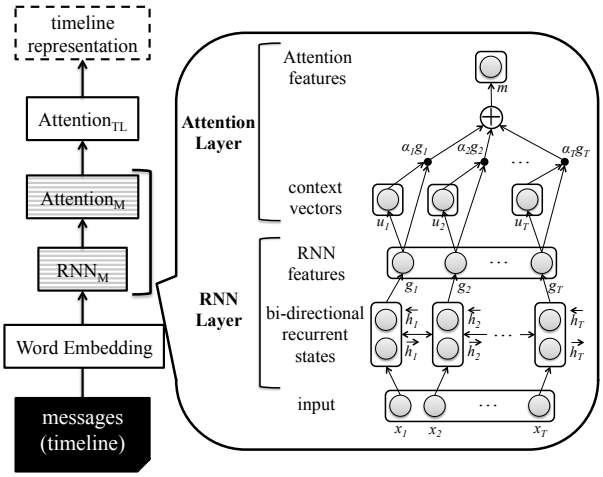

Figure 2: Overview of the text component with detailed description of $\mathrm{RNN_M}$ and $\mathrm{Attention_M}$.

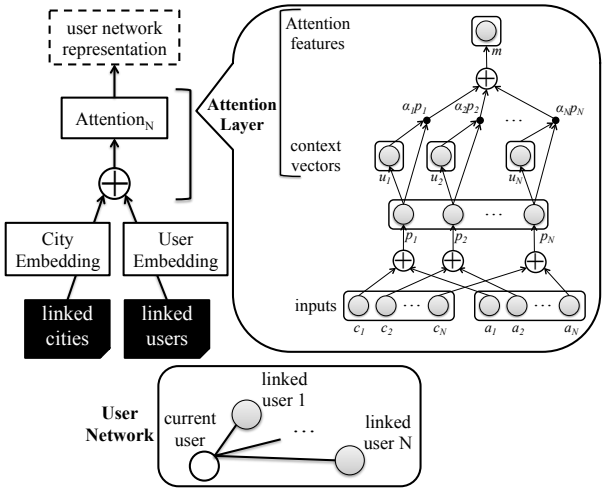

Figure 3: Overview of the user network component with a detailed description of the element-wise addition and $\mathrm{Attention_N}$.

and $\overleftarrow{\boldsymbol{h}}$ are concatenated to form $\boldsymbol{g}$ *where* $\boldsymbol{g}_t = \overrightarrow{\boldsymbol{h}_t} \| \overleftarrow{\boldsymbol{h}_t}$ and are passed to the first attention layer $\mathrm{Attention_M}$.

$\mathrm{Attention_M}$ computes a message representation $\boldsymbol{m}$ as a weighted sum of $\boldsymbol{g}_t$ with weight α_t:

$$\boldsymbol{m} = \sum_t \alpha_t \boldsymbol{g}_t \tag{5}$$

$$\alpha_t = \frac{\exp\left(\boldsymbol{v}_\alpha^T \boldsymbol{u}_t\right)}{\sum_t \exp\left(\boldsymbol{v}_\alpha^T \boldsymbol{u}_t\right)} \tag{6}$$

$$\boldsymbol{u}_t = \tanh\left(\boldsymbol{W}_\alpha \boldsymbol{g}_t + \boldsymbol{b}_\alpha\right) \tag{7}$$

where $\boldsymbol{v}_\alpha$ is a weight vector, $\boldsymbol{W}_\alpha$ is a weight matrix, and $\boldsymbol{b}_\alpha$ a bias vector. $\boldsymbol{u}_t$ is an attention context vector calculated from $\boldsymbol{g}_t$ with a single fully-connected layer (Eq. 7). $\boldsymbol{u}_t$ is normalized with softmax to obtain α_t as a probability (Eq. 6). The message representation $\boldsymbol{m}$ is passed to the second attention layer $\mathrm{Attention_{TL}}$ to obtain a timeline representation from message representations.

3.1.2 Text and Metadata Component

We describe text and metadata components of the model, which is the "TEXT&META" section in Figure 1. This component considers the following three types of metadata along with text: **location** a text field in which a user is allowed to write the user location freely, **description** a text field a user can use for self-description, and **timezone** a selective field from which a user can choose a timezone. Note that certain percentages of these fields are not available[2], and *unknown* tokens are used for inputs in such cases.

We process location fields and description fields similarly to messages using an RNN layer and an attention layer. Because there is only one location and one description per user, a second attention layer is not required, as it is in the text component. We also chose to share word embeddings among the messages, the location, and the description processes because these inputs are all textual information. For the timezone, an embedding is assigned for each timezone value. A processed timeline representation, a location representation, and a description representation are then passed to the attention layer $\mathrm{Attention_U}$ with a timezone representation. $\mathrm{Attention_U}$ combines these four representations and outputs a user representation. This combination is done as in $\mathrm{Attention_{TL}}$ with four representations as $g_1 \ldots g_4$ in Eq. 5.

3.1.3 User Network Component

We describe the user network component of the model, which is the "USERNET" section in Figure 1. Figure 3 presents an overview of the user network component. The model has two inputs *linked cities* and *linked users*. Users connected with a user network are extracted as linked users. We treat their cities[3] as linked cities. Linked cities and linked users are assigned with city embeddings $\boldsymbol{c}$ and user embeddings $\boldsymbol{a}$ respectively. $\boldsymbol{c}$ and $\boldsymbol{a}$ are then processed to output $\boldsymbol{p} = \boldsymbol{c} \oplus \boldsymbol{a}$, where $\oplus$ is an element-wise addition operator. $\boldsymbol{p}$ is then passed to the subsequent attention layer $\mathrm{Attention_N}$ to obtain a user network representa-

[2]Han et al. (2014) reported missing percentages of 19% for location, 24% for description, and 25%for timezone.

[3]A user with city information implies that the user is included in a training set.

	TwitterUS (train)	W-NUT (train)

#edge	3.69M	3.21M
#reduced-edge	2.11M	1.01M
reduced-edge/user	7.04	1.29
#city	339	3028

Table 1: Some properties of TwitterUS (train) and W-NUT (train). We were able to obtain approximately 70–78% of the full datasets because of accessibility changes in Twitter.

tion as in $\mathrm{Attention_U}$.

3.1.4 Model Output

An output of the text and metadata component and an output of the mention network component are further passed to the final attention layer $\mathrm{Attention_{UN}}$ to obtain a merged user representation as in $\mathrm{Attention_U}$. The merged user representation is then connected to labels with a fully connected layer $\mathrm{FC_{UN}}$.

3.2 Sub-models of the Proposed Model

SUB-NN-TEXT We prepare a sub-model SUB-NN-TEXT by adding $\mathrm{FC_U}$ and $\mathrm{FC_{UN}}$ to the text component. This sub-model can be considered as a variant of a neural network model by Yang et al. (2016), which learns a representation of hierarchical text.

SUB-NN-UNET We prepare a sub-model SUB-NN-UNET by connecting the text component and the user network component with $\mathrm{FC_U}$, $\mathrm{Attention_{UN}}$, and $\mathrm{FC_{UN}}$. This model can be regarded as a model that uses text and user network information.

SUB-NN-META We prepare a sub-model SUB-NN-META by adding $\mathrm{FC_U}$ and $\mathrm{FC_{UN}}$ to the metadata component. This model is a text-meta-based model that uses text and metadata.

4 Data

4.1 Dataset Specifications

TwitterUS The first dataset we used is TwitterUS assembled by Roller et al. (2012), which consists of 429K training users, 10K development users, and 10K test users in a North American region. The ground truth location of a user is set to the first geotag of the user in the dataset. We collected TwitterUS tweets using TwitterAPI to reconstruct TwitterUS to obtain metadata along with text. Up to date versions in November–December 2016 were used for the metadata[4]. We additionally assigned city centers to ground truth geotags using the city category of Han et al. (2012) to make city prediction possible in this dataset. TwitterUS (train) in Table 1 presents some properties related to the TwitterUS training set.

W-NUT The second dataset we used is W-NUT, a user-level dataset of the geolocation prediction shared task of W-NUT 2016 (Han et al., 2016). The dataset consists of 1M training users, 10K development users, and 10K test users. The ground truth location of a user is decided by majority voting of the closest city center. Like in TwitterUS, we obtained metadata and texts using TwitterAPI. Up to date versions in August–September 2016 were used for the metadata. W-NUT (train) in Table 1 presents some properties related to the W-NUT training set.

4.2 Construction of the User Network

We construct mention networks (Jurgens, 2013; Compton et al., 2014; Rahimi et al., 2015a,b) from datasets as user networks. To do so, we follow the approach of Rahimi et al. (2015a) and Rahimi et al. (2015b) who use uni-directional mention to set edges of a mention network. An edge is set between the two users nodes if a user mentions another user. The number of uni-directional mention edges for TwitterUS and W-NUT can be found in Table 1.

The uni-directional setting results to large numbers of edges, which often are computationally expensive to process. We restricted edges to satisfy one of the following conditions to reduce the size: (1) both users have ground truth locations or (2) one user has a ground truth location and another user is mentioned 5 times or more in a training set. The number of reduced-edges with these conditions in TwitterUS and W-NUT can be confirmed in Table 1.

5 Evaluation

5.1 Implemented Baselines

5.1.1 LR

LR is an l_1-regularized logistic regression model with k-d tree regions (Roller et al., 2012) used

[4]TwitterAPI returns the current version of metadata even for an old tweet.

in Rahimi et al. (2015a). The model uses tf-idf weighted bag-of-words unigrams for features. This model is simple, but it has shown state-of-the-art performance in cases when only text is available.

5.1.2 MADCEL-B-LR

MADCEL-B-LR, a model presented by (Rahimi et al., 2015a), combines LR with Modified Adsorption (MAD) (Talukdar and Crammer, 2009). MAD is a graph-based label propagation algorithm that optimizes an objective with a prior term, a smoothness term, and an uninformativeness term. LR is combined with MAD by introducing LR results as dongle nodes to MAD.

This model includes an algorithm for the construction of a mention network. The algorithm removes *celebrity users*[5] and *collapses a mention network*[6]. We use binary edges for user network edges because they performed slightly better than weighted edges by accuracy@161 metric in Rahimi et al. (2015a).

5.1.3 LR-STACK

LR-STACK is an ensemble learning model that combines four LR classifiers (LR-MSG, LR-LOC, LR-DESC, LR-TZ) with an l_2-regularized logistic regression meta-classifier (LR-2ND). LR-MSG, LR-LOC, LR-DESC, and LR-TZ respectively use messages, location fields, description fields, and timezones as their inputs. This model is similar to the stacking (Wolpert, 1992) approach taken in Han et al. (2013) and Han et al. (2014), which showed superior performance compared to a feature concatenation approach.

The model takes the following three steps to combine text and metadata: **Step 1** LR-MSG, LR-LOC, LR-DESC, and LR-TZ are trained using a training set, **Step 2** the outputs of the four classifiers on the training set are obtained with 10-fold cross validation, and **Step 3** LR-2ND is trained using the outputs of the four classifiers.

5.1.4 MADCEL-B-LR-STACK

MADCEL-B-LR-STACK is a combined model of MADCEL-B-LR and LR-STACK. LR-STACK results are introduced as dongle nodes to MAD instead of LR results to combine text, metadata, and network information.

[5]Users with more than t unique mentions.

[6]Users not included in training users or test users are removed and disconnected edges with the removals are converted to direct edges.

5.2 Model Configurations

5.2.1 Text Processor

We applied a lower case conversion, a unicode normalization, a Twitter user name normalization, and a URL normalization for text pre-processing. The pre-processed text is then segmented using Twokenizer (Owoputi et al., 2013) to obtain words.

5.2.2 Pre-training of Embeddings

We pre-trained word embeddings using messages, location fields, and description fields of a training set using fastText (Bojanowski et al., 2016) with the skip-gram algorithm. We also pre-trained user embeddings using the non-reduced mention network described in Section 4.2 of a training set with LINE (Tang et al., 2015). The detail of pre-training parameters are described in Appendix A.1.

5.2.3 Neural Network Optimization

We chose an objective function of our models to cross-entropy loss. l_2 regularization was applied to the RNN layers, the attention context vectors, and the FC layers of our models to avoid overfitting. The objective function was minimized through stochastic gradient descent over shuffled mini-batches with Adam (Kingma and Ba, 2014).

5.2.4 Model Parameters

The layers and the embeddings in our models have unit size and embedding dimension parameters. Our models and the baseline models have regularization parameter α, which is sensitive to a dataset. The baseline models have additional k-d tree bucket size c, celebrity threshold t, and MAD parameters μ_1, μ_2, and μ_3, which are also data sensitive.

We chose optimal values for these parameters in terms of accuracy with a grid search using the development sets of TwitterUS and W-NUT. Details of the parameter selection strategies and the selected values are described in Appendix A.2.

5.2.5 Metrics

We evaluate the models in the following four commonly used metrics in geolocation prediction: **accuracy** the percentage of correctly predicted cities, **accuracy@161** a relaxed accuracy that takes prediction errors within 161 km as correct predictions, **median error distance** median value of error distances in predictions, and **mean error distance** mean value of error distances in predictions.

	Model	Sign. Test ID	Accuracy	Accuracy @161	Error Distance

Table 3: Performance of our models and baseline models on W-NUT. The same notations as those in Table 2 are used in this table.

5.3 Result

Performance on TwitterUS

Table 2 presents results of our models and the implemented baseline models on TwitterUS. We also list values from earlier reports (Han et al., 2012; Wing and Baldridge, 2014; Rahimi et al., 2015a,b, 2016) to make our results readily comparable with past reported values.

We performed some statistical significance tests among model pairs that share the same inputs. The values in the Sign. Test ID column of Table 2 represent the IDs of these pairs. As a preparation of statistical significance tests, accuracies, accuracy@161s, and error distances of each test user were calculated for each model pair. Two-sided Fisher-Pittman Permutation tests were used for testing accuracy and accuracy@161. Mood's median test was used for testing error distance in terms of median. Paired t-tests were used for testing error distance in terms of mean.

We confirmed the significance of improvements in accuracy@161 and mean distance error for all of our models. Three of our models also improved in terms of accuracy. Especially, the proposed model achieved a 2.8% increase in accuracy and a 2.4% increase in accuracy@161 against the counterpart baseline model MADCEL-B-LR-STACK. One negative result we found was the median error distance between SUB-NN-META and LR-STACK. The baseline model LR-STACK performed 4.5 km significantly better than our model.

Performance on W-NUT

Table 3 presents the results of our models and the implemented baseline models on W-NUT. As for TwitterUS, we listed values from Miura et al. (2016) and Jayasinghe et al. (2016). We tested the significance of these results in the same way as we did for TwitterUS.

We confirmed significant improvement in the four metrics for all of our models. The proposed model achieved a 4.8% increase in accuracy and a

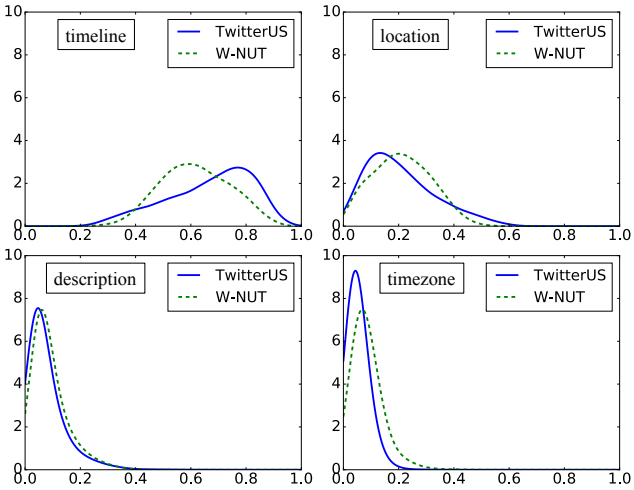

Figure 4: Estimated probability density functions of the four representations in $\text{Attention}_{\text{U}}$.

6.6% increase in accuracy@161 against the counterpart baseline model MADCEL-B-LR-STACK. The accuracy is 3.8% higher against the previously reported best value (Jayasinghe et al., 2016) which combined texts, metadata, and user network information with an ensemble method.

6 Discussion

6.1 Analyses of Attention Probabilities

6.1.1 Unification Strategies

In the evaluation, the proposed model has implicitly shown effectiveness at unifying text, metadata, and user network representations through improvements in the four metrics. However, details of the unification processes are not clear from the model outputs because they are merely the probabilities of estimated locations. To gain insight into the unification processes, we analyzed the states of two attention layers: $\text{Attention}_{\text{U}}$ and $\text{Attention}_{\text{UN}}$ in Figure 1.

Figure 4 presents the estimated probability density functions (PDFs) of the four input representations for $\text{Attention}_{\text{U}}$. These PDFs are estimated with kernel density estimation from the development sets of TwitterUS and W-NUT, where all four representations are available. From the PDFs, it is apparent that the model assigns higher probabilities to time line representations than to other three representations in TwitterUS compared to W-NUT. This finding is reasonable because timelines in TwitterUS consist of more tweets (tweet/user in Table 1) and are likely to be more informative than in W-NUT.

Figure 5 presents the estimated PDFs of user network representations for $\text{Attention}_{\text{UN}}$. These

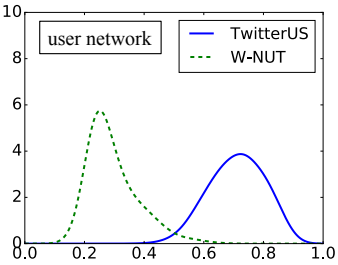

Figure 5: Estimated probability density functions of user network representations in $\text{Attention}_{\text{UN}}$.

PDFs are estimated from the development sets of TwitterUS and W-NUT, where both input representations are available. Strong preference of network representation for TwitterUS against W-NUT is found in the PDFs. This finding is intuitive because TwitterUS has substantially more user network edges (reduced-edge/user in Table 1) than W-NUT, which is likely to benefit more from user network information.

6.1.2 Attention Patterns

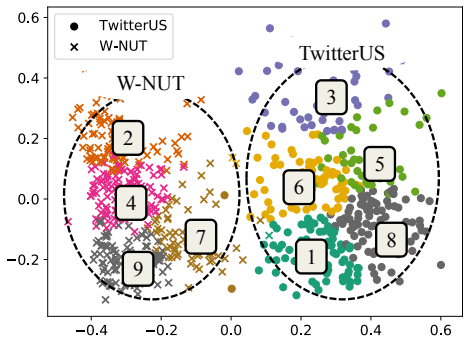
We further analyzed the proposed model by clustering attention probabilities to capture typical attention patterns. For each user, we assigned six attention probabilities of $\text{Attention}_{\text{U}}$ and $\text{Attention}_{\text{UN}}$ as features for a clustering. A k-means clustering was performed over these users with 9 clusters. The clustering clearly separated the users to 5 clusters for TwitterUS users and 4 clusters for W-NUT users. We extracted typical users of each cluster by selecting the closest users of the cluster centroids. Figure 6 shows a clustering result and the attention probabilities of these users.

These attention probabilities can be considered as typical attention patterns of the proposed model and match with the previously estimated PDFs. For example, cluster 2 and 3 represent an attention pattern that processes users by balancing the representations of locations along with the representations of timelines. Additionally, the location probabilities in this pattern are in the right tail region of the location PDF.

6.2 Limitations of Proposed Model

6.2.1 City Prediction

The evaluation produced improvements in most of our models in the four metrics. One exception we found was the median distance error between SUB-NN-META and LR-STACKING in TwitterUS. Because the median distance error of SUB-NN-META was quite low (46.8 km), we



Cluster ID	Dataset	Timeline	Location	Description	Timezone	User	User Network
1	TwitterUS	0.843	0.082	0.040	0.035	0.359	0.641
2	W-NUT	0.517	0.317	0.081	0.085	0.732	0.268
3	TwitterUS	0.432	0.430	0.069	0.069	0.319	0.681
4	W-NUT	0.637	0.160	0.097	0.105	0.737	0.263
5	TwitterUS	0.593	0.219	0.114	0.075	0.230	0.770
6	TwitterUS	0.672	0.214	0.069	0.045	0.365	0.635
7	W-NUT	0.741	0.077	0.080	0.102	0.605	0.395
8	TwitterUS	0.766	0.099	0.068	0.067	0.222	0.778
9	W-NUT	0.800	0.067	0.056	0.078	0.730	0.270

Figure 6: A k-means clustering result and the attention probabilities of users that are closest to the cluster centroids. The underlined values are the max values of the two datasets for each column.

Model	Error Distance		
	Median	Mean	σ
Oracle	23.3	31.4	30.1

Table 4: Error distance values in TwitterUS with oracle predictions. σ in the table denotes the standard deviation.

measured the performance of an oracle model where city predictions are all correct (accuracy of 100%) in the test set.

Table 4 denotes this oracle performance. The oracle mean error distance is 31.4 km. Its standard deviation is 30.1. Note that ground truth locations of TwitterUS are geotags and will not exactly match the oracle city centers. These oracle values imply that the current median error distances are close to the lower bound of the city classification approach and that they are difficult to improve.

6.2.2 Errors with High Confidences

The proposed model still contains 28–30% errors even in accuracy@161. A qualitative analysis of errors with high confidences was performed to investigate cases that the model fails. We found two common types of error in the error analysis. The first is a case when a location field is incorrect due to a reason such as a house move. For example, the model predicted "Hong Kong" for a user with a location field of "Hong Kong" but has the gold location of "Toronto". The second is a case when a user tweets a place name of a travel. For example, the model predicted "San Francisco" for a user who tweeted about a travel to "San Francisco" but has the gold location of "Boston".

These two types of error are difficult to handle with the current architecture of the proposed model. The architecture only supports single location field which disables the model to track location changes. The architecture also treats each tweet independently which forbids the model to express a temporal state like traveling.

7 Conclusion

As described in this paper, we proposed a complex neural network model for geolocation prediction. The model unifies text, metadata, and user network information. The model achieved the maximum of a 3.8% increase in accuracy and a maximum of 6.6% increase in accuracy@161 against several previous state-of-the-art models. We further analyzed the states of several attention layers, which revealed that the probabilities assigned to timeline representations and user network representations match to some statistical characteristics of datasets.

As future works of this study, we are planning to expand the proposed model to handle multiple locations and a temporal state to capture location changes and states like traveling. Additionally, we plan to apply the proposed model to other social media analyses such as gender analysis and age analysis. In these analyses, metadata like location fields and timezones may not be effective like in geolocation prediction. However, a user network is known to include various user attributes information including gender and age (McPherson et al., 2001) which suggests the unification of text and user network information to result in a success as in geolocation prediction.

A Supplemental Materials

A.1 Parameters of Embedding Pre-training

Word embeddings were pre-trained with the parameters of learning rate=0.025, window size=5, negative sample size=5, and epoch=5. User embeddings were pre-trained with the parameters of initial learning rate=0.025, order=2, negative sample size=5, and training sample size=100M.

A.2 Model Parameters and Parameter Selection Strategies

Unit Sizes, Embedding Dimensions, and a Max Tweet Number

The layers and the embeddings in our models have unit size and embedding dimension parameters. We also restricted the maximum number of tweets per user for TwitterUS to reduce memory footprints. Table 5 shows the values for these parameters. Smaller values were set for TwitterUS because TwitterUS is approximately 2.6 times larger in terms of tweet number. It was computationally expensive to process TwiiterUS in the same settings as W-NUT.

Regularization Parameters and Bucket Sizes

We chose optimal values of α using a grid search with the development sets of TwitterUS and W-NUT. The range of α was set as the following:
$\alpha \in \{1e^{-4}, 5e^{-5}, 1e^{-5}, 5e^{-6}, 1e^{-6}, 5e^{-7}, 1e^{-7}, 5e^{-8}, 1e^{-8}\}$.

We also chose optimal values of c using grid search with the development sets of TwitterUS and W-NUT for the baseline models. The range of c was set as the following for TwitterUS:
$c \in \{50, 100, 150, 200, 250, 300, 339\}$.
The following was set for W-NUT:
$c \in \{100, 200, 300, 400, 500, 600, 700, 800, 900, 1000, 1500, 2000, 2500, 3000, 3028\}$.
Table 6 presents selected values of α and c. For LR-STACK and MADCEl-B-LR-STACK, different parameters of α and c were selected for each logistic regression classifier.

MAD Parameters and Celebrity Threshold

The MAD parameters μ_1, μ_2, and μ_3 and celebrity threshold t were also chosen using grid search with the development sets of TwitterUS and W-NUT. The ranges of μ_1, μ_2, and μ_3 were set as the following:
$\mu_1 \in \{1.0\}$, $\mu_2 \in \{0.001, 0.01, 0.1, 1.0, 10.0\}$,
$\mu_3 \in \{0.0, 0.001, 0.01, 0.1, 1.0, 10.0\}$.
The range of t for TwitterUS was set as $t \in \{2, \ldots, 16\}$. The range of t for W-NUT was set as $t \in \{2, \ldots, 6\}$. Table 6 presents selected values of μ_1, μ_2, μ_3, and t.

	TwitterUS	W-NUT
RNN unit size	100	200
Attention context vector size	200	400
FC unit size	200	400
Word embedding dimension	100	200
Timezone embedding dimension	200	400
City embedding dimension	200	400
User embedding dimension	200	400
Max tweet number per user	200	-

Multi-Task Video Captioning with Video and Entailment Generation

Ramakanth Pasunuru and **Mohit Bansal**
UNC Chapel Hill
{ram, mbansal}@cs.unc.edu

Abstract

Video captioning, the task of describing the content of a video, has seen some promising improvements in recent years with sequence-to-sequence models, but accurately learning the temporal and logical dynamics involved in the task still remains a challenge, especially given the lack of sufficient annotated data. We improve video captioning by sharing knowledge with two related directed-generation tasks: a temporally-directed unsupervised video prediction task to learn richer context-aware video encoder representations, and a logically-directed language entailment generation task to learn better video-entailing caption decoder representations. For this, we present a many-to-many multi-task learning model that shares parameters across the encoders and decoders of the three tasks. We achieve significant improvements and the new state-of-the-art on several standard video captioning datasets using diverse automatic and human evaluations. We also show mutual multi-task improvements on the entailment generation task.

1 Introduction

Video captioning is the task of automatically generating a natural language description of the content of a video, as shown in Fig. 1. It has various applications such as assistance to a visually impaired person and improving the quality of online video search or retrieval. This task has gained recent momentum in the natural language processing and computer vision communities, esp. with the advent of powerful image processing features as well as sequence-to-sequence LSTM models. It is also a step forward from static image captioning, because in addition to modeling the spatial visual features, the model also needs to learn the temporal across-frame action dynamics and the logical storyline language dynamics.

Ground truth: A person is mixing powdered ingradients with water.
A woman is mixing flour and water in a bowl.
Our model: A person is mixing ingredients in a bowl.

Figure 1: A video captioning example from the YouTube2Text dataset, with the ground truth captions and our many-to-many multi-task model's predicted caption.

Previous work in video captioning (Venugopalan et al., 2015a; Pan et al., 2016b) has shown that recurrent neural networks (RNNs) are a good choice for modeling the temporal information in the video. A sequence-to-sequence model is then used to 'translate' the video to a caption. Venugopalan et al. (2016) showed linguistic improvements over this by fusing the decoder with external language models. Furthermore, an attention mechanism between the video frames and the caption words captures some of the temporal matching relations better (Yao et al., 2015; Pan et al., 2016a). More recently, hierarchical two-level RNNs were proposed to allow for longer inputs and to model the full paragraph caption dynamics of long video clips (Pan et al., 2016a; Yu et al., 2016).

Despite these recent improvements, video captioning models still suffer from the lack of sufficient temporal and logical supervision to be able to correctly capture the action sequence and story-dynamic language in videos, esp. in the case of short clips. Hence, they would benefit from incorporating such complementary directed knowledge, both visual and textual. We address this by jointly training the task of video captioning with two related directed-generation tasks: a temporally-

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1273–1283
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1117

directed unsupervised video prediction task and a logically-directed language entailment generation task. We model this via many-to-many multi-task learning based sequence-to-sequence models (Luong et al., 2016) that allow the sharing of parameters among the encoders and decoders across the three different tasks, with additional shareable attention mechanisms.

The unsupervised video prediction task, i.e., video-to-video generation (adapted from Srivastava et al. (2015)), shares its encoder with the video captioning task's encoder, and helps it learn richer video representations that can predict their temporal context and action sequence. The entailment generation task, i.e., premise-to-entailment generation (based on the image caption domain SNLI corpus (Bowman et al., 2015)), shares its decoder with the video captioning decoder, and helps it learn better video-entailing caption representations, since the caption is essentially an entailment of the video, i.e., it describes subsets of objects and events that are logically implied by or follow from the full video content). The overall many-to-many multi-task model combines all three tasks.

Our three novel multi-task models show statistically significant improvements over the state-of-the-art, and achieve the best-reported results (and rank) on multiple datasets, based on several automatic and human evaluations. We also demonstrate that video captioning, in turn, gives mutual improvements on the new multi-reference entailment generation task.

2 Related Work

Early video captioning work (Guadarrama et al., 2013; Thomason et al., 2014; Huang et al., 2013) used a two-stage pipeline to first extract a subject, verb, and object (S,V,O) triple and then generate a sentence based on it. Venugopalan et al. (2015b) fed mean-pooled static frame-level visual features (from convolution neural networks pre-trained on image recognition) of the video as input to the language decoder. To harness the important frame sequence temporal ordering, Venugopalan et al. (2015a) proposed a sequence-to-sequence model with video encoder and language decoder RNNs.

More recently, Venugopalan et al. (2016) explored linguistic improvements to the caption decoder by fusing it with external language models. Moreover, an attention or alignment mechanism was added between the encoder and the decoder to learn the temporal relations (matching) between the video frames and the caption words (Yao et al., 2015; Pan et al., 2016a). In contrast to static visual features, Yao et al. (2015) also considered temporal video features from a 3D-CNN model pre-trained on an action recognition task.

To explore long range temporal relations, Pan et al. (2016a) proposed a two-level hierarchical RNN encoder which limits the length of input information and allows temporal transitions between segments. Yu et al. (2016)'s hierarchical RNN generates sentences at the first level and the second level captures inter-sentence dependencies in a paragraph. Pan et al. (2016b) proposed to simultaneously learn the RNN word probabilities and a visual-semantic joint embedding space that enforces the relationship between the semantics of the entire sentence and the visual content. Despite these useful recent improvements, video captioning still suffers from limited supervision and generalization capabilities, esp. given the complex action-based temporal and story-based logical dynamics that need to be captured from short video clips. Our work addresses this issue by bringing in complementary temporal and logical knowledge from video prediction and textual entailment generation tasks (respectively), and training them together via many-to-many multi-task learning.

Multi-task learning is a useful learning paradigm to improve the supervision and the generalization performance of a task by jointly training it with related tasks (Caruana, 1998; Argyriou et al., 2007; Kumar and Daumé III, 2012). Recently, Luong et al. (2016) combined multi-task learning with sequence-to-sequence models, sharing parameters across the tasks' encoders and decoders. They showed improvements on machine translation using parsing and image captioning. We additionally incorporate an attention mechanism to this many-to-many multi-task learning approach and improve the multimodal, temporal-logical video captioning task by sharing its video encoder with the encoder of a video-to-video prediction task and by sharing its caption decoder with the decoder of a linguistic premise-to-entailment generation task.

Image representation learning has been successful via supervision from very large object-labeled datasets. However, similar amounts of supervision are lacking for video representation learning. Srivastava et al. (2015) address this by propos-

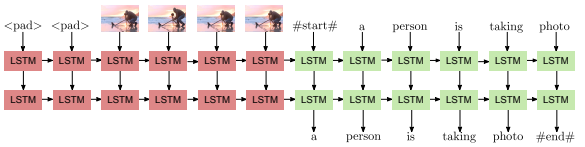

Figure 2: Baseline sequence-to-sequence model for video captioning: standard encoder-decoder LSTM-RNN model.

ing unsupervised video representation learning via sequence-to-sequence RNN models, where they reconstruct the input video sequence or predict the future sequence. We model video generation with an attention-enhanced encoder-decoder and harness it to improve video captioning.

The task of recognizing textual entailment (RTE) is to classify whether the relationship between a premise and hypothesis sentence is that of entailment (i.e., logically follows), contradiction, or independence (neutral), which is helpful for several downstream NLP tasks. The recent Stanford Natural Language Inference (SNLI) corpus by Bowman et al. (2015) allowed training end-to-end neural networks that outperform earlier feature-based RTE models (Lai and Hockenmaier, 2014; Jimenez et al., 2014). However, directly generating the entailed hypothesis sentences given a premise sentence would be even more beneficial than retrieving or reranking sentence pairs, because most downstream generation tasks only come with the source sentence and not pairs. Recently, Kolesnyk et al. (2016) tried a sequence-to-sequence model for this on the original SNLI dataset, which is a single-reference setting and hence restricts automatic evaluation. We modify the SNLI corpus to a new multi-reference (and a more challenging zero train-test premise overlap) setting, and present a novel multi-task training setup with the related video captioning task (where the caption also entails a video), showing mutual improvements on both the tasks.

3 Models

We first discuss a simple encoder-decoder model as a baseline reference for video captioning. Next, we improve this via an attention mechanism. Finally, we present similar models for the unsupervised video prediction and entailment generation tasks, and then combine them with video captioning via the many-to-many multi-task approach.

3.1 Baseline Sequence-to-Sequence Model

Our baseline model is similar to the standard machine translation encoder-decoder RNN model (Sutskever et al., 2014) where the final state of the encoder RNN is input as an initial state to the decoder RNN, as shown in Fig. 2. The RNN is based on Long Short Term Memory (LSTM) units, which are good at memorizing long sequences due to forget-style gates (Hochreiter and Schmidhuber, 1997). For video captioning, our input to the encoder is the video frame features[1] $\{f_1, f_2, ..., f_n\}$ of length n, and the caption word sequence $\{w_1, w_2, ..., w_m\}$ of length m is generated during the decoding phase. The distribution of the output sequence w.r.t. the input sequence is:

$$p(w_1, ..., w_m | f_1, ..., f_n) = \prod_{t=1}^{m} p(w_t | h_t^d) \quad (1)$$

where h_t^d is the hidden state at the t^{th} time step of the decoder RNN, obtained from h_{t-1}^d and w_{t-1} via the standard LSTM-RNN equations. The distribution $p(w_t|h_t^d)$ is given by *softmax* over all the words in the vocabulary.

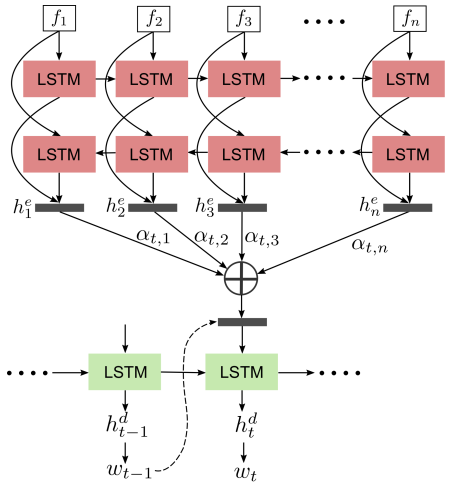

Figure 3: Attention-based sequence-to-sequence baseline model for video captioning (similar models also used for video prediction and entailment generation).

3.2 Attention-based Model

Our attention model architecture is similar to Bahdanau et al. (2015), with a bidirectional LSTM-RNN as the encoder and a unidirectional LSTM-RNN as the decoder, see Fig. 3. At each time step t, the decoder LSTM hidden state h_t^d is a non-linear recurrent function of the previous decoder hidden state h_{t-1}^d, the previous time-step's generated word w_{t-1}, and the context vector c_t:

$$h_t^d = S(h_{t-1}^d, w_{t-1}, c_t) \quad (2)$$

[1] We use several popular image features such as VGGNet, GoogLeNet and Inception-v4. Details in Sec. 4.1.

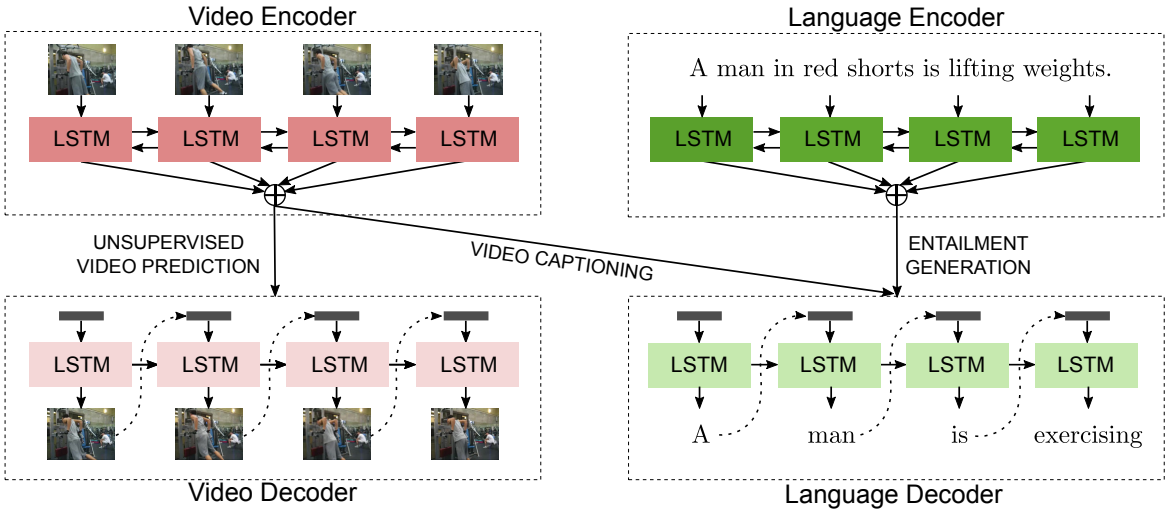

Figure 4: Our many-to-many multi-task learning model to share encoders and decoders of the video captioning, unsupervised video prediction, and entailment generation tasks.

where c_t is a weighted sum of encoder hidden states $\{h_i^e\}$:

$$c_t = \sum_{i=1}^{n} \alpha_{t,i} h_i^e \tag{3}$$

These attention weights $\{\alpha_{t,i}\}$ act as an alignment mechanism by giving higher weights to certain encoder hidden states which match that decoder time step better, and are computed as:

$$\alpha_{t,i} = \frac{exp(e_{t,i})}{\sum_{k=1}^{n} exp(e_{t,k})} \tag{4}$$

where the attention function $e_{t,i}$ is defined as:

$$e_{t,i} = w^T tanh(W_a^e h_i^e + W_a^d h_{t-1}^d + b_a) \tag{5}$$

where w, W_a^e, W_a^d, and b_a are learned parameters. This attention-based sequence-to-sequence model (Fig. 3) is our enhanced baseline for video captioning. We next discuss similar models for the new tasks of unsupervised video prediction and entailment generation and then finally share them via multi-task learning.

3.3 Unsupervised Video Prediction

We model unsupervised video representation by predicting the sequence of future video frames given the current frame sequence. Similar to Sec. 3.2, a bidirectional LSTM-RNN encoder and an LSTM-RNN decoder is used, along with attention. If the frame level features of a video of length n are $\{f_1, f_2, ..., f_n\}$, these are divided into two sets such that given the current frames $\{f_1, f_2, .., f_k\}$ (in its encoder), the model has to predict (decode) the rest of the frames $\{f_{k+1}, f_{k+2}, .., f_n\}$. The motivation is that this helps the video encoder learn rich temporal representations that are aware of their action-based context and are also robust to missing frames and varying frame lengths or motion speeds. The optimization function is defined as:

$$\underset{\phi}{\text{minimize}} \sum_{t=1}^{n-k} ||f_t^d - f_{t+k}||_2^2 \tag{6}$$

where ϕ are the model parameters, f_{t+k} is the true future frame feature at decoder time step t and f_t^d is the decoder's predicted future frame feature at decoder time step t, defined as:

$$f_t^d = S(h_{t-1}^d, f_{t-1}^d, c_t) \tag{7}$$

similar to Eqn. 2, with h_{t-1}^d and f_{t-1}^d as the previous time step's hidden state and predicted frame feature respectively, and c_t as the attention-weighted context vector.

3.4 Entailment Generation

Given a sentence (premise), the task of entailment generation is to generate a sentence (hypothesis) which is a logical deduction or implication of the premise. Our entailment generation model again uses a bidirectional LSTM-RNN encoder and LSTM-RNN decoder with an attention mechanism (similar to Sec. 3.2). If the premise s^p is a sequence of words $\{w_1^p, w_2^p, ..., w_n^p\}$ and the hypothesis s^h is $\{w_1^h, w_2^h, ..., w_m^h\}$, the distribution of the entailed hypothesis w.r.t. the premise is:

$$p(w_1^h, ..., w_m^h | w_1^p, ..., w_n^p) = \prod_{t=1}^{m} p(w_t^h | h_t^d) \tag{8}$$

where the distribution $p(w_t^h | h_t^d)$ is again obtained via softmax over all the words in the vocabulary and the decoder state h_t^d is similar to Eqn. 2.

3.5 Multi-Task Learning

Multi-task learning helps in sharing information between different tasks and across domains. Our primary aim is to improve the video captioning model, where visual content translates to a textual form in a directed (entailed) generation way. Hence, this presents an interesting opportunity to share temporally and logically directed knowledge with both visual and linguistic generation tasks. Fig. 4 shows our overall many-to-many multi-task model for jointly learning video captioning, unsupervised video prediction, and textual entailment generation. Here, the video captioning task shares its video encoder (parameters) with the encoder of the video prediction task (one-to-many setting) so as to learn context-aware and temporally-directed visual representations (see Sec. 3.3).

Moreover, the decoder of the video captioning task is shared with the decoder of the textual entailment generation task (many-to-one setting), thus helping generate captions that can 'entail', i.e., are logically implied by or follow from the video content (see Sec. 3.4).[2] In both the one-to-many and the many-to-one settings, we also allow the attention parameters to be shared or separated. The overall many-to-many setting thus improves both the visual and language representations of the video captioning model.

We train the multi-task model by alternately optimizing each task in mini-batches based on a mixing ratio. Let α_v, α_f, and α_e be the number of mini-batches optimized alternately from each of these three tasks – video captioning, unsupervised video future frames prediction, and entailment generation, resp. Then the mixing ratio is defined as $\frac{\alpha_v}{(\alpha_v+\alpha_f+\alpha_e)} : \frac{\alpha_f}{(\alpha_v+\alpha_f+\alpha_e)} : \frac{\alpha_e}{(\alpha_v+\alpha_f+\alpha_e)}$.

4 Experimental Setup

4.1 Datasets

Video Captioning Datasets We report results on three popular video captioning datasets. First, we use the YouTube2Text or MSVD (Chen and Dolan, 2011) for our primary results, which contains 1970 YouTube videos in the wild with several different reference captions per video (40 on average). We also use MSR-VTT (Xu et al., 2016) with $10,000$ diverse video clips (from a video search engine) – it has $200,000$ video clip-sentence pairs and around 20 captions per video; and M-VAD (Torabi et al., 2015) with $49,000$ movie-based video clips but only 1 or 2 captions per video, making most evaluation metrics (except paraphrase-based METEOR) infeasible. We use the standard splits for all three datasets. Further details about all these datasets are provided in the supplementary.

Video Prediction Dataset For our unsupervised video representation learning task, we use the UCF-101 action videos dataset (Soomro et al., 2012), which contains $13,320$ video clips of 101 action categories, and suits our video captioning task well because it also contains short video clips of a single action or few actions. We use the standard splits – further details in supplementary.

Entailment Generation Dataset For the entailment generation encoder-decoder model, we use the Stanford Natural Language Inference (SNLI) corpus (Bowman et al., 2015), which contains human-annotated English sentence pairs with classification labels of entailment, contradiction and neutral. It has a total of $570,152$ sentence pairs out of which $190,113$ correspond to true entailment pairs, and we use this subset in our multi-task video captioning model. For improving video captioning, we use the same training/validation/test splits as provided by Bowman et al. (2015), which is $183,416$ training, $3,329$ validation, and $3,368$ testing pairs (for the entailment subset).

However, for the entailment generation multi-task results (see results in Sec. 5.3), we modify the splits so as to create a multi-reference setup which can afford evaluation with automatic metrics. A given premise usually has multiple entailed hypotheses but the original SNLI corpus is set up as single-reference (for classification). Due to this, the different entailed hypotheses of the same premise land up in different splits of the dataset (e.g., one in train and one in test/validation) in many cases. Therefore, we regroup the premise-entailment pairs and modify the split as follows: among the $190,113$ premise-entailment pairs subset of the SNLI corpus, there are $155,898$ unique premises; out of which $145,822$ have only one hy-

[2] Empirically, logical entailment helped captioning more than simple fusion with language modeling (i.e., partial sentence completion with no logical implication), because a caption also entails a video in a logically-directed sense and hence the entailment generation task matches the video captioning task better than language modeling. Moreover, a multi-task setup is more suitable to add directed information such as entailment (as opposed to pretraining or fusion with only the decoder). Details in Sec. 5.1.

pothesis and we make this the training set, and the rest of them $(10,076)$ have more than one hypothesis, which we randomly shuffle and divide equally into test and validation sets, so that each of these two sets has approximately the same distribution of the number of reference hypotheses per premise.

These new validation and test sets hence contain premises with multiple entailed hypotheses as ground truth references, thus allowing for automatic metric evaluation, where differing generations still get positive scores by matching one of the multiple references. Also, this creates a more challenging dataset for entailment generation because of zero premise overlap between the training and val/test sets. We will make these split details publicly available.

Pre-trained Visual Frame Features For the three video captioning and UCF-101 datasets, we fix our sampling rate to $3fps$ to bring uniformity in the temporal representation of actions across all videos. These sampled frames are then converted into features using several state-of-the-art pre-trained models on ImageNet (Deng et al., 2009) – VGGNet (Simonyan and Zisserman, 2015), GoogLeNet (Szegedy et al., 2015; Ioffe and Szegedy, 2015), and Inception-v4 (Szegedy et al., 2016). Details of these feature dimensions and layer positions are in the supplementary.

4.2 Evaluation (Automatic and Human)

For our video captioning as well as entailment generation results, we use four diverse automatic evaluation metrics that are popular for image/video captioning and language generation in general: METEOR (Denkowski and Lavie, 2014), BLEU-4 (Papineni et al., 2002), CIDEr-D (Vedantam et al., 2015), and ROUGE-L (Lin, 2004). Particularly, METEOR and CIDEr-D have been justified to be better for generation tasks, because CIDEr-D uses consensus among the (large) number of references and METEOR uses soft matching based on stemming, paraphrasing, and WordNet synonyms. We use the standard evaluation code from the Microsoft COCO server (Chen et al., 2015) to obtain these results and also to compare the results with previous papers.[3]

We also present human evaluation results based on relevance (i.e., how related is the generated caption w.r.t. the video contents such as actions, objects, and events; or is the generated hypothesis entailed or implied by the premise) and coherence (i.e., a score on the logic, readability, and fluency of the generated sentence).

4.3 Training Details

We tune all hyperparameters on the dev splits: LSTM-RNN hidden state size, learning rate, weight initializations, and mini-batch mixing ratios (tuning ranges in supplementary). We use the following settings in all of our models (unless otherwise specified): we unroll video encoder/decoder RNNs to 50 time steps and language encoder/decoder RNNs to 30 time steps. We use a 1024-dimension RNN hidden state size and 512-dim vectors to embed visual features and word vectors. We use Adam optimizer (Kingma and Ba, 2015). We apply a dropout of 0.5. See subsections below and supp for full details.

5 Results and Analysis

5.1 Video Captioning on YouTube2Text

Table 1 presents our primary results on the YouTube2Text (MSVD) dataset, reporting several previous works, all our baselines and attention model ablations, and our three multi-task models, using the four automated evaluation metrics. For each subsection below, we have reported the important training details inline, and refer to the supplementary for full details (e.g., learning rates and initialization).

Baseline Performance We first present all our baseline model choices (ablations) in Table 1. Our baselines represent the standard sequence-to-sequence model with three different visual feature types as well as those with attention mechanisms. Each baseline model is trained with three random seed initializations and the average is reported (for stable results). The final baseline model $\otimes$ instead uses an ensemble (E), which is a standard denoising method (Sutskever et al., 2014) that performs inference over ten randomly initialized models, i.e., at each time step t of the decoder, we generate a word based on the avg. of the likelihood probabilities from the ten models. Moreover, we use beam search with size 5 for all baseline models. Overall, the final baseline model with Inception-v4 features, attention, and 10-ensemble performs

[3] We use avg. of these four metrics on validation set to choose the best model, except for single-reference M-VAD dataset where we only report and choose based on METEOR.

Table 1: Primary video captioning results on Youtube2Text (MSVD), showing previous works, our several strong baselines, and our three multi-task models. Here, V, G, I, C, A are short for VGGNet, GoogLeNet, Inception-v4, C3D, and AlexNet visual features; E = ensemble. The multi-task models are applied on top of our best video captioning baseline $\otimes$, with an ensemble. All the multi-task models are statistically significant over the baseline (discussed inline in the corresponding results sections).

well (and is better than all previous state-of-the-art), and so we next add all our novel multi-task models on top of this final baseline.

Multi-Task with Video Prediction (1-to-M) Here, the video captioning and unsupervised video prediction tasks share their encoder LSTM-RNN weights and image embeddings in a one-to-many multi-task setting. Two important hyperparameters tuned (on the validation set of captioning datasets) are the ratio of encoder vs decoder frames for video prediction on UCF-101 (where we found that 80% of frames as input and 20% for prediction performs best); and the mini-batch mixing ratio between the captioning and video prediction tasks (where we found $100 : 200$ works well). Table 1 shows a statistically significant improvement[4] in all metrics in comparison to the best baseline (non-multitask) model as well as w.r.t. all previous works, demonstrating the effectiveness of multi-task learning for video captioning with video prediction, even with unsupervised signals.

Multi-Task with Entailment Generation (M-to-1) Here, the video captioning and entailment generation tasks share their language decoder LSTM-RNN weights and word embeddings in a many-to-one multi-task setting. We observe that a mixing ratio of $100 : 50$ alternating mini-batches (between the captioning and entailment tasks) works well here. Again, Table 1 shows statistically significant improvements[5] in all the metrics in comparison to the best baseline model (and all previous works) under this multi-task setting. Note that in our initial experiments, our entailment generation model helped the video captioning task significantly more than the alternative approach of simply improving fluency by adding (or deep-fusing) an external language model (or pre-trained word embeddings) to the decoder (using both in-domain and out-of-domain language models), again because a caption also 'entails' a video in a logically-directed sense and hence this matches our captioning task better (also see results of Venugopalan et al. (2016) in Table 1).

Multi-Task with Video and Entailment Generation (M-to-M) Combining the above one-to-many and many-to-one multi-task learning models, our full model is the 3-task, many-to-many model (Fig. 4) where both the video encoder and the language decoder of the video captioning model are shared (and hence improved) with that of the unsupervised video prediction and entailment generation models, respectively.[6] A mixing ratio of $100 : 100 : 50$ alternate mini-batches

[4]Statistical significance of $p < 0.01$ for CIDEr-D and ROUGE-L, $p < 0.02$ for BLEU-4, $p < 0.03$ for METEOR, based on the bootstrap test (Noreen, 1989; Efron and Tibshirani, 1994) with 100K samples.

[5]Statistical significance of $p < 0.01$ for all four metrics.

[6]We found the setting with unshared attention parameters to work best, likely because video captioning and video prediction prefer very different alignment distributions.

of video captioning, unsupervised video prediction, and entailment generation, resp. works well. Table 1 shows that our many-to-many multi-task model again outperforms our strongest baseline (with statistical significance of $p < 0.01$ on all metrics), as well as all the previous state-of-the-art results by large absolute margins on all metrics. It also achieves significant improvements on some metrics over the one-to-many and many-to-one models.[7] Overall, we achieve the best results to date on YouTube2Text (MSVD) on all metrics.

5.2 Video Captioning on MSR-VTT, M-VAD

In Table 2, we also train and evaluate our final many-to-many multi-task model on two other video captioning datasets (using their standard splits; details in supplementary). First, we evaluate on the new MSR-VTT dataset (Xu et al., 2016). Since this is a recent dataset, we list previous works' results as reported by the MSR-VTT dataset paper itself.[8] We improve over all of these significantly. Moreover, they maintain a leaderboard[9] on this dataset and we also report the top 3 systems from it. Based on their ranking method, our multi-task model achieves the new rank 1 on this leaderboard. In Table 3, we further evaluate our model on the challenging movie-based M-VAD dataset, and again achieve improvements over all previous work (Venugopalan et al., 2015a; Pan et al., 2016a; Yao et al., 2015).[10]

Entailment Generation	28.0	108.4	59.7	36.6
+Video Caption (M-to-1)	**28.7**	**114.5**	**60.8**	**38.9**

Table 4: Entailment generation results with the four metrics.

5.3 Entailment Generation Results

Above, we showed that the new entailment generation task helps improve video captioning. Next, we show that the video captioning task also inversely helps the entailment generation task. Given a premise, the task of entailment generation is to generate an entailed hypothesis. We use only the entailment pairs subset of the SNLI corpus for this, but with a multi-reference split setup to allow automatic metric evaluation and a zero train-test premise overlap (see Sec. 4.1). All the hyperparameter details (again tuned on the validation set) are presented in the supplementary. Table 4 presents the entailment generation results for the baseline (sequence-to-sequence with attention, 3-ensemble, beam search) and the multi-task model which uses video captioning (shared decoder) on top of the baseline. A mixing ratio of $100:20$ alternate mini-batches of entailment generation and video captioning (resp.) works well.[11] The multi-task model achieves stat. significant ($p < 0.01$) improvements over the baseline on all metrics, thus demonstrating that video captioning and entailment generation both mutually help each other.

5.4 Human Evaluation

In addition to the automated evaluation metrics, we present pilot-scale human evaluations on the YouTube2Text (Table 1) and entailment generation (Table 4) results. In each case, we compare our strongest baseline with our final multi-task model by taking a random sample of 200 generated captions (or entailed hypotheses) from the test set and removing the model identity to anonymize the two models, and ask the human evaluator to choose the better model based on *relevance* and *coherence* (described in Sec. 4.2). As shown in Table 5, the multi-task models are always better than the strongest baseline for both video captioning and entailment generation, on both relevance

[7] Many-to-many model's improvements have a statistical significance of $p < 0.01$ on all metrics w.r.t. baseline, and $p < 0.01$ on CIDEr-D w.r.t. both one-to-many and many-to-one models, and $p < 0.04$ on METEOR w.r.t. one-to-many.

[8] In their updated supplementary at `https://www.microsoft.com/en-us/research/wp-content/uploads/2016/10/cvpr16.supplementary.pdf`

[9] `http://ms-multimedia-challenge.com/leaderboard`

[10] Following previous work, we only use METEOR because M-VAD only has a single reference caption per video.

[11] Note that this many-to-one model prefers a different mixing ratio and learning rate than the many-to-one model for improving video captioning (Sec. 5.1), because these hyperparameters depend on the primary task being improved, as also discussed in previous work (Luong et al., 2016).

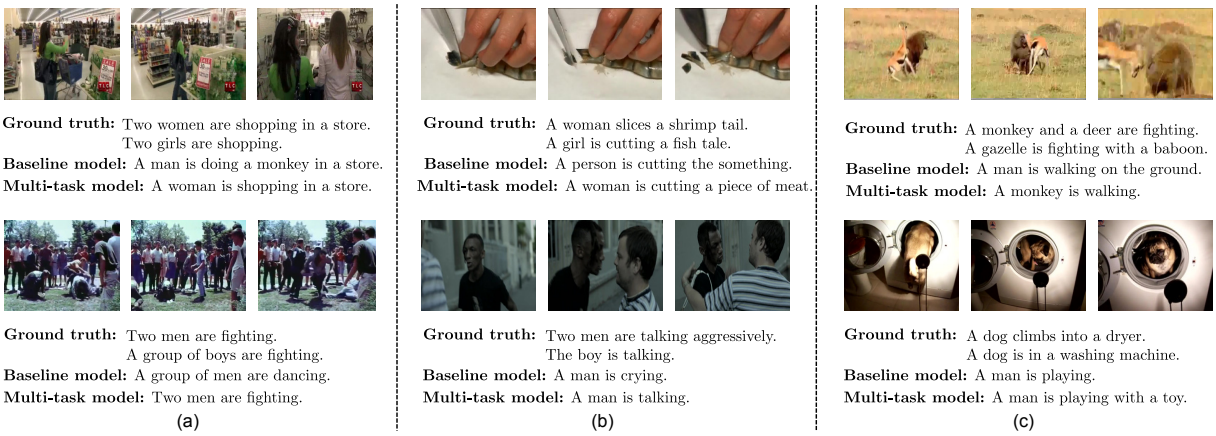

Figure 5: Examples of generated video captions on the YouTube2Text dataset: (a) complex examples where the multi-task model performs better than the baseline; (b) ambiguous examples (i.e., ground truth itself confusing) where multi-task model still correctly predicts one of the possible categories (c) complex examples where both models perform poorly.

	YouTube2Text		Entailment

and coherence, and with similar improvements (2-7%) as the automatic metrics (shown in Table 1).

5.5 Analysis

Fig. 5 shows video captioning generation results on the YouTube2Text dataset where our final M-to-M multi-task model is compared with our strongest attention-based baseline model for three categories of videos: (a) complex examples where the multi-task model performs better than the baseline; (b) ambiguous examples (i.e., ground truth itself confusing) where multi-task model still correctly predicts one of the possible categories (c) complex examples where both models perform poorly. Overall, we find that the multi-task model generates captions that are better at both temporal action prediction and logical entailment (i.e., correct subset of full video premise) w.r.t. the ground truth captions. The supplementary also provides ablation examples of improvements by the 1-to-M video prediction based multi-task model alone, as well as by the M-to-1 entailment based multi-task model alone (over the baseline).

On analyzing the cases where the baseline is better than the final M-to-M multi-task model, we find that these are often scenarios where the multi-task model's caption is also correct but the baseline caption is a bit more specific, e.g., "a man is holding a gun" vs "a man is shooting a gun".

Finally, Table 6 presents output examples of our entailment generation multi-task model (Sec. 5.3), showing how the model accurately learns to produce logically implied subsets of the premise.

6 Conclusion

We presented a multimodal, multi-task learning approach to improve video captioning by incorporating temporally and logically directed knowledge via video prediction and entailment generation tasks. We achieve the best reported results (and rank) on three datasets, based on multiple automatic and human evaluations. We also show mutual multi-task improvements on the new entailment generation task. In future work, we are applying our entailment-based multi-task paradigm to other directed language generation tasks such as image captioning and document summarization.

Enriching Complex Networks with Word Embeddings for Detecting Mild Cognitive Impairment from Speech Transcripts

Abstract

Mild Cognitive Impairment (MCI) is a mental disorder difficult to diagnose. Linguistic features, mainly from parsers, have been used to detect MCI, but this is not suitable for large-scale assessments. MCI disfluencies produce non-grammatical speech that requires manual or high precision automatic correction of transcripts. In this paper, we modeled transcripts into complex networks and enriched them with word embedding (CNE) to better represent short texts produced in neuropsychological assessments. The network measurements were applied with well-known classifiers to automatically identify MCI in transcripts, in a binary classification task. A comparison was made with the performance of traditional approaches using Bag of Words (BoW) and linguistic features for three datasets: DementiaBank in English, and Cinderella and Arizona-Battery in Portuguese. Overall, CNE provided higher accuracy than using only complex networks, while Support Vector Machine was superior to other classifiers. CNE provided the highest accuracies for DementiaBank and Cinderella, but BoW was more efficient for the Arizona-Battery dataset probably owing to its short narratives. The approach using linguistic features yielded higher accuracy if the transcriptions of the Cinderella dataset were manually revised. Taken together, the results indicate that complex networks enriched with embedding is promising for detecting MCI in large-scale assessments.

1 Introduction

Mild Cognitive Impairment (MCI) can affect one or multiple cognitive domains (e.g. memory, language, visuospatial skills and executive functions), and may represent a pre-clinical stage of Alzheimer's disease (AD). The impairment that affects memory, referred to as amnestic MCI, is the most frequent, with the highest conversion rate for AD, at 15% per year versus 1 to 2% for the general population. Since dementias are chronic and progressive diseases, their early diagnosis ensures a greater chance of success to engage patients in non-pharmacological treatment strategies such as cognitive training, physical activity and socialization (Teixeira et al., 2012).

Language is one of the most efficient information sources to assess cognitive functions. Changes in language usage are frequent in patients with dementia and are normally first recognized by the patients themselves or their family members. Therefore, the automatic analysis of discourse production is promising in diagnosing MCI at early stages, which may address potentially reversible factors (Muangpaisan et al., 2012). Proposals to detect language-related impairment in dementias include machine learning (Jarrold et al., 2010; Roark et al., 2011; Fraser et al., 2014, 2015), magnetic resonance imaging (Dyrba et al., 2015), and data screening tests added to demographic information (Weakley et al., 2015). Discourse production (mainly narratives) is attractive because it allows the analysis of linguistic microstructures, including phonetic-phonological, morphosyntactic and semantic-lexical components, as well as semantic-pragmatic macrostructures.

Automated discourse analysis based on Natural Language Processing (NLP) resources and tools to diagnose dementias via machine learning methods has been used for English language (Lehr et al.,

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1284–1296
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1118

2012; Jarrold et al., 2014; Orimaye et al., 2014; Fraser et al., 2015; Davy et al., 2016) and for Brazilian Portuguese (Aluísio et al., 2016). A variety of features are required for this analysis, including Part-of-Speech (PoS), syntactic complexity, lexical diversity and acoustic features. Producing robust tools to extract these features is extremely difficult because speech transcripts used in neuropsychological evaluations contain disfluencies (repetitions, revisions, paraphasias) and patient's comments about the task being evaluated. Another problem in using linguistic knowledge is the high dependence on manually created resources, such as hand-crafted linguistic rules and/or annotated corpora. Even when traditional statistical techniques (Bag of Words or ngrams) are applied, problems still appear in dealing with disfluencies, because mispronounced words will not be counted together. Indeed, other types of disfluencies (repetition, amendments, patient's comments about the task) will be counted, thus increasing the vocabulary.

An approach applied successfully to several areas of NLP (Mihalcea and Radev, 2011), which may suffer less from the problems mentioned above, relies on the use of complex networks and graph theory. The word adjacency network model (i Cancho and Solé, 2001; Roxas and Tapang, 2010; Amancio et al., 2012a; Amancio, 2015b) has provided good results in text classification (de Arruda et al., 2016) and related tasks, namely author detection (Amancio, 2015a), identification of literary movements (Amancio et al., 2012c), authenticity verification (Amancio et al., 2013) and word sense discrimination (Amancio et al., 2012b).

In this paper, we show that speech transcripts (narratives or descriptions) can be modeled into complex networks that are enriched with word embedding in order to better represent short texts produced in these assessments. When applied to a machine learning classifier, the complex network features were able to distinguish between control participants and mild cognitive impairment participants. Discrimination of the two classes could be improved by combining complex networks with linguistic and traditional statistical features.

With regard to the task of detecting MCI from transcripts, this paper is, to the best of our knowledge, the first to: a) show that classifiers using features extracted from transcripts modeled into complex networks enriched with word embedding present higher accuracy than using only complex networks for 3 datasets; and b) show that for languages that do not have competitive dependency and constituency parsers to exploit syntactic features, e.g. Brazilian Portuguese, complex networks enriched with word embedding constitute a source to extract new, language independent features from transcripts.

2 Related Work

Detection of memory impairment has been based on linguistic, acoustic, and demographic features, in addition to scores of neuropsychological tests. Linguistic and acoustic features were used to automatically detect aphasia (Fraser et al., 2014); and AD (Fraser et al., 2015) or dementia (Orimaye et al., 2014) in the public corpora of DementiaBank[1]. Other studies distinguished different types of dementia (Garrard et al., 2014; Jarrold et al., 2014), in which speech samples were elicited using the Picnic picture of the Western Aphasia Battery (Kertesz, 1982). Davy et al. (2016) also used the Picnic scene to detect MCI, where the subjects were asked to write (by hand) a detailed description of the scene.

As for automatic detection of MCI in narrative speech, Roark et al. (2011) extracted speech features and linguistic complexity measures of speech samples obtained with the Wechsler Logical Memory (WLM) subtest (Wechsler et al., 1997), and Lehr et al. (2012) fully automatized the WLM subtest. In this test, the examiner tells a short narrative to a subject, who then retells the story to the examiner, immediately and after a 30-minute delay. WLM scores are obtained by counting the number of story elements recalled.

Tóth et al. (2015) and Vincze et al. (2016) used short animated films to evaluate immediate and delayed recalls in MCI patients who were asked to talk about the first film shown, then about their previous day, and finally about another film shown last. Tóth et al. (2015) adopted automatic speech recognition (ASR) to extract a phonetic level segmentation, which was used to calculate acoustic features. Vincze et al. (2016) used speech, morphological, semantic, and demographic features collected from their speech transcripts to automatically identify patients suffering from MCI.

For the Portuguese language, machine learning

[1] talkbank.org/DementiaBank/

algorithms were used to identify subjects with AD and MCI. Aluísio et al. (2016) used a variety of linguistic metrics, such as syntactic complexity, idea density (da Cunha et al., 2015), and text cohesion through latent semantics. NLP tools with high precision are needed to compute these metrics, which is a problem for Portuguese since no robust dependency or constituency parsers exist. Therefore, the transcriptions had to be manually revised; they were segmented into sentences, following a semantic-structural criterion and capitalization was applied. The authors also removed disfluencies and inserted omitted subjects when they were hidden, in order to reduce parsing errors. This process is obviously expensive, which has motivated us to use complex networks in the present study to model transcriptions and avoid a manual preprocessing step.

3 Modeling and Characterizing Texts as Complex Networks

The theory and concepts of complex networks have been used in several NLP tasks (Mihalcea and Radev, 2011; Cong and Liu, 2014), such as text classification (de Arruda et al., 2016), summarization (Antiqueira et al., 2009; Amancio et al., 2012a) and word sense disambiguation (Silva and Amancio, 2012). In this study, we used the word co-occurrence model (also called word adjacency model) because most of the syntactical relations occur among neighboring words (i Cancho et al., 2004). Each distinct word becomes a node and words that are adjacent in the text are connected by an edge. Mathematically, a network is defined as an undirected graph $G = \{V, E\}$, formed by a set $V = \{v_1, v_2, ..., v_n\}$ of nodes (words) and a set $E = \{e_1, e_2, ..., e_m\}$ of edges (co-occurrence) that are represented by an adjacency matrix A, whose elements A_{ij} are equal to 1 whenever there is an edge connecting nodes (words) i and j, and equal to 0 otherwise.

Before modeling texts into complex networks, it is often necessary to do some preprocessing in the raw text. Preprocessing starts with tokenization where each document/text is divided into tokens (meaningful elements, e.g., words and punctuation marks) and then *stopwords* and punctuation marks are removed, since they have little semantic meaning. One last step we decided to eliminate from the preprocessing pipeline is lemmatization, which transforms each word into its canonical

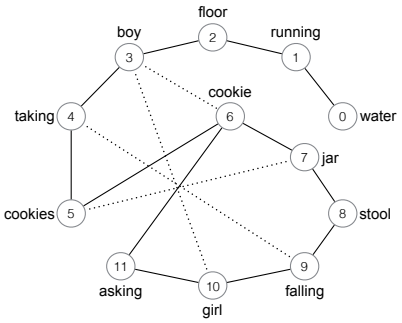

Figure 1: Example of co-occurrence network enriched with semantic information for the following transcription: "*The water's running on the floor. Boy's taking cookies out of cookie out of the cookie jar. The stool is falling over. The girl was asking for a cookie.*". The solid edges of the network represent co-occurrence edges and the dotted edges represent connections between words that had similarity higher than 0.5.

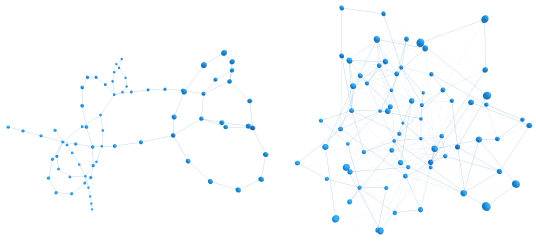
form. This decision was made based on two factors. First, a recent work has shown that lemmatization has little or no influence when network modeling is adopted in related tasks (Machicao et al., 2016). Second, the lemmatization process requires part-of-speech (POS) tagging that may introduce undesirable noises/errors in the text, since the transcriptions in our work contain disfluencies.

Another problem with transcriptions in our work is their size. As demonstrated by Amancio (2015c), classification of small texts using networks can be impaired, since short texts have almost linear networks, and the topological measures of these networks have little or no information relevant to classification. To solve this problem, we adapted the approach of inducing language networks from word embeddings, proposed by Perozzi et al. (2014) to enrich the networks with semantic information. In their work, language networks were generated from continuous word representations, in which each word is represented by a dense, real-valued vector obtained by training neural networks in the language model task (or variations, such as context prediction) (Bengio et al., 2003; Collobert et al., 2011; Mikolov et al., 2013a,b). This structure is known to capture syntactic and semantic information. Perozzi et al. (2014), in particular, take advantage of word embeddings to build networks where each word is



(a) (b)

Figure 2: Example of (a) co-occurrence network created for a transcript of the Cookie Theft dataset (see Supplementary Information, Section A) and (b) the same co-occurrence network enriched with semantic information. Note that (b) is a more informative network than (a), since (a) is practically a linear network.

a vertex and edges are defined by similarity between words established by the proximity of the word vectors.

Following this methodology, in our model we added new edges to the co-occurrence networks considering similarities between words, that is, for all pairs of words in the text that were not connected, an edge was created if their vectors (from word embedding) had a cosine similarity higher than a given threshold. Figure 1 shows an example of a co-occurrence network enriched by similarity links (the dotted edges). The gain in information by enriching a co-occurrence network with semantic information is readily apparent in Figure 2.

4 Datasets, Features and Methods

4.1 Datasets

The datasets[2] used in our study consisted of: (i) manually segmented and transcribed samples from the DementiaBank and Cinderella story and (ii) transcribed samples of Arizona Battery for Communication Disorders of Dementia (ABCD) automatically segmented into sentences, since we are working towards a fully automated system to detect MCI in transcripts and would like to evaluate a dataset which was automatically processed.

The DementiaBank dataset is composed of short English descriptions, while the Cinderella dataset contains longer Brazilian Portuguese narratives. ABCD dataset is composed of very short narratives, also in Portuguese. Below, we describe in further detail the datasets, participants, and the task in which they were used.

[2]All datasets are made available in the same representations used in this work, upon request to the authors.

4.1.1 The Cookie Theft Picture Description Dataset

The clinical dataset used for the English language was created during a longitudinal study conducted by the University of Pittsburgh School of Medicine on Alzheimer's and related dementia, funded by the National Institute of Aging. To be eligible for inclusion in the study, all participants were required to be above 44 years of age, have at least 7 years of education, no history of nervous system disorders nor be taking neuroleptic medication, have an initial Mini-Mental State Exam (MMSE) score of 10 or greater, and be able to give informed consent. The dataset contains transcripts of verbal interviews with AD and related Dementia patients, including those with MCI (for further details see (Becker et al., 1994)).

We used 43 transcriptions with MCI in addition to another 43 transcriptions sampled from 242 healthy elderly people to be used as the control group. Table 1 shows the demographic information for the two diagnostic groups.

Demographic	Control	MCI
Avg. Age (SD)	64.1 (7.2)	69.3 (8.2)
No. of Male/Female	23/20	27/16

Table 1: Demographic information of participants in the Cookie Theft dataset.

For this dataset, interviews were conducted in English and narrative speech was elicited using the Cookie Theft picture (Goodglass et al., 2001) (Figure 3 from Goodglass et al. (2001) in Section A.1). During the interview, patients were given the picture and were told to discuss everything they could see happening in the picture. The patients' verbal utterances were recorded and then transcribed into the CHAT (Codes for the Human Analysis of Transcripts) transcription format (MacWhinney, 2000).

We extracted the word-level transcript patient sentences from the CHAT files and discarded the annotations, as our goal was to create a fully automated system that does not require the input of a human annotator. We automatically removed filled pauses such as *uh*, *um* , *er* , and *ah* (e.g. *uh it seems to be summer out*), short false starts (e.g. *just t the ones*), and repetition (e.g. *mother's finished certain of the the dishes*), as in (Fraser et al.,

2015). The control group had an average of 9.58 sentences per narrative, with each sentence having an average of 9.18 words; while the MCI group had an average of 10.97 sentences per narrative, with 10.33 words per sentence in average.

4.1.2 The Cinderella Narrative Dataset

The dataset examined in this study included 20 subjects with MCI and 20 normal elderly control subjects, as diagnosed at the Medical School of the University of São Paulo (FMUSP). Table 2 shows the demographic information of the two diagnostic groups, which were also used in Aluísio et al. (2016).

Demographic	Control	MCI
Avg. Age (SD)	74.8 (11.3)	73.3 (5.9)
Avg. Years of Education (SD)	11.4 (2.6)	10.8 (4.5)
No. of Male/Female	27/16	29/14

Table 2: Demographic information of participants in the Cinderella dataset.

The criteria used to diagnose MCI came from Petersen (2004). Diagnostics were carried out by a multidisciplinary team consisting of psychiatrists, geriatricians, neurologists, neuropsychologists, speech pathologists, and occupational therapists, by a criterion of consensus. Inclusion criteria for the control group were elderlies with no cognitive deficits and preservation of functional capacity in everyday life. The exclusion criteria for the normal group were: poorly controlled clinical diseases, sensitive deficits that were not being compensated for and interfered with the performance in tests, and other neurological or psychiatric diagnoses associated with dementia or cognitive deficits and use of medications in doses that affected cognition.

Speech narrative samples were elicited by having participants tell the Cinderella story; participants were given as much time as they needed to examine a picture book illustrating the story (Figure 4 in Section A). When each participant had finished looking at the pictures, the examiner asked the subject to tell the story in their own words, as in Saffran et al. (1989). The time was recorded, but there was no limit imposed to the narrative length. If the participant had difficulty initiating or continuing speech, or took a long pause, an evaluator would use the stimulus question "What happens next ?", seeking to encourage the participant to continue his/her narrative. When the subject was unable to proceed with the narrative, the examiner asked if he/she had finished the story and had something to add. Each speech sample was recorded and then manually transcribed at the word level following the NURC/SP N. 338 EF and 331 D2 transcription norms[3].

Other tests were applied after the narrative, in the following sequence: phonemic verbal fluency test, action verbal fluency, Camel and Cactus test (Bozeat et al., 2000), and Boston Naming test (Kaplan et al., 2001), in order to diagnose the groups.

Since our ultimate goal is to create a fully automated system that does not require the input of a human annotator, we manually segmented sentences to simulate a high-quality ASR transcript with sentence segmentation, and we automatically removed the disfluencies following the same guidelines of TalkBank project. However, other disfluencies (revisions, elaboration, paraphasias and comments about the task) were kept. The control group had an average of 30.80 sentences per narrative, and each sentence averaged 12.17 words. As for the MCI group, it had an average of 29.90 sentences per narrative, and each sentence averaged 13.03 words.

We also evaluated a different version of the dataset used in Aluísio et al. (2016), where narratives were manually annotated and revised to improve parsing results. The revision process was the following: (i) in the original transcript, segments with hesitations or repetitions of more than one word or segment of a single word were annotated to become a feature and then removed from the narrative to allow the extraction of features from parsing; (ii) empty emissions, which were comments unrelated to the topic of narration or confirmations, such as "*né*" (alright), were also annotated and removed; (iii) prolongations of vowels, short pauses and long pauses were also annotated and removed; and (iv) omitted subjects in sentences were inserted. In this revised dataset, the control group had an average of 45.10 sentences per narrative, and each sentence averaged 8.17 words. The MCI group had an average of 31.40 sentences per narrative, with each sentence averaging 10.91 words.

4.1.3 The ABCD Dataset

The subtest of immediate/delayed recall of narratives of the ABCD battery was administered to 23

[3] albertofedel.blogspot.com.br/2010_11_01_archive.html

participants with a diagnosis of MCI and 20 normal elderly control participants, as diagnosed at the Medical School of the University of São Paulo (FMUSP).

MCI subjects produced 46 narratives while the control group produced 39 ones. In order to carry out experiments with a balanced corpus, as with the previous two datasets, we excluded seven transcriptions from the MCI group. We used the automatic sentence segmentation method referred to as DeepBond (Treviso et al., 2017) in the transcripts.

Table 3 shows the demographic information. The control group had an average of 5.23 sentences per narrative, with 11 words per sentence on average, and the MCI group had an average of 4.95 sentences per narrative, with an average of 12.04 words per sentence. Interviews were conducted in Portuguese and the subject listened to the examiner read a short narrative. The subject then retold the narrative to the examiner twice: once immediately upon hearing it and again after a 30-minute delay (Bayles and Tomoeda, 1991). Each speech sample was recorded and then manually transcribed at the word level following the NURC/SP N. 338 EF and 331 D2 transcription norms.

Demographic	Control	MCI
Avg. Age (SD)	61 (7.5)	72,0 (7.4)
Avg. Years of Education (SD)	16 (7.6)	13.3 (4.2)
No. of Male/Female	6/14	16/7

Table 3: Demographic information of participants in the ABCD dataset.

4.2 Features

Features of three distinct natures were used to classify the transcribed texts: topological metrics of co-occurrence networks, linguistic features and bag of words representations.

4.2.1 Topological Characterization of Networks

Each transcription was mapped into a co-occurrence network, and then enriched via word embeddings using the cosine similarity of words. Since the occurrence of out-of-vocabulary words is common in texts of neuropsychological assessments, we used the method proposed by Bojanowski et al. (2016) to generate word embeddings. This method extends the skip-gram model to use character-level information, with each word being represented as a bag of character n-grams. It provides some improvement in comparison with the traditional skip-gram model in terms of syntactic evaluation (Mikolov et al., 2013b) but not for semantic evaluation.

Once the network has been enriched, we characterize its topology using the following ten measurements:

1. **PageRank:** is a centrality measurement that reflects the relevance of a node based on its connections to other relevant nodes (Brin and Page, 1998);
2. **Betweenness:** is a centrality measurement that considers a node as relevant if it is highly accessed via shortest paths. The betweenness of a node v is defined as the fraction of shortest paths going through node v;
3. **Eccentricity:** of a node is calculated by measuring the shortest distance from the node to all other vertices in the graph and taking the maximum;
4. **Eigenvector centrality:** is a measurement that defines the importance of a node based on its connectivity to high-rank nodes;
5. **Average Degree of the Neighbors of a Node:** is the average of the degrees of all its direct neighbors;
6. **Average Shortest Path Length of a Node:** is the average distance between this node and all other nodes of the network;
7. **Degree:** is the number of edges connected to the node;
8. **Assortativity Degree:** or degree correlation measures the tendency of nodes to connect to other nodes that have similar degree;
9. **Diameter:** is defined as the maximum shortest path;
10. **Clustering Coefficient:** measures the probability that two neighbors of a node are connected.

Most of the measurements described above are local measurements, i.e. each node i possesses a value X_i, so we calculated the average $\mu(X)$, standard deviation $\sigma(X)$ and skewness $\gamma(X)$ for each measurement (Amancio, 2015b).

4.2.2 Linguistic Features

Linguistic features for classification of neuropsychological assessments have been used in several studies (Roark et al., 2011; Jarrold et al., 2014; Fraser et al., 2014; Orimaye et al., 2014; Fraser et al., 2015; Vincze et al., 2016; Davy et al., 2016). We used the Coh-Metrix[4](Graesser et al., 2004) tool to extract features from English transcripts, resulting in 106 features. The metrics are divided into eleven categories: Descriptive, Text Easability Principal Component, Referential Cohesion, Latent Semantic Analysis (LSA), Lexical Diversity, Connectives, Situation Model, Syntactic Complexity, Syntactic Pattern Density, Word Information, and Readability (Flesch Reading Ease, Flesch-Kincaid Grade Level, Coh-Metrix L2 Readability).

For Portuguese, Coh-Metrix-Dementia (Aluísio et al., 2016) was used. The metrics affected by constituency and dependency parsing were not used because they are not robust with disfluencies. Metrics based on manual annotation (such as proportion short pauses, mean pause duration, mean number of empty words, and others) were also discarded. The metrics of Coh-Metrix-Dementia are divided into twelve categories: Ambiguity, Anaphoras, Basic Counts, Connectives, Co-reference Measures, Content Word Frequencies, Hypernyms, Logic Operators, Latent Semantic Analysis, Semantic Density, Syntactical Complexity, and Tokens. The metrics used are shown in detail in Section A.2. In total, 58 metrics were used, from the 73 available on the website[5].

4.2.3 Bag of Words

The representation of text collections under the BoW assumption (i.e., with no information relating to word order) has been a robust solution for text classification. In this methodology, transcripts are represented by a table in which the columns represent the terms (or existing words) in the transcripts and the values represent frequency of a term in a document.

4.3 Classification Algorithms

In order to quantify the ability of the topological characterization of networks, linguistic metrics and BoW features were used to distinguish subjects with MCI from healthy controls. We employed four machine learning algorithms to induce classifiers from a training set. These techniques were the Gaussian Naive Bayes (GNB), k-Nearest Neighbor (k-NN), Support Vector Machine (SVM), linear and radial bases functions (RBF), and Random Forest (RF). We also combined these classifiers through ensemble and multi-view learning. In ensemble learning, multiple models/classifiers are generated and combined using a majority vote or the average of class probabilities to produce a single result (Zhou, 2012).

In multi-view learning, multiple classifiers are trained in different feature spaces and thus combined to produce a single result. This approach is an elegant solution in comparison to combining all features in the same vector or space, for two main reasons. First, combination is not a straightforward step and may lead to noise insertion since the data have different natures. Second, using different classifiers for each feature space allows for different weights to be given for each type of feature, and these weights can be learned by a regression method to improve the model. In this work, we used majority voting to combine different feature spaces.

5 Experiments and Results

All experiments were conducted using the Scikit-learn[6] (Pedregosa et al., 2011), with classifiers evaluated on the basis of classification accuracy i.e. the total proportion of narratives which were correctly classified. The evaluation was performed using 5-fold cross-validation instead of the well-accepted 10-fold cross-validation because the datasets in our study were small and the test set would have shrunk, leading to less precise measurements of accuracy. The threshold parameter was optimized with the best values being 0.7 in the Cookie Theft dataset and 0.4 in both the Cinderella and ABCD datasets.

We used the model proposed by Bojanowski et al. (2016) with default parameters (100 dimensional embeddings, context window equal to 5 and 5 epochs) to generate word embedding. We trained the models in Portuguese and English Wikipedia dumps from October and November 2016 respectively.

The accuracy in classification is given in Tables 4 through 6. CN, CNE, LM, and BoW denote, respectively, complex networks, complex network

[4] cohmetrix.com
[5] http://143.107.183.175:22380
[6] http://scikit-learn.org

enriched with embedding, linguistic metrics and Bag of Words, and CNE-LM, CNE-BoW, LM-BoW and CNE-LM-BoW refer to combinations of the feature spaces (multiview learning), using the majority vote. Cells with the "–" sign mean that it was not possible to apply majority voting because there were two classifiers. The last line represents the use of an ensemble of machine learning algorithms, in which the combination used was the majority voting in both ensemble and multiview learning.

In general, CNE outperforms the approach using only complex networks (CN), while SVM (Linear or RBF kernel) provides higher accuracy than other machine learning algorithms. The results for the three datasets show that characterizing transcriptions into complex networks is competitive with other traditional methods, such as the use of linguistic metrics. In fact, among the three types of features, using enriched networks (CNE) provided the highest accuracies in two datasets (Cookie Theft and original Cinderella). For the ABCD dataset, which contains short narratives, the small length of the transcriptions may have had an effect, since BoW features led to the highest accuracy. In the case of the revised Cinderella dataset, segmented into sentences and capitalized as reported in Aluísio et al. (2016), Table 7 shows that the manual revision was an important factor, since the highest accuracies were obtained with the approach based on linguistic metrics (LM). However, this process of manually removing disfluencies demands time; therefore it is not practical for large-scale assessments.

Ensemble and multi-view learning were helpful for the Cookie Theft dataset, in which multi-view learning achieved the highest accuracy (65% of accuracy for narrative texts, a 3% of improvement compared to the best individual classifier). However, neither multi-view or ensemble learning enhanced accuracy in the Cinderella dataset, where SVM-RBF with CNE space achieved the highest accuracy (65%). For the ABCD dataset, multiview CNE-LM-BoW with SVM-RBF and KNN classifiers improved the accuracy to 4% and 2%, respectively. Somewhat surprising were the results of SVM with linear kernel in BoW feature space (75% of accuracy).

6 Conclusions and Future Work

In this study, we employed metrics of topological properties of CN in a machine learning classification approach to distinguish between healthy patients and patients with MCI. To the best of our knowledge, these metrics have never been used to detect MCI in speech transcripts; CN were enriched with word embeddings to better represent short texts produced in neuropsychological assessments. The topological properties of CN outperform traditional linguistic metrics in individual classifiers' results. Linguistic features depend on grammatical texts to present good results, as can be seen in the results of the manually processed Cinderella dataset (Table 7). Furthermore, we found that combining machine and multi-view learning can improve accuracy. The accuracies found here are comparable to the values reported by other authors, ranging from 60% to 85% (Prud'hommeaux and Roark, 2011; Lehr et al., 2012; Tóth et al., 2015; Vincze et al., 2016), which means that it is not easy to distinguish between healthy subjects and those with cognitive impairments. The comparison with our results is not straightforward, though, because the databases used in the studies are different. There is a clear need for publicly available datasets to compare different methods, which would optimize the detection of MCI in elderly people.

In future work, we intend to explore other methods to enrich CN, such as the Recurrent Language Model, and use other metrics to characterize an adjacency network. The pursuit of these strategies is relevant because language is one of the most efficient information sources to evaluate cognitive functions, commonly used in neuropsychological assessments. As this work is ongoing, we will keep collecting new transcriptions of the ABCD retelling subtest to increase the corpus size and obtain more reliable results in our studies. Our final goal is to apply neuropsychological assessment batteries, such as the ABCD retelling subtest, to mobile devices, specifically tablets. This adaptation will enable large-scale applications in hospitals and facilitate the maintenance of application history in longitudinal studies, by storing the results in databases immediately after the test application.

Figure 3 is Cookie Theft picture, which was used in DementiaBank project.

Figure 4 is a sequence of pictures from the Cinderella story, which were used to elicit speech narratives.

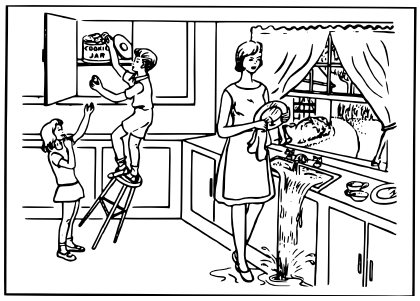

Figure 3: The Cookie Theft Picture, taken from the Boston Diagnostic Aphasia Examination (Goodglass et al., 2001).

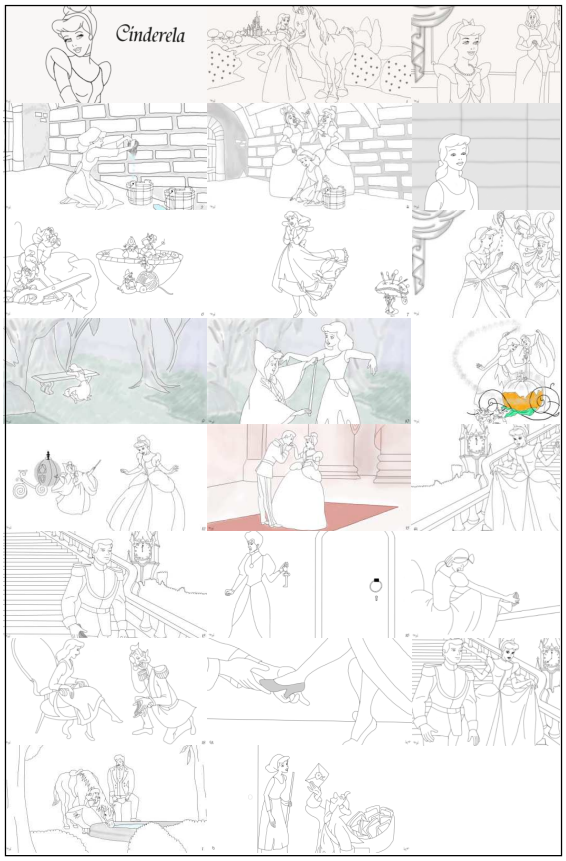

Figure 4: Sequence of Pictures of the of Cinderella story.

A.1 Examples of transcriptions

Below follows an example of a transcript of the Cookie Theft dataset.

You just want me to start talking ? Well the little girl is asking her brother we 'll say for a cookie . Now he 's getting the cookie one for him and one for her . He unbalances the step the little stool and he 's about to fall . And the lid 's off the cookie jar . And the mother is drying the dishes abstractly so she 's left the water running in the sink and it is spilling onto the floor . And there are two there 's look like two cups and a plate on the sink and board . And that boy 's wearing shorts and the little girl is in a short skirt . And the mother has an apron on . And she 's standing at the window . The window 's opened . It must be summer or spring . And the curtains are pulled back . And they have a nice walk around their house . And there 's this nice shrubbery it appears and grass . And there 's a big picture window in the background that has the drapes pulled off . There 's a not pulled off but pulled aside . And there 's a tree in the background . And the house with the kitchen has a lot of cupboard space under the sink board and under the cabinet from which the cookie you know cookies are being removed .

Below follows an excerpt of a transcript of the Cinderella dataset.

Original transcript in Portuguese:

ela morava com a madrasta as irmã né e ela era diferenciada das três era maltratada ela tinha que fazer limpeza na casa toda no castelo alias e as irmãs não faziam nada até que um dia chegou um convite do rei ele ia fazer um baile e a madrasta então é colocou que todas as filhas elas iam menos a cinderela bom como ela não tinha o vestido sapato as coisas tudo então ela mesmo teve que fazer a roupa dela começou a fazer ...

Translation of the transcript in English:

she lived with the stepmother the sister right and she was differentiated from the three was mistreated she had to do the cleaning in the entire house actually in the castle and the sisters didn't do anything until one day the king's invitation arrived he would invite everyone to a ball and then the stepmother is said that all the daughters they would go except for cinderella well since she didn't have a dress shoes all the things she had to make her own clothes she started to make them ...

A.2 Coh-Metrix-Dementia metrics

1. **Ambiguity**: verb ambiguity, noun ambiguity, adjective ambiguity, adverb ambiguity;
2. **Anaphoras**: adjacent anaphoric references, anaphoric references;
3. **Basic Counts**: Flesch index, number of word, number of sentences, number of paragraphs, words per sentence, sentences per paragraph, syllables per content word, verb incidence, noun incidence, adjective incidence, adverb incidence, pronoun incidence, content word incidence, function word incidence;
4. **Connectives**: connectives incidence, additive positive connectives incidence, additive negative connectives incidence, temporal positive connectives incidence, temporal negative connectives incidence, casual positive connectives incidence, casual negative connectives incidence, logical positive connectives incidence, logical negative connectives incidence;
5. **Co-reference Measures**: adjacent argument overlap, argument overlap, adjacent stem overlap, stem overlap, adjacent content word overlap;
6. **Content Word Frequencies**: Content words frequency, minimum among content words frequency;
7. **Hypernyms**: Mean hypernyms per verb;
8. **Logic Operators**: Logic operators incidence, and incidence, or incidence, if incidence, negation incidence;
9. **Latent Semantic Analysis (LSA)**: Average and standard deviation similarity between pairs of adjacent sentences in the text, Average and standard deviation similarity between all sentence pairs in the text, Average and standard deviation similarity between pairs of adjacent paragraphs in the text, Givenness average and standard deviation of each sentence in the text;
10. **Semantic Density**: content density;
11. **Syntactical Complexity**: only cross entropy;
12. **Tokens**: personal pronouns incidence, type-token ratio, Brunet index, Honoré Statistics.

Adversarial Adaptation of Synthetic or Stale Data

Abstract

Two types of data shift common in practice are 1. transferring from synthetic data to live user data (a deployment shift), and 2. transferring from stale data to current data (a temporal shift). Both cause a distribution mismatch between training and evaluation, leading to a model that overfits the flawed training data and performs poorly on the test data. We propose a solution to this mismatch problem by framing it as domain adaptation, treating the flawed training dataset as a source domain and the evaluation dataset as a target domain. To this end, we use and build on several recent advances in neural domain adaptation such as adversarial training (Ganin et al., 2016) and domain separation network (Bousmalis et al., 2016), proposing a new effective adversarial training scheme. In both supervised and unsupervised adaptation scenarios, our approach yields clear improvement over strong baselines.

1 Introduction

Spoken language understanding (SLU) systems analyze various aspects of a user query by classifying its domain, intent, and semantic slots. For instance, the query `how is traffic to target in bellevue` has domain `PLACES`, intent `CHECK_ROUTE_TRAFFIC`, and slots `PLACE_NAME: target` and `ABSOLUTE_LOCATION: bellevue`.

We are interested in addressing two types of data shift common in SLU applications. The first data shift problem happens when we transfer from synthetic data to live user data (a deployment shift). This is also known as the "cold-start" problem; a model cannot be trained on the real usage data prior to deployment simply because it does not exist. A common practice is to generate a large quantity of synthetic training data that mimics the expected user behavior. Such synthetic data is crafted using domain-specific knowledge and can be time-consuming. It is also flawed in that it typically does not match the live user data generated by actual users; the real queries submitted to these systems are different from what the model designers expect to see.

The second data shift problem happens when we transfer from stale data to current data (a temporal shift). In our use case, we have one set of training data from 2013 and wish to handle data from 2014–2016. This is problematic since the content of the user queries changes over time (e.g., new restaurant or movie names may be added). Consequently, the model performance degrades over time.

Both shifts cause a distribution mismatch between training and evaluation, leading to a model that overfits the flawed training data and performs poorly on the test data. We propose a solution to this mismatch problem by framing it as domain adaptation, treating the flawed training dataset as a source domain and the evaluation dataset as a target domain. To this end, we use and build on several recent advances in neural domain adaptation such as adversarial training (Ganin et al., 2016) and domain separation network (Bousmalis et al., 2016), proposing a new adversarial training scheme based on randomized predictions.

We consider both supervised and unsupervised adaptation scenarios (i.e., absence/presence of labeled data in the target domain). We find that unsupervised DA can greatly improve performance without requiring additional annotation. Super-

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1297–1307

https://doi.org/10.18653/v1/P17-1119

vised DA with a small amount of labeled data gives further improvement on top of unsupervised DA. In experiments, we show clear gains in both deployment and temporal shifts across 5 test domains, yielding average error reductions of 74.04% and 41.46% for intent classification and 70.33% and 32.0% for slot tagging compared to baselines without adaptation.

2 Related Work

2.1 Domain Adaptation

Our work builds on the recent success of DA in the neural network framework. Notably, Ganin et al. (2016) propose an adversarial training method for unsupervised DA. They partition the model parameters into two parts: one inducing domain-specific (or private) features and the other domain-invariant (or shared) features. The domain-invariant parameters are adversarially trained using a gradient reversal layer to be poor at domain classification; as a consequence, they produce representations that are domain agnostic. This approach is motivated by a rich literature on the theory of DA pioneered by Ben-David et al. (2007). We describe our use of adversarial training in Section 3.2.3. A special case of Ganin et al. (2016) is developed independently by Kim et al. (2016c) who motivate the method as a generalization of the feature augmentation method of Daumé III (2009).

Bousmalis et al. (2016) extend the framework of Ganin et al. (2016) by additionally encouraging the private and shared features to be mutually exclusive. This is achieved by minimizing the dot product between the two sets of parameters and simultaneously reconstructing the input (for all domains) from the features induced by these parameters.

Both Ganin et al. (2016) and Bousmalis et al. (2016) discuss applications in computer vision. Zhang et al. (2017) apply the method of Bousmalis et al. (2016) to tackle transfer learning in NLP. They focus on transfer learning between classification tasks over the same domain ("aspect transfer"). They assume a set of keywords associated with each aspect and use these keywords to inform the learner of the relevance of each sentence for that aspect.

2.2 Spoken Language Understanding

Recently, there has been much investment on the personal digital assistant (PDA) technology in industry (Sarikaya, 2015; Sarikaya et al., 2016). Apples Siri, Google Now, Microsofts Cortana, and Amazons Alexa are some examples of personal digital assistants. Spoken language understanding (SLU) is an important component of these examples that allows natural communication between the user and the agent (Tur, 2006; El-Kahky et al., 2014). PDAs support a number of scenarios including creating reminders, setting up alarms, note taking, scheduling meetings, finding and consuming entertainment (i.e. movie, music, games), finding places of interest and getting driving directions to them (Kim et al., 2016a).

Naturally, there has been an extensive line of prior studies for domain scaling problems to easily scale to a larger number of domains: pre-training (Kim et al., 2015c), transfer learning (Kim et al., 2015d), constrained decoding with a single model (Kim et al., 2016a), multi-task learning (Jaech et al., 2016), neural domain adaptation (Kim et al., 2016c), domainless adaptation (Kim et al., 2016b), a sequence-to-sequence model (Hakkani-Tür et al., 2016), domain attention (Kim et al., 2017) and zero-shot learning(Chen et al., 2016; Ferreira et al., 2015).

There are also a line of prior works on enhancing model capability and features: jointly modeling intent and slot predictions (Jeong and Lee, 2008; Xu and Sarikaya, 2013; Guo et al., 2014; Zhang and Wang, 2016; Liu and Lane, 2016a,b), modeling SLU models with web search click logs (Li et al., 2009; Kim et al., 2015a) and enhancing features, including representations (Anastasakos et al., 2014; Sarikaya et al., 2014; Celikyilmaz et al., 2016, 2010; Kim et al., 2016d) and lexicon (Liu and Sarikaya, 2014; Kim et al., 2015b).

All the above works assume that there are no any data shift issues which our work try to solve.

3 Method

3.1 BiLSTM Encoder

We use an LSTM simply as a mapping $\phi : \mathbb{R}^d \times \mathbb{R}^{d'} \rightarrow \mathbb{R}^{d'}$ that takes an input vector x and a state vector h to output a new state vector $h' = \phi(x, h)$. See Hochreiter and Schmidhuber (1997) for a detailed description.

Let $\mathcal{C}$ denote the set of character types and $\mathcal{W}$ the set of word types. Let $\oplus$ denote the vector concatenation operation. We encode an utterance using the wildly successful architecture given by bidirectional LSTMs (BiLSTMs) (Schuster and

Paliwal, 1997; Graves, 2012). The model parameters Θ associated with this BiLSTM layer are

- Character embedding $e_c \in \mathbb{R}^{25}$ for each $c \in \mathcal{C}$
- Character LSTMs $\phi^{\mathcal{C}}_f, \phi^{\mathcal{C}}_b : \mathbb{R}^{25} \times \mathbb{R}^{25} \to \mathbb{R}^{25}$
- Word embedding $e_w \in \mathbb{R}^{100}$ for each $w \in \mathcal{W}$
- Word LSTMs $\phi^{\mathcal{W}}_f, \phi^{\mathcal{W}}_b : \mathbb{R}^{150} \times \mathbb{R}^{100} \to \mathbb{R}^{100}$

Let $w_1 \dots w_n \in \mathcal{W}$ denote a word sequence where word w_i has character $w_i(j) \in \mathcal{C}$ at position j. First, the model computes a character-sensitive word representation $v_i \in \mathbb{R}^{150}$ as

$$\begin{aligned} f^{\mathcal{C}}_j &= \phi^{\mathcal{C}}_f\left(e_{w_i(j)}, f^{\mathcal{C}}_{j-1}\right) && \forall j = 1 \dots |w_i| \\ b^{\mathcal{C}}_j &= \phi^{\mathcal{C}}_b\left(e_{w_i(j)}, b^{\mathcal{C}}_{j+1}\right) && \forall j = |w_i| \dots 1 \\ v_i &= f^{\mathcal{C}}_{|w_i|} \oplus b^{\mathcal{C}}_1 \oplus e_{w_i} \end{aligned}$$

for each $i = 1 \dots n$.[1] Next, the model computes

$$\begin{aligned} f^{\mathcal{W}}_i &= \phi^{\mathcal{W}}_f\left(v_i, f^{\mathcal{W}}_{i-1}\right) && \forall i = 1 \dots n \\ b^{\mathcal{W}}_i &= \phi^{\mathcal{W}}_b\left(v_i, b^{\mathcal{W}}_{i+1}\right) && \forall i = n \dots 1 \end{aligned}$$

and induces a character- and context-sensitive word representation $h_i \in \mathbb{R}^{200}$ as

$$h_i = f^{\mathcal{W}}_i \oplus b^{\mathcal{W}}_i \tag{1}$$

for each $i = 1 \dots n$. For convenience, we write the entire operation as a mapping BiLSTM_Θ:

$$(h_1 \dots h_n) \leftarrow \text{BiLSTM}_\Theta(w_1 \dots w_n)$$

3.2 Unsupervised DA

In unsupervised domain adaptation, we assume labeled data for the source domain but not the target domain. Our approach closely follows the previous work on unsupervised neural domain adaptation by Ganin et al. (2016) and Bousmalis et al. (2016). We have three BiLSTM encoders described in Section 3.1:

1. Θ^{src}: induces source-specific features
2. Θ^{tgt}: induces target-specific features
3. Θ^{shd}: induces domain-invariant features

We now define a series of loss functions defined by these encoders.

[1] For simplicity, we assume some random initial state vectors such as $f^{\mathcal{C}}_0$ and $b^{\mathcal{C}}_{|w_i|+1}$ when we describe LSTMs.

3.2.1 Source Side Tagging Loss

The most obvious objective is to minimize the model's error on labeled training data for the source domain. Let $w_1 \dots w_n \in \mathcal{W}$ be an utterance in the source domain annotated with labels $y_1 \dots y_n \in \mathcal{L}$. We induce

$$\begin{aligned} (h^{\text{src}}_1 \dots h^{\text{src}}_n) &\leftarrow \text{BiLSTM}_{\Theta^{\text{src}}}(w_1 \dots w_n) \\ (h^{\text{shd}}_1 \dots h^{\text{shd}}_n) &\leftarrow \text{BiLSTM}_{\Theta^{\text{shd}}}(w_1 \dots w_n) \end{aligned}$$

Then we define the probability of tag $y \in \mathcal{L}$ for the i-th word as

$$\begin{aligned} z_i &= W^2_{\text{tag}} \tanh\left(W^1_{\text{tag}} \bar{h}_i + b^1_{\text{tag}}\right) + b^2_{\text{tag}} \\ p(y|h_i) &\propto \exp\left([z_i]_y\right) \end{aligned}$$

where $\bar{h}_i = h^{src}_i \oplus h^{\text{shd}}_i$ and $\Theta^{\text{tag}} = \{W^1_{\text{tag}}, W^2_{\text{tag}}, b^1_{\text{tag}}, b^2_{\text{tag}}\}$ denotes additional feed-foward parameters. The tagging loss is given by the negative log likelihood

$$L^{\text{tag}}\left(\Theta^{\text{src}}, \Theta^{\text{shd}}, \Theta^{\text{tag}}\right) = -\sum_i \log p\left(y_i|\bar{h}_i\right)$$

where we iterate over annotated words (w_i, y_i) on the source side.

3.2.2 Reconstruction Loss

Following previous works, we ground feature learning by reconstructing encoded utterances. Both Bousmalis et al. (2016) and Zhang et al. (2017) use mean squared errors for reconstruction, the former of image pixels and the latter of words in a context window. In contrast, we use an attention-based LSTM that fully re-generates the input utterance and use its log loss.

More specifically, let $w_1 \dots w_n \in \mathcal{W}$ be an utterance in domain $d \in \{\text{src}, \text{tgt}\}$. We first use the relevant encoders as before

$$\begin{aligned} (h^d_1 \dots h^d_n) &\leftarrow \text{BiLSTM}_{\Theta^d}(w_1 \dots w_n) \\ (h^{\text{shd}}_1 \dots h^{\text{shd}}_n) &\leftarrow \text{BiLSTM}_{\Theta^{\text{shd}}}(w_1 \dots w_n) \end{aligned}$$

The concatenated vectors $\bar{h}_i = h^d_i \oplus h^{\text{shd}}_i$ are fed into the standard attention-based decoder (Bahdanau et al., 2014) to define the probability of word w at each position i with state vector μ_{i-1} (where $\mu_0 = \bar{h}_n$):

$$\begin{aligned} \alpha_j &\propto \exp\left(\mu^\top_{i-1} \bar{h}_j\right) \quad \forall j \in \{1 \dots n\} \\ \tilde{h}_i &= \sum_{j=1}^{n} \alpha_j \bar{h}_j \\ \mu_i &= \phi^{\mathcal{R}}(\mu_{i-1} \oplus \tilde{h}_i, \mu_{i-1}) \\ p(w|\mu_i) &\propto \exp\left([W^1_{\text{rec}} \mu_i + b^1_{\text{rec}}]_w\right) \end{aligned}$$

where $\Theta^{\text{rec}} = \{\phi^{\mathcal{R}}, W^1_{\text{rec}}, b^1_{\text{rec}}\}$ denotes additional parameters. The reconstruction loss is given by the negative log likelihood

$$L^{\text{rec}}\left(\Theta^{\text{src}}, \Theta^{\text{tgt}}, \Theta^{\text{shd}}, \Theta^{\text{rec}}\right) = -\sum_i \log p\left(w_i|\mu_i\right)$$

where we iterate over words w_i in both the source and target utterances.

3.2.3 Adversarial Domain Classification Loss

Ganin et al. (2016) propose introducing an adversarial loss to make shared features domain-invariant. This is motivated by a theoretical result of Ben-David et al. (2007) who show that the generalization error on the target domain depends on how "different" the source and the target domains are. This difference is approximately measured by

$$2\left(1 - 2\inf_{\Theta} \text{error}(\Theta)\right) \tag{2}$$

where $\text{error}(\Theta)$ is the domain classification error using model Θ. It is assumed that the source and target domains are balanced so that $\inf_\Theta \text{error}(\Theta) \leq 1/2$ and the difference lies in $[0, 2]$. In other words, we want to make $\text{error}(\Theta)$ as large as possible in order to generalize well to the target domain. The intuition is that the more domain-invariant our features are, the easier it is to benefit from the source side training when testing on the target side. It can also be motivated as a regularization term (Ganin et al., 2016).

Let $w_1 \dots w_n \in \mathcal{W}$ be an utterance in domain $d \in \{\text{src}, \text{tgt}\}$. We first use the shared encoder

$$(h^{\text{shd}}_1 \dots h^{\text{shd}}_n) \leftarrow \text{BiLSTM}_{\Theta^{\text{shd}}}(w_1 \dots w_n)$$

It is important that we only use the shared encoder for this loss. Then we define the probability of domain d for the utterance as

$$z_i = W^2_{\text{adv}} \tanh\left(W^1_{\text{adv}} \sum_{i=1}^{n} h^{\text{shd}}_i + b^1_{\text{adv}}\right) + b^2_{\text{adv}}$$

$$p(d|h_i) \propto \exp\left([z_i]_d\right)$$

where $\Theta^{\text{adv}} = \{W^1_{\text{adv}}, W^2_{\text{adv}}, b^1_{\text{adv}}, b^2_{\text{adv}}\}$ denotes additional feedfoward parameters. The adversarial domain classification loss is given by the *positive* log likelihood

$$L^{\text{adv}}\left(\Theta^{\text{shd}}, \Theta^{\text{adv}}\right) = \sum_i \log p\left(d^{(i)}|w^{(i)}\right)$$

where we iterate over domain-annotated utterances $(w^{(i)}, d^{(i)})$.

Random prediction training While past work only consider using a negative gradient (Ganin et al., 2016; Bousmalis et al., 2016) or positive log likelihood (Zhang et al., 2017) to perform adversarial training, it is unclear whether these approaches are optimal for the purpose of "confusing" the domain predictor. For instance, minimizing log likelihood can lead to a model accurately predicting the *opposite* domain, compromising the goal of inducing domain-invariant representations. Thus we propose to instead optimize the shared parameters for *random domain predictions*. Specifically, the above loss is replaced with

$$L^{\text{adv}}\left(\Theta^{\text{shd}}, \Theta^{\text{adv}}\right) = -\sum_i \log p\left(d^{(i)}|w^{(i)}\right)$$

where $d^{(i)}$ is set to be `src` with probability 0.5 and `tgt` with probability 0.5. By optimizing for random predictions, we achieve the desired effect: the shared parameters are trained to induce features that cannot discriminate between the source and the target domains.

3.2.4 Non-Adversarial Domain Classification Loss

In addition to the adversarial loss for domain-invariant parameters, we also introduce a non-adversarial loss for domain-specific parameters. Given $w_1 \dots w_n \in \mathcal{W}$ in domain $d \in \{\text{src}, \text{tgt}\}$, we use the private encoder

$$(h^{\text{d}}_1 \dots h^{\text{d}}_n) \leftarrow \text{BiLSTM}_{\Theta^{\text{d}}}(w_1 \dots w_n)$$

It is important that we only use the private encoder for this loss. Then we define the probability of domain d for the utterance as

$$z_i = W^2_{\text{nadv}} \tanh\left(W^1_{\text{nadv}} \sum_{i=1}^{n} h^{\text{d}}_i + b^1_{\text{nadv}}\right) + b^2_{\text{nadv}}$$

$$p(d|h_i) \propto \exp\left([z_i]_d\right)$$

where $\Theta^{\text{nadv}} = \{W^1_{\text{nadv}}, W^2_{\text{nadv}}, b^1_{\text{nadv}}, b^2_{\text{nadv}}\}$ denotes additional feedfoward parameters. The non-adversarial domain classification loss is given by the negative log likelihood

$$L^{\text{nadv}}\left(\Theta^{\text{d}}, \Theta^{\text{nadv}}\right) = \sum_i \log p\left(d^{(i)}|w^{(i)}\right)$$

where we iterate over domain-annotated utterances $(w^{(i)}, d^{(i)})$.

3.2.5 Orthogonality Loss

Finally, following Bousmalis et al. (2016), we further encourage the domain-specific features to be mutually exclusive with the shared features by imposing soft orthogonality constraints. This is achieved as follows. Given an utterance $w_1 \dots w_n \in \mathcal{W}$ in domain $d \in \{\text{src}, \text{tgt}\}$. We compute

$$(h_1^d \dots h_n^d) \leftarrow \text{BiLSTM}_{\Theta^d}(w_1 \dots w_n)$$
$$(h_1^{\text{shd}} \dots h_n^{\text{shd}}) \leftarrow \text{BiLSTM}_{\Theta^{\text{shd}}}(w_1 \dots w_n)$$

The orthogonality loss for this utterance is given by

$$L^{\text{orth}}\left(\Theta^{\text{src}}, \Theta^{\text{tgt}}, \Theta^{\text{shd}}\right) = \sum_i (h_i^d)^\top h_i^{\text{shd}}$$

where we iterate over words i in both the source and target utterances.

3.2.6 Joint Objective

For unsupervised DA, we optimize

$$\begin{aligned} L^{\text{unsup}}\left(\Theta^{\text{src}}, \Theta^{\text{tgt}}, \Theta^{\text{shd}}, \Theta^{\text{tag}}, \Theta^{\text{rec}}, \Theta^{\text{adv}}\right) = \\ L^{\text{tag}}\left(\Theta^{\text{src}}, \Theta^{\text{shd}}, \Theta^{\text{tag}}\right) + \\ L^{\text{rec}}\left(\Theta^{\text{src}}, \Theta^{\text{tgt}}, \Theta^{\text{shd}}, \Theta^{\text{rec}}\right) + \\ L^{\text{adv}}\left(\Theta^{\text{shd}}, \Theta^{\text{adv}}\right) + \\ L^{\text{nadv}}\left(\Theta^{\text{src}}, \Theta^{\text{nadv}}\right) + \\ L^{\text{nadv}}\left(\Theta^{\text{tgt}}, \Theta^{\text{nadv}}\right) + \\ L^{\text{orth}}\left(\Theta^{\text{src}}, \Theta^{\text{tgt}}, \Theta^{\text{shd}}\right) \end{aligned}$$

with respect to all model parameters. In an online setting, given an utterance we compute its reconstruction, adversarial, orthogonality, and tagging loss if in the source domain, and take a gradient step on the sum of these losses.

3.3 Supervised DA

In supervised domain adaptation, we assume labeled data for both the source domain and the target domain. We can easily incorporate supervision in the target domain by adding $L^{\text{tag}}\left(\Theta^{\text{tgt}}, \Theta^{\text{shd}}, \Theta^{\text{tag}}\right)$ to the unsupervised DA objective:

$$\begin{aligned} L^{\text{sup}}\left(\Theta^{\text{src}}, \Theta^{\text{tgt}}, \Theta^{\text{shd}}, \Theta^{\text{tag}}, \Theta^{\text{rec}}, \Theta^{\text{adv}}\right) = \\ L^{\text{unsup}}\left(\Theta^{\text{src}}, \Theta^{\text{tgt}}, \Theta^{\text{shd}}, \Theta^{\text{tag}}, \Theta^{\text{rec}}, \Theta^{\text{adv}}\right) + \\ L^{\text{tag}}\left(\Theta^{\text{tgt}}, \Theta^{\text{shd}}, \Theta^{\text{tag}}\right) \end{aligned} \quad (3)$$

We mention that the approach by Kim et al. (2016c) is a special case of this objective; they optimize

$$\begin{aligned} L^{\text{sup2}}\left(\Theta^{\text{src}}, \Theta^{\text{tgt}}, \Theta^{\text{shd}}, \Theta^{\text{tag}}\right) = L^{\text{tag}}\left(\Theta^{\text{src}}, \Theta^{\text{shd}}, \Theta^{\text{tag}}\right) + \\ L^{\text{tag}}\left(\Theta^{\text{tgt}}, \Theta^{\text{shd}}, \Theta^{\text{tag}}\right) \end{aligned} \quad (4)$$

which is motivated as a neural extension of the feature augmentation method of Daumé III (2009).

4 Experiments

In this section, we conducted a series of experiments to evaluate the proposed techniques on datasets obtained from real usage.

4.1 Test Domains and Tasks

We test our approach on a suite of 5 Microsoft Cortana domains with 2 separate tasks in spoken language understanding: (1) intent classification and (2) slot (label) tagging. The intent classification task is a multi-class classification problem with the goal of determining to which one of the n intents a user utterance belongs conditioning on the given domain. The slot tagging task is a sequence labeling problem with the goal of identifying entities and chunking of useful information snippets in a user utterance. For example, a user could say `reserve a table at joeys grill for thursday at seven pm for five people`. Then the goal of the first task would be to classify this utterance as `MAKE_RESERVATION` intent given the domain `PLACES`, and the goal of the second task would be to tag `joeys grill` as `RESTAURANT`, `thursday` as `DATE`, `seven pm` as `TIEM`, and `five` as `NUMBER_PEOPLE`.

Table 1 gives a summary of the 5 test domains. We note that the domains have various levels of label granularity.

Domain	Intent	Slot	Description
calendar	23	43	Set appointments in calendar
comm.	38	45	Make calls & send messages
places	35	64	Find locations & directions
reminder	14	35	Remind tasks in a to-do list
weather	13	19	Get weather information

Table 1: The number of intents, the number of slots and a short description of the test domains.

4.2 Experimental Setup

We consider 2 possible domain adaptation (DA) scenarios: (1) adaptation of an engineered dataset to a live user dataset and (2) adaptation of an old

dataset to a new dataset. For the first DA scenario, we test whether our approach can effectively make a system adapt from experimental, engineered data to real-world, live data. We use synthetic data which domain experts manually create based on a given domain schema[2] before the system goes live as the engineered data. We use transcribed dataset from users' speech input as the live user data. For the second scenario, we test whether our approach can effectively make a system adapt over time. A large number of users will quickly generate a large amount of data, and the usage pattern could also change. We use annotation data over 1 month in 2013 (more precisely August of 2013) as our old dataset, and use the whole data between 2014 and 2016 as our new dataset regardless of whether the data type is engineered or live user.

As we describe in the earlier sections, we consider both supervised and unsupervised DA. We apply our DA approach with labeled data in the target domain for the supervised setting and with unlabeled data for the unsupervised one. We give details of the baselines and variants of our approach below.

Unsupervised DA baselines and variants:

- *SRC*: a single LSTM model trained on a source domain without DA techniques
- DA^W: an unsupervised DA model with a word-level decoder (i.e., re-generate each word independently)
- DA^S: an unsupervised DA model with a sentence-level decoder described in Section 3.2

Supervised DA baselines and variants:

- *SRC*: a single LSTM model trained only on a source domain
- *TGT*: a single LSTM model trained only on a target domain
- *Union*: a single LSTM model trained on the union of source and target domains.
- DA: a supervised DA model described in Section 3.3
- DA^A: *DA* with adversary domain training
- DA^U: *DA* with reasonably sufficient unlabeled data

In our experiments, all the models were implemented using Dynet (Neubig et al., 2017) and were trained using Stochastic Gradient Descent (SGD) with Adam (Kingma and Ba, 2015)—an adaptive learning rate algorithm. We used the initial learning rate of 4×10^{-4} and left all the other hyper parameters as suggested in Kingma and Ba (2015). Each SGD update was computed without a minibatch with Intel MKL (Math Kernel Library)[3]. We used the dropout regularization (Srivastava et al., 2014) with the keep probability of 0.4.

We encode user utterances with BiLSTMs as described in Section 3.1. We initialize word embeddings with pre-trained embeddings used by Lample et al. (2016). In the following sections, we report intent classification results in accuracy percentage and slot results in F1-score. To compute slot F1-score, we used the standard CoNLL evaluation script[4]

4.3 Results: Unsupervised DA

We first show our results in the unsupervised DA setting where we have a labeled dataset in the source domain, but only unlabeled data in the target domain. We assume that the amount of data in both datasets is sufficient. Dataset statistics are shown in Table 2.

The performance of the baselines and our model variants are shown in Table 3. The left side of the table shows the results of the DA scenario of adapting from engineered data to live user data, and the baseline which trained only on the source domain (SRC) show a poor performance, yielding on average 48.5% on the intent classification and 42.7% F1-score on the slot tagging. Using our DA approach with a word-level decoder (DA^W) shows a significant increase in performance in all 5 test domains, yielding on average 82.2% intent accuracy and 80.5% slot F1-score. The performance increases further using the DA approach with a sentence-level decoder DA^S, yielding on average 85.6% intent accuracy and 83.0% slot F1-score.

The right side of the table shows the results of the DA scenario of adapting from old to new data, and the baseline trained only on SRC also show

[2]This is a semantic template that defines a set of intents and slots for each domain according to the intended functionality of the system.

Table 5: Intent classification accuracy (%) and slot tagging F1-score (%) for the supervised domain adaptation.

a similar poor performance, yielding on average 51.7% accuracy and 43.7% F1-score. DA^W approach shows a significant performance increase in all 5 test domains, yielding on average 86.9% intent accuracy and 85.7% slot F1-score. Similarly, the performance increases further with the DA^S with 90.2% intent accuracy and 89.3% F1-score.

Our DA approach variants yield average error reductions of 72.04% and 79.71% for intent classification and 70.33% and 80.99% for slot tagging. The results suggest that our DA approach can quickly make a model adapt from synthetic data to real-world data and from old data to new data with the additional use of only 2 to 2.5 more data from the target domain. Aside from the performance boost itself, the approach shows even more power since the new data from the target down do not need to be labeled and it only requires collecting a little more data from the target domain. We note that the model development sets were created only from the source domain for a fully unsupervised setting. But having the development set from the target domain shows even more boost in performance although not shown in the results, and labeling only the development set from the target domain is relatively less expensive than labeling the whole dataset.

4.4 Results: Supervised DA

Second, we show our results in the supervised DA setting where we have a sufficient amount of labeled data in the source domain but relatively insufficient amount of labeled data in the target domain. Having more labeled data in the target domain would most likely help with the performance, but we intentionally made the setting more disadvantageous for our DA approach to better simulate real-world scenarios where there is usually lack of resources and time to label a large amount of new data. For each personal assistant test domain, we only used 1000 training utterances to simulate scarcity of newly labeled data, and dataset statistics are shown in Table 2. Unlike the unsupervised DA scenario, here we used the development sets created from the target domain shown in Table 4.

The left side of Table 5 shows the results of the supervised DA approach of adapting from engineered data to live user data. The baseline trained only on the source (SRC) shows on average 48.5% intent accuracy and 42.7% slot F1-score. Training only on the target domain (TGT) increases the performance to 71.3% and 65.0%, but training on the union of the source and target domains (Union) again brings the performance down to 48.7% and 42.3%. As shown in the unsupervised setting, using our DA approach (DA) shows significant performance increase in all 5 test domains, yielding on average 81.7% intent accuracy and 76.2% slot tagging. The DA approach with adversary domain training (DA^A) shows similar performance compared to that of DA, and performance shows more increase when using our DA approach with sufficient unlabeled data[5] (DA^U), yielding on average 83.6% and 77.6%. For the second scenario of adapting from old to new dataset, the results show a very similar trend in performance.

The results show that our supervised DA (DA) approach also achieves a significant performance gain in all 5 test domains, yielding average error reductions of 68.18% and 51.35% for intent classification and 60.90% and 50.09% for slot tagging. The results suggest that an effective domain adaptation can be done using the supervised DA by having only a handful more data of 1k newly labeled data points. In addition, having both a small amount of newly labeled data combined with sufficient unlabeled data can help the models perform even better. The poor performance of using the union of both source and target domain data might be due to the relatively very small size of the target domain data, overwhelmed by the data in the source domain.

4.5 Results: Adversarial Domain Classification Loss

Task	Domain	Eng. → User RAND	Eng. → User ADV
Intent	calendar	**84.6**	81.1
	communication	**81.2**	77.9
	places	**86.3**	83.5
	reminder	**88.7**	85.8
	weather	**87.1**	84.2
	AVG	**85.6**	82.5
Slot	calendar	**81.7**	78.7
	communication	**79.1**	75.7
	places	**83.8**	80.6
	reminder	**85.7**	82.4
	weather	**84.7**	81.7
	AVG	**83.0**	79.8

Table 6: Intent classification accuracy (%) and slot tagging F1-score (%) for the unsupervised domain adaptation with two different adversarial classification losses – our claimed random domain predictions (RAND) and adversarial loss (ADVR) of Ganin et al. (2016) as explained in 3.2.3.

[5]This data is used for unsupervised DA experiments (Table 2).

The impact on the performance of two different adversarial classification losses are shown in Table 6. RAND represents the unsupervised DA model with sentence-level decoder (DA^S) using random prediction loss. The ADV shows the performance of same model using the adversarial loss of Ganin et al. (2016) as described in 3.2.3. Unfortunately, in the deployment shift scenario, using the adversarial loss fails to provide any improvement on intent classification accuracy and slot tagging F1 score, achieving 82.5% intent accuracy and 79.8% slot F1 score. These results align with our hypothesis that the adversarial loss using does not confuse the classifier sufficiently.

4.6 Proxy $\mathcal{A}$-distance

	Eng. → User	Old → New
Domain	$d_{\mathcal{A}}$	$d_{\mathcal{A}}$
calendar	0.58	0.43
comm.	0.54	0.44
places	0.68	0.62
reminder	0.54	0.57
weather	0.57	0.54
AVG	0.58	0.52

Table 7: Proxy $\mathcal{A}$-distance of resulting models: (1) engineered and live user dataset and (2) old and new dataset.

The results in shown in Table 7 show Proxy $\mathcal{A}$-distance(Ganin et al., 2016) to check if our adversary domain training generalize well to the target domain. The distance between two datasets is computed by

$$\hat{d}_A = 2(1 - 2\min\{\varepsilon, 1-\varepsilon\}) \quad (5)$$

where ε is a generalization error in discriminating between the source and target datasets.

The range of $\hat{d}_A$ distance is between 0 and 2.0. 0 is the best case where adversary training successfully fake shared encoder to predict domains. In other words, thanks to adversary training our model make the domain-invariant features in shared encoder in order to generalize well to the target domain.

4.7 Vocabulary distance between engineered data and live user data

The results in shown in Table 8 show the discrepancy between two datasets. We measure the degree of overlap between vocabulary V employed by the two datasets. We simply take the Jaccard coefficient between the two sets of such vocabulary:

$$d_V(s,t) = 1 - JC(V_s, V_t),$$

where V_s is the set of vocabulary in source s domain, and V_t is the corresponding set for target t domain and $JC(A,B) = \frac{|A \cap B|}{|A \cup B|}$ is the Jaccard coefficient, measuring the similarity of two sets. The distance d_V is the high it means that they are not shared with many words. Overall, the distance between old and new dataset are still far and the number of overlapped are small, but better than live user case.

	Eng. → User	Old → New
Domain	d_V	d_V
calendar	0.80	0.72
comm.	0.80	0.93
places	0.82	0.72
reminder	0.89	0.71
weather	0.72	0.73
AVG	0.80	0.76

Table 8: Distance between different datasets: (1) engineered and live user dataset and (2) old and new dataset.

5 Conclusion

In this paper, we have addressed two types of data shift common in SLU applications: 1. transferring from synthetic data to live user data (a deployment shift), and 2. transferring from stale data to current data (a temporal shift). Our method is based on domain adaptation, treating the flawed training dataset as a source domain and the evaluation dataset as a target domain. We use and build on several recent advances in neural domain adaptation such as adversarial training and domain separation network, proposing a new effective adversarial training scheme based on randomized predictions. In both supervised and unsupervised adaptation scenarios, our approach yields clear improvement over strong baselines.

Chat Detection in an Intelligent Assistant: Combining Task-oriented and Non-task-oriented Spoken Dialogue Systems

Abstract

Recently emerged intelligent assistants on smartphones and home electronics (*e.g.*, Siri and Alexa) can be seen as novel hybrids of domain-specific task-oriented spoken dialogue systems and open-domain non-task-oriented ones. To realize such hybrid dialogue systems, this paper investigates determining whether or not a user is going to have a chat with the system. To address the lack of benchmark datasets for this task, we construct a new dataset consisting of 15,160 utterances collected from the real log data of a commercial intelligent assistant (and will release the dataset to facilitate future research activity). In addition, we investigate using tweets and Web search queries for handling open-domain user utterances, which characterize the task of chat detection. Experiments demonstrated that, while simple supervised methods are effective, the use of the tweets and search queries further improves the F_1-score from 86.21 to 87.53.

1 Introduction

1.1 Chat detection

Conventional studies on spoken dialogue systems (SDS) have investigated either domain-specific task-oriented SDS[1] (Williams and Young, 2007) or open-domain non-task-oriented SDS (*a.k.a.*, chatbots or chat-oriented SDS) (Wallace, 2009). The former offers convenience by helping users complete tasks in specific domains, while the latter offers entertainment through open-ended chatting (or smalltalk) with users. Although the functionalities offered by the two types of SDS are complementary to each other, little practical effort has been made to combine them. This unfortunately has limited the potential of SDS.

This situation is now being changed by the emergence of voice-activated intelligent assistants on smartphones and home electronics (*e.g.*, Siri[2] and Alexa[3]). These intelligent assistants typically perform various tasks (*e.g.*, Web search, weather checking, and alarm setting) while being able to have chats with users. They can be seen as a novel hybrid of multi-domain task-oriented SDS and open-domain non-task-oriented SDS.

To realize such hybrid SDS, we have to determine whether or not a user is going to have a chat with the system. For example, if a user says "*What is your hobby?*" it is considered that she is going to have a chat with the system. On the other hand, if she says "*Set an alarm at 8 o'clock*," she is probably trying to operate her smartphone. We refer to this task as *chat detection* and treat it as a binary classification problem.

Chat detection has not been explored enough in past studies. This is primarily because little attempts have been made to develop hybrids of task-oriented and non-task-oriented SDS (see Section 2 for related work). Although task-oriented and non-task-oriented SDS have long research histories, both of them do not require chat detection. Typically, users of task-oriented SDS do not have chats with the systems and users of non-task-oriented SDS always have chats with the systems.

1.2 Summary of this paper

In this work, we construct a new dataset for chat detection. As we already discussed, chat detection

*Work done during internship at Yahoo Japan Corporation.

[1] They can be classified as single-domain or multi-domain task-oriented SDS.

[2] http://www.apple.com/ios/siri

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1308–1319
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1120

has not been explored enough, and thus there exist no benchmark datasets available. To address this situation, we collected $15,160$ user utterances from real log data of a commercial intelligent assistant, and recruited crowd workers to annotate those utterances with whether or not the users are going to have chats with the intelligent assistant. The resulting dataset will be released to facilitate future studies.

The technical challenge in chat detection is that we have to handle open-ended utterances of intelligent assistant users. Commercial intelligent assistants have a vast amount of users and they talk about a wide variety of topics especially when chatting with the assistants. It consequently becomes labor-intensive to collect a sufficiently large amount of annotated data for training accurate chat detectors.

We develop supervised binary classifiers to perform chat detection. We address the open-ended user utterances, which characterize chat detection, by using unlabeled external resources. We specifically utilize tweets (*i.e.*, Twitter posts) and Web search queries to enhance the supervised classifiers.

Experimental results demonstrated that, while simple supervised methods are effective, the external resources are able to further improve them. The results demonstrated that the use of the external resources increases over 1 point of F_1-score (from 86.21 to 87.53).

2 Related Work

2.1 Previous studies on combining task-oriented and non-task-oriented SDS

Task-oriented and non-task-oriented SDS have long been investigated independently, and little attempts have been made to develop hybrids of the two types of SDS. As a consequence, previous studies have not investigated chat detection without only a few exceptions.[4]

Niculescu and Banchs (2015) explored using non-task-oriented SDS as a back-off mechanism for task-oriented SDS. They, however, did not propose any concrete methods of automatically determining when to switch to non-task-oriented SDS.

[4]Unfortunately, we cannot discuss little about chat detection in existing commercial intelligent assistants since most of their technical details have not been disclosed. We make the best effort to compensate for it by comparing the proposed methods with our in-house intelligent assistant in the experiment.

Lee et al. (2007) proposed an example-based dialogue manager to combine task-oriented and non-task-oriented SDS. In such a framework, however, it is difficult to flexibly utilize state-of-the-art supervised classifiers as a component.

Other studies proposed machine-learning-based frameworks for combining multi-domain task-oriented SDS and non-task-oriented SDS (Wang et al., 2014; Sarikaya, 2017). These assume that several components including a chat detector are already available, and explore integrating those components. They discuss little on how to develop each of the components. On the other hand, the focus of this work is to develop one of those components, a chat detector. Although it lies outside the scope of this paper to explore how to exploit chat detection method in a full dialogue system, the chat detection method is considered to serve, for example, as one component within those frameworks.

2.2 Intent and domain determination

Chat detection is related to, but different from, intent and domain determination that have been studied in the field of SDS (Guo et al., 2014; Xu and Sarikaya, 2014; Ravuri and Stolcke, 2015; Kim et al., 2016; Zhang and Wang, 2016).

Both intent and domain determination have been investigated in domain-specific task-oriented SDS. Intent determination aims to determine the type of information a user is seeking in single-domain task-oriented SDS. For example, in the ATIS dataset, which is collected from an airline travel information service system, the information type includes flight, city, and so on (Tur et al., 2010). On the other hand, domain determination aims to determine which domain is relevant to a given user utterance in multi-domain task-oriented SDS (Xu and Sarikaya, 2014). Note that it is possible that domain determination is followed by intent determination.

Unlike intent and domain determination, chat detection targets hybrid systems of multi-domain task-oriented SDS and open-domain non-task-oriented SDS, and aims to determine whether the non-task-oriented component is responsible to a given user utterance or not (*i.e.*, the user is going to have a chat or not). Therefore, the objective of chat detection is different from intent and domain determination.

It may be possible to see chat detection as a spe-

cific problem of domain determination (Sarikaya, 2017). We, nevertheless, discuss it as a different problem because of the uniqueness of the "chat domain." It greatly differs from ordinary domains in that it plays a role of combining the two different types of SDS that have long been studied independently, rather than combining multiple SDS of the same types. In addition, we discuss the use of external resources, especially tweets, for chat detection. This approach is unique to chat detection and is not considered effective for ordinary domain determination.

It is interesting to note that chat detection is not followed by slot-filling unlike intent and domain determination, as far as we use a popular response generator such as seq2seq model (Sutskever et al., 2014) or an information retrieval based approach (Yan et al., 2016). Although joint intent (or domain) determination and slot-filling has been widely studied to improve accuracy (Guo et al., 2014; Zhang and Wang, 2016), the same approach is not feasible in chat detection.

2.3 Intelligent assistant

Previous studies on intelligent assistants have not investigated chat detection. Their research topics are centered around those on user behaviors including the prediction of user satisfaction and engagement (Jiang et al., 2015; Kobayashi et al., 2015; Sano et al., 2016; Kiseleva et al., 2016a,b) and gamification (Otani et al., 2016). For example, Jiang et al. (2015) investigated predicting whether users are satisfied with the responses of intelligent assistants by combining diverse features including clicks and utterances. Sano et al. (2016) explored predicting whether users will keep using the intelligent assistants in the future by using long-term usage histories.

Some earlier works used the Cortana dataset as a benchmark of domain determination (Guo et al., 2014; Xu and Sarikaya, 2014; Kim et al., 2016) or proposed a development framework for Cortana (Crook et al., 2016). Those studies, however, regarded the intelligent assistant as merely one example of multi-domain task-oriented SDS and did not explore chat detection.

2.4 Non-task-oriented SDS

Non-task-oriented SDS have long been studied in the research community. While early studies adopted rule-based methods (Weizenbaum, 1966; Wallace, 2009), statistical approaches have recently gained much popularity (Ritter et al., 2011; Vinyals and Le, 2015). This research direction was pioneered by Ritter et al. (2011), who applied a phrase-based SMT model to the response generation. Later, Vinyals and Le (2015) used the seq2seq model (Sutskever et al., 2014). To date, a number follow-up studies have been made to improve on the response quality (Hasegawa et al., 2013; Shang et al., 2015; Sordoni et al., 2015; Li et al., 2016a,b; Gu et al., 2016; Yan et al., 2016). Those studies assume that users always want to have chats with systems and investigate only methods of generating appropriate responses to given utterances. Chat detection is required for integrating those response generators into intelligent assistants.

2.5 Use of conversational data

The recent explosion of conversational data on the Web, especially tweets, have triggered a variety of dialogue studies. Those typically used tweets either for training response generators (*c.f.*, Section 2.4) or for discovering dialogue acts in an unsupervised fashion (Ritter et al., 2010; Higashinaka et al., 2011). This treatment of tweets differs from that in our work.

3 Chat Detection Dataset

In this section we explain how we constructed the new benchmark dataset for chat detection. We then analyze the data to provide insights into the actual user behavior.

3.1 Construction procedure

We sampled $15,160$ unique utterances[5] (*i.e.*, automatic speech recognition results) from the real log data of a commercial intelligent assistant, Yahoo! Voice Assist.[6] The log data were collected between Jan. and Aug. 2016. In the log data, some utterances such as "Hello" appear frequently. To construct a dataset containing both high and low frequency utterances, we set frequency thresholds[7] to divide the utterances into three groups (high, middle, and low frequency) and then randomly sampled the same number of utterances

[5]The utterances are all in Japanese. Example utterances given in this paper are English translations.

[6]`https://v-assist.yahoo.co.jp`

[7]We cannot disclose the exact threshold values so as to keep the detailed statistics of the original log data confidential.

Label	Example	No. of votes
CHAT	Let's talk about something.	5
	What is your hobby?	7
	I don't have any holidays this month.	5
	I'm walking around now.	6
	Do you like cats?	5
	You are a serious geek.	7
NONCHAT	Show me a picture of Mt. Fuji.	6
	What's the highest building in the world?	5
	A nice restaurant near here.	7
	Wake me up at 9:10.	7
	Brighten the screen.	6
	Turn off the alarm.	7

Table 1: Example utterances and the numbers of votes. NONCHAT utterances are further divided into information seeking (top) and device control (bottom) to facilitate readers' understanding.

#Votes	No. of utterances
4	1701
5	2670
6	4978
7	5811

Table 2: Distribution of the numbers of votes.

from each of the three groups. During the data collection, we ensured privacy by manually removing utterances that included the full name of a person or detailed address information.

Next, we recruited crowd workers to annotate the $15,160$ utterances with two labels, CHAT and NONCHAT. The workers annotated the CHAT label when users were going to have chats with the intelligent assistant and annotated the NONCHAT label when users were seeking some information (*e.g.*, searching the Web or checking the weather) or were trying to operate the smartphones (*e.g.*, setting alarms or controlling volume). Note that our intelligent assistant works primarily on smartphones and thus the NONCHAT utterances include many operational instructions such as alarm setting. Example utterances are given in Table 1.

Seven workers were assigned to each utterance, and the final labels were obtained by majority vote to address the quality issue inherent in crowdsourcing. The last column in Table 1 shows the number of votes that the majority label obtained. For example, five workers provided the CHAT label (and the other two provided the NONCHAT label) to the first utterance "Let's talk about something."

3.2 Data analysis

The construction process described above yielded a dataset made up of $4,833$ CHAT and $10,327$ NONCHAT utterances.

We investigated the annotation agreement among the crowd workers. Table 2 shows the distribution of the numbers of votes that the majority labels obtained. The annotation given by the seven workers agreed perfectly in $5,811$ of the $15,160$ utterances (38%). Also, at least six workers agreed in the majority of cases, $10,789$ $(= 4,978 + 5,811)$ utterances (71%). This indicates high agreement among the workers and the reliability of the annotation results.

During the data construction, we found that a typical confusing case arises when the utterance can be interpreted as an implicit information request. For example, the utterance "*I am hungry*" can be seen as the user trying to have a chat with the assistant, but it might be the case that she is looking for a local restaurant. Similar examples include "*I have a backache*" and so on. One solution in this case might be to ask the user a clarification question (Schlöder and Fernandez, 2015). Such an exploration is left for our future research.

Additionally, we manually classified the CHAT utterances according to their dialogue acts to figure out how real users have chats with the intelligent assistant (Table 3). The set of dialogue acts was designed by referring to (Meguro et al., 2010). As shown in Table 3, while some of the utterances are boilerplates (*e.g.*, those in the GREETING act) and thus have limited variety, the majority of the utterances exhibit tremendous diversity. We see

Dialogue act (No. of Utter.)	Example
GREETING (206)	Hello. Merry Christmas.
SELFDISCLOSURE (1164)	I am free today. I have a sore throat.
ORDER (716)	Please cheer me up. Give me a song!
QUESTION (1551)	Do you have emotions? Are you angry?
INVITATION (130)	Let's play with me! Let's go to karaoke next time.
INFORMATION (214)	My cat is acting strange. It snowed a lot.
THANKS (126)	Thank you. You are cool!
CURSE (172)	You're an idiot. You are useless.
APOLOGY (9)	I'm sorry. I mistook, sorry.
INTERJECTION (151)	Whoof. Yeah, yeah.
MISC (394)	May the force be with you. Cock-a-doodle-doo.

Table 3: Distribution over dialogue acts and example utterances.

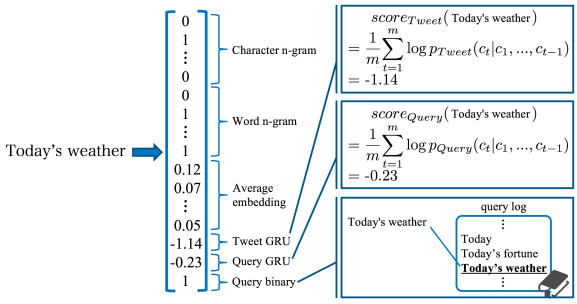

Figure 1: Feature vector representation of the example utterance "Today's weather." The upper three parts of the vector represent the features described in Section 4.1 (character n-gram, word n-gram, and average of the word embeddings). The three additional features explained in Section 4.2 are added as two real-valued features (Tweet GRU and Query GRU) and one binary feature (Query binary).

a wide variety of topics including private issues (*e.g.*, "*I am free today*") and questions to the assistant (*e.g.*, "*Are you angry?*"). Also, we even see a movie quote ("*May the force be with you*") and a rooster crow ("*Cock-a-doodle-doo*") in the MISC act. These clearly represent the open-domain nature of the user utterances in intelligent assistants.

Interestingly, some users curse at the intelligent assistant probably because it failed to make appropriate responses (see the CURSE act). Although such user behavior would not be observed from paid research participants, we observe a certain amount of curse utterances in the real data.

4 Detection Method

We formulate chat detection as a binary classification problem to train supervised classifiers. In this section, we first explain the two types of classifiers explored in this paper, and then investigate the use of external resources for enhancing those classifiers.

4.1 Base classifiers

The first classifier utilizes SVM for its popularity and efficiency. It uses character and word n-gram ($n = 1$ and 2) features. It also uses word embedding features (Turian et al., 2010). A skip-gram model (Mikolov et al., 2013) is trained on the entire intelligent assistant log[8] to learn word embeddings. The embeddings of the words in the utterance are then averaged to produce additional features.

The second classifier uses a convolutional neural network (CNN) because it has recently proven to perform well on text classification problems (Kim, 2014; Johnson and Zhang, 2015a,b). We follow (Kim, 2014) to develop a simple CNN that has a single convolution and max-pooling layer followed by the soft-max layer. We use a rectified linear unit (ReLU) as the non-linear activation function. The same word embeddings as SVM are used for the pre-training.

4.2 Using external resources

We next investigate using external resources for enhancing the base classifiers. Thanks to the rapid evolution of the Web in the past decade, a variety of textual data including not only conversational (*i.e.*, chat-like) but also non-conversational ones are abundantly available nowadays. These data offer an effective way of enhancing the base classifiers. We specifically use tweets and Web search queries as conversational and non-conversational text data, respectively.

We train character-based[9] language models on

[8] We used the same log data used in Section 3. The detailed statistics is confidential.

[9] We also trained word-based language models in prelim-

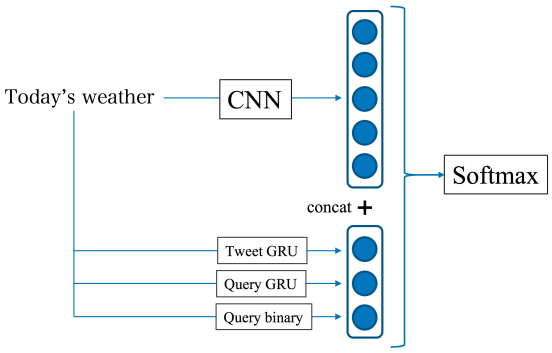

Figure 2: Architecture of our CNN-based classifier when the input utterance is "Today's weather." The output layer of CNN and the three additional features explained in Section 4.2 are concatenated. The resulting vector is fed to the soft-max function.

tweets and Web search queries, and use their scores (*i.e.*, the normalized log probabilities of the utterance) as two additional features. Let $u = c_1, c_2, \ldots, c_m$ be an utterance made up of m characters. Then, the score $score_r(u)$ of the language model trained on the external resource $r \in \{\text{tweet}, \text{query}\}$ is defined as

$$score_r(u) = \frac{1}{m} \sum_{t=1}^{m} \log p_r(c_t \mid c_1, \ldots, c_{t-1}).$$

The GRU language model is adopted for its superior performance (Cho et al., 2014; Chung et al., 2014). Let $\mathbf{x}_t$ be the embedding of t-th character and $\mathbf{h}_t$ be the t-th hidden state. GRU computes the hidden state as

$$\begin{aligned}
\mathbf{h}_t &= (1 - \mathbf{z}_t) \odot \mathbf{h}_{t-1} + \mathbf{z}_t \odot \tilde{\mathbf{h}}_t \\
\mathbf{z}_t &= \sigma(\mathbf{W}^{(z)}\mathbf{z}_t + \mathbf{U}^{(z)}\mathbf{h}_{t-1}) \\
\tilde{\mathbf{h}}_t &= \tanh(\mathbf{W}^{(h)}\mathbf{x}_t + \mathbf{U}^{(h)}(\mathbf{r}_t \odot \mathbf{h}_{t-1})) \\
\mathbf{r}_t &= \sigma(\mathbf{W}^{(r)}\mathbf{x}_t + \mathbf{U}^{(r)}\mathbf{h}_{t-1})
\end{aligned}$$

where $\odot$ is the element-wise multiplication, σ is the sigmoid and $\tanh$ is the hyperbolic tangent. $\mathbf{W}^{(z)}$, $\mathbf{U}^{(z)}$, $\mathbf{W}^{(h)}$, $\mathbf{U}^{(h)}$, $\mathbf{W}^{(r)}$, and $\mathbf{U}^{(r)}$ are weight matrices. The hidden states are fed to the soft-max to predict the next word.

We also use a binary feature indicating whether the utterance appears in the Web search query log or not. We observe that some NONCHAT utterances are made up of single entities such as location and product names. Such utterances are considered to be seeking information on those entities. We therefore use the query log as an entity dictionary to derive a feature indicating whether the utterance is likely to be a single entity.

The resulting three features are incorporated into the SVM-based classifier straightforwardly (Figure 1). For the CNN-based classifier, they are provided as additional inputs to the soft-max layer (Figure 2).

5 Experimental Results

We empirically evaluate the proposed methods on the chat detection dataset.

5.1 Experimental settings

We performed 10-fold cross validation on the chat detection dataset to train and evaluate the proposed classifiers. In each fold, we used 80%, 10%, and 10% of the data for the training, development, and evaluation, respectively.

We used `word2vec`[10] to learn 300 dimensional word embeddings. They were used to induce the additional 300 features for SVM. They were also used as the pre-trained word embeddings for CNN.

We used the `faster-rnn` toolkit[11] to train the GRU language models. The size of the embedding and hidden layer was set to 256. Noise contrastive estimation (Gutmann and Hyvärinen, 2010) was used to train the soft-max function and the number of noise samples was set to 50. Maximum entropy 4-gram models were also trained to yield a combined model (Mikolov et al., 2011).

The language models were trained on 100 millions tweets collected between Apr. and July 2016 and 100 million Web search queries issued between Mar. and Jun. 2016. The tweets were sampled from those received replies to collect only conversational tweets (Ritter et al., 2011). The same Web search queries were used to derive the binary feature. Although it is difficult to release those data, we plan to make the feature values available together with the benchmark dataset.

We used `liblinear`[12] to train L_2-regularized L_2-loss SVM. The hyperparameter c was tuned

inary experiments and found that character-based ones perform consistently better.

Table 4: Chat detection results.

over $\{2^{-10}, 2^{-9}, \ldots, 2^{10}\}$.

The CNN was implemented with `chainer`.[13] We tuned the number of feature maps over $\{100, 150\}$, and filter region sizes over $\{\{2\}, \{3\}, \{1,2\}, \{2,3\}, \{3,4\}, \{1,2,3\}, \{2,3,4\}\}$. The mini-batch size was set to 32. The dropout rate was set to 0.5. We used Adam ($\alpha = 0.001$, $\beta 1 = 0.9$, $\beta 2 = 0.999$, and $\epsilon = 10^{-8}$) to perform stochastic gradient descent (Kingma and Ba, 2015).

5.2 Baselines

The following baseline methods were implemented for comparison:

Majority Utterances are always classified as the majority class, NONCHAT.

Tweet GRU Utterances are classified as CHAT if the score of the GRU language model trained on the tweets exceeds a threshold. We used exactly the same GRU language model as the one that was used for deriving the feature. The threshold was calibrated on the development data by maximizing the F_1-score of the CHAT class.

In-house IA Our in-house intelligent assistant system, which adopts a hybrid of rule-based and example-based approaches. Since we cannot disclose its technical details, the result is presented just for reference.

5.3 Result

Table 4 gives the precision, recall, F_1-score (for the CHAT class), and overall classification accuracy results. We report only accuracy for **Majority** baseline. **+embed.** and **+pre-train.** represent using the word embedding features for SVM and the pre-trained word embeddings for CNN, respectively. **+tweet-query** represents using the three features derived from the tweets and Web search query.

Table 4 represents that both of the classifiers, SVM and CNN, perform accurately. We see that both **+embed.** and **+pre-train.** improve the results. The best performing method, **SVM+embed.+tweet-query**, achieves 92% accuracy and 87% F_1-score, outperforming all of the baselines. CNN performed worse than SVM contrary to results reported by recent studies (Kim, 2014). We think this is because the architecture of our CNN is rather simplistic. It might be possible to improve the CNN-based classifier by adopting more complex network, although it is likely to come at the cost of extra training time. Another reason would be that our SVM classifier uses carefully designed features beyond word 1-grams.

Table 4 also represents that the external resources are effective, improving F_1-scores almost 1 points in both SVM and CNN. Table 5 illustrates example utterances and their language model scores. We see that the language models trained on the tweets and queries successfully provide the CHAT utterances with high and low scores, respectively. Table 6 shows chat detection results when each of the three features derived from the external resources is added to **SVM+embed.** The results represent that they are all worse than **SVM+embed.+tweet-query** and thus it is crucial to combine all of them for achieving the best performance.

Table 7 shows examples of feature weights of **SVM+embed.+tweet-query**. Tweet GRU and query GRU denote the language model score features. The others are word n-gram features. We see that the language model scores have the large

[13] http://chainer.org

Score (tweet/query)		Label	Utterance
−0.964	−1.427	CHAT	Halloween has already finished.
−0.957	−1.610	CHAT	Let's sleep.
−1.233	−0.562	NONCHAT	Pokemon Go install.
−1.837	−0.682	NONCHAT	Weekly weather forecast.

Table 5: Examples of the language model scores. The first two columns represent the scores provided by the GRU language models trained on the tweets and Web search queries, respectively. The third and fourth columns represent the label and utterance.

Feature	Acc.	P	R	F_1
tweet GRU	91.53	87.62	85.49	86.53
query GRU	91.38	87.55	85.06	86.28
query binary	91.42	87.56	85.21	86.36

Table 6: Effect of the three features derived from the tweets and Web search queries.

Feature	Weight	Feature	Weight
tweet GRU	1.128	query GRU	−0.771
I	0.215	call to	−0.217
Sing	0.195	volume	−0.196

Table 7: Examples feature weights of **SVM+embed+tweet-query**.

positive and negative weights, respectively. This indicates that effectiveness of the language models. We also see that the first person has a large positive weight, while terms related to device controlling ("call to" and "volume") have large negative weights.

Table 8 represents chat detection results of **SVM+embd.+tweet-query** across the numbers of votes that the majority label obtained. As expected, we see that all metrics get higher as the number of agreement among the crowd workers becomes larger. In fact, we see as much as 98% accuracy when all seven workers agree. This implies that utterances easy for humans to classify are also easy for the classifiers.

5.4 Training data size

We next investigate the effect of the training data size on the classification accuracy.

Figure 3 illustrates the learning curve. It represents that the classification accuracy improves almost monotonically as the training data size increases. Although our training data is by no means small, the shape of the learning curve nevertheless suggests that further improvement would be achieved by adding more training data. This implies that a very large amount of training data are required for covering open-domain utterances in intelligent assistants.

#Votes	#Utter.	Acc.	P	R	F_1
4	1701	66.67	55.41	59.81	57.53
5	2670	87.72	80.46	83.01	81.72
6	4978	96.02	92.73	93.87	93.30
7	5811	98.33	96.73	97.68	97.20

Table 8: Chat detection results across the numbers of votes that the majority label obtained.

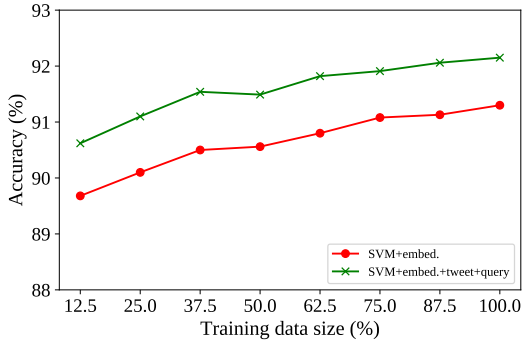

Figure 3: Learning curve of the proposed methods. The horizontal axis represents what percentage of the training portion is used in each fold of the cross validation. The vertical axis represents the classification accuracy.

The figure at the same time represents the usefulness of the external resources. We see that **SVM+embed.+tweet-query** trained on about 25% of the training data is able to achieve comparable accuracy with **SVM+embed.** trained on the entire training data. This result suggests that the external resources are able to compensate for the scarcity of annotated data.

5.5 Utterance length

We finally investigate how the utterance length correlates with the classification accuracy. Fig-

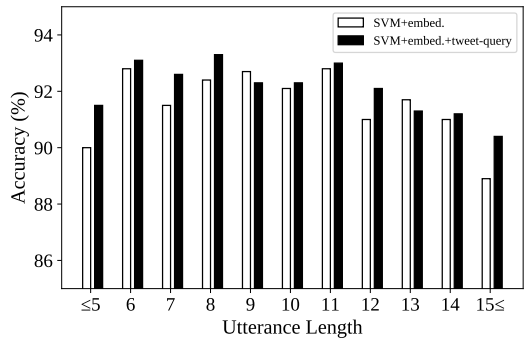

Figure 4: Classification accuracy across utterance lengths in the number of characters.

ure 4 illustrates the classification accuracies of **SVM+embed.** and **SVM+embed.+tweet-query** for each utterance length in the number of characters.

Figure 4 reveals that the difference between the two proposed methods is evident in short utterances (*i.e.*, ≤ 5). This is because those utterances are too short to contain sufficient information required for classification, and the additional features are helpful. We note that Japanese writing system uses ideograms and thus even five characters is enough to represent a simple sentence.

We also see a clear difference in longer utterances (*i.e.*, $15 \leq$) as well. We consider those long utterances are difficult to classify because some words in the utterances are irrelevant for the classification and the n-gram and embedding features include those irrelevant ones. On the other hand, we consider that the language model scores are good at capturing stylistic information irrespective of the utterance length.

6 Future Work

As discussed in Section 3.2, some user utterances such as "*I am hungry*" are ambiguous in nature and thus are difficult to handle in the current framework. An important future work is to develop a sophisticated dialogue manager to handle such utterances, for example, by making clarification questions (Schlöder and Fernandez, 2015).

We manually investigated the dialogue acts in the chat detection dataset (*c.f.*, Section 3.2). It is interesting to automatically determine the dialogue acts to help producing appropriate system responses. Some related studies exist in such a research direction (Meguro et al., 2010).

Although we used only text data to perform chat detection, we can also utilize contextual information such as the previous utterances (Xu and Sarikaya, 2014), the acoustic information (Jiang et al., 2015), and the user profile (Sano et al., 2016). It is an interesting research topic to use such contextual information beyond text. It is considered promising to make use of a neural network for integrating such heterogeneous information.

An automatic speech recognition (ASR) error is a popular problem in SDS, and previous studies have proposed sophisticated techniques, including re-ranking (Morbini et al., 2012) and POMDP (Williams and Young, 2007), for addressing the ASR errors. Incorporating these techniques into our methods is also an important future work.

Although the studies on non-task-oriented SDS have made substantial progress in the past few years, it unfortunately remains difficult for the systems to fluently chat with users (Higashinaka et al., 2015). Further efforts on improving non-task-oriented dialogue systems is an important future work.

7 Conclusion

This paper investigated chat detection for combining domain-specific task-oriented SDS and open-domain non-task-oriented SDS. To address the scarcity of benchmark datasets for this task, we constructed a new benchmark dataset from the real log data of a commercial intelligent assistant. In addition, we investigated using the external resources, tweets and Web search queries, to handle open-domain user utterances, which characterize the task of chat detection. The empirical experiment demonstrated that the off-the-shelf supervised methods augmented with the external resources perform accurately, outperforming the baseline approaches. We hope that this study contributes to remove the long-standing boundary between task-oriented and non-task-oriented SDS.

To facilitate future research, we are going to release the dataset together with the feature values derived from the tweets and Web search queries.[14]

Abstract

We propose a local coherence model based on a convolutional neural network that operates over the entity grid representation of a text. The model captures long range entity transitions along with entity-specific features without loosing generalization, thanks to the power of distributed representation. We present a pairwise ranking method to train the model in an end-to-end fashion on a task and learn task-specific high level features. Our evaluation on three different coherence assessment tasks demonstrates that our model achieves state of the art results outperforming existing models by a good margin.

1 Introduction and Motivation

What distinguishes a coherent text from a random sequence of sentences is that it binds the sentences together to express a meaning as a whole — the interpretation of a sentence usually depends on the meaning of its neighbors. *Coherence models* that can distinguish a coherent from incoherent texts have a wide range of applications in text generation, summarization, and coherence scoring.

Several formal theories of coherence have been proposed (Mann and Thompson, 1988a; Grosz et al., 1995; Asher and Lascarides, 2003), and their principles have inspired development of many existing coherence models (Barzilay and Lapata, 2008; Lin et al., 2011; Li and Hovy, 2014). Among these models, the *entity grid* (Barzilay and Lapata, 2008), which is based on Centering Theory (Grosz et al., 1995), is arguably the most popular, and has seen a number of improvements over the years. As shown in Figure 1, the entity grid model represents a text by a grid that captures how grammatical roles of different entities change from sentence to sentence. The grid is then converted into a feature vector containing probabilities of local entity transitions, which enables machine learning models to learn the degree of text coherence. Extensions of this basic grid model incorporate entity-specific features (Elsner and Charniak, 2011), multiple ranks (Feng and Hirst, 2012), and coherence relations (Feng et al., 2014).

While the entity grid and its extensions have been successful in many applications, they are limited in several ways. First, they use discrete representation for grammatical roles and features, which prevents the model from considering sufficiently long transitions (Bengio et al., 2003). Second, feature vector computation in existing models is decoupled from the target task, which limits the model's capacity to learn task-specific features.

In this paper, we propose a *neural* architecture for coherence assessment that can capture long range entity transitions along with arbitrary entity-specific features. Our model obtains generalization through *distributed representations* of entity transitions and entity features. We also present an end-to-end training method to learn task-specific high level features automatically in our model.

We evaluate our approach on three different evaluation tasks: discrimination, insertion, and summary coherence rating, proposed previously for evaluating coherence models (Barzilay and Lapata, 2008; Elsner and Charniak, 2011). Discrimination and insertion involve identifying the right order of the sentences in a text with different levels of difficulty. In the summary coherence rating task, we compare the rankings, given by the model, against human judgments of coherence.

The experimental results show that our neural models consistently improve over the non-neural counterparts (i.e., existing entity grid models) yielding absolute gains of about 4% on dis-

crimination, up to 2.5% on insertion, and more than 4% on summary coherence rating. Furthermore, our model achieves state of the art results in all these tasks. We have released our source code for research purposes.[1]

The remainder of this paper is organized as follows. We describe entity grid, its extensions, and its limitations in Section 2. In Section 3, we present our neural model. We describe evaluation tasks and results in Sections 4 and 5. We give a brief account of related work in Section 6. Finally, we conclude with future directions in Section 7.

2 Entity Grid and Its Extensions

Motivated by Centering Theory (Grosz et al., 1995), Barzilay and Lapata (2008) proposed an entity-based model for representing and assessing text coherence. Their model represents a text by a two-dimensional array called *entity grid* that captures transitions of discourse entities across sentences. As shown in Figure 1, the rows of the grid correspond to sentences, and the columns correspond to discourse entities appearing in the text. They consider noun phrases (NP) as entities, and employ a coreference resolver to detect mentions of the same entity (e.g., *Obama*, *the president*). Each entry $G_{i,j}$ in the entity grid represents the syntactic role that entity e_j plays in sentence s_i, which can be one of: subject (**S**), object (**O**), or other (**X**). In addition, entities not appearing in a sentence are marked by a special symbol (**-**). If an entity appears more than once with different grammatical roles in the same sentence, the role with the highest rank (S $\succ$ O $\succ$ X) is considered.

To represent the entity grid using a feature vector, Barzilay and Lapata (2008) compute probability for each local entity transition of length k (i.e., $\{S, O, X, -\}^k$), and represent each grid by a vector of 4^k transitions probabilities. To distinguish between transitions of important entities from unimportant ones, they consider the *salience* of the entities, which they quantify by their occurrence frequency in the document. Assessment of text coherence is then formulated as a ranking problem in an SVM preference ranking framework (Joachims, 2002).

Subsequent studies proposed to extend the basic entity grid model. Filippova and Strube (2007) attempted to improve the model by grouping entities based on semantic relatedness, but did not get significant improvement. Elsner and Charniak (2011) proposed a number of improvements. They initially show significant improvement by including non-head nouns (i.e., nouns that do not head NPs) as entities in the grid.[2] Then, they extend the grid to distinguish between entities of different types by incorporating entity-specific features like named entity, noun class, modifiers, etc. These extensions led to the best results reported so far.

s_1: Terms were not disclosed.

s_2: Pacific Sierra, based in Los Angeles, has 200 employees and supplies professional services and advanced products to industry.

s_3: Eaton is an automotive parts, controls and aerospace electronics concern.

Figure 1: Entity grid representation (top) for a document (below) from WSJ (id: 0079).

The Entity grid and its extensions have been successfully applied to many downstream tasks including coherence rating (Barzilay and Lapata, 2008), essay scoring (Burstein et al., 2010), story generation (McIntyre and Lapata, 2010), and readability assessment (Pitler et al., 2010; Barzilay and Lapata, 2008). They have also been critical components in state-of-the-art sentence ordering models (Soricut and Marcu, 2006; Elsner and Charniak, 2011; Lin et al., 2011).

2.1 Limitations of Entity Grid Models

Despite its success, existing entity grid models are limited in several ways.

• Existing models use discrete representation for grammatical roles and features, which leads to the so-called **curse of dimensionality** problem (Bengio et al., 2003). In particular, to model transitions of length k with $\mathcal{R}$ different grammatical roles, the basic entity grid model needs to compute $\mathcal{R}^k$ tran-

[1] https://github.com/datienguyen/cnn_coherence/

[2] They match the nouns to detect coreferent entities.

sition probabilities from a grid. One can imagine that the estimated distribution becomes sparse as k increases. This prevents the model from considering longer transitions – existing models use $k \leq 3$. This problem is exacerbated when we want to include entity-specific features, as the number of parameters grows exponentially with the number of features (Elsner and Charniak, 2011).

• Existing models compute feature representations from entity grids in a task-agnostic way. In other words, feature extraction is decoupled from the target downstream tasks. This can limit the model's capacity to learn task-specific features. Therefore, models that can be trained in an end-to-end fashion on different target tasks are desirable.

In the following section, we present a neural architecture that allows us to capture long range entity transitions along with arbitrary entity-specific features without loosing generalization. We also present an end-to-end training method to learn task-specific features automatically.

3 The Neural Coherence Model

Figure 2 summarizes our neural architecture for modeling local coherence, and how it can be trained in a pairwise fashion. The architecture takes a document as input, and first extracts its entity grid.[3] The first layer of the neural network transforms each grammatical role in the grid into a distributed representation, a real-valued vector. The second layer computes high-level features by going over each column (transitions) of the grid. The following layer selects the most important high-level features, which are in turn used for coherence scoring. The features computed at different layers of the network are automatically trained by backpropagation to be relevant to the task. In the following, we elaborate on the layers of the neural network model.

(I) Transforming grammatical roles into feature vectors: Grammatical roles are fed to our model as indices taken from a finite vocabulary $\mathcal{V}$. In the simplest scenario, $\mathcal{V}$ contains $\{S, O, X, -\}$. However, we will see in Section 3.1 that as we include more entity-specific features, $\mathcal{V}$ can contain more symbols. The first layer of our network maps each of these indices into a distributed representation $\mathbb{R}^d$ by looking up a shared embedding matrix $E \in \mathbb{R}^{|\mathcal{V}| \times d}$. We consider E a model parameter to be learned by backpropagation on a given task. We can initialize E randomly or using pretrained vectors trained on a general coherence task.

Given an entity grid G with columns representing entity transitions over sentences in a document, the lookup layer extracts a d-dimensional vector for each entry $G_{i,j}$ from E. More formally,

$$\mathcal{L}(G) = \Big\langle E(G_{1,1}) \ \cdots \ E(G_{i,j}) \ \cdots \ E(G_{m,n}) \Big\rangle \tag{1}$$

where $E(G_{i,j})$ refers to the row in E that corresponds to the grammatical role $G_{i,j} \in \mathcal{V}$; m is the total number of sentences and n is the total number of entities in the document. The output $\mathcal{L}(G)$ is a tensor in $\mathbb{R}^{m \times n \times d}$, which is fed to the next layer of the network as we describe below.

(II) Modeling entity transitions: The vectors produced by the lookup layer are combined by subsequent layers of the network to generate a coherence score for the document. To compose higher-level features from the embedding vectors, we make the following modeling assumptions:

• Similar to existing entity grid models, we assume there is no spatio-temporal relation between the entities in a document. In other words, columns in a grid are treated independently.

• We are interested in modeling entity transitions of arbitrary lengths in a *location-invariant* way. This means, we aim to compose local patches of entity transitions into higher-level representations, while treating the patches independently of their position in the entity grid.

Under these assumptions, the natural choice to tackle this problem is to use a *convolutional* approach, used previously to solve other NLP tasks (Collobert et al., 2011; Kim, 2014).

Convolution layer: A convolution operation involves applying a *filter* $\mathbf{w} \in \mathbb{R}^{k.d}$ (i.e., a vector of weight parameters) to each entity transition of length k to produce a new abstract feature

$$h_t = f(\mathbf{w}^T \mathcal{L}_{t:t+k-1,j} + b_t) \tag{2}$$

where $\mathcal{L}_{t:t+k-1,j}$ denotes the concatenation of k vectors in the lookup layer representing a transition of length k for entity e_j in the grid, b_t is a bias

[3] For clarification, pairwise input as shown in the figure is required only to train the model.

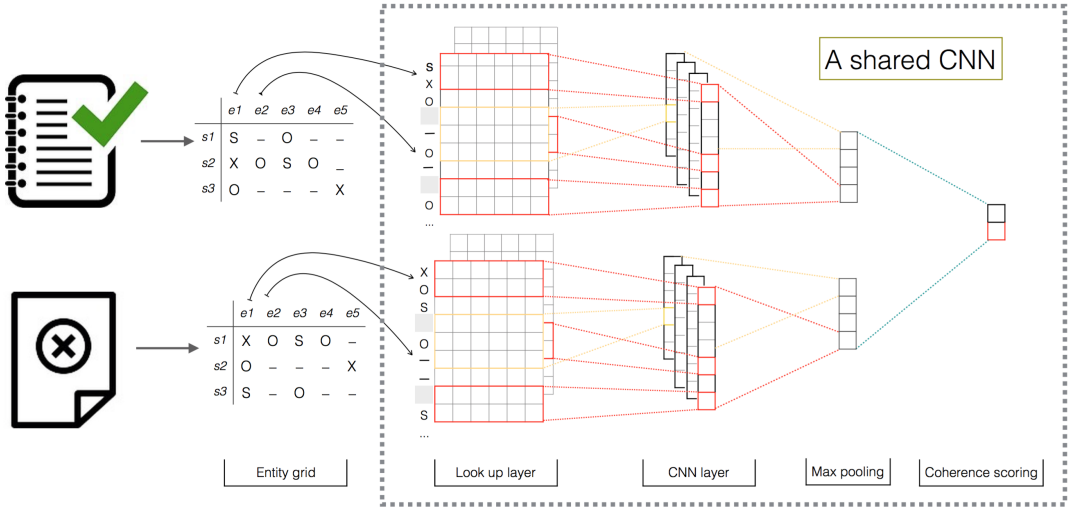

Figure 2: Neural architecture for modeling local coherence and the pairwise training method.

term, and f is a nonlinear activation function, e.g., ReLU (Nair and Hinton, 2010) in our model.

We apply this filter to each possible k-length transitions of different entities in the grid to generate a *feature map*, $\mathbf{h}^i = [h_1, \cdots, h_{m.n+k-1}]$. We repeat this process N times with N different filters to get N different feature maps (Figure 2). Notice that we use a *wide* convolution (Kalchbrenner et al., 2014), as opposed to *narrow*, to ensure that the filters reach entire columns of a grid, including the boundary entities. This is done by performing *zero-padding*, where out-of-range (i.e., for $t < 0$ or $t > \{m, n\}$) vectors are assumed to be zero.

Convolutional filters learn to compose local transition features of a grid into higher-level representations automatically. Since it operates over the distributed representation of grid entries, compared to traditional grid models, the transition length k can be sufficiently large (e.g., $5 - 8$ in our experiments) to capture long-range transitional dependencies without overfitting on the training data. Moreover, unlike existing grid models that compute transition probabilities from a single document, embedding vectors and convolutional filters are learned from all training documents, which helps the neural framework to obtain better generalization and robustness.

Pooling layer: After the convolution, we apply a *max-pooling* operation to each feature map.

$$\mathbf{m} = [\mu_p(\mathbf{h}^1), \cdots, \mu_p(\mathbf{h}^N)] \quad (3)$$

where $\mu_p(\mathbf{h}^i)$ refers to the max operation applied to each non-overlapping[4] window of p features in the feature map $\mathbf{h}^i$. Max-pooling reduces the output dimensionality by a factor of p, and it drives the model to capture the most salient local features from each feature map in the convolutional layer.

Coherence scoring: Finally, the max-pooled features are used in the output layer of the network to produce a coherence score $y \in \mathbb{R}$.

$$y = \mathbf{v}^T \mathbf{m} + b \quad (4)$$

where $\mathbf{v}$ is the weight vector and b is a bias term.

Why it works: Intuitively, each filter detects a specific transition pattern (e.g., 'SS-O-X' for a coherent text), and if this pattern occurs somewhere in the grid, the resulting feature map will have a large value for that particular region and small values for other regions. By applying max pooling on this feature map, the network then discovers that the transition appeared in the grid.

3.1 Incorporating Entity-Specific Features

Our model as described above neuralizes the basic entity grid model that considers only entity transitions without distinguishing between types of the entities. However, as Elsner and Charniak (2011) pointed out entity-specific features could be crucial for modeling local coherence. One simple way to incorporate entity-specific features into our model is to attach the feature value (e.g., named entity type) with the grammatical role in the grid.

[4] We set the *stride size* to be the same as the pooling length p to get non-overlapping regions.

For example, if an entity e_j of type PERSON appears as a subject (S) in sentence s_i, the grid entry $G_{i,j}$ can be encoded as PERSON-S.

3.2 Training

Our neural model assigns a coherence score to an input document d based on the degree of local coherence observed in its entity grid G. Let $y = \phi(G|\theta)$ define our model that transforms an input grid G to a coherence score y through a sequence of lookup, convolutional, pooling, and linear projection layers with parameter set θ. The parameter set θ includes the embedding matrix E, the filter matrix W, the weight vector $\mathbf{v}$, and the biases. We use a *pairwise ranking* approach (Collobert et al., 2011) to learn θ.

The training set comprises *ordered* pairs (d_i, d_j), where document d_i exhibits a higher degree of coherence than document d_j. As we will see in Section 4 such orderings can be obtained automatically or through manual annotation. In training, we seek to find θ that assigns a higher coherence score to d_i than to d_j. We minimize the following ranking objective with respect to θ:

$$\mathcal{J}(\theta) = \max\{0, 1 - \phi(G_i|\theta) + \phi(G_j|\theta)\} \quad (5)$$

where G_i and G_j are the entity grids corresponding to documents d_i and d_j, respectively. Notice that (also shown in Figure 2) the network shares its layers (and hence θ) to obtain $\phi(G_i|\theta)$ and $\phi(G_j|\theta)$ from a pair of input grids (G_i, G_j).

Barzilay and Lapata (2008) adopted a similar ranking criterion using an SVM preference kernel learner as they argue coherence assessment is best seen as a ranking problem as opposed to classification (*coherent* vs. *incoherent*). Also, the ranker gives a scoring function ϕ that a text generation system can use to compare alternative hypotheses.

4 Evaluation Tasks

We evaluate the effectiveness of our coherence models on two different evaluation tasks: sentence ordering and summary coherence rating.

4.1 Sentence Ordering

Following Elsner and Charniak (2011), we evaluate our models on two sentence ordering tasks: discrimination and insertion.

In the *discrimination* task (Barzilay and Lapata, 2008), a document is compared to a random permutation of its sentences, and the model is considered correct if it scores the original document higher than the permuted one. We use 20 permutations of each document in the test set in accordance with previous work.

In the *insertion* task (Elsner and Charniak, 2011), we evaluate models based on their ability to locate the original position of a sentence previously removed from a document. To measure this, each sentence in the document is removed in turn, and an insertion place is located for which the model gives the highest coherence score to the document. The insertion score is then computed as the average fraction of sentences per document reinserted in their actual position.

Discrimination can be easier for longer documents, since a random permutation is likely to be different than the original one. Insertion is a much more difficult task since the candidate documents differ only by the position of one sentence.

	Sections	# Doc.	# Pairs	Avg. # Sen.
TRAIN	00-13	1,378	26,422	21.5
TEST	14-24	1,053	20,411	22.3

Table 1: Statistics on the WSJ dataset.

Dataset: For sentence ordering tasks, we use the Wall Street Journal (WSJ) portion of Penn Treebank, as used by Elsner and Charniak (2008, 2011); Lin et al. (2011); Feng et al. (2014). Table 1 gives basic statistics about the dataset. Following previous works, we use 20 random permutations of each article, and we exclude permutations that match the original document.[5] The fourth column (# Pairs) in Table 1 shows the resulting number of (*original*, *permuted*) pairs used for training our model and for testing in the discrimination task.

Some previous studies (Barzilay and Lapata, 2008; Li and Hovy, 2014) used the AIRPLANES and the EARTHQUAKES corpora, which contain reports on airplane crashes and earthquakes, respectively. Each of these corpora contains 100 articles for training and 100 articles for testing. The average number of sentences per article in these two corpora is 10.4 and 11.5, respectively.

We preferred the WSJ corpus for several reasons. First and most importantly, the WSJ corpus is larger than other corpora (see Table 1). A large training set is crucial for learning effective

[5] Short articles may produce many matches.

deep learning models (Collobert et al., 2011), and a large enough test set is necessary to make a general comment about model performance. Second, as Elsner and Charniak (2011) pointed out, texts in AIRPLANES and EARTHQUAKES are constrained in style, whereas WSJ documents are more like normal informative articles. Third, we could reproduce results on this dataset for the competing systems (e.g., entity grid and its extensions) using the publicly available Brown coherence toolkit.[6]

4.2 Summary Coherence Rating

We further evaluate our models on the summary coherence rating task proposed by Barzilay and Lapata (2008), where we compare rankings given by a model to a pair of summaries against rankings elicited from human judges.

Dataset: The summary dataset was extracted from the Document Understanding Conference (DUC'03), which contains 6 clusters of multi-document summaries produced by human experts and 5 automatic summarization systems. Each cluster has 16 summaries of a document with pairwise coherence rankings given by humans judges; see (Barzilay and Lapata, 2008) for details on the annotation method. There are 144 pairs of summaries for training and 80 pairs for testing.

5 Experiments

In this section, we present our experiments — the models we compare, their settings, and the results.

5.1 Models Compared

We compare our coherence model against a random baseline and several existing models.

Random: The Random baseline makes a random decision for the evaluation tasks.

Graph-based Model: This is the graph-based unsupervised model proposed by Guinaudeau and Strube (2013). We use the implementation from the cohere[7] toolkit (Smith et al., 2016), and run it on the test set with syntactic projection (command line option 'projection=3') for graph construction. This setting yielded best scores for this model.

Distributed Sentence Model: Li and Hovy (2014) proposed this neural model for measuring text coherence. The model first encodes each sentence in a document into a fixed-length vector using a recurrent or a recursive neural network. Then it computes the coherence score of the document by aggregating the scores estimated for each window of three sentences in the document. We used the implementation made publicly available by the authors.[8] We trained the model on our WSJ corpus with 512, 1024 and 1536 minibatch sizes for a maximum of 25 epochs.[9] The model that used minibatch size of 512 and completed 23 epochs achieved the best accuracy on the DEV set. We applied this model to get the scores on the TEST set.

Grid-all nouns (E&C): This is the simple extension of the original entity grid model, where all nouns are considered as entities. Elsner and Charniak (2011) report significant gains by considering all nouns as opposed to only head-nouns. Results for this model were obtained by training the baseline entity grid model (command line option '-n') in the Brown coherence toolkit on our dataset.

Extended grid (E&C): This represents the extended entity grid model of Elsner and Charniak (2011) that uses 9 entity-specific features; 4 of them were computed from external corpora. This model considers all nouns as entities. For this system, we train the extended grid model (command line option '-f') in the Brown coherence toolkit.

Grid-CNN: This is our proposed neural extension of the basic entity grid (all nouns), where we only consider entity transitions as input.

Extended Grid-CNN: This corresponds to our neural model that incorporates entity-specific features following the method described in Section 3.1. To keep the model simple, we include only three entity-specific features from (Elsner and Charniak, 2011) that are easy to compute and do not require any external corpus. The features are: (*i*) *named entity* type, (*ii*) *salience* as determined by occurrence frequency of the entity, and

[6] https://bitbucket.org/melsner/browncoherence

[7] https://github.com/karins/CoherenceFramework

[8] http://cs.stanford.edu/ bdlijiwei/code/

[9] Our WSJ corpus is about 14 times larger than their ACCIDENT or EARTHQUAKE corpus (1378 vs. 100 training articles), and the articles in our corpus are generally longer than the articles in their corpus (on average 22 vs. 10 sentences per article). Also, the vocabulary in our corpus is much larger than their vocabulary (45462 vs. 4758). Considering these factors and the fact that their Java-based implementation does not support GPU and parallelization, it takes quite long to train and to validate their model on our dataset. In our experiments, depending on the minibatch size, it took approximately 3-5 days to complete only one epoch of training!

	Batch	Emb.	Dropout	Filter	Win.	Pool
Grid-CNN	128	100	0.5	150	6	6
Ext. Grid-CNN	32	100	0.5	150	5	6

Table 2: Optimal hyper-parameter setting for our neural models based on development set accuracy.

(*iii*) whether the entity has a *proper* mention.

5.2 Settings for Neural Models

We held out 10% of the training documents to form a development set (DEV) on which we tune the hyper-parameters of our neural models. For discrimination and insertion tasks, the resulting DEV set contains 138 articles and 2,678 pairs after removing the permutations that match the original documents. For the summary rating task, DEV contains 14 pairs of summaries.

We implement our models in Theano (Theano Development Team, 2016). We use rectified linear units (ReLU) as activations (f). The embedding matrix is initialized with samples from uniform distribution $\mathcal{U}(-0.01, 0.01)$, and the weight matrices are initialized with samples from glorot-uniform distribution (Glorot and Bengio, 2010).

We train the models by optimizing the pairwise ranking loss in Equation 5 using the gradient-based online learning algorithm RMSprop with parameters (ρ and ϵ) set to the values suggested by Tieleman and Hinton (2012).[10] We use up to 25 epochs. To avoid overfitting, we use dropout (Srivastava et al., 2014) of hidden units, and do *early stopping* by observing accuracy on the DEV set – if the accuracy does not increase for 10 consecutive epochs, we exit with the best model recorded so far. We search for optimal mini**batch** size in $\{16, 32, 64, 128\}$, **emb**edding size in $\{80, 100, 200\}$, **dropout** rate in $\{0.2, 0.3, 0.5\}$, **filter** number in $\{100, 150, 200, 300\}$, **win**dow size in $\{2, 3, 4, 5, 6, 7, 8\}$, and **pool**ing length in $\{3, 4, 5, 6, 7\}$. Table 2 shows the optimal hyper-parameter setting for our models. The best model on DEV is then used for the final evaluation on the TEST set. We run each experiment five times, each time with a different random seed, and we report the average of the runs to avoid any randomness in results. Statistical significance tests are done using an *approximate randomization* test based on the accuracy. We used SIGF V.2 (Padó, 2006) with 10,000 iterations.

[10]Other adaptive algorithms, e.g., ADAM (Kingma and Ba, 2014), ADADELTA (Zeiler, 2012) gave similar results.

	Discr. Acc	**Discr.** F_1	**Ins.**

Extended Grid-CNN	**88.69**†	**88.69**†	**25.95**†

Table 3: Coherence evaluation results on **Discr**imination and **Ins**ertion tasks. † indicates a neural model is significantly superior to its non-neural counterpart with p-value < 0.01.

5.3 Results on Sentence Ordering

Table 3 shows the results on discrimination and insertion tasks. The graph-based model gets the lowest scores. This is not surprising considering that this model works in an unsupervised way. The distributed sentence model surprisingly performed poorly on our dataset. Among the existing models, the grid models get the best scores on both tasks. This demonstrates that entity transition, as a method to capture local coherence, is more effective than the sentence representation method.

Neuralization of the existing grid models yields significant improvements in most cases. The Grid-CNN model delivers absolute improvements of about 4% in discrimination and 1% in insertion over the basic grid model. When we compare our Extended Grid-CNN with its non-neural counterpart Extended Grid, we observe similar gains in discrimination and more gains (2.5%) in insertion. Note that the Extended Grid-CNN yields these improvements considering only a subset of the Extended Grid features. This demonstrates the effectiveness of distributed representation and convolutional feature learning method.

Compared to the discrimination task, gain in the insertion task is less verbose. There could be two reasons for this. First, as mentioned before, insertion is a harder task than discrimination. Second, our models were not trained specifically on the insertion task. The model that is trained to distinguish an original document from its random permutation may learn features that are not specific enough to distinguish documents when only one sentence differs. In the future, it will be interesting

	Acc	F_1

to see how the model performs when it is trained on the insertion task directly.

5.4 Results on Summary Coherence Rating

Table 4 presents the results on the summary coherence rating task, where we compare our models with the *reported* results of the graph-based method (Guinaudeau and Strube, 2013) and the initial entity grid model (Barzilay and Lapata, 2008) on the same experimental setting.[11] The extended grid model does not use pairwise training, therefore could not be trained on the summarization dataset. Since there are not many training instances, our neural models may not learn well for this task. Therefore, we also present versions of our model, where we use pre-trained models from discrimination task on WSJ corpus (last two rows in the table). The pre-trained models are then *fine-tuned* on the summary rating task.

We can observe that even without pre-training our models outperform existing models, and pre-training gives further improvements. Specifically, Pre-trained Grid-CNN gives an improvement of 2.5% over the Grid model, and including entity features pushes the improvement further to 3.7%.

6 Related Work

Barzilay and Lapata (2005, 2008) introduced the entity grid representation of discourse to model local coherence that captures the distribution of discourse entities across sentences in a text. They also introduced three tasks to evaluate the performance of coherence models: discrimination, summary coherence rating, and readability.

[11] Since we do not have access to the output of their systems, we could not do a significance test for this task.

A number of extensions of the basic entity grid model has been proposed. Elsner and Charniak (2011) included entity-specific features to distinguish between entities. Feng and Hirst (2012) used the basic grid representation, but improved its learning to rank scheme. Their model learns not only from original document and its permutations but also from ranking preferences among the permutations themselves. Guinaudeau and Strube (2013) convert a standard entity grid into a bipartite graph representing entity occurrences in sentences. To model local entity transition, the method constructs a directed projection graph representing the connection between adjacent sentences. Two sentences have a connected edge if they share at least one entity in common. The coherence score of the document is then computed as the average out-degree of sentence nodes.

In addition, there are some approaches that model text coherence based on coreferences and discourse relations. Elsner and Charniak (2008) proposed the discourse-new model by taking into account mentions of all referring expression (i.e., NPs) whether they are first mention (*discourse-new*) or subsequent (*discourse-old*) mentions. Given a document, they run a maximum-entropy classifier to detect each NP as a label $L_{np} \in \{new, old\}$. The coherence score of the document is then estimated by $\prod_{np:NPs} P(L_{np}|np)$. In this work, they also estimate text coherence through pronoun coreference modeling. Lin et al. (2011) assume that a coherent text has certain discourse relation patterns. Instead of modeling entity transitions, they model discourse role transitions between sentences. In a follow up work, Feng et al. (2014) trained the same model but using features derived from deep discourse structures annotated with Rhetorical Structure Theory or RST (Mann and Thompson, 1988b) relations. Louis and Nenkova (2012) introduced a coherence model based on syntactic patterns in text by assuming that sentences in a coherent discourse should share the same structural syntactic patterns.

In recent years, there has been a growing interest in neuralizing traditional NLP approaches – language modeling (Bengio et al., 2003), sequence tagging (Collobert et al., 2011), syntactic parsing (Socher et al., 2013), and discourse parsing (Li et al., 2014), etc. Following this tradition, in this paper we propose to neuralize the popular entity grid models. Li and Hovy (2014) also proposed a

neural framework to compute the coherence score of a document by estimating coherence probability for every window of L sentences (in their experiments, $L = 3$). First, they use a recurrent or a recursive neural network to compute the representation for each sentence in L from its words and their pre-trained embeddings. Then the concatenated vector is passed through a non-linear hidden layer, and finally the output layer decides if the window of sentences is a coherent text or not. Our approach is fundamentally different from their approach; our model operates over entity grids, and we use convolutional architecture to model sufficiently long entity transitions.

7 Conclusion and Future Work

We presented a local coherence model based on a convolutional neural network that operates over the distributed representation of entity transitions in the grid representation of a text. Our architecture can model sufficiently long entity transitions, and can incorporate entity-specific features without loosing generalization power. We described a pairwise ranking approach to train the model on a target task and learn task-specific features. Our evaluation on discrimination, insertion and summary coherence rating tasks demonstrates the effectiveness of our approach yielding the best results reported so far on these tasks.

In future, we would like to include other sources of information in our model. Our initial plan is to include rhetorical relations, which has been shown to benefit existing grid models (Feng et al., 2014). We would also like to extend our model to other forms of discourse, especially, asynchronous conversations, where participants communicate with each other at different times (e.g., forum, email).

Acknowledgments

We thank Regina Barzilay and Mirella Lapata for making their summarization data available and Micha Elsner for making his coherence toolkit publicly available. We also thank the three anonymous ACL reviewers and the program chairs for their insightful comments on the paper.

Abstract

Opinionated natural language generation (ONLG) is a new, challenging, NLG task in which we aim to automatically generate human-like, subjective, responses to opinionated articles online. We present a data-driven architecture for ONLG that generates subjective responses triggered by users' agendas, based on automatically acquired wide-coverage generative grammars. We compare three types of grammatical representations that we design for ONLG. The grammars interleave different layers of linguistic information, and are induced from a new, enriched dataset we developed. Our evaluation shows that generation with Relational-Realizational (Tsarfaty and Sima'an, 2008) inspired grammar gets better language model scores than lexicalized grammars à la Collins (2003), and that the latter gets better human-evaluation scores. We also show that conditioning the generation on topic models makes generated responses more relevant to the document content.

1 Introduction

Interaction in social media has become increasingly prevalent nowadays. It fundamentally changes the way businesses and consumers behave (Qualman, 2012), it is instrumental to the success of individuals and businesses (Haenlein and Kaplan, 2009) and it also affects political regimes (Howard et al., 2011; Lamer, 2012). In particular, *automatic* interaction in natural language in social media is now a common theme, as seen in the rapid popularization of chat applications, chat-bots, and "smart agents" aiming to conduct human-like interactions in natural language.

So far, generation of human-like interaction in general has been addressed mostly commercially, where there is a movement towards online response automation (Owyang, 2012; Mah, 2012), and movement away from script-based interaction towards interactive chat bots (Mori et al., 2003; Feng et al., 2006). These efforts provide an automated one-size-fits-all type of interaction, with no particular expression of particular sentiments, topics, or opinions. In academia, work on generating human-like interaction focused so far on generating responses to tweets (Ritter et al., 2011; Hasegawa et al., 2013) or taking turns in short dialogs (Li et al., 2017). However, the architectures assumed in these studies implement *sequence to sequence* (seq2seq) mappings, which do not take into account topics, sentiments or agendas of the intended responders.

Many real-world tasks and applications would benefit from automatic interaction that is generated intendedly based on a certain user profile or agenda. For instance, this can help promoting a political candidate or a social idea in social media, aiding people forming and expressing opinions on specific topics, or, in *human-computer interfaces* (HCI), making the computer-side generated utterances more meaningful, and ultimately more human-like (assuming that human-like interaction is very often affected by opinion, agenda, style, etc.).

In this work we address the *opinionated natural language generation* (ONLG) task, in which we aim to automatically generate human-like responses to opinionated articles. These responses address particular topics and reflect diverse sentiments towards them, in accordance to predefined user agendas. This is an open-ended and unstructured generation challenge, which is closely tied to the communicative goals of actual human responders.

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1331–1341
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1122

In previous work we addressed the ONLG challenge using a *template-based* approach (Cagan et al., 2014). The proposed system generated subjective responses to articles, driven by *user agendas*. While the evaluation showed promising results in human-likeness and relevance ratings, the template-based system suffers from low output variety, which leads to a learning effect that reduced the perceived human-likeness of generated responses over time.

In this work we tackle ONLG from a data-driven perspective, aiming to circumvent such learning effects and repetitive patterns in template-based generation. Here, we approach generation via automatically inducing *broad-coverage generative grammars* from a large corpus, and using them for response generation. More specifically, we define a grammar-based generation architecture and design different grammatical representations suitable for the ONLG task. Our grammars interleave different layers of linguistic information — including phrase-structure and dependency labels, lexical items, and levels of sentiment — with the goal of making responses both human-like and relevant. In classical NLG terms, these grammars offer the opportunity for both *micro-planning* and *surface realization* (Reiter and Dale, 1997) to unfold together. We implement a generator and a search strategy to carry out the generation, and sort through possible candidates to get the best ones.

We evaluate the generated responses and the underlying grammars using automated metrics as well as human evaluation inspired by the Turing test (cf. Cagan et al. (2014) and Li et al. (2017)). Our evaluation shows that while *relational realizational* (RR) inspired grammars (Tsarfaty and Sima'an, 2008) get good language model scores, simple head-driven *lexicalized* grammars à la Collins (2003) get better human rating and are more sensitive to sentiment. Furthermore, we show that incorporating topic models into the grammar-based generation makes the generated responses more relevant to the document content. Finally, our human evaluations results show no learning effect. That is, human raters are unable to discover in the generated responses typical structures that would lead them to consider the responses machine-generated.

The remainder of this paper is organized as follows. In Section 2 we discuss the formal model, and in Section 3 we present the proposed end-to-end ONLG architecture. In Section 4 we introduce the grammars we define, and we describe how we use them for generation in Section 5. We follow that with our empirical evaluation in Section 6. In Section 7 we discuss related and future work, and in Section 8 we summarize conclude.

2 The Formal Model

Task Definition. Let d be a document containing a single article, and let a be a user agenda as in Cagan et al. (2014). Specifically, a user agenda a can consist of one or more pairs of a *topic* (represented by a weighted bag-of-words) and an associated *sentiment*. Let c be an analysis function on documents such that $c(d)$ yields a set of *content elements* which are also pairings of topics and sentiments. The operation $\otimes$ represents the intersection of the sets of content elements in the document and in the user agenda. We cast ONLG as a prediction function which maps the intersection $a \otimes c(d)$ to a sentence $y \in \Sigma^*$ in natural language (in our case, Σ is the vocabulary of English):

$$f_{response}(a \otimes c(d)) = y \tag{1}$$

For any non-empty intersection, a response is generated which is related to the topic of the intersection and the sentiments defined towards this topic. The relation between the sentiment in the user agenda and the sentiment reflected in the document is a simple *xor* function: when the user and the author share a sentiment toward a topic the response is positive, else it is negative.

Objective Function. Let G be a formal generative grammar and let T be the set of trees strongly generated by G. In our proposed data-driven, grammar-based, generation architecture, we define $f_{response}$ as a function selecting a most probable tree $t \in T$ derived by G, given the intersection of document content and user agenda.

$$f_{response}(a \otimes c(d)) = \underset{\{w|w=yield(t),t\in T\}}{\operatorname{argmax}} P(w,t|a \otimes c(d)) \tag{2}$$

Here, $w = yield(t)$ is the sequence of terminals that defines the leaves of the tree, which is then picked as the generated response.

Assuming that G is a context-free grammar, we can spell out the probabilistic expression in Equation (2) as a history-based probabilistic model where $root(t)$ selects a starting point for the

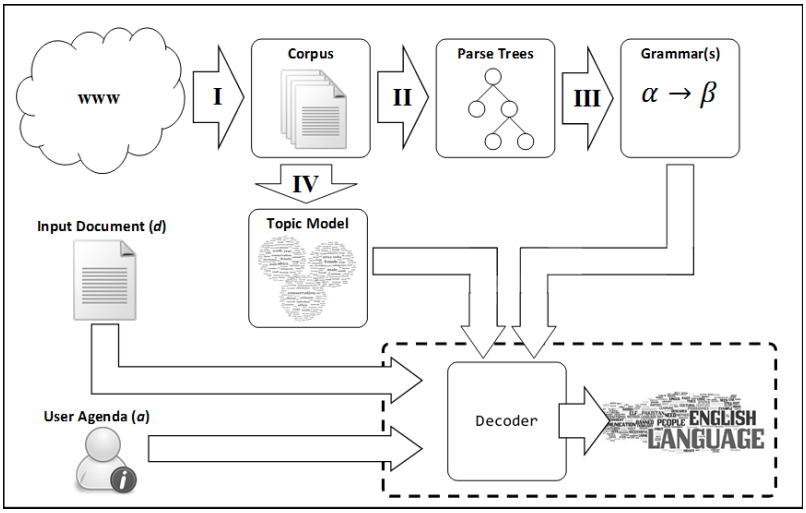

Figure 1: The end-to-end, data-driven, grammar-based generation architecture.

derivation, $der(t)$ selects the sequence of syntactic rules to be applied, and $yield(t)$ selects the sequence of terminals that forms the response all conditioned on the derivation history.

$$P(w,t|.) = P(root(t)|a \otimes c(d)) \quad (3a)$$
$$\times P(der(t)|root(t), a \otimes c(d)) \quad (3b)$$
$$\times P(yield(t)|root(t), der(t), a \otimes c(d)) \quad (3c)$$

Using standard independence assumptions, Eq. (3) may be re-written as a chain of local decisions, conditioned on selected aspects of the generation history, marked here by the function Φ.

$$P(w,t|.) \approx P(root|\Phi(a \otimes c(d))) \times \quad (4a)$$
$$\prod_{rule_j \in der(t)} P(rule_j|\Phi(root, a \otimes c(d))) \times \quad (4b)$$
$$\prod_{w_i \in yield(t)} P(w_i|\Phi(t, a \otimes c(d))) \quad (4c)$$

In words, the probability of the starting rule (4a) is multiplied with the probability of each of the rules in the derivation (4b) and the probability of each of the terminal nodes in the tree (4c). Each decision may be conditioned on previously generated part(s) of the structure, as well as the intersection of the input document content and user agenda.

3 The Architecture

A bird's-eye view of the architecture we propose is depicted in Figure 1. The process consists of an offline component containing (I) *corpus collection*, (II) *automatic annotation*, (III) *grammar induction*, and (IV) *topic-model training*. The induced grammar along with a predefined user agenda and the pre-trained topic model are provided as input to the online generation component, which is marked with the dashed box in Figure 1.

In (I) *corpus collection*, we collect a set of documents D with corresponding user comments. The documents in the corpus are used for training a topic model (IV), which is used for topic inference given a new input document d. The collected comments are used for inducing a wide-coverage grammar G for response generation.

To realize the goal of ONLG, we aim to jointly model opinion, structure and lexical decisions in our induced grammars. To this end, in (II) *automatic annotation* we enrich the user comments with annotations that reflect different levels of linguistic information, as detailed in Section 4.

In (III) *grammar induction* we induce a generative grammar G from the annotated corpus, following the common methodology of inducing PCFGs from syntactically annotated corpora (Charniak, 1995; Collins, 2003). We traverse the annotated trees from (III) and use maximum likelihood estimation for learning rule probabilities. No smoothing is done, and in order to filter noise from possibly erroneous parses, we use a frequency cap to define which rules can participate in derivations.

We finally define and implement an efficient grammar-based generator, termed here the *decoder*, which carries out the generation and calculates the objective function in Eq. (4). The algorithm is described in Section 5.

4 The Grammars

Base Grammar. A central theme in this research is generating sentences that express a certain sentiment. Our base grammatical representation is inspired by the Stanford sentiment classification parser (Socher et al., 2013) which annotates every non-ternminal node with one of five sentiment classes $s \in \{-2, -1, 0, 1, 2\}$.

Formally, each non-terminal in our base grammar includes a constituency category C and a sentiment class label s. The derivation of depth-1 trees with a parent node p and two daughters d_1, d_2 will thus appear as follows:

$$C_p[s_p] \rightarrow C_{d1}[s_{d1}] \;\; C_{d2}[s_{d2}]$$

The generative story imposed by this grammar is quite simple: each non-terminal node annotated with a sentiment can generate either a sequence of non-terminal daughters, or a single terminal node.

An example of a subtree and its generation sequence is given in Figure 2(Base). Here we see a positive NP which generates two daughters: a neutral DT and a positive NX. The positive NX generates a neutral noun NN and a positive modifying adjective JJ on its left. Such a derivation can yield NP terms such as "the good wife" or "an awesome movie", but will not generate "some terrible words". In this grammar, lexical realization is generated conditioned on local pre-terminals only, and independently of the syntactic structure.

While the generative story is simple, this grammar can capture complex interactions of sentiment. Such interactions take place in tree structures that include elements that may affect polarity, such as negation, modal verbs and so on (see Socher et al. (2013) and examples therein). In this work we assume a completely data-driven approach wherein such structures are derived based on previously observed sentiment-interactions in sentiment-augmented parses.

Lexicalized Grammar. Our base grammar suffers from a clear pitfall: the structure lacks sensitivity to lexical information, and vice versa. This base grammar essentially generates lexical items as an afterthought, conditioned only on the local part-of-speech label and sentiment value. Our first modification of the base grammar is *lexicalization* in the spirit of Collins (2003).

In this representation each non-terminal node is decorated with a phrase-structure category C and a sentiment label s, and it is augmented with a lexical *head* l_h. The lexical head is common to the parent and the left (or right) daughter. A new lexical item, termed *modifier* l_m, is introduced in the right (left) daughter. The resulting depth-1 subtree for a parent p with daughters d_1, d_2 and a lexical head on the left (without loss of generality) is:

$$C_p[s_p, l_h] \rightarrow C_{d1}[s_{d1}, l_h] \;\; C_{d2}[s_{d2}, l_m]$$

Lexicalization makes the grammar more useful for generation as lexical choices can be made at any stage of the derivation conditioned on part of the structure. But it has one drawback – it assumes very strong dependence between lexical items that happen to appear as sisters.

To overcome this, we define a *head-driven* generative story that follows the model of Collins (2003), where the mother non-terminal generates first the head node, and then, conditioned on the head it generates a modifying constituent to the left (right) of the head and its corresponding modifying lexical dependent. An example subtree and its associated head-driven generative story is illustrated in Figure 2(Lex).

Relational-Realizational Grammar. Generating phrase-structures along with lexical realization can manage *form* — control how sentences are built. For coherent generation we would like to also control for the *function* of nodes in the derivation. To this end, we define a grammar and a generative story in the spirit of the *Relational-Realizational* (RR) grammar of Tsarfaty (2010).

In our RR-augmented trees, each non-terminal node includes, on top of the phrase-structure category C, the lexical head l and the sentiment s, a relation label dep_i which determines its functional role in relation to its parent. The functional component will affect the selection of daughters so that the derived subtree fulfils its function. A depth-1 subtree will thus appear as follows:

$$C_i[s_i, dep_i, l_i] \rightarrow C_j[s_j, dep_j, l_i] \;\; C_k[s_k, dep_k, l_k]$$

The generative story of our RR representation follows the three-phase process defined by Tsarfaty and Sima'an (2008) and Tsarfaty (2010):

(i) *projection*: given a constituent and a sentiment value, generate a set of grammatical relations which define the functions of the daughters to be generated.

Figure 2: Our grammatical representations, with (a) a sample tree and (b) its generation sequence. A rule of type SYN marks syntactic rules, LEX indicates lexical realization, HEAD, MOD indicate head selection and modifier selection, PROJ,CONF,REAL indicate projection, configuration and realization, respectively. The @ sign indicates aspects in the generation history that the production is conditioned on (Φ in eq. 4).

(ii) *configuration*: given a constituent, sentiment and an unordered set of relations, an ordering for the relations is generated. Unlike the original RR derivations which fully order the set, here we partition the set into two disjoint sets (one of which is a singleton) and order them. This modification ensures that we adhere to binary trees.

(iii) *realization*: For each function-labels' set we select the daughter's constituent realizing it. We first generate the constituent and sentiment realizing this function, and then, conditioned on the constituent, sentiment, head and function, we select the lexical dependent.

An example tree along with its RR derivation is given in Figure 2(RR).

5 Grammar-Based Generation

Our grammar-based generator is a top-down algorithm which starts with a frontier that includes a selected root, and expands the tree continually by substituting non-terminals at the left-hand-side of rules with their daughters on the right hand side, until no more non-terminals exist. This generation procedure yields one sentence for any given root. Due to independence assumptions inherent in the generative processes we defined, there is no guarantee that generated sentences will be completely grammatical, relevant and human-like. To circumvent this, we develop an over-generation algorithm that modifies the basic algorithm to select multiple rules at each generation point, and apply them to uncover several derivation trees, or a *forest*.

We then use a variation on the beam search algorithm (Reddy, 1977) and devise a methodology to select the k-best scoring trees to be carried on to the next iteration. Specifically, we use a Breadth-First algorithm for expanding the tree and define a dynamic programming algorithm that takes the score of a derivation tree of $n-1$ *expanded* nodes, selects a new rule for the next non-expanded node, and from it, calculates the score of the expanded tree with now n nodes. For comparing the trees, we computed a score according to Eq. (4) for the tree generated so far, and used an average node score to neutralize size difference between trees.

To make sure our responses target a particular topic, we propose to condition the selection of lexical items at the root on the *topic* at the intersection of the document content and user agenda, essentially preferring derivations that yield words related to the input topic distribution. In practice we use topic model scores to estimate the root rule probability, selecting lexical item(s) for generation to start with:

$$\hat{P}(root(t)|a \otimes c(d)) = \hat{P}(\text{ROOT} \rightarrow l_1 l_2 | a \otimes c(d)) = \sum_{c=1}^{N} \sum_{i=1}^{2} tm\_weight(c) * word\_weight(c, l_i) \quad (5)$$

where $tm\_weight(c)$ is the weight of topic c in the topic distribution at the document-agenda intersection, and $word\_weight(c, l_i)$ is the weight of the lexical head word l_i within the word distribution of topic c in the given topic model.

The generation process ends when all derivations reach (at most) a pre-defined height (to avoid endless recursions). We then re-rank the generated candidates. The re-ranking is based on a 3-grams language model on the raw yield of the sentence, divided by the length of the sentence to obtain a per-word average and avoid length biases.[1]

6 Evaluation

Goal. We aim to evaluate the grammars' applicability to the ONLG task. Set in an open domain, it is not trivial to find a "gold-standard" for this task, or even a method to obtain one. Our evaluation thus follows two tracks: an automated assessment track, where we quantitatively assess the responses, and a Turing-like test similar to that of Cagan et al. (2014), where we aim to gauge human-likeness and response relevance.

[1]Here we use Microsoft's WebLM API which is part of the Microsoft Oxford Project (Microsoft, 2011).

Materials. We collected a new corpus of news articles and corresponding user comments from the NY-Times®web site, using their open Community API. We focus on sports news, which gave us 3,583 news articles and 13,100 user comments, or 55,700 sentences. The articles are then used for training a topic model using the Mallet library (McCallum, 2002). Next, we use the comments in the corpus to induce the grammars. To obtain our Base representation we parse the sentences using the Stanford CoreNLP suite (Manning et al., 2014) which can provide both phrase-structure and sentiment annotation. To obtain our Lexicalized representation we follow the same procedure, this time also using a head-finder which locates the head word for each non-terminal. To obtain the Relational-Realizational representation we followed the algorithm described in Tsarfaty et al. (2011), which, given both a constituency parse and a dependency parse of a sentence, unifies them into a lexicalized and functional phrase-structure. The merging is based on matching spans over words within the sentence.[2]

Setup. We simulated several scenarios. In each, the system generates sentences with one grammar ($G \in \{$*Base, Lex, RR*$\}$) and one scoring scheme (with/without topic model scores). The results of each simulation are 5,000 responses for each variant of the system, consisting of 1,000 sentences for each sentiment class, $s \in \{-2, -1, 0, 1, 2\}$. The same 5000 generated sentences were used in all experiments. We set the generator for trees of maximum depth of 13 which can yield up to 4096 words. In reality, the realization was of much shorter sentences. Examples for generated responses are given in Table 1.

6.1 Comparing Grammars

Goal and Metrics. In this experiment we compare and contrast the generation capacity of the grammars, using the following metrics:

(i) *Fluency* measures how grammatical or natural the generated sentences are. We base this measure on a probabilistic language model which gives an indication of how common word-sequences within the sentence are. We express fluency as a Language Model (LM) score which is calculated using the Microsoft Web ML API to get aggregated minus-log probabilities of all 3-grams

[2]The collected corpus and supplementary annotations are available at www.tomercagan.com/onlg.

in the sentence. The aggregated score is then normalized to give a per-word average in order to cancel any effects of sentence length.

(ii) *Sentiment Agreement* measures whether the inferred sentiment of the response matches the input sentiment parameter used for generation. Specifically, we take the raw yield of the generated tree (a sentence) and run it through the sentiment classifier implemented in Socher et al. (2013), to assign the full sentence one of 5 sentiment classes between -2 and $+2$. During evaluation, we compare the classified sentiment of the generated sentence is with the sentiment entered as input for the derivation of the sentence, and report the rate of agreement on (a) level ($-2.. + 2$) and (b) polarity ($-/+$), which is a more relaxed measure.

(iii) The *Consiceness/tightness* metric aims to evaluate which grammar derives a simpler structure across generations of similar content. Our tightness evaluation is based on the percentage of sentences that were fully realization as terminals within the specific height limit;[3] we simply observe how many trees have all leaves as terminal symbols. Intuitively, tighter grammars lead to improved performance and better control over the generated content. It is possible to think of what it captures in terms Occams Razor, preferring the simpler structure to derive comparable outcome.

Empirical Results The results of our evaluation are presented in Table 2. With respect to the above metrics, the RR grammar was more compact and natural compared to the lexicalized (LEX) grammar: the per-word LM Score for the RR is -5.6 as compared to -6.5 for LEX. Also, RR has 95.7% complete sentences as compared to only 67.3% for LEX. The LEX grammar was more sensitive to the sentiment input but only slightly, having a 44.6% sentiment agreement and 63.9% sentiment polarity agreement compared to 43.8% and 61.0% for RR grammar. The BASE grammar gave the worst performance for all measures. This provides preliminary evidence in support of incorporating surface realization (lexicalization) into the syntactic generation, rather than filling slots in retrospect.

6.2 Testing Relevance

Goal and Metrics Next we aim to evaluate the relevance of the responses to the input document triggering the response. We do so by calculating

[3] A height of 13 makes a maximum sentence length of $2^{13-1} = 2^{12} = 4096$ words.

Grammar	Sentiment	Sentence
BASE	-2	(and badly should doesn't..
	-1	doesn't of the yankees..
	0	who is the the game,.
	1	is the the united states..
	2	is the best players..
LEX	-2	is a rhyme ... mahi mahi, and, I not quote Bunny.
	-1	Dumpster unpire are the villans.
	0	Derogatory big names symbols wider
	1	New england has been playful, and infrequent human.
	2	That's a huge award – having get fined!
RR	-2	he is very awkward, and to any ridiculous reason.
	-1	the malfeasance underscores the the widespread belief.
	0	the programs serve the purposes.
	1	McIlroy is a courageous competitor.
	2	The urgent service's a grand idea.

Table 1: Responses generated by the system with the different grammars and sentiment levels.

Grammar	Avg. LM Score		Avg. LM Score per word		Complete Sentences (%)	Sentiment Agreement / Polarity (%)	Avg. Length (words)
	Mean	CI	Mean	CI			
BASE	-79.7	±0.054	-8.9	±0.007	20.1	13.3 / 41.8	9.5
LEX	-73.7	±0.016	-6.5	±0.002	67.3	**44.6 / 63.9**	12.3
RR	**-51.8**	±0.011	**-5.6**	±0.001	**95.7**	43.8 / 61.0	9.6
HUMAN	-50.1	±0.000	-5.4	±0.000	N/A	N/A	10.3

Table 2: Mean and 95% Confidence Interval (CI) of language model scores, and measures of compactness and sentiment agreement. The last row, *HUMAN* refers to the collected human responses.

Topic Agreement, a measure that, given a trained topic model, determines how close the topic distribution of the input document and that of the generated response are. We use L2 to calculate the distance between the inferred topic distribution vectors. We focus here on relevance testing for the RR grammar, which gave superior LM scores. In this test we use two generators – RR generator as defined above, and RRTM generator that uses the scoring scheme of Equation (5) to select a start rule deriving the root lexical item. Example sentences of each generator are presented in Table 3.

Empirical Results The results of the two generators and their average distance from the topic distribution of the input document are presented in Table 4. Here we see that the generator using topic models for selecting start rules (RRTM) gets topic distribution that is closer to the input document's topic distribution. The last row, HUMAN, calculates the distance between the topic distributions in the documents and their human responses from the collected corpus. The fact that RRTM outperforms HUMAN is not necessarily surprising, as sentences in human responses are typically from longer paragraphs where some sentences are more generic, used as connectives, interjections, etc.

Grammar	Sentiment	Sentence
RR	-2	they deserve it, but I is fear.
	-1	the saga is correct.
	0	the indirect penalty?
	1	the job is correct.
	2	a salaries excels.
RRTM	-2	Unfortunately, they remind that to participate in baseball.
	-1	the franchise would he made?
	0	Probably the LONG time .
	1	In a good addition, he is a good baseball player.
	2	the baseball game sublime.

Table 3: Responses generated by the system using emission probabilities and topic models for the start rule selection.

Generator	Mean	CI
RR	0.473	$\pm$ 0.003
RRTM	0.424	$\pm$ 0.003
HUMAN	0.429	$\pm$ 0.000

Table 4: Mean and 95% Confidence Interval (CI) for generators with / without topic models scores (RRTM / RR respectively). The last row, *HUMAN* refers to the collected human responses.

6.3 Human Surveys

Goal and Procedure. We evaluate human-likeness of the generated responses by collecting data via an online survey on Amazon Mechanical Turk. In the survey, participants were asked to judge whether generated sentences were written by a human or a computer. The participants were screened to have a good level of English and reside in the US. Each survey comprised of 50 randomly ordered trials. In each trial the participant was shown a response. The task was to categorize each response on a 7-point scale with labels 'Certainly human/computer', 'Probably human/computer', 'Maybe human/computer' and 'Unsure'. In 50 trials the participant was exposed to 3-4 sentences for each grammar/sentiment combination.

Empirical Results. Average human-likeness ratings (scale 1–7) are presented in Table 5. Here, we see that sentences generated by the lexicalized grammar were perceived as most human-like. This result is in contrast with the automatic evaluation. Such a discrepancy need not be very surprising, as noted by others before (Belz and Reiter, 2006). Cagan et al. (2014) show that there are extra-grammatical factors affecting human-likeness, e.g. world knowledge. We hypothesise that the LEX grammar, which relies heavily on lexical co-occurrences frequencies, is better at replicating world knowledge and idiomatic phrases thus judged as more human.

Grammar	Mean	CI
BASE	2.4561	$\pm$ 0.004
LEX	4.1681	$\pm$ 0.004
RR	3.7278	$\pm$ 0.004

Table 5: Mean and 95% Confidence Interval (CI) for human-likeness ratings (scaling 1:low–7:high).

Factor	b	Std. Error	z-value	$P(>\|z\|)$
G-LEX	2.90	0.189	15.32	<.00001
G-RR	2.33	0.164	14.20	<.00001
SENT	0.17	0.074	2.32	.020
NWORD	-1.60	0.107	-14.95	<.00001
POS	0.21	0.036	5.97	<.00001
G-LEX $\times$ SENT	-0.18	0.095	-1.91	.056
G-RR $\times$ SENT	0.44	0.096	4.53	<.00001
G-LEX $\times$ NWORD	1.31	0.117	11.16	<.00001
G-RR $\times$ NWORD	1.35	0.138	9.80	<.00001
NWORD $\times$ POS	0.10	0.037	2.81	.005

Table 6: Regression analysis of the human survey.

In a qualitative inspection on a sample of the results we could verify that the LEX grammar tends to replicate idiomatic sequences while the RR grammar generates novel phrases in a more compositional fashion. Grammaticality is not hindered by it, but apparently human-likeness is.

We also run an ordinal mixed-effects regression, which is an appropriate way to analyse discrete rating data. Regression model predictors were Grammar (G), sentiment level (SENT), response length (NWORD), position of response in rating session (POS), and all two-way interactions between these. Quantitative predictors were standardized and non-significant ($p > .05$) interactions were dropped from the fitted model. By-participant random intercepts and slopes of G and SENT were included as random effects.

Table 6 displays the fitted model fixed effects, with BASE grammar as the reference level. Consistent with Table 5, we see that LEX and RR score significantly higher on human likeness than BASE. These effects are modulated by sentiment: more positive sentiment makes BASE and RR more human-like (respectively: $b = 0.17$ and $b = 0.44$) whereas the LEX grammar becomes less human like (although this effect is only marginally significant: $b = -.18$). In addition, these effects are also modulated by sentence length in #words – longer sentences make BASE less human-like ($b = -1.60$) but RR and LEX more human-like (respectively: $b = 1.31$ and $b = 1.35$)

Importantly, there is a weak but significant *positive* effect of position ($b = 0.21$), indicating that human-likeness ratings increase over the course of a rating session. This effect does not depend on the grammar, but is somewhat stronger for longer

sentences ($b = 0.10$). The position effect contrasts markedly with the decrease of human-likeness ratings that (Cagan et al., 2014) ascribed to a learning effect: there, raters noticed the repetitive structure and took this to be a sign that the utterances were machine generated. The fact that we find no such effect means that our grammars successfully avoided such repetitiveness.

7 Related and Future Work

NLG is often cast as a *concept-to-text* (C2T) challenge, where a structured record is transformed into an utterance expressing its content. C2T is usually addressed using template-based (Becker, 2002) or data-driven (Konstas and Lapata, 2013; Yuan et al., 2015) approaches. In particular, researchers explored data-driven grammar-based approaches (Cahill and van Genabith, 2006), often assuming a custom grammar (Konstas and Lapata, 2013) or a closed-domain approach (DeVault et al., 2008). ONLG in contrast is set in an open domain, and expresses multiple dimensions (grammaticality, sentiment, topic).

In the context of social media, generating responses to tweets has been cast as a sequence-to-sequence (seq2seq) transduction problem, and has been addressed using statistical machine translation (SMT) methods (Ritter et al., 2011; Hasegawa et al., 2013). In this seq2seq setup, moods and sentiments expressed in the past are replicated or reused, but these responses do not target particular topics and are not driven by a concrete user agenda. An exception is a recent work by Li et al. (2016), exploring a persona-based conversational model, and Xu et al. (2016) who encode loose structured knowledge to condition the generation on. These studies present a stepping stone towards full-fledge neural ONLG architectures with some control over the user characteristics.

The surge of interest in neural network generation architectures has spawned the development of seq2seq models based on encoder-decoder setup (Sordoni et al. (2015); Li et al. (2016, 2017) and references therein). These architectures require a very large dataset to train on. In the future we aim to extend our dataset and explore neural network architectures for ONLG that can encode a user-agenda, a document, and possibly stylistic choices (Biber and Conrad, 2009; Reiter and Williams, 2010) — in the hope of yielding more diverse, relevant and coherent responses to online content.

8 Conclusion

We approached ONLG from a data-driven perspective, aiming to overcome the shortcomings of previous template-based approaches. Our contribution is threefold: (i) we designed three types of broad-coverage grammars appropriate for the task, (ii) we developed a new enriched data-set for inducing the grammars, and (iii) we empirically demonstrated the strengths of the LEX and RR grammars for generation, as well as the overall usefulness of sentiment and topic models incorporated into the syntactic derivation. Our results show that the proposed grammar-based architecture indeed avoids the repetitiveness and learning effects observed in the template-based ONLG.

To the best of our knowledge, this is the first data-driven agenda-driven baseline for ONLG, and we believe it can be further improved. Some future avenues for investigation include improving the relevance and human-likeness results by improving the automatic parses quality, acquiring more complex templates via abstract grammars, and experimenting with more sophisticated scoring functions for reranking. With the emergence of deep learning, we further embrace the opportunity to combine the *sequence-to-sequence* modeling view explored so far with conditioning generation on speakers agendas and user profiles, pushing the envelope of opinionated generation further. Finally, we believe that future work should be evaluated *in situ*, to examine if, and to what extent, the generated responses participate in and affect the discourse (feed) in social media.

Abstract

We study automatic question generation for sentences from text passages in reading comprehension. We introduce an attention-based sequence learning model for the task and investigate the effect of encoding sentence- vs. paragraph-level information. In contrast to all previous work, our model does not rely on hand-crafted rules or a sophisticated NLP pipeline; it is instead trainable end-to-end via sequence-to-sequence learning. Automatic evaluation results show that our system significantly outperforms the state-of-the-art rule-based system. In human evaluations, questions generated by our system are also rated as being more natural (*i.e.*, grammaticality, fluency) and as more difficult to answer (in terms of syntactic and lexical divergence from the original text and reasoning needed to answer).

1 Introduction

Question generation (QG) aims to create natural questions from a given a sentence or paragraph. One key application of question generation is in the area of education — to generate questions for reading comprehension materials (Heilman and Smith, 2010). Figure 1, for example, shows three manually generated questions that test a user's understanding of the associated text passage. Question generation systems can also be deployed as chatbot components (*e.g.*, asking questions to start a conversation or to request feedback (Mostafazadeh et al., 2016)) or, arguably, as a clinical tool for evaluating or improving mental health (Weizenbaum, 1966; Colby et al., 1971).

In addition to the above applications, question generation systems can aid in the development of

Sentence:
Oxygen is used in cellular respiration and released by photosynthesis, which uses the energy of sunlight to produce oxygen from water.

Questions:
– What life process produces oxygen in the presence of light?
photosynthesis
– Photosynthesis uses which energy to form oxygen from water?
sunlight
– From what does photosynthesis get oxygen?
water

Figure 1: Sample sentence from the second paragraph of the article *Oxygen*, along with the natural questions and their answers.

annotated data sets for natural language processing (NLP) research in reading comprehension and question answering. Indeed the creation of such datasets, *e.g.*, SQuAD (Rajpurkar et al., 2016) and MS MARCO (Nguyen et al., 2016), has spurred research in these areas.

For the most part, question generation has been tackled in the past via rule-based approaches (*e.g.*, Mitkov and Ha (2003); Rus et al. (2010). The success of these approaches hinges critically on the existence of well-designed rules for declarative-to-interrogative sentence transformation, typically based on deep linguistic knowledge.

To improve over a purely rule-based system, Heilman and Smith (2010) introduced an overgenerate-and-rank approach that generates multiple questions from an input sentence using a rule-based approach and then ranks them using a supervised learning-based ranker. Although the ranking algorithm helps to produce more ac-

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1342–1352
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1123

ceptable questions, it relies heavily on a manually crafted feature set, and the questions generated often overlap word for word with the tokens in the input sentence, making them very easy to answer.

Vanderwende (2008) point out that learning to ask good questions is an important task in NLP research in its own right, and should consist of more than the syntactic transformation of a declarative sentence. In particular, a natural sounding question often compresses the sentence on which it is based (*e.g.*, question 3 in Figure 1), uses synonyms for terms in the passage (*e.g.*, "form" for "produce" in question 2 and "get" for "produce" in question 3), or refers to entities from preceding sentences or clauses (*e.g.*, the use of "photosynthesis" in question 2). Othertimes, world knowledge is employed to produce a good question (*e.g.*, identifying "photosynthesis" as a "life process" in question 1). In short, constructing natural questions of reasonable difficulty would seem to require an *abstractive* approach that can produce fluent phrasings that do not exactly match the text from which they were drawn.

As a result, and in contrast to all previous work, we propose here to frame the task of question generation as a sequence-to-sequence learning problem that directly maps a sentence from a text passage to a question. Importantly, our approach is fully data-driven in that it requires no manually generated rules.

More specifically, inspired by the recent success in neural machine translation (Sutskever et al., 2014; Bahdanau et al., 2015), summarization (Rush et al., 2015; Iyer et al., 2016), and image caption generation (Xu et al., 2015), we tackle question generation using a conditional neural language model with a global attention mechanism (Luong et al., 2015a). We investigate several variations of this model, including one that takes into account paragraph- rather than sentence-level information from the reading passage as well as other variations that determine the importance of pre-trained vs. learned word embeddings.

In evaluations on the SQuAD dataset (Rajpurkar et al., 2016) using three automatic evaluation metrics, we find that our system significantly outperforms a collection of strong baselines, including an information retrieval-based system (Robertson and Walker, 1994), a statistical machine translation approach (Koehn et al., 2007), and the overgenerate-and-rank approach of Heilman and Smith (2010). Human evaluations also rated our generated questions as more grammatical, fluent, and challenging (in terms of syntactic divergence from the original reading passage and reasoning needed to answer) than the state-of-the-art Heilman and Smith (2010) system.

In the sections below we discuss related work (Section 2), specify the task definition (Section 3) and describe our neural sequence learning based models (Section 4). We explain the experimental setup in Section 5. Lastly, we present the evaluation results as well as a detailed analysis.

2 Related Work

Reading Comprehension is a challenging task for machines, requiring both understanding of natural language and knowledge of the world (Rajpurkar et al., 2016). Recently many new datasets have been released and in most of these datasets, the questions are generated in a synthetic way. For example, bAbI (Weston et al., 2016) is a fully synthetic dataset featuring 20 different tasks. Hermann et al. (2015) released a corpus of cloze style questions by replacing entities with placeholders in abstractive summaries of CNN/Daily Mail news articles. Chen et al. (2016) claim that the CNN/Daily Mail dataset is easier than previously thought, and their system almost reaches the ceiling performance. Richardson et al. (2013) curated MCTest, in which crowdworker questions are paired with four answer choices. Although MCTest contains challenging natural questions, it is too small for training data-demanding question answering models.

Recently, Rajpurkar et al. (2016) released the Stanford Question Answering Dataset[1] (SQuAD), which overcomes the aforementioned small size and (semi-)synthetic issues. The questions are posed by crowd workers and are of relatively high quality. We use SQuAD in our work, and similarly, we focus on the generation of natural questions for reading comprehension materials, albeit via automatic means.

Question Generation has attracted the attention of the natural language generation (NLG) community in recent years, since the work of Rus et al. (2010).

Most work tackles the task with a rule-based approach. Generally, they first transform the input sentence into its syntactic representation, which

[1] https://stanford-qa.com

they then use to generate an interrogative sentence. A lot of research has focused on first manually constructing question templates, and then applying them to generate questions (Mostow and Chen, 2009; Lindberg et al., 2013; Mazidi and Nielsen, 2014). Labutov et al. (2015) use crowdsourcing to collect a set of templates and then rank the relevant templates for the text of another domain. Generally, the rule-based approaches make use of the syntactic roles of words, but not their semantic roles.

Heilman and Smith (2010) introduce an overgenerate-and-rank approach: their system first overgenerates questions and then ranks them. Although they incorporate learning to rank, their system's performance still depends critically on the manually constructed generating rules. Mostafazadeh et al. (2016) introduce visual question generation task, to explore the deep connection between language and vision. Serban et al. (2016) propose generating simple factoid questions from logic triple (subject, relation, object). Their task tackles mapping from structured representation to natural language text, and their generated questions are consistent in terms of format and diverge much less than ours.

To our knowledge, none of the previous works has framed QG for reading comprehension in an end-to-end fashion, and nor have them used deep sequence-to-sequence learning approach to generate questions.

3 Task Definition

In this section, we define the question generation task. Given an input sentence $\mathbf{x}$, our goal is to generate a natural question $\mathbf{y}$ related to information in the sentence, $\mathbf{y}$ can be a sequence of an arbitrary length: $[y_1, ..., y_{|\mathbf{y}|}]$. Suppose the length of the input sentence is M, $\mathbf{x}$ could then be represented as a sequence of tokens $[x_1, ..., x_M]$. The QG task is defined as finding $\overline{\mathbf{y}}$, such that:

$$\overline{\mathbf{y}} = \arg\max_{\mathbf{y}} P\left(\mathbf{y}|\mathbf{x}\right) \tag{1}$$

where $P\left(\mathbf{y}|\mathbf{x}\right)$ is the conditional log-likelihood of the predicted question sequence $\mathbf{y}$, given the input $\mathbf{x}$. In section 4.1, we will elaborate on the global attention mechanism for modeling $P\left(\mathbf{y}|\mathbf{x}\right)$.

4 Model

Our model is partially inspired by the way in which a human would solve the task. To ask a natural question, people usually pay attention to certain parts of the input sentence, as well as associating context information from the paragraph. We model the conditional probability using RNN encoder-decoder architecture (Bahdanau et al., 2015; Cho et al., 2014), and adopt the global attention mechanism (Luong et al., 2015a) to make the model focus on certain elements of the input when generating each word during decoding.

Here, we investigate two variations of our models: one that only encodes the sentence and another that encodes both sentence and paragraph-level information.

4.1 Decoder

Similar to Sutskever et al. (2014) and Chopra et al. (2016), we factorize the the conditional in equation 1 into a product of word-level predictions:

$$P\left(\mathbf{y}|\mathbf{x}\right) = \prod_{t=1}^{|y|} P\left(y_t|\mathbf{x}, y_{<t}\right)$$

where probability of each y_t is predicted based on all the words that are generated previously (*i.e.*, $y_{<t}$), and input sentence $\mathbf{x}$.

More specifically,

$$P\left(y_t|\mathbf{x}, y_{<t}\right) = \text{softmax}\left(\mathbf{W}_s \text{tanh}\left(\mathbf{W}_t[\mathbf{h}_t; \mathbf{c}_t]\right)\right) \tag{2}$$

with $\mathbf{h}_t$ being the recurrent neural networks state variable at time step t, and $\mathbf{c}_t$ being the attention-based encoding of $\mathbf{x}$ at decoding time step t (Section 4.2). $\mathbf{W}_s$ and $\mathbf{W}_t$ are parameters to be learned.

$$\mathbf{h}_t = \text{LSTM}_1\left(y_{t-1}, \mathbf{h}_{t-1}\right) \tag{3}$$

here, LSTM is the Long Short-Term Memory (LSTM) network (Hochreiter and Schmidhuber, 1997). It generates the new state $\mathbf{h}_t$, given the representation of previously generated word y_{t-1} (obtained from a word look-up table), and the previous state $\mathbf{h}_{t-1}$.

The initialization of the decoder's hidden state differentiates our basic model and the model that incorporates paragraph-level information.

For the basic model, it is initialized by the sentence's representation $\mathbf{s}$ obtained from the sentence encoder (Section 4.2). For our paragraph-level model, the *concatenation* of the sentence

encoder's output $\mathbf{s}$ and the paragraph encoder's output $\mathbf{s}'$ is used as the initialization of decoder hidden state. To be more specific, the architecture of our paragraph-level model is like a "Y"-shaped network which encodes both sentence- and paragraph-level information via two RNN branches and uses the concatenated representation for decoding the questions.

4.2 Encoder

The attention-based sentence encoder is used in both of our models, while the paragraph encoder is only used in the model that incorporates paragraph-level information.

Attention-based sentence encoder:

We use a bidirectional LSTM to encode the sentence,

$$\overrightarrow{\mathbf{b}_t} = \overrightarrow{\text{LSTM}_2}\left(x_t, \overrightarrow{\mathbf{b}_{t-1}}\right)$$
$$\overleftarrow{\mathbf{b}_t} = \overleftarrow{\text{LSTM}_2}\left(x_t, \overleftarrow{\mathbf{b}_{t+1}}\right)$$

where $\overrightarrow{\mathbf{b}_t}$ is the hidden state at time step t for the forward pass LSTM, $\overleftarrow{\mathbf{b}_t}$ for the backward pass.

To get *attention-based* encoding of $\mathbf{x}$ at decoding time step t, namely, $\mathbf{c}_t$, we first get the context dependent token representation by $\mathbf{b}_t = [\overrightarrow{\mathbf{b}_t}; \overleftarrow{\mathbf{b}_t}]$, then we take the weighted average over $\mathbf{b}_t$ ($t = 1, ..., |\mathbf{x}|$),

$$\mathbf{c}_t = \sum_{i=1,..,|\mathbf{x}|} a_{i,t}\mathbf{b}_i \tag{4}$$

The attention weight are calculated by the bilinear scoring function and softmax normalization,

$$a_{i,t} = \frac{\exp\left(\mathbf{h}_t^T \mathbf{W}_b \mathbf{b}_i\right)}{\sum_j \exp\left(\mathbf{h}_t^T \mathbf{W}_b \mathbf{b}_j\right)} \tag{5}$$

To get the sentence encoder's output for initialization of decoder hidden state, we concatenate last hidden state of the forward and backward pass, namely, $\mathbf{s} = [\overrightarrow{\mathbf{b}_{|\mathbf{x}|}}; \overleftarrow{\mathbf{b}_1}]$.

Paragraph encoder:

Given sentence $\mathbf{x}$, we want to encode the paragraph containing $\mathbf{x}$. Since in practice the paragraph is very long, we set a length threshold L, and truncate the paragraph at the L^{th} token. We call the truncated paragraph "paragraph" henceforth.

Denoting the paragraph as $\mathbf{z}$, we use another bidirectional LSTM to encode $\mathbf{z}$,

$$\overrightarrow{\mathbf{d}_t} = \overrightarrow{\text{LSTM}_3}\left(z_t, \overrightarrow{\mathbf{d}_{t-1}}\right)$$
$$\overleftarrow{\mathbf{d}_t} = \overleftarrow{\text{LSTM}_3}\left(z_t, \overleftarrow{\mathbf{d}_{t+1}}\right)$$

With the last hidden state of the forward and backward pass, we use the concatenation $[\overrightarrow{\mathbf{d}_{|\mathbf{z}|}}; \overleftarrow{\mathbf{d}_1}]$ as the paragraph encoder's output $\mathbf{s}'$.

4.3 Training and Inference

Giving a training corpus of sentence-question pairs: $\mathcal{S} = \left\{\left(\mathbf{x}^{(i)}, \mathbf{y}^{(i)}\right)\right\}_{i=1}^{S}$, our models' training objective is to minimize the negative log-likelihood of the training data with respect to all the parameters, as denoted by θ,

$$\begin{aligned}\mathcal{L} &= -\sum_{i=1}^{S} \log P\left(\mathbf{y}^{(i)}|\mathbf{x}^{(i)}; \theta\right) \\ &= -\sum_{i=1}^{S}\sum_{j=1}^{|\mathbf{y}^{(i)}|} \log P\left(y_j^{(i)}|\mathbf{x}^{(i)}, y_{<j}^{(i)}; \theta\right)\end{aligned}$$

Once the model is trained, we do inference using beam search. The beam search is parametrized by the possible paths number k.

As there could be many rare words in the input sentence that are not in the target side dictionary, during decoding many `UNK` tokens will be output. Thus, post-processing with the replacement of `UNK` is necessary. Unlike Luong et al. (2015b), we use a simpler replacing strategy for our task. For the decoded `UNK` token at time step t, we replace it with the token in the input sentence with the highest attention score, the index of which is $\arg\max_i a_{i,t}$.

5 Experimental Setup

We experiment with our neural question generation model on the processed SQuAD dataset. In this section, we firstly describe the corpus of the task. We then give implementation details of our neural generation model, the baselines to compare, and their experimental settings. Lastly, we introduce the evaluation methods by automatic metrics and human raters.

5.1 Dataset

With the SQuAD dataset (Rajpurkar et al., 2016), we extract sentences and pair them with the ques-

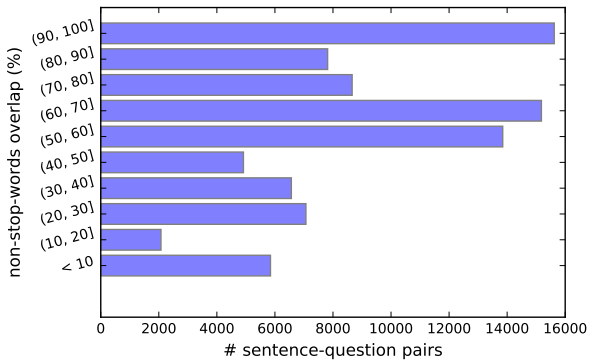

Figure 2: Overlap percentage of sentence-question pairs in training set. y-axis is # non-stop-words overlap with respect to the total # tokens in the question (a percentage); x-axis is # sentence-question pairs for a given overlap percentage range.

tions. We train our models with the sentence-question pairs. The dataset contains 536 articles with over 100k questions posed about the articles. The authors employ Amazon Mechanical Turks crowd-workers to create questions based on the Wikipedia articles. Workers are encouraged to use their own words without any copying phrases from the paragraph. Later, other crowd-workers are employed to provide answers to the questions. The answers are spans of tokens in the passage.

Since there is a hidden part of the original SQuAD that we do not have access to, we treat the accessible parts (∼90%) as the entire dataset henceforth.

We first run Stanford CoreNLP (Manning et al., 2014) for pre-processing: tokenization and sentence splitting. We then lower-case the entire dataset. With the offset of the answer to each question, we locate the sentence containing the answer and use it as the input sentence. In some cases (< 0.17% in training set), the answer spans two or more sentences, and we then use the concatenation of the sentences as the input "sentence".

Figure 2 shows the distribution of the token overlap percentage of the sentence-question pairs. Although most of the pairs have over 50% overlap rate, about 6.67% of the pairs have no non-stop-words in common, and this is mostly because of the answer offset error introduced during annotation. Therefore, we prune the training set based on the constraint: the sentence-question pair must have at least one non-stop-word in common. Lastly we add <SOS> to the beginning of the sentences, and <EOS> to the end of them.

# pairs (Train)	70484
# pairs (Dev)	10570
# pairs (Test)	11877
Sentence: avg. tokens	32.9
Question: avg. tokens	11.3
Avg. # questions per sentence	1.4

Table 1: Dataset (processed) statistics. Sentence average # tokens, question average # tokens, and average # questions per sentence statistics are from training set. These averages are close to the statistics on development set and test set.

We randomly divide the dataset at the article-level into a training set (80%), a development set (10%), and a test set (10%). We report results on the 10% test set.

Table 1 provides some statistics on the processed dataset: there are around 70k training samples, the sentences are around 30 tokens, and the questions are around 10 tokens on average. For each sentence, there might be multiple corresponding questions, and, on average, there are 1.4 questions for each sentence.

5.2 Implementation Details

We implement our models [2] in Torch7 [3] on top of the newly released OpenNMT system (Klein et al., 2017).

For the source side vocabulary $\mathcal{V}$, we only keep the 45k most frequent tokens (including <SOS>, <EOS> and placeholders). For the target side vocabulary $\mathcal{U}$, similarly, we keep the 28k most frequent tokens. All other tokens outside the vocabulary list are replaced by the UNK symbol. We choose word embedding of 300 dimensions and use the glove.840B.300d pre-trained embeddings (Pennington et al., 2014) for initialization. We fix the word representations during training.

We set the LSTM hidden unit size to 600 and set the number of layers of LSTMs to 2 in both the encoder and the decoder. Optimization is performed using stochastic gradient descent (SGD), with an initial learning rate of 1.0. We start halving the learning rate at epoch 8. The mini-batch size for the update is set at 64. Dropout with probability

Table 2: Automatic evaluation results of different systems by BLEU 1–4, METEOR and ROUGE_L. For a detailed explanation of the baseline systems, please refer to Section 5.3. The best performing system for each column is highlighted in boldface. Our system which encodes only sentence with pre-trained word embeddings achieves the best performance across all the metrics.

0.3 is applied between vertical LSTM stacks. We clip the gradient when the its norm exceeds 5.

All our models are trained on a single GPU. We run the training for up to 15 epochs, which takes approximately 2 hours. We select the model that achieves the lowest perplexity on the dev set.

During decoding, we do beam search with a beam size of 3. Decoding stops when every beam in the stack generates the `<EOS>` token.

All hyperparameters of our model are tuned using the development set. The results are reported on the test set.

5.3 Baselines

To prove the effectiveness of our system, we compare it to several competitive systems. Next, we briefly introduce their approaches and the experimental setting to run them for our problem. Their results are shown in Table 2.

IR stands for our information retrieval baselines. Similar to Rush et al. (2015), we implement the IR baselines to control memorizing questions from the training set. We use two metrics to calculate the distance between a question and the input sentence, *i.e.*, BM-25 (Robertson and Walker, 1994) and edit distance (Levenshtein, 1966). According to the metric, the system retrieves the training set to find the question with the highest score.

MOSES+ (Koehn et al., 2007) is a widely used phrase-based statistical machine translation system. Here, we treat sentences as source language text, we treat questions as target language text, and we perform the translation from sentences to questions. We train a tri-gram language model on target side texts with KenLM (Heafield et al., 2013), and tune the system with MERT on dev set. Performance results are reported on the test set.

DirectIn is an intuitive yet meaningful baseline in which the longest sub-sentence of the sentence is *directly* taken as the predicted question. [4] To split the sentence into sub-sentences, we use a set of splitters, *i.e.*, {"?", "!", ",", ".", ";"}.

H&S is the rule-based overgenerate-and-rank system that was mentioned in Section 2. When running the system, we set the parameter `just-wh` true (to restrict the output of the system to being only wh-questions) and set `max-length` equal to the longest sentence in the training set. We also set `downweight-pro` true, to down weight questions with unresolved pronouns so that they appear towards the end of the ranked list. For comparison with our systems, we take the top question in the ranked list.

Seq2seq (Sutskever et al., 2014) is a basic encoder-decoder sequence learning system for machine translation. We implement their model in Tensorflow. The input sequence is reversed before training or translating. Hyperparameters are tuned with dev set. We select the model with the lowest perplexity on the dev set.

[4] We also tried using the *entire* input sentence as the prediction output, but the performance is worse than taking sub-sentence as the prediction, across all the automatic metrics except for METEOR.

	Naturalness	Difficulty	Best %	Avg. rank
H&S	2.95	1.94	20.20	2.29
Ours	**3.36**	**3.03***	**38.38***	**1.94****
Human	3.91	2.63	66.42	1.46

Table 3: Human evaluation results for question generation. Naturalness and difficulty are rated on a 1–5 scale (5 for the best). Two-tailed t-test results are shown for our method compared to H&S (statistical significance is indicated with $^{*}(p < 0.005)$, $^{**}(p < 0.001)$).

5.4 Automatic Evaluation

We use the evaluation package released by Chen et al. (2015), which was originally used to score image captions. The package includes BLEU 1, BLEU 2, BLEU 3, BLEU 4 (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2014) and ROUGE_L (Lin, 2004) evaluation scripts. BLEU measures the average n-gram precision on a set of reference sentences, with a penalty for overly short sentences. BLEU-n is BLEU score that uses up to n-grams for counting co-occurrences. METEOR is a recall-oriented metric, which calculates the similarity between generations and references by considering synonyms, stemming and paraphrases. ROUGE is commonly employed to evaluate n-grams recall of the summaries with gold-standard sentences as references. ROUGE_L (measured based on longest common subsequence) results are reported.

5.5 Human Evaluation

We also perform human evaluation studies to measure the quality of questions generated by our system and the H&S system. We consider two modalities: *naturalness*, which indicates the grammaticality and fluency; and *difficulty*, which measures the sentence-question syntactic divergence and the reasoning needed to answer the question. We randomly sampled 100 sentence-question pairs. We ask four professional English speakers to rate the pairs in terms of the modalities above on a 1–5 scale (5 for the best). We then ask the human raters to give a ranking of the questions according to the overall quality, with ties allowed.

6 Results and Analysis

Table 2 shows automatic metric evaluation results for our models and baselines. Our model which only encodes sentence-level information achieves

Sentence 1: the largest of these is the eldon square shopping centre , one of the largest city centre shopping complexes in the uk .
Human: what is one of the largest city center shopping complexes in the uk ?
H&S: what is the eldon square shopping centre one of ?
Ours: what is one of the largest city centers in the uk ?

Sentence 2: free oxygen first appeared in significant quantities during the paleoproterozoic eon -lrb- between 3.0 and 2.3 billion years ago -rrb- .
Human: during which eon did free oxygen begin appearing in quantity ?
H&S: what first appeared in significant quantities during the paleoproterozoic eon ?
Ours: how long ago did the paleoproterozoic exhibit ?

Sentence 3: inflammation is one of the first responses of the immune system to infection .
Human: what is one of the first responses the immune system has to infection ?
H&S: what is inflammation one of ?
Ours: what is one of the first objections of the immune system to infection ?

Sentence 4: tea , coffee , sisal , pyrethrum , corn , and wheat are grown in the fertile highlands , one of the most successful agricultural production regions in Africa.
Human: (1) where is the most successful agricultural prodcution regions ? (2) what is grown in the fertile highlands ?
H&S: what are grown in the fertile highlands in africa ?
Ours: what are the most successful agricultural production regions in africa ?

Sentence 5: as an example , income inequality did fall in the united states during its high school movement from 1910 to 1940 and thereafter .
Human: during what time period did income inequality decrease in the united states ?
H&S: where did income inequality do fall during its high school movement from 1910 to 1940 and thereafter as an example ?
Ours: when did income inequality fall in the us ?

Sentence 6: however , the rainforest still managed to thrive during these glacial periods , allowing for the survival and evolution of a broad diversity of species .
Human: did the rainforest managed to thrive during the glacial periods ?
H&S: what are treaties establishing european union ?
Ours: why do the birds still grow during glacial periods ?

Sentence 7: maududi founded the jamaat-e-islami party in 1941 and remained its leader until 1972.
Human: when did maududi found the jamaat-e-islami party ?
H&S: who did maududi remain until 1972 ?
Ours: when was the jamaat-e-islami party founded ?

Figure 3: Sample output questions generated by human (ground truth questions), our system and the H&S system.

Category	(%)	H&S			Ours			Ours + paragraph		
		BLEU-3	BLEU-4	METEOR	BLEU-3	BLEU-4	METEOR	BLEU-3	BLEU-4	METEOR
w/ sentence	70.23 (243)	20.64	15.81	16.76	**24.45**	**17.63**	17.82	24.01	16.39	**19.19**
w/ paragraph	19.65 (68)	6.34	< 0.01	10.74	3.76	< 0.01	11.59	**7.23**	**4.13**	**12.13**
All*	100 (346)	19.97	14.95	16.68	23.63	**16.85**	17.62	**24.68**	16.33	**19.61**

Table 4: An estimate of categories of questions of the processed dataset and per-category performance comparison of the systems. The estimate is based on our analysis of the 346 pairs from the dev set. Categories are decided by the information needed to generate the question. Bold numbers represent the best performing method for a given metric. *Here, we leave out performance results for "w/ article" category (2 samples, 0.58%) and "not askable" category (33 samples, 9.54%).

the best performance across all metrics. We note that IR performs poorly, indicating that memorizing the training set is not enough for the task. The baseline DirectIn performs pretty well on BLEU and METEOR, which is reasonable given the overlap statistics between the sentences and the questions (Figure 2). H&S system's performance is on a par with DirectIn's, as it basically performs syntactic change without paraphrasing, and the overlap rate is also high.

Looking at the performance of our three models, it's clear that adding the pre-trained embeddings generally helps. While encoding the paragraph causes the performance to drop a little, this makes sense because, apart from useful information, the paragraph also contains much noise.

Table 3 shows the results of the human evaluation. We see that our system outperforms H&S in all modalities. Our system is ranked best in 38.4% of the evaluations, with an average ranking of 1.94. An inter-rater agreement of Krippendorff's Alpha of 0.236 is achieved for the overall ranking. The results imply that our model can generate questions of better quality than the H&S system.

For our qualitative analysis, we examine the sample outputs and the visualization of the alignment between the input and the output. In Figure 3, we present sample questions generated by H&S and our best model. We see a large gap between our results and H&S's. For example, in the first sample, in which the focus should be put on "the largest." Our model successfully captures this information, while H&S only performs some syntactic transformation over the input without paraphrasing. However, outputs from our system are not always "perfect", for example, in pair 6, our system generates a question about the reason why birds still grow, but the *most related* question would be why many species still grow. But from a different perspective, our question is more challenging (readers need to understand that birds are one kind of species), which supports our system's performance listed in human evaluations (See Table 3). It would be interesting to further investigate how to interpret why certain irrelavant words are generated in the question. Figure 4 shows the attention weights ($\alpha_{i,t}$) for the input sentence when generating each token in the question. We see that the key words in the output ("introduced", "teletext", etc.) aligns well with those in the input sentence.

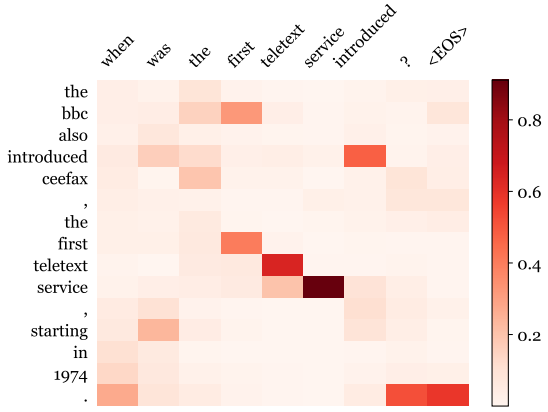

Figure 4: Heatmap of the attention weight matrix, which shows the soft alignment between the sentence (left) and the generated question (top).

Finally, we do a dataset analysis and fine-grained system performance analysis. We randomly sampled 346 sentence-question pairs from the dev set and label each pair with a category. [5] The four categories are determined by *how much* information is needed to ask the question. To be specific, "w/ sentence" means it only requires

[5]The IDs of the questions examined will be made available at https://github.com/xinyadu/nqg/blob/master/examined-question-ids.txt.

the sentence to ask the question; "w/ paragraph" means it takes other information in the paragraph to ask the question; "w/ article" is similar to "w/ paragraph"; and "not askable" means that world knowledge is needed to ask the question or there is mismatch of sentence and question caused by annotation error.

Table 4 shows the per-category performance of the systems. Our model which encodes paragraph information achieves the best performance on the questions of "w/ paragraph" category. This verifies the effectiveness of our paragraph-level model on the questions concerning information outside the sentence.

7 Conclusion and Future Work

We have presented a fully data-driven neural networks approach to automatic question generation for reading comprehension. We use an attention-based neural networks approach for the task and investigate the effect of encoding sentence- vs. paragraph-level information. Our best model achieves state-of-the-art performance in both automatic evaluations and human evaluations.

Here we point out several interesting future research directions. Currently, our paragraph-level model does not achieve best performance across all categories of questions. We would like to explore how to better use the paragraph-level information to improve the performance of QG system regarding questions of all categories. Besides this, it would also be interesting to consider to incorporate mechanisms for other language generation tasks (*e.g.*, copy mechanism for dialogue generation) in our model to further improve the quality of generated questions.

Joint Optimization of User-desired Content in Multi-document Summaries by Learning from User Feedback

Avinesh P.V.S and **Christian M. Meyer**

Abstract

In this paper, we propose an extractive multi-document summarization (MDS) system using joint optimization and active learning for content selection grounded in user feedback. Our method interactively obtains user feedback to gradually improve the results of a state-of-the-art integer linear programming (ILP) framework for MDS. Our methods complement fully automatic methods in producing high-quality summaries with a minimum number of iterations and feedbacks. We conduct multiple simulation-based experiments and analyze the effect of feedback-based concept selection in the ILP setup in order to maximize the user-desired content in the summary.

1 Introduction

The task of producing summaries from a cluster of multiple topic-related documents has gained much attention during the Document Understanding Conference[1] (DUC) and the Text Analysis Conference[2] (TAC) series. Despite a lot of research in this area, it is still a major challenge to automatically produce summaries that are on par with human-written ones. To a large extent, this is due to the complexity of the task: a good summary must include the most relevant information, omit redundancy and irrelevant information, satisfy a length constraint, and be cohesive and grammatical. But an even bigger challenge is the high degree of subjectivity in content selection, as it can be seen in the small overlap of what is considered important by different users. Optimizing a system towards one single best summary that fits all users, as it is assumed by current state-of-the-art systems, is highly impractical and diminishes the usefulness of a system for real-world use cases.

In this paper, we propose an interactive concept-based model to assist users in creating a personalized summary based on their feedback. Our model employs integer linear programming (ILP) to maximize user-desired content selection while using a minimum amount of user feedback and iterations. In addition to the joint optimization framework using ILP, we explore pool-based active learning to further reduce the required feedback. Although there have been previous attempts to assist users in single-document summarization, no existing work tackles the problem of multi-document summaries using optimization techniques for user feedback. Additionally, most existing systems produce only a single, globally optimal solution. Instead, we put the human in the loop and create a personalized summary that better captures the users' needs and their different notions of importance.

Need for personalization. Table 1 shows the ROUGE scores (Lin, 2004) of multiple existing summarization systems, namely TF*IDF (Luhn, 1958), LexRank (Erkan and Radev, 2004), TextRank (Mihalcea and Tarau, 2004), LSA (Gong and Liu, 2001), KL-Greedy (Haghighi and Vanderwende, 2009), provided by the sumy package[3] and ICSI[4] (Gillick and Favre, 2009; Boudin et al., 2015), a strong state-of-the-art approach (Hong et al., 2014) in comparison to the extractive upper bound on DUC'04 and DBS. DUC'04 is an English dataset of abstractive summaries from ho-

Table 1: ROUGE-1 (R1), ROUGE-2 (R2), and ROUGE-SU4 (SU4) scores of multiple systems compared to the extractive upper bound (UB)

mogenous news texts, whereas DBS (Benikova et al., 2016) is a German dataset of cohesive extracts from heterogeneous sources from the educational domain (see details in section 4.1). For each dataset, we compute an extractive upper bound (UB) by optimizing the sentence selection which maximizes ROUGE-2, i.e., the occurrence of bigrams as in the reference summary (Cao et al., 2016). Although some systems achieve state-of-the-art performance, their scores are still far from the extractive upper bound of individual reference summaries as shown in Figure 1. This is due to low inter-annotator agreement for concept selection: Zechner (2002) reports, for example, $\kappa = .13$ and Benikova et al. (2016) $\kappa = .23$. Most systems try to optimize for *all* reference summaries instead of personalizing, which we consider essential to capture user-desired content.

Need for user feedback. The goal of concept selection is finding the important information within a given set of source documents. Although existing summarization algorithms come up with a generic notion of importance, it is still far from the user-specific importance as shown in Figure 1. In contrast, humans can easily assess importance given a topic or a query. One way to achieve personalized summarization is thus by combining the advantages of both human feedback and the generic notion of importance built in a system. This allows users to interactively steer the summarization process and integrate their user-specific notion of importance.

Contributions. In this work, (1) we propose a novel ILP-based model using an interactive loop to create multi-document user-desired summaries, and (2) we develop models using pool-based active learning and joint optimization techniques to collect user feedback on identifying important concepts of a topic. In order to encourage the community to advance research and replicate our results, we provide our interactive summarizer implementation as open-source software.[5].

Our proposed method and our new interactive summarization framework can be used in multiple application scenarios: as an interactive annotation tool, which highlights important sentences for the annotators, as a journalistic writing aid that suggests important, user-adapted content from multiple source feeds (e.g., live blogs), and as a medical data analysis tool that suggests key information assisting a patient's personalized medical diagnosis.

The rest of the paper is structured as follows: In section 2, we discuss related work. Section 3

[5] https://github.com/UKPLab/acl2017-interactive_summarizer

introduces our computer-assisted summarization framework using the concept-based optimization. Section 4 describes our experiment data and setup. In section 5, we then discuss our results and analyze the performance of our models across different datasets. Finally, we conclude the paper in section 6 and discuss future work.

2 Related Work

Previous works related to our research address extractive summarization as a budgeted subset selection problem, computer-assisted approaches, and personalized summarization models.

Bugeted subset selection. Extractive summarization systems that compose a summary from a number of important sentences from the source documents are by far the most popular solution for MDS. This task can be modeled as a budgeted maximum coverage problem. Given a set of sentences in the document collection, the task is to maximize the coverage of the subset of sentences under a length constraint. The scoring function estimates the importance of the content units for a summary. Most previous works consider sentences as content units and try different scoring functions to optimize the summary.

One of the earliest systems by McDonald (2007) models a scoring function by simultaneously maximizing the relevance scores of the selected content units and minimizing their pairwise redundancy scores. They solve the global optimization problem using an ILP framework. Later, several state-of-the-art results employed an ILP to maximize the number of relevant concepts in the created summary: Gillick and Favre (2009) use an ILP with bigrams as concepts and hand-coded deletion rules for compression. Berg-Kirkpatrick et al. (2011) combine grammatical features relating to the parse tree and use a maximum-margin SVM trained on annotated gold-standard compressions. Woodsend and Lapata (2012) jointly optimize content selection and surface realization, Li et al. (2013) estimate the weights of the concepts using supervised methods, and Boudin et al. (2015) propose an approximation algorithm to achieve the optimal solution. Although these approaches achieve state-of-the-art performance, they produce only one globally optimal summary which is impractical for various users due to the subjectivity of the task. Therefore, we research interactive computer-assisted approaches in order to produce personalized summaries.

Computer-assisted summarization. The majority of the existing computer-assisted summarization tools (Craven, 2000; Narita et al., 2002; Orăsan et al., 2003; Orăsan and Hasler, 2006) present important elements of a document to the user. Creating a summary then requires the human to cut, paste, and reorganize the important elements in order to formulate a final text. The work by Orăsan and Hasler (2006) is closely related to ours, since they assist users in creating summaries for a source document based on the output of a given automatic summarization system. However, their system is neither interactive nor does it consider the user's feedback in any way. Instead, they suggest the output of the state-of-the-art (single-document) summarization method as a summary draft and ask the user to construct the summary without further interaction.

Personalized summarization. While most previous work focuses on generic summaries, there have been a few attempts to take a user's preferences into account. The study by Berkovsky et al. (2008) shows that users prefer personalized summaries that precisely reflect their interests. These interests are typically modeled with the help of a query (Park and An, 2010) or keyword annotations reflecting the user's opinions (Zhang et al., 2003).

In another strand of research, Díaz and Gervás (2007) create user models based on social tagging and Hu et al. (2012) rank sentences by combining informativeness scores with a user's interests based on fuzzy clustering of social tags. Extending the use of social content, another recent work showed how personalized review summaries (Poussevin et al., 2015) can be useful in recommender systems beyond rating predictions. Although these approaches show that personalized summaries are more useful than generic summaries, they do not attempt to iteratively refine a summary in an interactive user–system dialog.

3 Approach

The goal of our work is maximizing the user-desired content in a summary within a minimum number of iterations. To this end, we propose an interactive loop that alternates the automatic creation of a summary and the acquisition of user feedback to refine the next iteration's summary.

3.1 Summary Creation

Our starting point is the concept-based ILP summarization framework by Boudin et al. (2015). Let C be the set of concepts in a given set of source documents D, c_i the presence of the concept i in the resulting summary, w_i a concept's weight, ℓ_j the length of sentence j, s_j the presence of sentence j in the summary, and Occ_{ij} the occurrence of concept i in sentence j. Based on these definitions, we formulate the following ILP:

$$\max \quad \sum_i w_i c_i \tag{1}$$

$$\forall j. \quad \sum_j \ell_j s_j \leq L \tag{2}$$

$$\forall i, j. \quad \sum_j s_j Occ_{ij} \geq c_i \tag{3}$$

$$\forall i, j. \quad s_j Occ_{ij} \leq c_i \tag{4}$$

$$\forall i. \quad c_i \in \{0, 1\} \tag{5}$$

$$\forall j. \quad s_j \in \{0, 1\} \tag{6}$$

The objective function (1) maximizes the occurrence of concepts c_i in the summary based on their weights w_i. The constraint formalized in (2) ensures that the summary length is restricted to a maximum length L, (3) ensures the selection of all concepts in a sentence s_j if s_j has been selected for the summary. Constraint (4) ensures that a concept is only selected if it is present in at least one of the selected sentences.

The two key factors for the performance of this ILP are defining the concept set C and a method to estimate the weights $w_i \in W$. Previous works have used word bigrams as concepts (Gillick and Favre, 2009; Li et al., 2013; Boudin et al., 2015) and either use document frequency (i.e. the number of source documents containing the concept) as weights (Woodsend and Lapata, 2012; Gillick and Favre, 2009) or estimate them using a supervised regression model (Li et al., 2013). For our implementation, we likewise use bigrams as concepts and document frequency as weights, as Boudin et al. (2015) report good results with this simple strategy. Our approach is, however, not limited to this setup, as our interactive approach allows for any definition of C and W, including potentially more sophisticated weight estimation methods, e.g., based on deep neural networks. In section 5.2, we additionally analyze how other notions of concepts can be integrated into our approach.

3.2 Interactive Summarization Loop

Algorithm 1 provides an overview of our interactive summarization approach. The system takes the set of source documents D as input, derives the set of concepts C, and initializes their weights W. In line 5, we start the interactive feedback loop iterating over $t = 0, \ldots, T$. We first create a summary S_t (line 6) by solving the ILP and then extract a set of concepts Q_t (line 7), for which we query the user in line 11 As the user feedback in the current time step, we use the concepts $I_t \subseteq Q_t$ that have been considered important by the user. For updating the weights W in line 12, we may use all feedback collected until the current time step t, i.e., $I_0^t = \bigcup_{j=0}^{t} I_j$ and the set of concepts $Q_0^t = \bigcup_{j=0}^{t} Q_j$ seen by the user (with $Q_0^{-1} = \emptyset$). If there are no more concepts to query (i.e., $Q_t = \emptyset$), we stop the iteration and return the personalized summary S_t.

Algorithm 1 Interactive summarizer

```
1:  procedure INTERACTIVESUMMARIZER()
2:      input: Documents D
3:      C ← extractConcepts(D)
4:      W ← conceptWeights(C)
5:      for t = 0...T do
6:          S_t ← getSummary(C, W)
7:          Q_t ← extractConcepts(S_t) − Q_0^{t−1}
8:          if Q_t = ∅ then
9:              return S_t
10:         else
11:             I_t ← obtainFeedback(S_t, Q_t)
12:             W ← updateWeights(W, I_0^t, Q_0^t)
13:         end if
14:     end for
15: end procedure
```

3.3 User Feedback Optimization

To optimize the summary creation based on user feedback, we iteratively change the concept weights in the objective function of the ILP setup. We define the following models:

Accept model (ACCEPT). This model presents the current summary S_t with highlighted concepts Q_t to a user and asks him/her to select all important concepts I_t. We assign the maximum weight MAX to all concepts in I_t and consider the remaining $Q_t - I_t$ as unimportant by setting their weight to 0 (see equation 7 and 8). The intuition

behind this baseline is that the modified scores cause the ILP to prefer the user-desired concepts while avoiding unimportant ones.

$$\forall i \in I_0^t. \quad w_i = MAX \tag{7}$$

$$\forall i \in Q_0^t - I_0^t. \quad w_i = 0 \tag{8}$$

Joint ILP with User Feedback (JOINT). The ACCEPT model fails in cases where the user could not accept concepts that never appear in one of the S_t summaries. To tackle this, in our JOINT model, we change the objective function of the ILP in order to create S_t by jointly optimizing importance and user feedback. We thus replace the equation (1) with:

$$\max \begin{cases} \sum_{i \notin Q_0^t} w_i c_i - \sum_{i \in Q_0^t} w_i c_i & \text{if } t \leq \tau \\ \sum_i w_i c_i & \text{if } t > \tau \end{cases} \tag{9}$$

Equation (9) maximizes the use of concepts for which we yet lack feedback ($i \notin Q_0^t$) and minimizes the use of concepts for which we already have feedback ($i \in Q_0^t$). In this JOINT model, we use an exploration phase $t = 0 \ldots \tau$ to collect the feedback, which terminates when the user does not return any important concepts (i.e., $I_t = \emptyset$). In the exploratory phase, the minus term in the equation 9 helps to reduce the score of the sentences whose concepts have received feedback already. In other words, it causes higher scores for sentences consisting of concepts which yet lack feedback. After the exploration step, we fall back to the original importance-based optimization function from equation (1).

Active learning with uncertainty sampling (AL). Our JOINT model explores well in terms of prioritizing the concepts which yet lack user feedback. However, it gives equal probabilities to all the unseen concepts. The AL model employs pool-based active learning (Kremer et al., 2014) during the exploration phase in order to prioritize concepts for which the model is most uncertain. We distinguish the unlabeled concept pool $C_u = \{\Phi(\tilde{x}_1), \Phi(\tilde{x}_2), ..., \Phi(\tilde{x}_N)\}$ and the labeled concept pool $C_\ell = \{(\Phi(x_1), y_1), (\Phi(x_2), y_2), \ldots, (\Phi(x_N), y_N)\}$, where each concept x_i is represented as a d-dimensional feature vector $\Phi(x_i) \in \mathbb{R}^d$. The labels $y_i \in \{-1, 1\}$ are 1 for all important concepts in I_0^t and -1 for all unimportant concepts in $Q_0^t - I_0^t$. Initially, the labeled concept pool C_ℓ is small or empty, whereas the unlabeled concept pool C_u is relatively large.

The learning algorithm is presented with a $C = C_\ell \cup C_u$ and is first called to learn a decision function $f^{(0)}\colon \mathbb{R}^d \rightarrow \mathbb{R}$, where the function $f^{(0)}(\Phi(\tilde{x}))$ is taken to predict the label of the input vector $\Phi(\tilde{x})$. Then, in each t^{th} iteration, where $t = 1, 2, \ldots, \tau$, the querying algorithm selects an instance of $\tilde{x}_t \in C_u$ for which the learning algorithm is least certain. Thus, our learning goal of active learning is to minimize the expected loss $\mathcal{L}$ (i.e., hinge loss) with limited querying opportunities to obtain a decision function $f^{(1)}, f^{(2)}, \ldots, f^{(\tau)}$ that can achieve low error rates:

$$\min \mathbb{E}_{(\Phi(x),y) \in C_\ell} \left[\mathcal{L}(f^{(t)}(\Phi(x)), y) \right] \tag{10}$$

As the learning algorithm, we use a support vector machine (SVM) with a linear kernel. To obtain the probability distribution over classes we use Platt's calibration (Platt, 1999), an effective approach for transforming classification models into a probability distribution. Equation (11) shows the probability estimates for $f^{(t)}$, where $f^{(t)}$ is the uncalibrated output of the SVM in the t^{th} iteration and A, B are scalar parameters that are learned by the calibration algorithm. The uncertainty scores are calculated as described in the equation (12) for all the concepts which lack feedback (C_u).

$$p(y \mid f^{(t)}) = \frac{1}{1 + \exp(Af^{(t)} + B)} \tag{11}$$

$$u_i = 1 - \max_{y \in \{-1,1\}} p(y \mid f^{(t)}) \tag{12}$$

For our AL model, we now change the objective function in order to create S_t by multiplying uncertainty scores u_i to the weights w_i. We thus replace the objective function from (9) with

$$\max \begin{cases} \sum_{i \notin Q_0^t} u_i w_i c_i & \text{if } t \leq \tau \\ \sum_i w_i c_i & \text{if } t > \tau \end{cases} \tag{13}$$

Active learning with positive sampling (AL+). One way to sample the unseen concepts is using uncertainty as in AL, but another way is to actively choose samples for which the learning algorithm predicts as a possible important concept. In AL+, we introduce the notion of certainty $(1 - u_i)$ for the positively predicted samples ($f^{(t)}(\Phi(\tilde{x}_i)) = 1$) in

Dataset	Lang	Topics	Summary type	Length

Table 2: Statistics of the MDS datasets used

the objective function (1) for producing S_t

$$\max \begin{cases} \sum_{i \notin Q_0^t} (1 - u_i) \ell_i w_i c_i & \text{if } t \leq \tau \\ \sum_i w_i c_i & \text{if } t > \tau \end{cases} \quad (14)$$

$$\text{where } \ell_i = \begin{cases} 0 & \text{if } f^{(t)}(\Phi(\tilde{x}_i)) = -1 \\ 1 & \text{if } f^{(t)}(\Phi(\tilde{x}_i)) = 1 \end{cases} \quad (15)$$

4 Experimental Setup

4.1 Data

For our experiments, we mainly focus on the DBS corpus, which is an MDS dataset of coherent extracts created from heterogeneous sources about multiple educational topics (Benikova et al., 2016). This corpus is well-suited for our evaluation setup, since we are able to easily simulate a user's feedback based on the overlap between generated and reference summary.

Additionally, we carry out experiments on the most commonly used evaluation corpora published by DUC/NIST from the generic multi-document summarization task carried out in DUC'01, DUC'02 and DUC'04. The documents are all from the news domain and are grouped into various topic clusters. Table 2 shows the properties of these corpora.

For evaluating the summaries against the reference summary we use ROUGE (Lin, 2004) with the parameters suggested by (Owczarzak et al., 2012) yielding high correlation with human judgments (i.e., with stemming and without stopword removal).[6] Since DBS summaries do not have a fixed length, we use a variable length parameter L for evaluation, where L denotes the length of the reference summary. All results are averaged across all topics and reference summaries.

4.2 Data Pre-processing and Features

To pre-process the datasets, we perform tokenization and stemming with NLTK (Loper and Bird, 2002) and constituency parsing with the Stanford parser (Klein and Manning, 2003) for English and German. The parse trees will be used in section 5.2 below to experiment with a syntactically motivated concept notion.

As a concept's feature representation Φ for our active learning setups AL and AL+, we use pre-trained word embeddings. We use the Google News embeddings with 300 dimensions by Mikolov et al. (2013) for English and the 100-dimensional news- and Wikipedia-based embeddings by Reimers et al. (2014) for German. Additionally, we add TF*IDF, number of stop words, presence of named entities, and word capitalization as features. Discrete features, such as part-of-speech tags, are mapped into the word representation via lookup tables.

4.3 Oracle-Based Simulation of User Feedback

The presence of a human in the loop typically demands for a user study based evaluation, but to collect sufficient data for various settings of our models would be too expensive. Therefore, we resort to an oracle-based approach, where the oracle is a system simulating the user by generating the feedback based on reference outputs. This idea has been widely used in the development of interactive systems (González-Rubio et al., 2012; Knowles and Koehn, 2016) for studying the problem and exhibiting solutions in a theoretical and controlled environment.

To simulate user feedback in our setting, we consider all concepts $I_t \subseteq Q_t$ from the system-suggested summary S_t as important if they are present in the reference summary. Let Ref be the set of concepts in the reference summary. In the t^{th} iteration, we return $I_t = Q_t \cap Ref$ as the simulated user feedback. Thus, the goal of our system is to reach the upper bound for a user's reference summary within a minimal number of iterations.

We limit our experiments to ten iterations, since it appears unrealistic that users are willing to participate in more feedback cycles. Petrie and Bevan (2009) even report only three to five iterations.

5 Results and Analysis

5.1 Methods

Table 3 shows the evaluation results of our four models. When evaluating a summarization system, it is common to report the mean ROUGE scores across clusters using all the reference summaries. However, since we aim at personalizing

Table 4: Average amount of user feedback (#F) considered by our models at the end of the tenth iteration of the interactive summarization loop

the summary for an individual user, we evaluate our models based on the mean ROUGE scores across clusters per reference summary. In Table 4, we additionally evaluate the models based on the amount of feedback (#F $= |I_0^T|$) taken by the oracles to converge to the upper bound within ten iterations.

To examine the system performance based on user feedback, we analyze our models' performance on multiple datasets. The results in Table 3 show that our idea of interactive multi-document summarization allows users to steer a general summary towards a personalized summary consistently across all datasets. From the results, we can see that the AL model starts from the concept-based ILP summarization and nearly reaches the upper bound for all the datasets within ten iterations. AL+ performs similar to AL in terms of ROUGE, but requires less feedback (compare Table 4). Furthermore, the ACCEPT and JOINT models get stuck in a local optimum due to the less exploratory nature of the models.

5.2 Concept Notion

Our interactive summarization approach is based on the scalable global concept-based model which uses bigrams as concepts. Thus, it is intuitive to use bigrams for collecting user feedback as well.[7] Although our models reach the upper bound when using bigram-based feedback, they require a significantly large number of iterations and much feedback to converge, as shown in Table 4.

To reduce the amount of feedback, we also consider content phrases to collect feedback. That is, syntactic chunks from the constituency parse trees consisting of non-function words (i.e., nouns, verbs, adjectives, and adverbs). For DBS being extractive dataset, we use bigrams and content phrases as concepts, both for the objective function in equation (1) and as feedback items, whereas for the DUC datasets, the concepts are always bigrams for both the feedback types (bigrams/content phrases). For DUC being abstractive, in the case of feedback given on content phrases, they are projected back to the bigrams to change the concept weights in order to have more overlap of simulated feedback. Table 4 shows feedbacks based on the content phrases reduces the number of feedbacks by a factor of 2. Furthermore, when content phrases are used as concepts for DBS, the performance of the models is lower compared to bigrams, as seen in Table 3.

5.3 Datasets

Figure 2 compares the ROUGE-2 scores and the amount of feedback used over time when applied to the DBS and the DUC'04 corpus. We can see from the figure that all models show an improvement of +.45 ROUGE-2 after merely 4 iterations

[7] We prune bigrams consisting of only functional words.

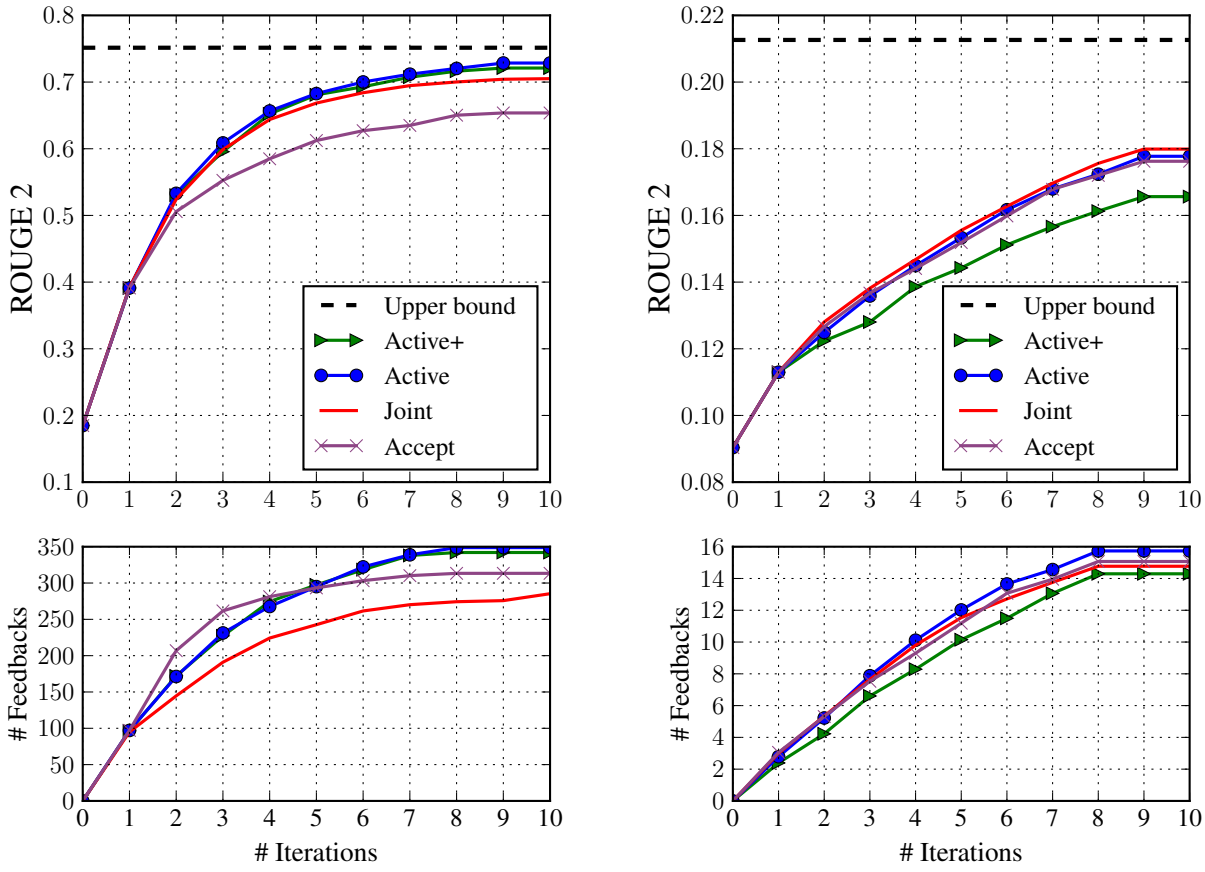

Figure 2: Analysis for the models over the DBS (left) and DUC'04 (right) datasets

on DBS. For DUC'04, the improvements are +.1 ROUGE-2 after ten iterations, which is relatively notable considering the lower upper bound of .21 ROUGE-2. This is primarily because DBS is a corpus of cohesive extracts, whereas DUC'04 consists of abstractive summaries. As a result, the oracles created using abstractive reference summaries have lower overlap of concepts as compared to that of the oracles created using extractive summaries.

For DBS, it becomes clear that the JOINT model converges faster with an optimum amount of feedback as compared to other models. ACCEPT takes relatively more feedbacks than JOINT, but performs low in terms of ROUGE scores. The best performing models are AL and AL+, which reach closest to the upper bound. This is clearly due to the exploratory nature of the models which use semantic representations of the concepts to predict uncertainty and importance of possible concepts for user feedback.

For DUC'04, the JOINT model reaches the closest to the upper bound, closely followed by AL. The JOINT model consistently stays above all other models and it gathers more important concepts due to optimizing feedbacks for concepts which lack feedback. Interestingly, AL+ performs rather worse in terms of both ROUGE scores and gathering important concepts. The primary reason for this is the fewer feedback collected from the simulation due to the abstractive property of reference summaries, which makes the AL+ model's prediction inconsistent.

5.4 Personalization

Figure 3 shows the performance of different models in comparison to two different oracles for the same document cluster. For DBS, the JOINT, AL, and AL+ models consistently converge to the upper bound in 4 iterations for different oracles, whereas ACCEPT takes longer for one oracle and does not reach the upper bound for the other.

For DUC'04, JOINT and AL show consistent performance across the oracles, whereas AL+ performs worse than the state-of-the-art system (iteration 0) for oracle created using abstractive summaries as shown in Figure 3 (right) for User:1.

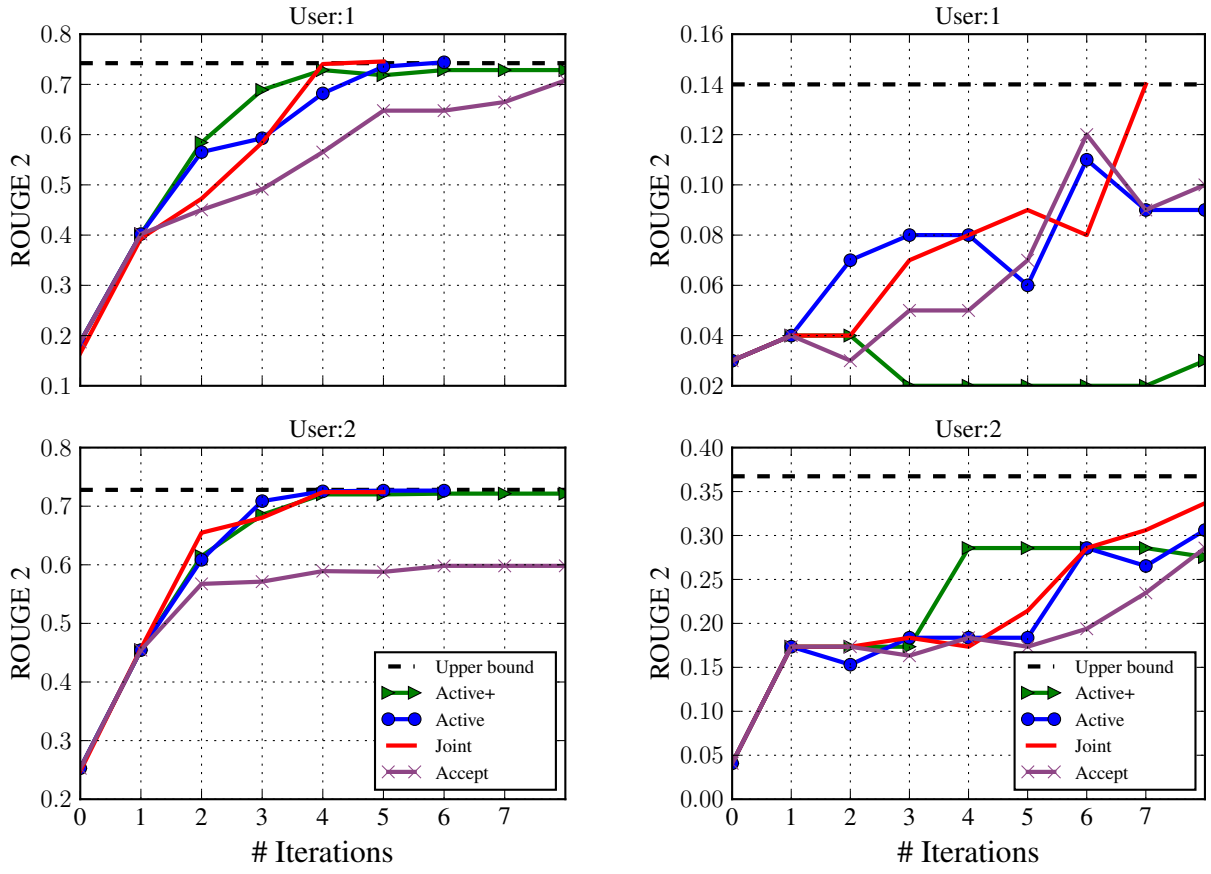

Figure 3: Analysis of models over cluster 7 from DBS (left) and cluster d30051t from DUC'04 (right) respectively for different oracles

However, for User:2, we observe a ROUGE-2 improvement of +.1 indicating that the predictions of the active learning system are better if there is more feedback. Nevertheless, we expect that in practical use, the human summarizers may give more feedback similar to DBS in comparison to DUC'04 simulation setting.

6 Conclusion and Future Work

We propose a novel ILP-based approach using interactive user feedback to create multi-document user-desired summaries. In this paper, we investigate pool-based active learning and joint optimization techniques to collect user feedback for identifying important concepts for a summary. Our models show that interactively collecting feedback consistently steers a general summary towards a user-desired personalized summary. We empirically checked the validity of our approach on standard datasets using simulated user feedback and observed that our framework shows promising results in terms of producing personalized multi-document summaries.

As future work, we plan to investigate more sophisticated sampling strategies based on active learning and concept graphs to incorporate lexical-semantic information for concept selection. We also plan to look into ways to propagate feedback to similar and related concepts with partial feedback, to reduce the total amount of feedback. This is a promising direction as we have shown that interactive methods help to create user-desired personalized summaries, and with minimum amount of feedbacks, it has propitious use in scenarios where user-adapted content is a requirement.

Abstract

It has been shown that Chinese poems can be successfully generated by sequence-to-sequence neural models, particularly with the attention mechanism. A potential problem of this approach, however, is that neural models can only learn abstract rules, while poem generation is a highly creative process that involves not only rules but also innovations for which pure statistical models are not appropriate in principle. This work proposes a memory-augmented neural model for Chinese poem generation, where the neural model and the augmented memory work together to balance the requirements of linguistic accordance and aesthetic innovation, leading to innovative generations that are still rule-compliant. In addition, it is found that the memory mechanism provides interesting flexibility that can be used to generate poems with different styles.

1 Introduction

Classical Chinese poetry is a special cultural heritage with over 2,000 years of history and is still fascinating us today. Among the various genres, perhaps the most popular one is the quatrain, a special style with a strict structure (four lines with five or seven characters per line), a regulated rhythmical form (the last characters in the second and fourth lines must follow the same rhythm), and a required tonal pattern (tones of characters in some positions should satisfy a predefined regulation) (Wang, 2002). This genre flourished mostly in the Tang Dynasty, and so are often called 'Tang poems'. An example of a quatrain written by Wei Wang, a famous poet in the Tang Dynasty, is shown in Table 1.

Due to the stringent restrictions in both rhythm and tone, it is not trivial to create a fully rule-compliant quatrain. More importantly, besides such strict regulations, a good quatrain should also read fluently, hold a consistent theme, and express a unique affection. Therefore, poem generation is widely recognized as a very intelligent activity and can be performed only by knowledgeable people with a lot of training.

乐游原
Climbing the Paradise Mound
向晚意不适， (* Z Z P Z)
As I was not in a good mood this evening round,
驱车登古原。(P P P Z P)
I went by cart to climb the Ancient Paradise Mound.
夕阳无限好， (* P P Z Z)
It is now nearing dusk,
只是近黄昏。(* Z Z P P)
When the setting sun is infinitely fine, which is a must.

Table 1: An example of a 5-char quatrain. The tonal pattern is shown at the end of each line, where 'P' indicates a level tone, 'Z' indicates a downward tone, and '*' indicates the tone can be either. The translation is from (Tang, 2005).

In this paper we are interested in machine poetry generation. Several approaches have been studied by researchers. For example, rule-based methods (Zhou et al., 2010), statistical machine translation (SMT) models (Jiang and Zhou, 2008; He et al., 2012) and neural models (Zhang and Lapata, 2014; Wang et al., 2016a,c). Compared to previ-

https://doi.org/10.18653/v1/P17-1125

ous approaches (e.g., rule-based or SMT), the neural model approach tends to generate more fluent poems and some generations are so natural that even professional poets can not tell they are the work of machines (Wang et al., 2016a).

In spite of these promising results, neural models suffer from a particular problem in poem generation, a lack of innovation. Due to the statistical nature of neural models, they pay much more attention to high-frequency patterns, whereas they ignore low-frequency ones. In other words, the more regular and common the patterns, the better the neural model is good at learning them and tends to use them more frequently at run-time. This property certainly helps to generate fluent sentences, but it is not always useful: the major value of poetry is not fluency, but the aesthetic innovation that can stimulate some unique feelings. This is particularly true for Chinese quatrains that are highly compact and expressive: it is nearly impossible to find two similar works in the thousands of years of history in this genre, demonstrating the importance of uniqueness or innovation. Ironically, the most important thing, innovation, is largely treated as trivial, if not noise, by present neural models.

Actually this problem is shared by all generation models based on statistics (although it is more serious for neural models) and has aroused a long-standing criticism for machine poem generation: it can generate, and sometimes generate well, but the generation tends to be unsurprising and not particularly interesting. More seriously, this problem exists not only in poem generation, but also in all generation tasks that require innovation.

This paper tries to solve this extremely challenging problem. We argue that the essential problem is that statistical models are good at learning general rules (usage of regular words and their combinations) but are less capable of remembering special instances that are difficult to cover with general rules. In other words, there is only rule-based reasoning, no instance-based memory. We therefore present a memory-augmented neural model which involves a neural memory so that special instances can be saved and referred to at run-time. This is like a human poet who creates poems by not only referring to common rules and patterns, but also recalls poems that he has read before. It is hard to say whether this combination of rules and instances produces true innovation (which often requires real-life motivation rather than simple word reordering), but it indeed offers interesting flexibility to generate new outputs that look creative and are still rule-compliant. Moreover, this flexibility can be used in other ways, e.g., generating poems with different styles.

In this paper, we use the memory-augmented neural model to generate flexible and creative Chinese poems. We investigate three scenarios where adding a memory may contribute: the first scenario involves a well trained neural model where we aim to promote innovation by adding a memory, the second scenario involves an over-fitted neural model where we hope the memory can regularize the innovation, and in the third scenario, the memory is used to encourage generation of poems of different styles.

2 Related Work

A multitude of methods have been proposed for automatic poem generation. The first approach is based on rules and/or templates. For example, phrase search (Tosa et al., 2009; Wu et al., 2009), word association norm (Netzer et al., 2009), template search (Oliveira, 2012), genetic search (Zhou et al., 2010), text summarization (Yan et al., 2013). Another approach involves various SMT methods, e.g., (Jiang and Zhou, 2008; He et al., 2012). A disadvantage shared by the above methods is that they are based on the surface forms of words or characters, having no deep understanding of the meaning of a poem.

More recently, neural models have been the subject of much attention. A clear advantage of the neural-based methods is that they can 'discover' the meaning of words or characters, and can therefore more deeply understand the meaning of a poem. Here we only review studies on Chinese poetry generation that are mostly related to our research. The first study we have found in this direction is the work by Zhang and Lapata (2014), which proposed an RNN-based approach that produces each new line character-by-character using a recurrent neural network (RNN), with all the lines generated already (in the form of a vector) as a contextual input. This model can generate quatrains of reasonable quality. Wang et al. (2016b) proposed a much simpler neural model that treats a poem as an entire character sequence, and poem generation is conducted character-by-character. This approach can be

easily extended to various genres such as Song Iambics. To avoid theme drift caused by this long-sequence generation, Wang et al. (2016b) utilized the neural attention mechanism (Bahdanau et al., 2014) by which human intention is encoded by an RNN to guide the generation. The same model was used by Wang et al. (2016a) for Chinese quatrain generation. Yan (2016) proposed a hierarchical RNN model that conducts iterative generation. Recently, Wang et al. (2016c) proposed a similar sequence generation model, but with the difference that attention is placed not only on the human input, but also on all the characters that have been generated so far. They also proposed a topic planning scheme to encourage a smooth and consistent theme.

All the neural models mentioned above try to generate fluent and meaningful poems, but none of them consider innovation. The memory-augmented neural model proposed in this study intends to address this issue. Our system was built following the model structure and training strategy proposed by Wang et al. (2016a) due to its simplicity and demonstrated quality, but the memory mechanism is general and can be applied to any of the models presented above.

The idea of memory argumentation was inspired by the recent advance in neural Turing machine (Graves et al., 2014, 2016) and memory network (Weston et al., 2014). These new models equip neural networks with an external memory that can be accessed and manipulated via some trainable operations. In comparison, the memory in our work plays a simple role of knowledge storage, and the only operation is simple pre-defined READ. In this sense, our model can be regarded as a simplified neural Turing machine that omits training.

3 Memory-augmented neural model

In this section, we first present the idea of memory augmentation, and then describe the model structure and training method.

3.1 Memory augmentation

The idea of memory augmentation is illustrated in Fig. 1. It contains two components, the neural model component on the left, and the memory component on the right. In this work, the attention-based RNN generation model presented by (Wang et al., 2016a) is used as the neural model component, although any neural model is suitable. The memory component involves a set of 'direct' mappings from input to output, and therefore can be used to memorize some special cases of the generation that can not be represented by the neural model. For poem generation, the memory stores the information regarding which character should be generated in a particular context. The output from the two components are then integrated, leading to a consolidated output.

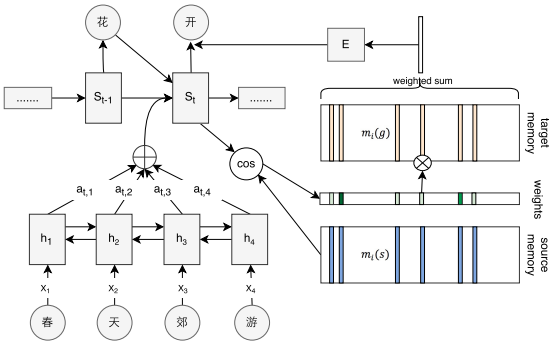

Figure 1: The memory-augmented neural model used for Chinese poetry generation.

There are several ways to understand the memory-augmented neural model. Firstly, it can be regarded as a way of combining reasoning (neural model) and knowledge (memory). Secondly, it can be regarded as a way of combining rule-based inference (neural model) and instance-based retrieval (memory). Thirdly, it can be regarded as a way of combining predictions from complementary systems, where the neural model is continuous and parameter-shared, while the memory is discrete and contains no parameter sharing. Finally, the memory can be regarded as an effective regularization that constrains and modifies the behavior of the neural model, resulting in generations with desired properties. Note that this memory-augmented neural model is inspired by and related to the memory network proposed by Weston et al.(2014) and Graves et al.(2016), but we more focus on an accompanying memory that plays the role of assistance and regularization.

3.2 Model structure

Using the Chinese poetry generation model shown in Fig. 1 as an example, this section discusses the creation of a memory-augmented neural model. Firstly, the neural model part is an attention-based sequence-to-sequence model (Bahdanau et al., 2014). The encoder is a bi-

directional RNN (with GRU units) that converts the input topic words, denoted by the embeddings of the compositional characters $(x_1, x_2, ..., x_N)$, into a sequence of hidden states $(h_1, h_2, ..., h_N)$. The decoder then generates the whole quatrain character-by-character, denoted by the corresponding embeddings $(y_1, y_2, ...)$. At each step t, the prediction for the state s_t is based on the last generation y_{t-1}, the previous status s_{t-1} of the decoder, as well as all the hidden states $(h_1, h_2, ...)$ of the encoder. Each hidden state h_i contributes to the generation according to a relevance factor α_t that measures the similarity between s_{t-1} and h_i. This is written as:

$$s_t = f_d(y_{t-1}, s_{t-1}, \sum_{i=1}^{N} \alpha_{t,i} h_i)$$

where $\alpha_{t,i}$ represents the contribution of h_i to the present generation, and can be implemented as any function. The output of the model is a posterior probability over the whole set of characters, written by

$$z_t = \sigma(s_t W)$$

where W is the projection parameter.

The memory consists of a set of elements $\{m_i\}_{i=1}^{K}$, where K is the size of the memory. Each element m_i involves two parts, the source part $m_i(s)$, that encodes the context, i.e. when this element should be selected, and the target part $m_i(g)$, that encodes what should be output if this element is selected. In our study, the neural model is firstly trained, and then the memory is created by running f_d (the decoder of the neural model). Specifically, for the k-th poem selected to be in the memory, the character sequence is input to the decoder one by one, with the contribution from the encoder set to zero. Denoting the starting position of this poem in the memory is p_k, the status of the decoder at the j-th step is used as the source part of the $(p_k + j)$-th element of the memory, and the embedding of the corresponding character, x_j, is set to be the target part. this is formally written as:

$$m_i(s) = f_d(x_{j-1}, s_{j-1}, 0) \quad (1)$$

and

$$m_i(g) = x_j$$

where

$$i = p_k + j.$$

At run-time, the memory elements are selected according to their fit to the present decoder status s_t, and then the outputs of the selected elements are averaged as the output of the memory component. We choose cosine distance to measure the fitting degree, and have[1]:

$$v_t = \sum_{i=1}^{K} cos(s_t, m_i(s)) m_i(g). \quad (2)$$

The output of the neural model and the memory can be combined in various ways. Here, a simple linear combination before the softmax is used, i.e.,

$$z_t = \sigma(s_t W + \beta v_t E) \quad (3)$$

where β is a pre-defined weighting factor, and E contains word embeddings of all the characters. Although it is possible to train β from the data, we found that the learned β is not better than the manually-selected one. This is probably because β is a factor to trade-off the contribution from the model and the memory, and how to make the trade-off should be a 'prior knowledge' rather than a tunable parameter. In fact, if it is trained, than it will be immediately adapted to match the training data, which will nullify our effort to encourage innovative generation.

3.3 Model Training

In our implementation, only the neural model component is required to be trained. The training algorithm follows the scheme defined in (Wang et al., 2016a), where the cross entropy between the distributions over Chinese characters given by the decoder and the ground truth is used as the objective function. The optimization uses the SGD algorithm together with AdaDelta to adjust the learning rate (Zeiler, 2012).

4 Memory augmentation for Chinese poetry generation

This section describes how the memory mechanism can be used to trade-off between the requirements for rule-compliant generation and aesthetic innovation, and how it can also be used to do more interesting things, for example style transfer.

4.1 Memory for innovative generation

In this section, we describe how the memory mechanism promotes innovation. Monitoring the

[1] In fact, we run a parallel decoder to provide s_t in Eq.(2). This decoder does not accept input from the encoder and so is consistent with the memory construction process as Eq.(1).

training process for the attention-based model, we found that the cost on the training set will keep decreasing until approaching zero, but on the validation set, the degradation stops after only one iteration. This can be explained by the fact that Chinese quatrains are highly unique, so the common patterns can be fully learned in one iteration, resulting in overfitting with additional iterations. Due to the overfitting, we observe that with the one-iteration model, reasonable poems can be generated, and with the over-fitted model, the generated poems are meaningless, in that they do not resemble feasible character sequences.

The energy model perspective helps to explain this difference. For the one-iteration model, the energy surface is smooth and the energy of the training data is not very low, as illustrated in plot (a) in Fig. 2, where the x-axis represents the input and y-axis represents the output, and the z-axis represents the energy. With this model, inputs with small variance will be attracted to the same low-energy area, leading to similar generations. These generations are trivial, but at least reasonable. If the model is overfitted, however, the energy at the locations of the training data becomes much lower than their surrounding areas, leading to a bumpy energy surface as shown in plot (b) in Fig. 2. With this model, inputs with a small variation may be attracted to very different low-energy areas, leading to significantly different generations. Since many of the low-energy areas are nothing to do with good generations but are simply caused by the complex energy function, the generations can be highly surprising for human readers, and the quality is not guaranteed. In some sense, these generations can be regarded as 'innovative' , but based on observations made in our experiments, most of them are meaningless.

The augmented memory introduces a new energy function, which is combined with the energy function of the neural model to change the energy surface of the generation system. This can be seen in Eq. (3), where $s_t W$ and $\beta v_t E$ can be regarded as the energy function of the neural model component and the memory component, respectively, and the energy function of the memory-augmented system is the sum of the energy functions of these two components. For this reason, the effect of the memory mechanism can be regarded as a regularization of the neural model that will adjust its generation behavior.

This regularization effect is illustrated in Fig. 2, where the energy function of the memory shown in plot (c) is added to the energy function of the one-iteration model and the overfitted model, as shown in plot (e) and plot (f) respectively. It can be seen that with the memory involved, the energy surface becomes more bumpy with the one-iteration model, and more smooth with the overfitted model. In the former case, the effect of the memory is to encourage innovation, while still focusing on rule-compliance, and in the latter case, the effect is to encourage rule compliance, while keeping the capability for innovation.

It is important to notice that the energy function of the memory component is a linear combination of the energy functions of the compositional elements (see Eq.(2)), each of which is convex and is minimized at the location represented by the element. This means that the energy surface of the memory is rather 'healthy', in the sense that low-energy locations mostly correspond to good generations. For this reason, the regularization provided by the memory is safe and helpful.

4.2 Memory for style transfer

The effect of the memory is easy to control. For example, the complexity of the behavior can be controlled by the memory size, the featured bias can be controlled by memory selection, and the strength of the impact can be controlled by the weighting parameter β. This means that the memory mechanism is very flexible and can be used to produce poems with desired properties.

In this work, we use these capabilities to generate poems with different styles. This has been illustrated in Fig. 2, where the energy function of the style memory shown in plot (d) is biased towards a particular style, and once it is added to energy function of the one-iteration model, the resulting energy function shown in plot (g) obtains lower values at locations corresponding to the locations of the memory, which encourages generation of poems with similar styles as those poems in the memory.

5 Experiments

This section describes the experiments and results carried out in this paper. Here, The baseline system was a reproduction of the Attention-based system presented in (Wang et al., 2016a). the model in This system has been shown to be rather flexi-

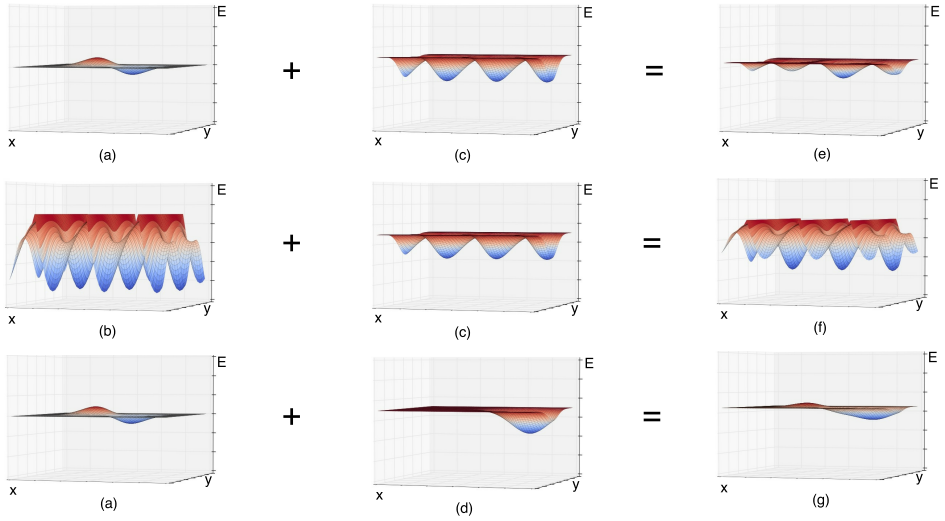

Figure 2: The energy surface for (a) one-iteration model (b) overfitted model (c) memory (d) style memory (e) one-iteration model augmented with memory (f) overfitted model augmented with memory (g) one-iteration model augmented with style memory.

ble and powerful: it can generate different genres of Chinese poems, and when generating quatrains it has been shown to be able to fool human experts in many cases (Wang et al., 2016a) and the authors had did a thorough comparison with competitive methods mentioned in the related work of this paper. We obtained the database and the source code (in theano), and reproduced their system using Tensorflow from Google[2]. We didn't make comparisons with some previous methods such as NNLM, SMT, RNNPG as they had been fully compared in (Wang et al., 2016a) and all of them were much worse than the attention-based system. Another reason was that the experts were not happy to evaluate poems with clearly bad quality. We also reproduced the model in (Wang et al., 2016c) with the help of the first author. However, since their implementation did not involve any restrictions on rhythm and tone, the experts were reluctant to recognize them as good poems. With a larger dataset (e.g., 1 Million poems), it is assumed that the rhythm and tone can be learned and their system would be good in both fluency and rule compliance. It should be also emphasized that the memory approach proposed in this paper is a general technique and is complementary to other efforts such as the planning approach (Wang et al., 2016c) and the recursive approach (Yan, 2016).

Based on the baseline system, we built the memory-augmented model, and conducted two experiments to demonstrate its power. The first is an innovation experiment which employs memory to promote or regularize the generation of innovative poems, and the second is a style-transfer experiment which employs memory to generate flexible poems in different styles.

We invited 34 experts to participate in the experiments, and all of them have rich experience not only evaluating poems, but also in writing them. Most of the experts are from prestigious institutes, including Peking university and the Chinese Academy of Social Science (CASS). Following the suggestions of the experts, we use five metrics to evaluate the generation, as listed below:

- Compliance: if regulations on tones and rhymes are satisfied;
- Fluency: if the sentences read fluently and convey reasonable meaning;
- Theme consistency: if the entire poem adheres to a single theme;
- Aesthetic innovation: if the quatrain stimulates any aesthetic feeling with elaborate innovation;
- Scenario consistency: if the scenario remains consistent.

5.1 Datasets

The baseline system was built with two customized datasets. The first dataset is a Chinese po-

[2]https://www.tensorflow.org/

em corpus (CPC), which we used in this work to train the embeddings of Chinese characters. Our CPC dataset contains 284,899 traditional Chinese poems in various genres, including Tang quatrains, Song Iambics, Yuan Songs, and Ming and Qing poems. This large quantity of data ensures reliable learning for the semantic content of most Chinese characters.

Our second dataset is a Chinese quatrain corpus (CQC) that we have collected from the internet, which consists of $13,299$ 5-char quatrains and $65,560$ 7-char quatrains. This corpus was used to train the attention-based RNN baseline. We filtered out the poems whose characters are all low-frequency (less than 100 counts in the database). After the filtering, the remaining corpus contains 9,195 5-char quatrains and 49,162 7-char quatrains. We used 9,000 5-char and 49,000 7-char quatrains to train the attention model, and the rest for validation.

Another two datasets were created for use in the memory-augmented system. Our first dataset, MEM-I, contains 500 quatrains randomly selected from our CQC corpus. This dataset was used to produce the memory in the innovation experiment; the second dataset, MEM-S, contains 300 quatrains with clear styles, including 100 pastoral, 100 battlefield and 100 romantic quatrains. It was used to generate memory with different styles in the style-transfer experiment. All the datasets will be released online[3].

5.2 Evaluation Process

We invited 34 experts to evaluate the quality of the poem generation. In the innovation experiment, the evaluation consisted of a comparison between different systems and configurations in terms of the five metrics. The innovation questions presented the expert with two poems, and asked them to judge which of the poems was better in terms of the five metrics; in the style-transfer experiment, the evaluation was performed by identifying the style of a generated poem. The evaluation was conducted online, with each questionnaire containing 11 questions focusing on innovation and 4 questions concerned with style-transfer. Each of the style-transfer questions presented the expert with a single poem and asked them to score it between 1 to 5, with a larger score being better, in terms of compliance, aesthetic innovation, scenario consistency, and fluency. They were also asked to specify the style of the poem.

Using the poems generated by our systems, we generated many different questions of both types, and then created a number of online questionnaires that randomly selected from these questions. This meant that as discussed above, each questionnaire had 11 randomly selected innovation questions, and 4 randomly selected style transfer questions. Each question was only used once, meaning that it was not duplicated on multiple questionnaires, and so each questionnaire was different.

Experts could choose to answer multiple questionnaires if they wished, as each one was different. From the 34 experts, we collected 69 completed questionnaires, which equals to 759 innovation questions and 276 style-transfer questions.

5.3 Innovation experiment

This experiment focuses on the contribution of memory for innovative poem generation. We experimented with two configurations: one is with a one-iteration model (C_1) and the other is with an overfitted model (C_∞). The memory was generated from the 500 quatrains in MEM-I, and the weighting factor was defined empirically as 16 for C_1 and 49 for C_∞.

The topics of the generation were 160 keywords randomly selected from Shixuhanyinge (Liu, 1735). Given a pair of poems generated by two different configurations using the same topic, the experts were asked to choose which one they preferred. The evaluation is therefore pair-wised, and each pair of configurations contains at least 180 evaluations. The results are shown in Table 2, where the preference ratio for each pair of configurations was tested in terms of the 5 metrics.

From the first row of Table 2, we observe that the experts have a clear preference for the poems generated by the C_1 model, the one that can produce fluent yet uninteresting poems. In particular, the 'aesthetic innovation' score for C_∞ is not better than C_1, which was different from what we expected. Informal offline discussions with the poetry experts found that the experts identified some innovative expression in the C_∞ condition, but most of the them was regarded as being nonsense in the opinion of many of the experts. In comparison to sparking innovation, fluency and being meaningful is more important not only for non-expert readers, but also for professional poet-

[3] http://vivi.cslt.org

	Preference Ratio				
	Compliance	Fluency	Theme Consistency	Aesthetic Innovation	Scenario Consistency
C_1 vs C_∞	0.59:0.41	0.68:0.32	0.70:0.30	0.68:0.32	0.69:0.31
C_1 vs C_1+Mem	0.41:0.59	0.36:0.64	0.37:0.63	0.33:0.67	0.43:0.57
C_∞ vs C_∞+Mem	0.40:0.60	0.26:0.74	0.32:0.68	0.30:0.70	0.36:0.64
C_1 vs C_∞+Mem	0.43:0.57	0.58:0.42	0.59:0.41	0.50:0.50	0.59:0.41

Table 2: Preference ratios for systems with or without overfitting and with or without memory augmentation.

s. In other words, only meaningful innovation is regarded as innovation, and irrational innovation is simply treated as junk.

From the second and third rows of Table 2, it can be seen that involving memory significantly improves both C_1 and C_∞, particularly for C_∞. For C_1, the most substantial improvement is observed in terms of 'Aesthetic innovation', which is consistent with our argument that memory can help encourage innovation for this model. For C_∞, 'Fluency' seems to be the most improved metric. This is also consistent with our argument that involving memory constrains over-innovation for over-fitted models.

The last row of Table 2 is an extra experiment that investigates if C_∞ is regularized well enough after introducing the memory. It seems that with the regularization, the overfitting problem is largely solved, and the generation is nearly as fluent and consistent as the C_1 condition. Interestingly, the score for aesthetic innovation is also significantly improved. Since the regularization is not supposed to boost innovation, this seems confusing at first glance (in comparison to the result on the same metric in the first row), but this is probably because the increased fluency and consistency makes the innovation more appreciated, therefore doubly confirming our argument that true innovation should be reasonable and meaningful.

5.4 Style-transfer experiment

In the second experiment, the memory mechanism is used to generate poems in different styles. We chose three styles: pastoral, battlefield, and romantic. A style-specific memory, which we call style memory, was constructed for each style by the corresponding quatrains in the MEM-S dataset. The system with one-iteration model C_1 was used as the baseline. Two sets of topics were used in the experiment, one is general and the other is style-biased. The experiments then investigate if the memory mechanism can produce a clear style if the topic is general, and can transfer to a different style if the topic is style-biased already. The experts were asked to specify the style from four options including the three defined above and a 'unclear style' option. In addition, the experts were asked to score the poems in terms of compliance, fluency, aesthetic innovation, and scenario consistency, which we can use to check if the style transfer impacts the quality of the poem generation. Note that we did not ask for the theme consistency to be scored in this experiment because the topic words were not presented to the experts, in order to prevent the topic affecting their judgment regarding the style. The score ranges from 1 to 5, with a larger score being better.

Table 3 presents the results with the general topics. The numbers show the probabilities that the poems generated by a particular system were labeled as having various styles. Since the topics are unbiased in types, the generation of the baseline system is assumed to be with unclear styles. For other systems, the style of the generation is assumed to be the same as the style of their memories. The results in Table 3 clearly demonstrates these assumptions. The tendency that romantic poems are recognized as pastoral poems is a little surprising. Further analysis shows that experts tend to recognize romantic poems as pastoral poems only if there are any related symbols such as trees, mountain, river. These words are very general in Chinese quatrains. The indicator words of romantic poems such as skirt, rouge, and singing are not as popular and their indication power is not as strong, leading to less labeling of romantic poems, as shown in the results.

	Probability			
Model	Pastoral	Battlefield	Romantic	Unclear
C_1 (Baseline)	0.09	0.04	0.18	0.69
C_1 + Pastoral Mem	0.94	0.00	0.06	0.00
C_1 + Battlefield Mem	0.05	0.93	0.00	0.02
C_1 + Romantic Mem	0.17	0.00	0.61	0.22

Table 3: Probability that poems generated by each configuration with general topics are labeled as various styles.

We also tested transferring from one style to

another. This was achieved by generating poems with some style-biased topics, and then using a style memory to force the generation to change the style. Our experiments show that in 73% cases the style can be successfully transferred.

Finally, the scores of the poems generated with and without the style memories are shown in Table 4, where the poems generated with both general and style-biased topics are accounted for. It can be seen that overall, the style transfer may degrade fluency a little. This is understandable, as enforcing a particular style has to break the optimal generation with the baseline, which is assumed to be good at generating fluent poems. Nevertheless the sacrifice is not significant.

Method	Compliance	Fluency	Aesthetic Innovation	Scenario Consistence
C_1 (baseline)	4.10	3.01	2.53	2.94
C_1 + Pastoral Mem	4.07	3.00	3.07	3.17
C_1 + Battlefield Mem	3.82	2.63	2.60	2.95
C_1 + Romantic Mem	4.00	2.78	2.59	3.00
C_1 + All Mem	3.95	2.80	2.74	3.05

Table 4: Averaged scores for systems with or without style memory.

5.5 Examples

Table 5 to Table 7 shows example poems generated by the system C_1, C_1+Mem and C_1+Style Mem where the style in this case is set to be romantic. The three poems were generated with the same, very general, topic ('自(oneself)'). More examples are given in the supporting material.

自从此意无心物，
Nothing in my heart,
一日东风不可怜。
Spring wind is not a pity.
莫道人间何所在，
Don't ask where it is,
我今已有亦相传。
I've noticed that and tell others.

Table 5: Example poems generated by the C_1 system.

6 Conclusions

In this paper, we proposed a memory mechanism to support innovative Chinese poem generation by neural models augmented with a memory. Experimental results demonstrated that memory can boost innovation from two opposite directions: either by encouraging creative generation for regularly-trained models, or by encouraging rule-compliance for overfitted models. Both strategies work well, although the former generated poetry that was preferred by experts in our experiments. Furthermore, we found that the memory can be used to modify the style of the generated poems in a flexible way. The experts we collaborated with feel that the present generation is comparable to today's experienced amateur poets. Future work involves investigating a better memory selection scheme. Other regularization methods (e.g., norm or drop out) are also interesting and may alleviate the over-fitting problem.

一山自有无人语，
Nobody speaking in the mountain,
不是青云入水边。
Also no green cloud stepping into the river.
莫把春风吹落叶，
Spring wind does not stir leaves,
花开绿树满江船。
But flowers blooming in trees and flying to boats.

Abstract

This paper presents a novel encoder-decoder model for automatically generating market comments from stock prices. The model first encodes both short- and long-term series of stock prices so that it can mention short- and long-term changes in stock prices. In the decoding phase, our model can also generate a numerical value by selecting an appropriate arithmetic operation such as subtraction or rounding, and applying it to the input stock prices. Empirical experiments show that our best model generates market comments at the fluency and the informativeness approaching human-generated reference texts.

1 Introduction

Various industries such as finance, pharmaceuticals, and telecommunications have been increasingly providing opportunities to treat various types of large-scale numerical time-series data. Such data are hard for non-specialists to interpret in detail and time-consuming even for specialists to construe. As a result, there has been a growing interest in automatically generating concise descriptions of such data, i.e., data summarization. This interest in data summarization is encouraged by the recent development of neural network-based text generation methods. Given an appropriate architecture, a neural network can generate a sentence that is mostly grammatical and semantically reasonable.

In this study, we focus on the task of generating market comments from a time-series of stock prices. We adopt an encoder-decoder model (Sutskever et al., 2014) and exploit its capability to learn to capture the behavior of the input and generate a description of it. Although encoder-decoder models can learn to do this, they need to be provided with an appropriate network-architecture and necessary information. We use Figure 1 to illustrate the characteristic problems of comment generation for time-series of stock prices. The figure shows the Nikkei Stock Average (*Nikkei 225*, or simply *Nikkei*), which is a stock market index calculated from 225 selected issues, on some consecutive trading days accompanied by the market comments made at some specific time points in the span. The first problem is that market comments do not merely describe the increase and decrease of the price. They also often describe how the price changes compared with the previous period, such as "*continues to fall*" in (3) of Figure 1, "*turns to rise*" in (2), and "*rebound*" in (6). Market comments sometimes describe the change in price compared with the prices in the previous week. The second problem is that market comments also

	Time	Comment
(1)	09:00	Nikkei opens with a continual fall.
(2)	09:29	Nikkei turns to rise.
(3)	11:30	Nikkei continues to fall. The closing price of the morning session decreases by 5 yen to 19,386 yen.
(4)	12:30	Nikkei rises at the beginning of the afternoon session.
(5)	13:54	Nikkei gains more than 100 yen.
(6)	15:00	Nikkei rebounds and closes up 102 yen to 19,494 yen.

Figure 1: Nikkei 225 and market comments.

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1374–1384
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1126

contain expressions that depend on their delivery time: e.g., "*opens with*" in (1), "*closing price of the morning session*" in (3), and "*beginning of the afternoon session*" in (4). The third problem is that market comments typically contain numerical values, which often cannot be copied from the input prices. Such numerical values probably cannot be generated as other words are generated by the standard decoder. This difficulty can be easily understood as analogous with the difficulty of generating named entities by encoder-decoder models. To derive such values, the model needs arithmetic operations such as subtraction as in examples (3) and (6) mentioning the difference in price and rounding as in example (5).

To address these problems, we present a novel encoder-decoder model to automatically generate market comments from stock prices. To address the first problem of capturing various types of change in different time scales, the model first encodes data consisting of both short- and long-term time-series, where a multi-layer perceptron, a recurrent neural network, or a convolutional network is adopted as a basic encoder. In the decoding phase, we feed our model with the delivery time of the market comment to generate the expressions depending on time of day to address the second problem. To address the third problem regarding with numerical values mentioned in the generated text, we allow our model to choose an arithmetic operation such as subtraction or rounding instead of generating a word.

The proposed methods are evaluated on the task of generating Japanese market comments on the Nikkei Stock Average. Automatic evaluation with BLEU score (Papineni et al., 2002) and F-score of time-dependent expressions reveals that our model outperforms a baseline encoder-decoder model significantly. Furthermore, human assessment and error analysis prove that our best model generates characteristic expressions discussed above almost perfectly, approaching the fluency and the informativeness of human-generated market comments.

2 Related Work

The task of generating descriptions from time-series or structured data has been tackled in various domains such as weather forecasts (Belz, 2007; Angeli et al., 2010), healthcare (Portet et al., 2009; Banaee et al., 2013b), and sports (Liang et al., 2009). Traditionally, many studies used hand-crafted rules (Goldberg et al., 1994; Dale et al., 2003; Reiter et al., 2005). On the other hand, interest has recently been growing in automatically learning a correspondence relationship from data to text and generating a description of this relationship since large-scale data in diversified formats have become easy to acquire. In fact, a data-driven approach has been extensively studied nowadays for various tasks such as image caption generation (Vinyals et al., 2015) and weather forecast generation (Mei et al., 2016b).

The task, called data-to-text or concept-to-text, is generally divided into two subtasks: content selection and surface realization. Whereas previous studies tackled the subtasks separately (Barzilay and Lapata, 2005; Wong and Mooney, 2007; Lu et al., 2009), recent work has focused on solving them jointly using a single framework (Chen and Mooney, 2008; Kim and Mooney, 2010; Angeli et al., 2010; Konstas and Lapata, 2012, 2013).

More recently, there has been some work on an encoder-decoder model (Sutskever et al., 2014) for generating a description from time-series or structured data to solve the subtasks jointly in a single framework, and this model has been proven to be useful (Mei et al., 2016b; Lebret et al., 2016). However, the task of generating a description from numerical time-series data presents difficulties such as the second and third problems mentioned in Section 1. For the second problem, the model needs to be fed with information on delivery time. Also, the model needs arithmetic operations such as subtraction for the third problem because even if we simply apply a copy mechanism (Gu et al., 2016; Gulcehre et al., 2016) to the model, it cannot derive a calculated value such as (3), (5), or (6) in Figure 1 from input. Thus, in this work, we tackle these problems and develop a model on the basis of the encoder-decoder model that can mention a specific numerical value by referring to the input data or producing a processed value with mathematical calculation and mention time-dependent expressions by incorporating the information on delivery time into its decoder.

There has also been some work on generating market comments. Kukich (1983) developed a system consisting of rule-based components for generating stock reports from a database of daily stock quotes. Although she used several components individually and had to define a number of rules for the generation, our encoder-decoder model can

perform it with fewer and simpler rules for the calculation. Aoki and Kobayashi (2016) developed a method on the basis of a weighted bi-gram language model for automatically describing trends of time-series data such as the Nikkei Stock Average. However, they did not attempt to refer to specific numerical values such as closing prices and amounts of rises in price although such descriptions are often used in market comments as shown in Figure 1 (3), (5), and (6). In contrast, we present a novel approach to generate natural language descriptions of time-series data that can not only able to describe trends of the data but also mention specific numerical values by referring to the time-series data.

3 Generating Market Comments

To generate market comments on stock prices, we introduce an encoder-decoder model. Encoder-decoder models have been widely used and proven useful in various tasks of natural language generation such as machine translation (Cho et al., 2014) and text summarization (Rush et al., 2015). Our task is similar to these tasks in that the system takes sequential data and generates text. Therefore, it is natural to use an encoder-decoder model in modeling stock prices.

Figure 2 illustrates our model. In describing time-series data, the model is expected to capture various types of change and important values in the given sequence, such as absolute or relative changes and maximum or minimum value, in different time-scales. Moreover, it is necessary to generate time-dependent comments and numerical values that require arithmetic operations for derivation, such as "The closing price of *the morning session* decreases by *5 yen*...". To achieve these, we present three strategies that alter the standard encoder-decoder model.

First (Section 3.1), we use several encoding methods for time-series data, as in (1) of Figure 2, to capture the changes and important values. Second (Section 3.2), we incorporate delivery-time information into the decoder, as in (2) of Figure 2, to generate time-dependent comments. For the decoder, we use a recurrent neural network language model (RNNLM) (Mikolov et al., 2010), which is widely used in language generation tasks. Finally (Section 3.3), we extend the decoder to estimate arithmetic operations, as in (3) of Figure 2, to generate numerical values in market comments.

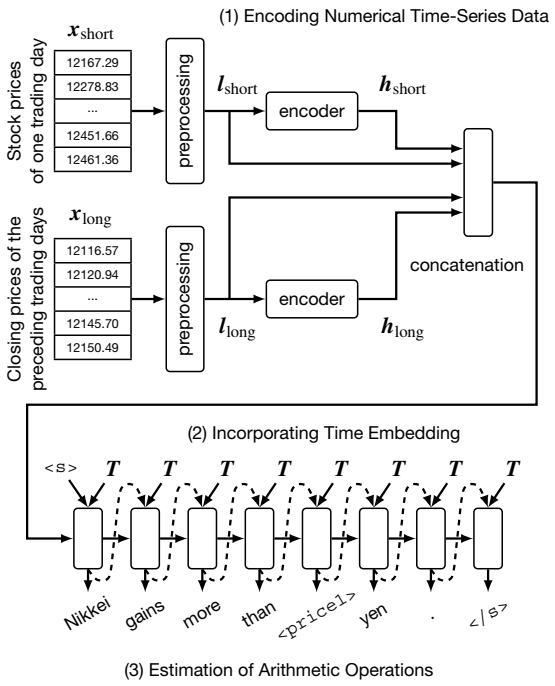

Figure 2: Overview of our model. Here $\boldsymbol{l}_{\text{short}}$ and $\boldsymbol{l}_{\text{long}}$ represent two vectors of preprocessed values, and $\boldsymbol{h}_{\text{short}}$ and $\boldsymbol{h}_{\text{long}}$ indicate hidden states of the encoder. $\boldsymbol{T}$ represents a time embedding vector.

3.1 Encoding Numerical Time-Series Data

We prepare short- and long-term data, using the five-minute chart of Nikkei 225. A vector for short-term data consists of the prices of one trading day and has N elements. We denote it as $\boldsymbol{x}_{\text{short}} = \left(x_{\text{short},\,i}\right)_{i=0}^{N-1}$. On the other hand, a vector for long-term data consists of the closing prices of the M preceding trading days. It is denoted as $\boldsymbol{x}_{\text{long}} = \left(x_{\text{long},\,i}\right)_{i=0}^{M-1}$.

Data are commonly preprocessed to remove noise and enhance generalizability of a model (Zhang and Qi, 2005; Banaee et al., 2013a). We use two preprocessing methods: *standardization* and *moving reference*. Standardization substitutes each element x_i of input $\boldsymbol{x}$ by

$$x_i^{\text{std}} = \frac{x_i - \mu}{\sigma}, \tag{1}$$

where μ and σ are the mean and standard deviation of the values in the training data, respectively. Standardized values are less affected by scale. The second method, moving reference (Freitas et al., 2009), substitutes each element x_i of input $\boldsymbol{x}$ by

$$x_i^{\text{move}} = x_i - r_i, \tag{2}$$

where r_i is the closing price of the previous trading day of $\boldsymbol{x}$. This is introduced to capture price fluctuations from the previous day.

By applying one of the preprocessing methods to $\boldsymbol{x}_{\text{short}}$ and $\boldsymbol{x}_{\text{long}}$, we obtain two vectors of preprocessed values $\boldsymbol{l}_{\text{short}}$ and $\boldsymbol{l}_{\text{long}}$. Given these, each encoder emits the corresponding hidden states $\boldsymbol{h}_{\text{short}}$ and $\boldsymbol{h}_{\text{long}}$. After obtaining the hidden states, we concatenate the two vectors of the preprocessed values and the outputs of the encoders as a *multi-level representation* of the input time-series data. The multi-level representation is an approach developed by Mei et al. (2016a) that enable the decoder to take into account both the high-level representation, e.g., $\boldsymbol{h}_{\text{short}}$, $\boldsymbol{h}_{\text{long}}$, and the low-level representation, e.g., $\boldsymbol{l}_{\text{short}}$, $\boldsymbol{l}_{\text{long}}$, at the same time. They have shown that it improves performance in terms of selecting salient objects in input data. We thus set the initial hidden state $\boldsymbol{s}_0$ of the decoder as

$$\boldsymbol{s}_0 = \boldsymbol{l}_{\text{short}} \oplus \boldsymbol{l}_{\text{long}} \oplus \boldsymbol{h}_{\text{short}} \oplus \boldsymbol{h}_{\text{long}}, \quad (3)$$

where $\oplus$ is the concatenation operator.

When we use both preprocessing methods, we have four preprocessed input vectors: $\boldsymbol{l}^{\text{move}}_{\text{short}}$, $\boldsymbol{l}^{\text{std}}_{\text{short}}$, $\boldsymbol{l}^{\text{move}}_{\text{long}}$, and $\boldsymbol{l}^{\text{std}}_{\text{long}}$. In this case, we introduce four encoders, and set the initial hidden state $\boldsymbol{s}_0$ of the decoder as

$$\begin{aligned}\boldsymbol{s}_0 = {} & \boldsymbol{l}^{\text{move}}_{\text{short}} \oplus \boldsymbol{l}^{\text{std}}_{\text{short}} \oplus \boldsymbol{l}^{\text{move}}_{\text{long}} \oplus \boldsymbol{l}^{\text{std}}_{\text{long}} \\ & \oplus \boldsymbol{h}^{\text{move}}_{\text{short}} \oplus \boldsymbol{h}^{\text{std}}_{\text{short}} \oplus \boldsymbol{h}^{\text{move}}_{\text{long}} \oplus \boldsymbol{h}^{\text{std}}_{\text{long}}. \quad (4)\end{aligned}$$

Since several encoding methods can be used for the time-series data, we use any one of the three conventional neural networks: Multi-Layer Perceptron (MLP), Convolutional Neural Network (CNN), or Recurrent Neural Network (RNN) with Long Short-Term Memory cells (Hochreiter and Schmidhuber, 1997). In the experiments, we empirically evaluate and compare the encoding methods.

3.2 Incorporating Time Embedding

Even if identical sequences of values are observed, comments usually vary in accordance with price history or the time they are observed. For instance, when the market opens, comments usually mention how much the stock price has increased or decreased compared with the closing price of the previous trading day, as in (1) and (3) in Figure 1.

Our model creates vectors called *time embedding* vectors $\boldsymbol{T}$ on the basis of the time when the comment is delivered (e.g., 9:00 a.m. or 3:00 p.m.). Then a time embedding vector is added to each hidden state $\boldsymbol{s}_j$ in decoding so that words are generated depending on time. This mechanism is inspired by *speaker embedding* introduced by Li et al. (2016). They use an encoder-decoder model for a conversational agent that inherits the characteristics of a speaker, such as his/her manner of speaking. They encode speaker-specific information (e.g., dialect, age, and gender) into speaker embedding vectors and used them in decoding.

3.3 Estimation of Arithmetic Operations

Text generation systems based on language models such as RNNLM often generate erroneous words for named entities; that is, they often mention a similar but incorrect entity, e.g., Nissan for Toyota. To overcome this problem, Gulcehre et al. (2016) developed a text generation method called *copy mechanism*. The method copies rare words missing from the vocabulary from a given sequence of words using an attention mechanism, and emits the copied words.

Market comments often mention numerical values that appear in the input data, but they also mention values obtained through arithmetic operations, such as differences in prices as in (3) and (6) in Figure 1, or rounded values as in (5). Thus, another problem arises: what *type of operation* is suitable for text to be generated? In this work, we solve this problem by extending the idea of copy mechanism.

To enable our model to generate text with values calculated from input values, we add *generalization tags* to the vocabulary used in the model. Each generalization tag represents a type of arithmetic operation. When a generalization tag is emitted, the model performs the operations on the designated values in accordance with the tag, replaces the tag with the calculated value, and finally outputs text containing numerical values. For preprocessing, we replace each numerical value appearing in the market comments in the training data with generalization tags such as `<price1>`. The tag for a numerical value depends on what the value stands for in the text. Table 1 displays all the tags and the corresponding types of calculation. To illustrate, suppose a market comment says

(a) *Nikkei rebounds. The closing price of the morning session is 16,610 yen, which is 227 yen higher.*

Since this comment omits the phrase "than the

Tag	Arithmetic operation
<price1>	Return Δ
<price2>	Round down Δ to the nearest 10
<price3>	Round down Δ to the nearest 100
<price4>	Round up Δ to the nearest 10
<price5>	Round up Δ to the nearest 100
<price6>	Return z as it is
<price7>	Round down z to the nearest 100
<price8>	Round down z to the nearest 1,000
<price9>	Round down z to the nearest 10,000
<price10>	Round up z to the nearest 100
<price11>	Round up z to the nearest 1,000
<price12>	Round up z to the nearest 10,000

Table 1: Generalization tags and corresponding arithmetic operations. Here z and Δ stand for latest price and difference between z and closing price of previous trading day.

closing price of the previous day", 227 in this example indicates the difference between the closing price of the previous trading day $x_{\text{long},\,M-1}$ and the latest price $x_{\text{short},\,N-1}$ denoted by z in Table 1. Therefore, we replace 227 with the tag <price1>. Likewise, we replace 16,610 with <price6> because it represents the latest price z. To find the optimal tag for each value, we try all the types of operations listed in Table 1 using the values appearing in the text, i.e., 227 and 16,610 in this case. Then, we select the tag that has the operation that yields the value closest to the original one.

In prediction, the model first generates a tentative comment, which includes tags as well as words. Suppose that the input vectors are $\boldsymbol{x}_{\text{short}}$ and $\boldsymbol{x}_{\text{long}}$, with $x_{\text{short},\,N-1} = 14508$ and $x_{\text{long},\,M-1} = 14612$, and that the model generates the comment below:

(b) *Nikkei opens turning down. The loss exceeds* <price2> *yen, and it falls to the* <price7> *yen level.*

Since the tag <price2> represents "the difference between $x_{\text{short},\,N-1}$ and $x_{\text{long},\,M-1}$ rounded down to the nearest 10", we replace the tag with 100. Similarly, we replace <price7>, which is "the last price $x_{\text{short},\,N-1}$ rounded down to the nearest 100", with 14,500. Finally, we have a market comment containing the numbers as below:

(c) *Nikkei opens turning down. The loss exceeds 100 yen, and it falls to the 14,500 yen level.*

4 Experiments

4.1 Experimental Settings

We used the five-minute chart of Nikkei 225 from March 2013 to October 2016 as numerical time-series data, which were collected from IBI-Square Stocks[1], and 7,351 descriptions as market comments, which are written in Japanese and provided by Nikkei QUICK News. We divided the dataset into three parts: 5,880 for training, 730 for validation, and 741 for testing. For a human evaluation, we randomly selected 100 comments and their time-series data included in the test set.

We set $N = 62$, which is the number of time steps for stock prices for one trading day, and $M = 7$, which is the number of the time steps for closing prices of the preceding trading days. We used Adam (Kingma and Ba, 2015) for optimization with a learning rate of 0.001 and a mini-batch size of 100. The dimensions of word embeddings, time embeddings, and hidden states for both the encoder and decoder are set to 128, 64, and 256, respectively. For CNN, we used a single convolutional layer and set the filter size to 3.

In the experiments, we conducted three types of evaluation: two for automatic evaluation, and one for human evaluation. For one automatic evaluation, we used BLEU (Papineni et al., 2002) to measure the matching degree between the market comments written by humans as references and output comments generated by our model. We applied paired bootstrap resampling (Koehn, 2004) for a significance test. For the other automatic evaluation metric, we calculate F-measures for time-dependent expressions, using market comments written by humans as references, to investigate whether our model can correctly output time-dependent expressions such as "*open with*" and describe how the price changes compared with the previous period referring to the series of preceding prices such as "*continual fall*". Specifically, we calculate F-measures for 13 expressions shown in Figure 3.

For the human evaluation, we recruited a specialist in financial engineering as a judge to evaluate the quality of generated market comments. To evaluate the difference in the quality of generated comments between our models and human, we showed both system-generated and human-generated market comments together with their

time-series data consisting of $\boldsymbol{x}_{\text{short}}$ and $\boldsymbol{x}_{\text{long}}$, without letting the judge know which comment is generated by which method. We asked the judge to give each market comment two scores: one for informativeness and one for fluency. Both scores have two levels, 0 or 1, where 1 indicates high informativeness or fluency. For informativeness, the judge used both generated comments and their input stock prices to rate the comments. Specifically, if the judge deem that a generated comment describes an important price movement or an outline of the movement properly, such comments are considered to be informative. For fluency, the judge read only the generated comments and rate them in terms of readability, regardless of their content of the comment.

In addition, since some of the market comments written by humans sometimes include external information such as "*Nikkei opens with a continual fall as yen pressures exporters*", we also asked the judge to ignore the correctness of external information mentioned in comments, for the sake of fairness in comparison, because external information cannot be retrieved from the time-series data.

To assess the effectiveness of the techniques we introduced, we conducted experiments with 11 models. Table 2 shows an overview of the models we compared. We compared three types of models: a baseline, full models (e.g., *mlp-enc*), and ablated models (e.g., *-short*). For example, *-short* is a model that does not use the short-term time series.

Model	baseline	mlp-enc	cnn-enc	rnn-enc	-short	-long

Each example is accompanied by original Japanese comment transliterated into English alphabet, its literal translation, and the corresponding English sentence. Abbreviations used here are as follows. TOP: topic case, GEN: genitive case, INSTR: instrumental case, and IMPERF: imperfect form of a verb.

enc, *cnn-enc*, *rnn-enc*). In the comparison between the models that took two types of the time-series data $\boldsymbol{x}_{\text{short}}$, $\boldsymbol{x}_{\text{long}}$ as input (e.g., *mlp-enc* or *rnn-enc*) and the models that only used one of them (*-short*, *-long*), the models using both types of data such as *mlp-enc* and *rnn-enc* gained higher BLEU scores than *-short* and *-long*. Also, the models that encoded the two types of time-series data to capture their short- and long-term changes correctly output more expressions that described the changes such as "*turn to rise*", "*continue to fall*", and "*rebound*" than *-short* and *-long* as shown in Figure 3.

According to the comparison between preprocessing methods, *mlp-enc*, which used both standardization and moving reference as preprocessing methods, obtained a higher BLEU score than the models that used neither (*-std*, *-move*). In terms of the F-measure values, *mlp-enc* output phrases mentioning changes more appropriately and therefore achieved the higher values than the other two models as in "turn to rise" or "turn to fall" in Figure 3. Furthermore, we found that the BLEU score of *-multi*, which did not use the multi-level representation of the data, was inferior. In other words, incorporating the multi-level representation along with an output of an encoder into a decoder seems

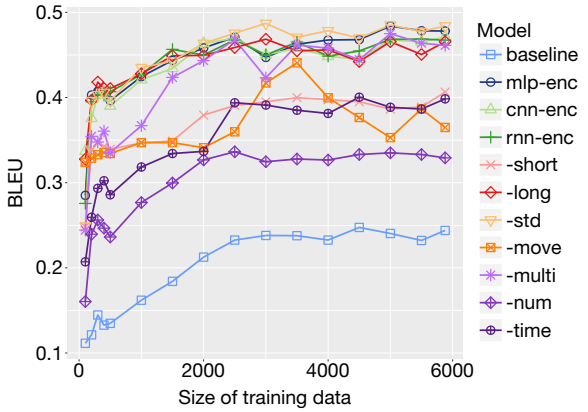

Figure 5: BLEU scores of market comments generated by models for each size of training data on the validation set.

to contribute to improving the automatic evaluation and producing a better representation of the input data.

baseline and *-num* output numerical values as "words" from the vocabulary for RNNLM because these models do not use any arithmetic operation. Therefore, there were many cases including <unk> that should be output as a numerical value as shown in Figure 4 (a). We found that *-num* had a lower BLEU score than the models such as *mlp-enc* and *-std* that used arithmetic operations. Furthermore, we observed that the models with arithmetic operations correctly generated stock prices in most cases.

By comparing *-time*, which did not incorporate time-embeddings into a decoder, and other models such as *mlp-enc* with respect to the F-measure of expressions depending on delivery time (e.g., "*open with*" or "*closing session*"), we found that the models that took time information into account, such as *mlp-enc*, generated those phrases more accurately than *-time*.

Moreover, we analyzed the effect of different sizes of training data. Figure 5 shows BLEU scores of market comments generated by our models for each size of training data on the validation set. According to the results, we found that the BLEU scores for the models saturated when we used 3000 training data. In addition, there was not much difference in convergence speed among the models.

The human evaluation results in Table 4 indicate that market comments generated by our model (*mlp-enc*) achieved a quality comparable even to that of market comments written by humans. Moreover, we found that *mlp-enc* significantly outperformed *baseline* in terms of informativeness but was outperformed by *baseline* in terms of fluency. The reason was that *mlp-enc* occasionally generated a market comment such as "*Nikkei gains more than 0 yen*" because of an error in the prediction of the operation, and such comments were not considered not to be fluent or informative by the judge, although most of comments generated by *mlp-enc* were as fluent as those of *baseline*. Note that *baseline* does not generate expressions like "*0 yen*" because they are not normally used in market comments and so not included in the vocabulary. Therefore, the judge considered all the comments generated by *baseline* to be fluent.

Model	Informativeness	Fluency	External
Human	**95**	95	25
mlp-enc	85	93	1
baseline	28	**100**	6

Table 4: Results of human evaluation. Each score indicates number of market comments judged to be level-1. External shows number of market comments including external information.

For another possibility to enhance our model, we have to consider that the model should mention a difference or gain for a duration from when to when. For example, our current model sometimes generated a market comment such as "*Nikkei gains more than 200 yen*", although Nikkei actually gained more than 300 yen. Such a comment is not incorrect but is imprecise. Therefore, we consider that a mechanism is needed to select the period to be mentioned when the model generates a comment to this problem and increase the generalizability of our model for generating a description from various time-series data.

5 Conclusion and Future Work

In this study, we presented a novel encoder-decoder model to automatically generate market comments from numerical time-series data of stock prices, using the Nikkei Stock Average as an example. Descriptions of numerical time-series data written by humans such as market comments have several writing style characteristics. For example, (1) content to be mentioned in the market comments varies depending on short- or long-term changes of the time-series data, (2) expressions depending on delivery time at which text is written are used, and (3) numerical values obtained through arith-

metic operations applied to the input data are often described. We developed approaches for generating comments that have these characteristics and showed the effectiveness of the proposed model.

In future work, we plan to apply our model to descriptions of time-series data in various domains such as weather forecasts and sports, which share the above writing-style characteristics. We also plan to use multiple time-series as input such as multiple brands of stock.

Abstract

In this paper, we study how to improve the domain adaptability of a deletion-based Long Short-Term Memory (LSTM) neural network model for sentence compression. We hypothesize that syntactic information helps in making such models more robust across domains. We propose two major changes to the model: using explicit syntactic features and introducing syntactic constraints through Integer Linear Programming (ILP). Our evaluation shows that the proposed model works better than the original model as well as a traditional non-neural-network-based model in a cross-domain setting.

1 Introduction

Sentence compression is the task of compressing long, verbose sentences into short, concise ones. It can be used as a component of a text summarization system. Figure 1 shows two example input sentences and the compressed sentences written by human. The task has been studied for almost two decades. Early work on this task mostly relies on syntactic information such as constituency-based parse trees to help decide what to prune from a sentence or how to re-write a sentence (Jing, 2000; Knight and Marcu, 2000). Recently, there has been much interest in applying neural network models to solve the problem, where little or no linguistic analysis is performed except for tokenization (Filippova et al., 2015; Rush et al., 2015; Chopra et al., 2016).

Although neural network-based models have achieved good performance on this task recently, they tend to suffer from two problems: (1) They require a large amount of data for training. For example, Filippova et al. (2015) used close to two million sentence pairs to train an LSTM-based sentence compression model. Rush et al. (2015) used about four million title-article pairs from the Gigaword corpus (Napoles et al., 2012) as training data. Although it may be easy to automatically obtain such training data in some domains (e.g., the news domain), for many other domains, it is not possible to obtain such a large amount of training data. (2) These neural network models trained on data from one domain may not work well on out-of-domain data. For example, when we trained a standard neural sequence-to-sequence model[1] on 3.8 million title-article pairs from the Gigaword corpus and applied it to both in-domain data and out-of-domain data, we found that the performance on in-domain data was good but the performance on out-of-domain data could be very

In-domain

Input: *The southern Chinese city of Guangzhou has set up a special zone allowing foreign consulates to build permanent offices and residences and avoid prohibitive local rents, the china daily reported Tuesday.*
Compressed (by human): *Guangzhou opens new consulate area.*
Compressed (by machine): *Guangzhou sets up special zone for foreign consulates.*

Out-of-domain

Input: *Wherever she was, she helped other loyal and flexible wives cope.*
Compressed (by human): *she helped other wives cope.*
Compressed (by machine): *wives and flexible wives*

Figure 1: Examples of in-domain and out-of-domain results by a standard abstractive sequence-to-sequence model trained on the Gigaword corpus. The first input sentence comes from the Gigaword corpus while the second input sentence comes from the written news corpus used by Clarke and Lapata (2008).

poor. Two example compressed sentences by this trained model are shown in Figure 1 to illustrate the comparison between in-domain and out-of-domain performance.

The two limitations above imply that these neural network-based models may not be good at learning generalizable patterns, or in other words, they tend to overfit the training data. This is not surprising because these models do not explicitly use much syntactic information, which is more general than lexical information.

In this paper, we aim to study how syntactic information can be incorporated into neural network models for sentence compression to improve their domain adaptability. We hope to train a model that performs well on both in-domain and out-of-domain data. To this end, we extend the deletion-based LSTM model for sentence compression by Filippova et al. (2015). Although deletion-based sentence compression is not as flexible as abstractive sentence compression, we chose to work on deletion-based sentence compression for the following reason. Abstractive sentence compression allows new words to be used in a compressed sentence, i.e., words that do not occur in the input sentence. Oftentimes these new words serve as paraphrases of some words or phrases in the source sentence. But to generate such paraphrases, the model needs to have seen them in the training data. Because we are interested in a cross-domain setting, the paraphrases learned in one domain may not work well in another domain if the two domains have very different vocabularies. On the other hand, a deletion-based method does not face such a problem in a cross-domain setting.

Specifically, we propose two major changes to the model by Filippova et al. (2015): (1) We explicitly introduce POS embeddings and dependency relation embeddings into the neural network model. (2) Inspired by a previous method (Clarke and Lapata, 2008), we formulate the final predictions as an Integer Linear Programming problem to incorporate constraints based on syntactic relations between words and expected lengths of the compressed sentences. In addition to the two major changes above, we also use bi-directional LSTM to include contextual information from both directions into the model.

We evaluate our method using around 10,000 sentence pairs released by Filippova et al. (2015) and two other data sets representing out-of-domain data. We test both in-domain and out-of-domain performance. The experimental results showed that our proposed method can achieve competitive performance compared with the original method in the single-domain setting but with much less training data (around 8,000 sentence pairs for training instead of close to two million sentence pairs). In the cross-domain setting, our proposed method can clearly outperform the original method. We also compare our method with a traditional ILP-based method using syntactic structures of sentences but not based on neural networks (Clarke and Lapata, 2008). We find that our method can outperform this baseline for both in-domain and out-of-domain data.

2 Method

In this section, we present our sentence compression method that is aimed at working in a cross-domain setting.

2.1 Problem Definition

Recall that we focus on deletion-based sentence compression. Our problem setup is the same as that by Filippova et al. (2015). Let us use $\boldsymbol{s} = (w_1, w_2, \ldots, w_n)$ to denote an input sentence, which consists of a sequence of words. Here $w_i \in \mathcal{V}$, where $\mathcal{V}$ is the vocabulary. We would like to delete some of the words in $\boldsymbol{s}$ to obtain a compressed sentence that still contains the most important information in $\boldsymbol{s}$. To represent such a compressed sentence, we can use a sequence of binary labels $\boldsymbol{y} = (y_1, y_2, \ldots, y_n)$, where $y_i \in \{0, 1\}$. Here $y_i = 0$ indicates that w_i is deleted, and $y_i = 1$ indicates that w_i is retained.

We assume that we have a set of training sentences and their corresponding deletion/retention labels, denoted as $\mathcal{D} = \{(\boldsymbol{s}_j, \boldsymbol{y}_j)\}_{j=1}^{N}$. Our goal is to learn a sequence labeling model from $\mathcal{D}$ so that for any unseen sentence $\boldsymbol{s}$ we can predict its label sequence $\boldsymbol{y}$ and thus compress the sentence.

2.2 Our Base Model

We first introduce our base model, which uses LSTM to perform sequence labeling. This base model is largely based on the model by Filippova et al. (2015) with some differences, which will be explained below.

We assume that each word in the vocabulary has a d-dimensional embedding vector. For input sentence $\boldsymbol{s}$, let us use $(\mathbf{w}_1, \mathbf{w}_2, \ldots, \mathbf{w}_n)$ to denote the

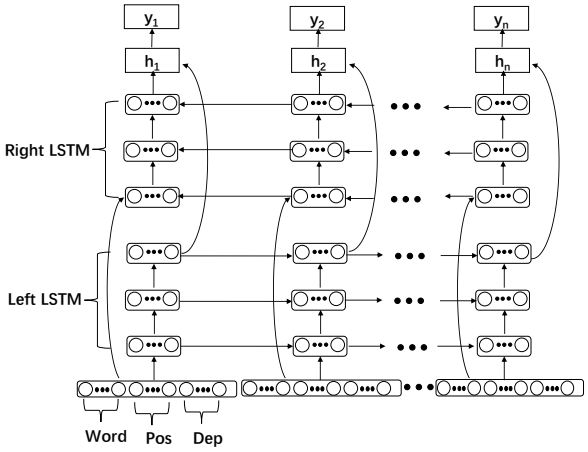

Figure 2: Our three-layered bi-LSTM model. Word embeddings, POS tag embeddings and dependency type embeddings are concatenated in the input layer.

sequence of the word embedding vectors, where $\mathbf{w}_i \in \mathbb{R}^d$. We use a standard bi-directional LSTM model to process these embedding vectors sequentially from both directions to obtain a sequence of hidden vectors $(\mathbf{h}_1, \mathbf{h}_2, \ldots, \mathbf{h}_n)$, where $\mathbf{h}_i \in \mathbb{R}^h$. We omit the details of the bi-LSTM and refer the interested readers to the work by Graves et al. (2013) for further explanation. Following Filippova et al. (2015), our bi-LSTM has three layers, as shown in Figure 2.

We then use the hidden vectors to predict the label sequence. Specifically, label y_i is predicted from $\mathbf{h}_i$ as follows:

$$p(y_i \mid \mathbf{h}_i) = \text{softmax}(\mathbf{W}\mathbf{h}_i + \mathbf{b}), \quad (1)$$

where $\mathbf{W} \in \mathbb{R}^{2\times h}$ and $\mathbf{b} \in \mathbb{R}^2$ are a weight matrix and a weight vector to be learned.

There are some differences between our base model and the LSTM model by Filippova et al. (2015). (1) Filippova et al. (2015) first encoded the input sentence in its reverse order using the same LSTM before processing the sentence for sequence labeling. (2) Filippova et al. (2015) used only a single-directional LSTM while we use bi-LSTM to capture contextual information from both directions. (3) Although Filippova et al. (2015) did not use any syntactic information in their basic model, they introduced some features based on dependency parse trees in their advanced models. Here we follow their basic model because later we will introduce more explicit syntax-based features. (4) Filippova et al. (2015) combined the predicted y_{i-1} with $\mathbf{w}_i$ to help predict y_i. This adds some dependency between consecutive labels. We do not do this because later we will introduce an ILP layer to introduce dependencies among labels.

2.3 Incorporation of Syntactic Features

Note that in the base model that we presented above, there is no explicit use of any syntactic information such as the POS tags of the words or the parse tree structures of the sentences. Because we believe that syntactic information is important for learning a generalizable model for sentence compression, we would like to introduce syntactic features into our model.

First, we perform part-of-speech tagging on the input sentences. For sentence $\boldsymbol{s}$, let us use $(t_1, t_2, \ldots, t_n)$ to denote the POS tags of the words inside, where $t_i \in \mathcal{T}$ and $\mathcal{T}$ is a POS tag set. We further assume that each $t \in \mathcal{T}$ has an embedding vector (to be learned). Let us use $(\mathbf{t}_1, \mathbf{t}_2, \ldots, \mathbf{t}_n)$ ($\mathbf{t}_i \in \mathbb{R}^p$, $p < |\mathcal{T}|$) to denote the sequence of POS embedding vectors of this sentence. We can then simply concatenate $\mathbf{w}_i$ with $\mathbf{t}_i$ as a new vector to be processed by the bi-LSTM model.

Next, we perform dependency parsing on the input sentences. For each word w_i in sentence $\boldsymbol{s}$, let $r_i \in \mathcal{R}$ denote the dependency relation between w_i and its parent word in the sentence, where $\mathcal{R}$ is the set of all dependency relation types. We then assume that each $r \in \mathcal{R}$ has an embedding vector (to be learned). Let $(\mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_n)$ ($\mathbf{r} \in \mathbb{R}^q$, $q < |\mathcal{R}|$) denote corresponding dependency embedding vectors of this sentence. We can also concatenate $\mathbf{w}_i$ with $\mathbf{r}_i$ and feed the new vector to the bi-LSTM model.

In our model, we combine the word embedding, POS embedding and dependency embedding into a single vector to be processed by the bi-LSTM model:

$$\begin{aligned}
\mathbf{x}_i &= \mathbf{w}_i \oplus \mathbf{t}_i \oplus \mathbf{r}_i, \\
\overrightarrow{\mathbf{h}}_i &= \text{LSTM}_{\overrightarrow{\Theta}}(\overrightarrow{\mathbf{h}}_{i-1}, \mathbf{x}_i), \\
\overleftarrow{\mathbf{h}}_i &= \text{LSTM}_{\overleftarrow{\Theta}}(\overleftarrow{\mathbf{h}}_{i+1}, \mathbf{x}_i), \\
\mathbf{h}_i &= \overrightarrow{\mathbf{h}}_i \oplus \overleftarrow{\mathbf{h}}_i,
\end{aligned}$$

where $\oplus$ represents concatenation of vectors, and $\overrightarrow{\Theta}$ and $\overleftarrow{\Theta}$ are parameters of the bi-LSTM model. The complete model is shown in Figure 2.

2.4 Global Inference through ILP

Although the method above has explicitly incorporated some syntactic information into the bi-LSTM model, the syntactic information is used in a soft manner through the learned model weights. We hypothesize that there are also hard constraints we can impose on the compressed sentences. For example, the method above as well as the original method by Filippova et al. (2015) cannot impose any length constraint on the compressed sentences. This is because the labels $y_1, y_2, \ldots, y_n$ are not jointly predicted.

We propose to use Integer Linear Programming (ILP) to find an optimal combination of the labels $y_1, y_2, \ldots, y_n$ for a sentence, subject to some constraints. Specifically, the ILP problem consists of two parts: the objective function, and the constraints.

The Objective Function

Recall that the trained bi-LSTM model above produces a probability distribution for each label y_i, as defined in Eqn. (1). Let us use α_i to denote the probability of $y_i = 1$ as estimated by the bi-LSTM model. Intuitively, we would like to set y_i to 1 if α_i is large.

Besides the probability estimated by the bi-LSTM model, here we also consider the depth of the word w_i in the dependency parse tree of the sentence. Intuitively, a word closer to the root of the tree is more likely to be retained. In order to incorporate this observation, we define $dep(w_i)$ to be the depth of the word w_i in the dependency parse tree of the sentence. The root node of the tree has a depth of 0, an immediate child of the root has a depth of 1, and so on. For example, the dependency parse tree of an example sentence together with the depth of each word is shown in Figure 3. We can see that some of the words that are deleted according to the ground truth have a relatively larger depth, such as the first "she" (with a depth of 4) and the word "flexible" (with a depth of 5).

Based on these considerations, we define the objective function to be the following:

$$\max \quad \sum_{i=1}^{n} y_i(\alpha_i - \lambda \cdot dep(w_i)), \qquad (2)$$

where λ is a positive parameter to be manually set, and y_i is the same as defined before, which is either 0 or 1 to indicate whether w_i is deleted or not.

Constraints

We further introduce some constraints to capture tow considerations. The first consideration is related to the syntactic structure of a sentence, and the second consideration is related to the length of the compressed sentence. Some of the constraints are inspired by Clarke and Lapata (2008).

Our constraints are listed below: (1) No missing parent: Generally, we believe that if a word is retained in the compressed sentence, its parent in the dependency parse tree should also be retained. (2) No missing child: For some dependency relations such as *nsubj*, if the parent word is retained, it makes sense to also keep the child word; otherwise the sentence may become ungrammatical. (3) Max length: Since we are trying to compress a sentence, we may need to impose a minimum compression rate. This could be achieved by setting a maximum value of the sum of y_i. (4) Min length: We observe that the original model sometimes produces very short compressed sentences. We therefore believe that it is also important to maintain a mininum length of the compressed sentence. This can be achieved by setting a minimum value of the sum of y_i.

Formally, the constraints are listed as follows:

$$\begin{aligned} \sum_{i=1}^{n} y_i &<= \beta n, \\ \sum_{i=1}^{n} y_i &>= \gamma n, \\ \forall y_i: \quad y_i &\leq y_{p_i}, \\ \forall r_i \in \mathcal{T}': \quad y_i &\geq y_{p_i}, \end{aligned}$$

where w_{p_i} is the parent word of w_i in the dependency parse tree, r_i is the dependency relation type between w_i and w_{p_i}, and $\mathcal{T}'$ is a set of dependency relations for which the child word is often retained when the parent word is retained in the compressed sentence.

The set $\mathcal{T}'$ is derived as follows. For each dependency relation type, based on the training data, we compute the conditional probability of the child word being retained given that the parent word is retained. If this probability is higher than 90%, we include this dependency relation type in $\mathcal{T}'$.

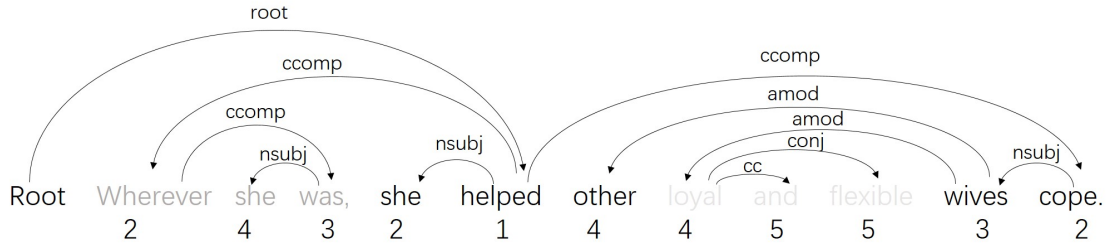

Figure 3: Dependency parse tree of an example sentence. The numbers below the words indicate the depths of the words in the tree. Words in gray are supposed to be deleted based on the ground truth.

3 Experiments

3.1 Datasets and Experiment Settings

Because we are mostly interested in a cross-domain setting where the model is trained on one domain and test on a different domain, we need data from different domains for our evaluation. Here we use three datasets.

***Google News*:** The first dataset contains 10,000 sentence pairs collected and released by Filippova et al. (2015)[2]. The sentences were automatically acquired from the web through Google News using a method introduced by Filippova and Altun (2013). The news articles were from 2013 and 2014.

***BNC News*:** The second dataset contains around 1,500 sentence pairs collected by Clarke and Lapata (2008)[3]. The sentences were from British National Corpus (BNC) and the American News Text corpus before 2008.

***Research Papers*:** The last dataset contains 100 sentences taken from 10 randomly selected papers published at the ACL conference in 2016.

For *Google News* and *BNC News*, we have the ground truth compressed sentences, which are deletion-based compressions, i.e., subsequences of the original sentences. For *Research Papers*, we use it only for manual evaluation in terms of readability and informativeness, as we will explain below.

We evaluate three settings of our method:

BiLSTM: In this setting, we use only the base bi-LSTM model without incorporating any syntactic feature.

BiLSTM+SynFeat: In this setting, we combine word embeddings with POS embeddings and dependency embeddings as input to the bi-LSTM model and use the predictions of $\boldsymbol{y}$ from the bi-LSTM model.

BiLSTM+SynFeat+ILP: In this setting, on top of **BiLSTM+SynFeat**, we solve the ILP problem as described in Section 2.4 to predict the final label sequence $\boldsymbol{y}$.

In the experiments, our model was trained using the Adam (Kingma and Ba, 2015) algorithm with a learning rate initialized at 0.001. The dimension of the hidden layers of bi-LSTM is 100. Word embeddings are initialized from GloVe 100-dimensional pre-trained embeddings (Pennington et al., 2014). POS and dependency embeddings are randomly initialized with 40-dimensional vectors. The embeddings are all updated during training. Dropping probability for dropout layers between stacked LSTM layers is 0.5. The batch size is set as 30. For the ILP part, λ is set to 0.5, β and γ are turned by the validation data and finally they are set to 0.7 and 0.2, respectively. We utilize an open source ILP solver[4] in our method.

We compare our methods with a few baselines:

LSTM: This is the basic LSTM-based deletion method proposed by (Filippova et al., 2015). We report both the performance they achieved using close to two million training sentence pairs and the performance of our re-implementation of their model trained on the 8,000 sentence pairs.

LSTM+: This is advanced version of the model proposed by Filippova et al. (2015), where the authors incorporated some dependency parse tree information into the LSTM model and used the prediction on the previous word to help the prediction on the current word.

Traditional ILP: This is the ILP-based method proposed by Clarke and Lapata (2008). This method does not use neural network models and

[3]Available at http://jamesclarke.net/research/resources/.

[4]gnu.org/software/glpk

is an unsupervised method that relies heavily on the syntactic structures of the input sentences[5].

Abstractive seq2seq: This is an abstractive sequence-to-sequence model trained on 3.8 million Gigaword title-article pairs as described in Section 1.

3.2 Automatic Evaluation

With the two datasets *Google News* and *BNC News* that have the ground truth compressed sentences, we can perform automatic evaluation. We first split the *Google News* dataset into a training set, a validation set and a test set. We took the first 1,000 sentence pairs from *Google News* as the test set, following the same practice as Filippova et al. (2015). We then use 8,000 of the remaining sentence pairs for training and the other 1,000 sentence pairs for validation. For the *NBC News* dataset, we use it only as a test set, applying the sentence compression models trained from the 8,000 sentence pairs from *Google News*.

We use the ground truth compressed sentences to compute accuracy and F1 scores. Accuracy is defined as the percentage of tokens for which the predicted label y_i is correct. F1 scores are derived from precision and recall values, where precision is defined as the percentage of retained words that overlap with the ground truth, and recall is defined as the percentage of words in the ground truth compressed sentences that overlap with the generated compressed sentences.

We report both in-domain performance and cross-domain performance in Table 1. From the table, we have the following observations: (1) For the abstractive sequence-to-sequence model, it was trained on the Gigaword data, so for both *Google News* and *NBC News*, the performance shown is cross-domain performance. We can see that indeed this abstractive method performed poorly in cross-domain settings. (2) In the in-domain setting, with the same amount of training data (8,000), our BiLSTM method with syntactic features (BiLSTM+SynFeat and BiLSTM+SynFeat+ILP) performs similarly to or better than the LSTM+ method proposed by Filippova et al. (2015), in terms of both F1 and accuracy. This shows that our method is comparable to the LSTM+ method in the in-domain setting. (3) In the in-domain setting, even compared with the performance of LSTM+ trained on 2 million sentence pairs, our method trained on 8,000 sentence pairs does not perform substantially worse. (4) In the out-of-domain setting, our BiLSTM+SynFeat and BiLSTM+SynFeat+ILP methods clearly outperform the LSTM and LSTM+ methods. This shows that by incorporating more syntactic features, our methods learn a sentence compression model that is less domain-dependent. (5) The Traditional ILP method also works better than the LSTM and LSTM+ methods in the out-of-domain setting. This is probably because the Traditional ILP method relies heavily on syntax, which is less domain-dependent compared with lexical patterns. But the Traditional ILP method performs worse in the in-domain setting than both the LSTM and LSTM+ methods and our methods.

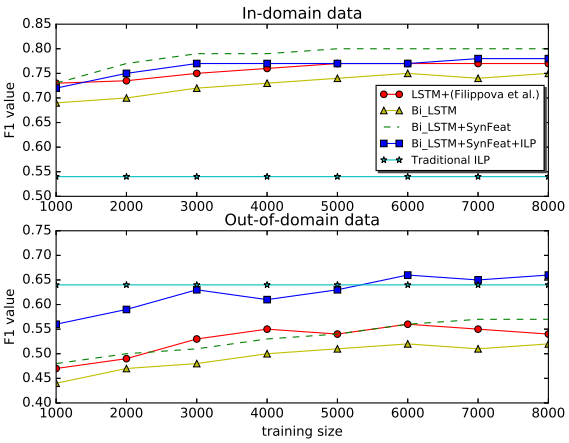

Figure 4: F1 scores with different sizes of training data for in-domain and cross-domain settings.

Overall, Table 1 shows that our proposed method combines both the strength of neural network models in the in-domain setting and the strength of the syntax-based methods in the cross-domain setting. Therefore, our method works reasonably well for both in-domain and out-of-domain data.

We also notice that on *Google News*, adding the ILP layer decreased the sentence compression performance. After some analysis, we think the reason is that some of the constraints used in the ILP layer have led to less deletion but the ground truth compressed sentences in the *Google News* data tend to be shorter compared with those in the *NBC News* data.

We also conduct additional experiments to see the effect of the training data size on our meth-

Table 1: Automatic evaluation of our sentence compression methods. CR standards for compression rate and is defined as the average percentage of words that are retained after compression.

ods and the LSTM+ method. Figure 4 shows the F1 scores on the in-domain *Google News* data and the out-of-domain *NBC News* data when we train the models using different amounts of sentence pairs. We can see that in the in-domain setting, our method does not have any advantage over the LSTM+ method. But in the cross-domain setting, our method that uses ILP to impose syntax-based constraints clearly performs better than LSTM+ when the amount of training data is relatively small.

3.3 Manual Evaluation

The evaluation above does not look at the readability of the compressed sentences. In order to evaluate whether sentences generated by our method are readable, we adopt the manual evaluation procedure by Filippova et al. (2015) to compare our method with LSTM+ and Traditional ILP in terms of readability and informativeness. We asked two raters to score a randomly selected set of 100 sentences from the *Research Papers* dataset. The compressed sentences were randomly ordered and presented to the human raters to avoid any bias. The raters were asked to score the sentences on a five-point scale in terms of both readability and informativeness. We show the average scores of the three methods we compare in Table 3. We can see that our BiLSTM+SynFeat+ILP method clearly outperforms the two baseline methods in the manual evaluation.

We also show a small sample of input sentences from the *Research Papers* dataset and the automatically compressed sentences by different methods in Table 2. As we can see from the table, a general weakness of the LSTM+ method is that the compressed sentences may not be grammatical. In comparison, our method does better in terms of preserving grammaticality.

4 Related Work

Sentence compression can be seen as sentence-level summarization. Similar to document summarization, sentence compression methods can be divided into extractive compression and abstractive compression methods, based on whether words in the compressed sentence all come from the source sentence. In this paper, we focus on deletion-based sentence compression, which is a spacial case of extractive sentence compression.

An early work on sentence compression was done by Jing (2000), who proposed to use several resources to decide whether a phrase in a sentence should be removed or not. Knight and Marcu (2000) proposed to apply a noisy-channel model from machine translation to the sentence compression task, but their model encountered the problem that many SCFG rules have unreliable probability estimates with inadequate data. Galley and McKeown (2007) tried to solve this problem by utilizing parent annotation, Markovization and lexicalization, which have all been shown to improve the quality of the rule probability estimates. Cohn and Lapata (2007) formulated sentence compression as a tree-to-tree rewrite problem. They utilized a synchronous tree substitution grammar (STSG) to license the space of all possible rewrites. Each rule has a weight learned from the training data. For prediction, an algorithm was used to search for the best scoring compression using the gram-

mar rules. Besides, Cohn and Lapata (2008) extended this model to abstractive sentence compression, which includes substitution, reordering and insertion. McDonald (2006) proposed a graph-based sentence compression method. The general idea is that each word pair in the original sentence has a score. The task then becomes how to find a compressed sentence with a length limit according word pair scores. Their method is similar to graph-based dependency parsing. Clarke and Lapata (2008) first used an ILP framework for sentence compression. In the paper, the author put forward three models. The first model is a language model reformulated by ILP. As the first model treats all the words equally, the second model uses a corpus to learn an importance score for each word and then incorporates it in the ILP model. The Last model, which is based on (McDonald, 2006), replaces the decoder with an ILP model and adds many linguistic constraints such as dependency parsing compared with the previous two ILP models. Filippova and Strube (2008) represented sentences with dependency parse trees and an ILP-based method was used to decide whether the dependencies were preserved or not. Different from most previous work that treats sentence extraction and sentence compression separately, Berg-Kirkpatrick et al. (2011) jointly model the two processes in one ILP problem. Bigrams and subtrees are represented by some features, and feature are learned on some training data. The ILP problem maximizes the coverage of weighted bigrams and deleted subtrees of the summary.

In recent years, neural network models, especially sequence-to-sequence models, have been applied to sentence compression. Our work is based on the deletion-based LSTM model for sentence compression by Filippova et al. (2015). There has also been much interest in applying sequence-to-sequence models for abstractive sentence compression (Rush et al., 2015; Chopra et al., 2016). As we pointed out in Section 1, in a cross-domain setting, abstractive sentence compression may not be suitable.

5 Conclusions

In this paper, we studied how to modify an LSTM model for deletion-based sentence compression so that the model works well in a cross-domain setting. We hypothesized that incorporation of syntactic information into the training of the LSTM model would help. We thus proposed two ways to incorporate syntactic information, one through directly adding POS tag embeddings and dependency type embeddings, and the other through the objective function and constraints of an Integer Linear Programming (ILP) model. The experiments showed that our proposed bi-LSTM model with syntactic features and an ILP layer works

well in both in-domain and cross-domain settings. In comparison, the original LSTM model does not work well in the cross-domain setting, and a traditional ILP method does not work well in the in-domain setting. Therefore, our proposed method is relatively more robust than these baselines. We also manually evaluated the compressed sentences generated by our method and found that the method works better than the baselines in terms of both readability and informativeness.

Abstract

Finding the correct hypernyms for entities is essential for taxonomy learning, fine-grained entity categorization, knowledge base construction, etc. Due to the flexibility of the Chinese language, it is challenging to identify hypernyms in Chinese accurately. Rather than extracting hypernyms from texts, in this paper, we present a transductive learning approach to establish mappings from entities to hypernyms in the embedding space directly. It combines linear and non-linear embedding projection models, with the capacity of encoding arbitrary language-specific rules. Experiments on real-world datasets illustrate that our approach outperforms previous methods for Chinese hypernym prediction.

1 Introduction

A hypernym of an entity characterizes the *type* or the *class* of the entity. For example, the word `country` is the hypernym of the entity `Canada`. The accurate prediction of hypernyms benefits a variety of NLP tasks, such as taxonomy learning (Wu et al., 2012; Fu et al., 2014), fine-grained entity categorization (Ren et al., 2016), knowledge base construction (Suchanek et al., 2007), etc.

In previous work, the detection of hypernyms requires lexical, syntactic and/or semantic analysis of relations between entities and their respective hypernyms from a language-specific knowledge source. For example, Hearst (1992) is the pioneer work to extract *is-a* relations from a text corpus based on handcraft patterns. The following-up work mostly focuses on *is-a* relation extraction using automatically generated patterns (Snow et al., 2004; Ritter et al., 2009; Sang and Hofmann, 2009; Kozareva and Hovy, 2010) and relation inference based on distributional similarity measures (Kotlerman et al., 2010; Lenci and Benotto, 2012; Shwartz et al., 2016).

While these approaches have relatively high precision over English corpora, extracting hypernyms for entities is still challenging for Chinese. From the linguistic perspective, Chinese is a lower-resourced language with very flexible expressions and grammatical rules (Wang et al., 2015). For instance, there are no word spaces, explicit tenses and voices, and distinctions between singular and plural forms in Chinese. The order of words can be changed flexibly in sentences. Hence, as previous research indicates, hypernym extraction methods for English are not necessarily suitable for the Chinese language (Fu et al., 2014; Wang et al., 2015; Wang and He, 2016).

Based on such conditions, several classification methods are proposed to distinguish *is-a* and *not-is-a* relations based on Chinese encyclopedias (Lu et al., 2015; Li et al., 2015). Similar to Princeton WordNet, a few Chinese wordnets have also been developed (Huang et al., 2004; Xu et al., 2008; Wang and Bond, 2013). The most recent approaches for Chinese *is-a* relation extraction (Fu et al., 2014; Wang and He, 2016) use word embedding based linear projection models to map embeddings of hyponyms to those of their hypernyms, which outperform previous algorithms.

However, we argue that these projection-based methods may have three potential limitations: (i) Only positive *is-a* relations are used for projection learning. The distinctions between *is-a* and *not-is-a* relations in the embedding space are not modeled. (ii) These methods lack the capacity to encode linguistic rules, which are designed by linguists and usually have high precision. (iii) It assumes that the linguistic regularities of *is-a* rela-

tions can be solely captured by single or multiple linear projection models.

In this paper, we address these limitations by a two-stage transductive learning approach. It distinguishes *is-a* and *not-is-a* relations given a Chinese word/phrase pair as input. In the initial stage, we train linear projection models on positive and negative training data separately and predict *is-a* relations jointly. In the transductive learning stage, the initial prediction results, linguistic rules and the non-linear mappings from entities to hypernyms are optimized simultaneously in a unified framework. This optimization problem can be efficiently solved by blockwise gradient descent. We evaluate our method over two public datasets and show that it outperforms state-of-the-art approaches for Chinese hypernym prediction.

The rest of this paper is organized as follows. We summarize the related work in Section 2. Our approach is introduced in Section 3. Experimental results are presented in Section 4. We conclude our paper in Section 5.

2 Related Work

In this section, we overview the related work on hypernym prediction and discuss the challenges of Chinese hypernym detection.

Pattern based methods identify *is-a* relations from texts by handcraft or automatically generated patterns. Hearst patterns (Hearst, 1992) are lexical patterns in English that are employed to extract *is-a* relations for taxonomy construction (Wu et al., 2012). Automatic approaches mostly use iterative learning paradigms such that the system learns new *is-a* relations and patterns simultaneously. A few relevant studies can be found in (Caraballo, 1999; Etzioni et al., 2004; Sang, 2007; Pantel and Pennacchiotti, 2006; Kozareva and Hovy, 2010). To avoid "semantic drift" in iterations, Snow et al. (2004) train a hypernym classifier based on syntactic features based on parse trees. Carlson et al. (2010) exploit multiple learners to extract relations via coupled learning. These approaches are not effective for Chinese for two reasons: i) Chinese *is-a* relations are expressed in a highly flexible manner (Fu et al., 2014) and ii) the accuracy of basic NLP tasks such as dependency parsing still need improvement for Chinese (Li et al., 2013).

Inference based methods take advantage of distributional similarity measures (DSM) to infer relations between words. They assume that a hypernym may appear in all contexts of the hyponyms and a hyponym can only appear in part of the contexts of its hypernyms. In previous work, Kotlerman et al. (2010) design directional DSMs to model the asymmetric property of *is-a* relations. Other DSMs are introduced in (Bhagat et al., 2007; Szpektor et al., 2007; Lenci and Benotto, 2012; Santus et al., 2014). Shwartz et al. (2016) combine dependency parsing and DSM to improve the performance of hypernymy detection. The reason why DSM is not effective for Chinese is that the contexts of entities in Chinese are flexible and sparse.

Encyclopedia based methods take encyclopedias as knowledge sources to construct taxonomies. Ponzetto and Strube (2007) design features from multiple aspects to predict *is-a* relations between entities and categories in English Wikipedia. The taxonomy in YAGO (Suchanek et al., 2007) is constructed by linking conceptual categories in Wikipedia to WordNet synsets (Miller, 1995). For Chinese, Li et al. (2015) propose an SVM-based approach to build a large Chinese taxonomy from Wikipedia. Similar classification based algorithms are presented in (Fu et al., 2013; Lu et al., 2015). Due to the lack of Chinese version of WordNet, several Chinese semantic dictionaries have been conducted, such as Sinica BOW (Huang et al., 2004), SEW (Xu et al., 2008), COW (Wang and Bond, 2013), etc. These approaches have higher accuracy than mining hypernym relations from texts directly. However, they heavily rely on existing knowledge sources and are difficult to extend to different domains.

To tackle these challenges, **word embedding based methods** directly model the task of hypernym prediction as learning a mapping from entity vectors to their respective hypernym vectors in the embedding space. The vectors can be pretrained by neural language models (Mikolov et al., 2013). For the Chinese language, Fu et al. (2014) train piecewise linear projection models based on a Chinese thesaurus. The state-of-the-art method (Wang and He, 2016) combines an iterative learning procedure and Chinese Hearst-style patterns to improve the performance of projection models. They can reduce data noise by avoiding direct parsing of Chinese texts, but still capture the linguistic regularities of *is-a* relations based on word embeddings. Additionally, several work aims to study how to combine word embeddings for re-

lation classification, such as (Mirza and Tonelli, 2016). In our paper, we extend these approaches by modeling non-linear mappings from entities to hypernyms and adding linguistic rules via a unified transductive learning framework.

3 Proposed Approach

This section begins with a brief overview of our approach. After that, the detailed steps and the learning algorithm are introduced in detail.

3.1 Overview

Given a word/phrase pair (x_i, y_i), the goal of our task is to learn a classification model to predict whether y_i is the hypernym of x_i.

As illustrated in Figure 1, our approach has two stages: initial stage and transductive learning stage. The input is a positive *is-a* set D^+, a negative *is-a* set D^- and an unlabeled set D^U, all of which are the collections of word/phrase pairs.

Denote $\mathbf{x}_i$ as the embedding vector of word x_i, pre-trained and stored in a lookup table. In the initial stage, we train a linear projection model over D^+ such that for each $(x_i, y_i) \in D^+$, a projection matrix maps the entity vector $\mathbf{x}_i$ to its hypernym vector $\mathbf{y}_i$. A similar model is also trained over D^-. Based on the two models, we estimate the prediction score and the confidence score for each $(x_i, y_i) \in D^U$. In the transductive learning stage, a joint optimization problem is formed to learn the final prediction score for each $(x_i, y_i) \in D^U$. It aims to minimize the prediction errors based on the human labeled data, the initial model prediction and linguistic rules. It also employs non-linear mappings to capture linguistic regularities of *is-a* relations other than linear projections.

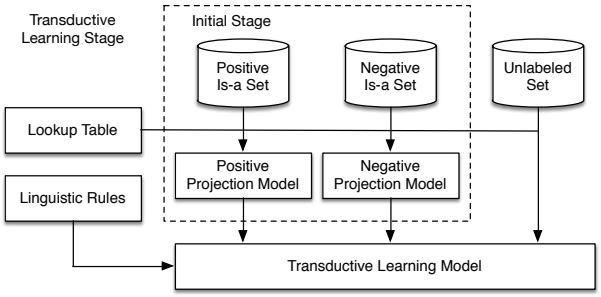

Figure 1: General framework of our approach.

3.2 Initial Model Training

The initial stage models how entities are mapped to their hypernyms or non-hypernyms by projection learning. We first train a *Skip-gram* model (Mikolov et al., 2013) to learn word embeddings over a large text corpus. Inspired by (Fu et al., 2014; Wang and He, 2016), for each $(x_i, y_i) \in D^+$, we assume there is a positive projection model such that $\mathbf{M}^+\mathbf{x}_i \approx \mathbf{y}_i$ where $\mathbf{M}^+$ is an $|\mathbf{x}_i| \times |\mathbf{x}_i|$ projection matrix[1]. However, this model does not capture the semantics of *not-is-a* relations. Thus, we learn a negative projection model $\mathbf{M}^-\mathbf{x}_i \approx \mathbf{y}_i$ where $(x_i, y_i) \in D^-$. This approach is equivalent to learning two separate translation models within the same semantic space. For parameter estimation, we minimize the two following objectives:

$$J(\mathbf{M}^+) = \frac{1}{2} \sum_{(x_i,y_i)\in D^+} \|\mathbf{M}^+\mathbf{x}_i - \mathbf{y}_i\|_2^2 + \frac{\lambda}{2}\|\mathbf{M}^+\|_F^2$$

$$J(\mathbf{M}^-) = \frac{1}{2} \sum_{(x_i,y_i)\in D^-} \|\mathbf{M}^-\mathbf{x}_i - \mathbf{y}_i\|_2^2 + \frac{\lambda}{2}\|\mathbf{M}^-\|_F^2$$

where $\lambda > 0$ is a Tikhonov regularization parameter (Golub et al., 1999).

In the testing phase, for each $(x_i, y_i) \in D^U$, denote $d^+(x_i, y_i) = \|\mathbf{M}^+\mathbf{x}_i - \mathbf{y}_i\|_2$ and $d^-(x_i, y_i) = \|\mathbf{M}^-\mathbf{x}_i - \mathbf{y}_i\|_2$. The *prediction score* is defined as:

$$score(x_i, y_i) = \tanh(d^-(x_i, y_i) - d^+(x_i, y_i))$$

where $score(x_i, y_i) \in (-1, 1)$. Higher prediction score indicates there is a larger probability of an *is-a* relation between x_i and y_i. We choose the hyperbolic tangent function rather than the sigmoid function to avoid the widespread saturation of sigmoid function (Menon et al., 1996). Because the semantics of Chinese is-a and not-is-a relations are complicated and difficult to model (Fu et al., 2014), we do not impose explicit connections between $\mathbf{M}^+$ and $\mathbf{M}^-$ and let the algorithm learn the parameters automantically.

The difference between $d^+(x_i, y_i)$ and $d^-(x_i, y_i)$ can be also used to indicate whether the models are confident enough to make a prediction.

[1] We have also examined piecewise linear projection models proposed in (Fu et al., 2014; Wang and He, 2016) as the initial models for transductive learning. However, we found that this practice is less efficient and the performance does not improve significantly.

In this paper, we calculate the *confidence score* as:

$$conf(x_i, y_i) = \frac{|d^+(x_i, y_i) - d^-(x_i, y_i)|}{\max\{d^+(x_i, y_i), d^-(x_i, y_i)\}}$$

where $conf(x_i, y_i) \in (0, 1)$. Higher confidence score means that there is a larger probability that the models can predict whether there is an *is-a* relation between x_i and y_i correctly. This score gives different data instances different weights in the transductive learning stage.

3.3 Transductive Non-linear Learning

Although linear projection methods are effective for Chinese hypernym prediction, it does not encode non-linear transformation and only leverages the positive data. We present an optimization framework for non-linear mapping utilizing both labeled and unlabeled data and linguistic rules by transductive learning (Gammerman et al., 1998; Chapelle et al., 2006).

Let F_i be the final prediction score of the word/phrase pair (x_i, y_i). In the initialization stage of our algorithm, we set $F_i = 1$ if $(x_i, y_i) \in D^+$, $F_i = -1$ if $(x_i, y_i) \in D^-$ and set F_i randomly in $(-1, 1)$ if $(x_i, y_i) \in D^U$. In matrix representation, denote $\mathbf{F}$ as the $m \times 1$ final prediction vector where $m = |D^+| + |D^-| + |D^U|$. F_i is the ith element in $\mathbf{F}$. The three components in our transductive learning model are as follows:

3.3.1 Initial Prediction

Denote $\mathbf{S}$ as an $m \times 1$ initial prediction vector. We set $S_i = 1$ if $(x_i, y_i) \in D^+$, $S_i = -1$ if $(x_i, y_i) \in D^-$ and $S_i = score(x_i, y_i)$ if $(x_i, y_i) \in D^U$. In order to encode the confidence of model prediction, we define $\mathbf{W}$ as an $m \times m$ diagonal weight matrix. The element in the ith row and the jth column of $\mathbf{W}$ is set as follows:

$$W_{i,j} = \begin{cases} conf(x_i, y_i) & i = j, (x_i, y_i) \in D^U \\ 1 & i = j, (x_i, y_i) \in D^+ \cup D^- \\ 0 & \text{Otherwise} \end{cases}$$

The objective function is defined as: $\mathscr{O}_s = \|\mathbf{W}(\mathbf{F} - \mathbf{S})\|_2^2$, which encodes the hypothesis that the final prediction should be similar to the initial prediction for unlabeled data or human labeling for training data. The weight matrix $\mathbf{W}$ gives the largest weight (i.e., 1) to all the pairs in $D^+ \cup D^-$ and a larger weight to the pair $(x_i, y_i) \in D^U$ if the initial prediction is more confident.

3.3.2 Linguistic Rules

Although linguistic rules can only cover a few circumstances, they are effective to guide the learning process. For Chinese hypernym prediction, Li et al. (2015) study the word formation of conceptual categories in Chinese Wikipedia. In our model, let C be the collection of linguistic rules. γ_i is the true positive (or negative) rate with respect to the respective positive (or negative) rule $c_i \in C$, estimated over the training set. Considering the word formation of Chinese entities and hypernyms, we design one positive rule (i.e., P1) and two negative rules (i.e., N1 and N2), shown in Table 1.

Let $\mathbf{R}$ be an $m \times 1$ linguistic rule vector and R_i is the ith element in $\mathbf{R}$. For training data, we set $R_i = 1$ if $(x_i, y_i) \in D^+$ and $R_i = -1$ if $(x_i, y_i) \in D^-$, which follows the same settings as those in $\mathbf{S}$. For unlabeled pairs that do not match any linguistic rules in C, we update $R_i = F_i$ in each iteration of the learning process, meaning no loss for errors imposed in this part.

For other conditions, denote $C_{(x_i,y_i)} \subseteq C$ as the collection of rules that (x_i, y_i) matches. If $C_{(x_i,y_i)}$ are positive rules, we set R_i as follows:

$$R_i = \max\{F_i, \max_{c_j \in C_{(x_i,y_i)}} \gamma_j\}$$

Similarly, if $C_{(x_i,y_i)}$ are negative rules, we have:

$$R_i = -\max\{-F_i, \max_{c_j \in C_{(x_i,y_i)}} \gamma_j\}$$

which means F_i receives a penalty only if $F_i < \max_{c_j \in C_{(x_i,y_i)}} \gamma_j$ for pairs that match positive rules or $F_i > -\max_{c_j \in C_{(x_i,y_i)}} \gamma_j$ for negative rules[2]. The objective function is: $\mathscr{O}_r = \|\mathbf{F} - \mathbf{R}\|_2^2$. In this way, our model can integrate arbitrary "soft" constraints, making it robust to false positives or negatives introduced by these rules.

3.3.3 Non-linear Learning

TransLP is a transductive label propagation framework (Liu and Yang, 2015) for link prediction, previously used for applications such as text classification (Xu et al., 2016). In our work, we extend their work for our task, modeling non-linear mappings from entities to hypernyms.

[2]We do not consider the cases where a pair matches both positive and negative rules because such cases are very rare, and even non-existent in our datasets. However, our method can deal with these cases by using some simple heuristics. For example, we can update R_i using either of the following two ways: i) $R_i = F_i$ and ii) $R_i = F_i + \sum_{c_j \in C_{(x_i,y_i)}} \gamma_j$.

P1	The head word of the entity x matches that of the candidate hypernym y. For example, 动物 (Animal) is the correct hypernym of 哺乳动物 (Mammal).
N1	The head word of the entity x matches the non-head word of the candidate hypernym y. For example, 动物学 (Zoology) is not a hypernym of 哺乳动物 (Mammal).
N2	The head word of the candidate hypernym y matches an entry in a Chinese lexicon extended based on the lexicon used in Li et al. (2015). It consists of 184 non-taxonomic, thematic words such as 政治 (Politics), 军事 (Military), etc.

Table 1: Three linguistic rules used in our work for Chinese hypernym prediction.

For *is-a* relations, we find that if y is the hypernym of x, it is likely that y is the hypernym of entities that are semantically close to x. For example, if we know `United States` is a `country`, we can infer `country` is the hypernym of similar entities such as `Canada`, `Australia`, etc. This intuition can be encoded in the similarity of the two pairs $p_i = (x_i, y_i)$ and $p_j = (x_j, y_j)$:

$$\text{sim}(p_i, p_j) = \begin{cases} \cos(\mathbf{x}_i, \mathbf{x}_j) & y_i = y_j \\ 0 & \text{otherwise} \end{cases} \quad (1)$$

where $\mathbf{x}_i$ is the embedding vector of x_i[3].

This similarity indicates there exists a non-linear mapping from entities to hypernyms, which can not be encoded in linear projection based methods (Fu et al., 2014; Wang and He, 2016). Based on *TransLP* (Liu and Yang, 2015), this intuition can be model as propagating class labels (*is-a* or *not-is-a*) of labeled word/phrase pairs to similar unlabeled ones based on Eq. (1). For example, the score of *is-a* relations between `United State` and `country` will propagate to pairs such as `(Canada, country)` and `(Australia, country)` by random walks.

Denote $\mathbf{F}^*$ as the optimal solution of the problem $\min \mathscr{O}_s + \mathscr{O}_r$. Inspired by (Liu and Yang, 2015; Xu et al., 2016), we can add a Gaussian prior $N(\mathbf{F}^*, \mathbf{\Sigma})$ to $\mathbf{F}$ where $\mathbf{\Sigma}$ is the covariance matrix and $\Sigma_{i,j} = \text{sim}(p_i, p_j)$. Hence the optimization objective of this part is defined as: $\mathscr{O}_n = \mathbf{F}^T\mathbf{\Sigma}^{-1}\mathbf{F}$ which is linearly proportional to the negative likelihood of the Gaussian random field prior. This means we minimize the training error and encourage $\mathbf{F}$ to have a smooth propagation with respect to the similarities among pairs defined by Eq. (1) at the same time.

[3]We only consider the similarity between entities and not candidate hypernyms because the similar rule for candidate hypernyms is not true. For example, nouns close to `country` in our *Skip-gram* model are `region`, `department`, etc. They are not all correct hypernyms of `United States`, `Canada`, `Australia`, etc.

3.3.4 Joint Optimization

By combining the three components together, we minimize the following function:

$$J(\mathbf{F}) = \mathscr{O}_s + \mathscr{O}_r + \frac{\mu_1}{2}\mathscr{O}_n + \frac{\mu_2}{2}\|\mathbf{F}\|_2^2 \quad (2)$$

where $\|\mathbf{F}\|_2^2$ imposes an additional smooth l_2-regularization on $\mathbf{F}$. μ_1 and μ_2 are regularization parameters that can be tuned manually.

Based on the convexity of the optimization problem, we can learn the optimal values of $\mathbf{F}$ is via gradient descent. The derivative of $\mathbf{F}$ with respect to $J(\mathbf{F})$ is:

$$\frac{\mathrm{d}J(\mathbf{F})}{\mathrm{d}\mathbf{F}} = \mathbf{W}^2(\mathbf{F}-\mathbf{S})+(\mathbf{F}-\mathbf{R})+\mu_1\mathbf{\Sigma}^{-1}\mathbf{F}+\mu_2\mathbf{F}$$

which is computationally expensive when m is large. After $\mathbf{W}^2$, $\mathbf{S}$, $\mathbf{R}$ and $\mathbf{\Sigma}^{-1}$ are pre-computed, the runtime complexity of the loop of gradient descent is $O(tm^2)$ where t is the number of iterations.

To speed up the learning process, we introduce a *blockwise gradient descent* technique. From the definition of Eq. (2), we can see that the optimal values of F_i and F_j with respect to (x_i, y_i) and (x_j, y_j) are irrelevant if $y_i \neq y_j$. Therefore, the original optimization problem can be decomposed and solved separately according to different candidate hypernyms.

Let H be the collection of candidate hypernyms in D^U. For each $h \in H$, denote D_h as the collection of word/phase pairs in $D^+ \cup D^- \cup D^U$ that share the same candidate hypernym h. The original problem can be decomposed into $|H|$ optimization subproblems over D_h for each $h \in H$. Denote $\mathbf{W}_h$, $\mathbf{S}_h$, $\mathbf{R}_h$, $\mathbf{F}_h$ and $\mathbf{\Sigma}_h$ as the weight matrix, the initial prediction vector, the rule prediction vector, the final prediction vector and the entity similarity covariance matrix with respect D_h. The objective function can be rewritten as:

$J(\mathbf{F}) = \sum_{h \in H} \tilde{J}(\mathbf{F}_h)$ where

$$\tilde{J}(\mathbf{F}_h) = \|\mathbf{W}_h(\mathbf{F}_h - \mathbf{S}_h)\|_2^2 + \|\mathbf{F}_h - \mathbf{R}_h\|_2^2 + \frac{\mu_1}{2}\mathbf{F}_h^T \mathbf{\Sigma}_h^{-1} \mathbf{F}_h + \frac{\mu_2}{2}\|\mathbf{F}_h\|_2^2$$

We additionally use $^{(n)}$ to denote the values of matrices or vectors in the nth iteration. $\mathbf{F}_h^{(n)}$ is iteratively updated based on the following equation:

$$\mathbf{F}_h^{(n+1)} = \mathbf{F}_h^{(n)} - \eta \cdot \frac{\mathrm{d}\tilde{J}(\mathbf{F}_h^{(n)})}{\mathrm{d}\mathbf{F}_h^{(n)}}$$

where η is the learning rate. To this end, we present the learning algorithm in Algorithm 1.

Algorithm 1 Learning Algorithm

1: Initialize $\mathbf{W}_h$ and $\mathbf{S}_h$ based on the initial prediction model;
2: Randomly initialize $\mathbf{F}_h^{(0)}$;
3: Compute $\mathbf{\Sigma}_h^{-1}$ based on entity similarities;
4: Initialize counter $n = 1$;
5: **for** each linguistic rule $c_i \in C$ **do**
6: Estimate γ_i over the training set;
7: **end for**
8: **while** $\|\mathbf{F}_h^{(n)} - \mathbf{F}_h^{(n+1)}\|_2 < 10^{-3}$ **do**
9: Compute $\mathbf{R}_h^{(n)}$ based on C and $\mathbf{F}_h^{(n)}$;
10: Calculate $\frac{\mathrm{d}\tilde{J}(\mathbf{F}_h^{(n)})}{\mathrm{d}\mathbf{F}_h^{(n)}} = \mathbf{W}_h^2(\mathbf{F}_h^{(n)} - \mathbf{S}_h) + (\mathbf{F}_h^{(n)} - \mathbf{R}_h^{(n)}) + \mu_1 \mathbf{\Sigma}_h^{-1}\mathbf{F}_h^{(n)} + \mu_2 \mathbf{F}_h^{(n)}$;
11: Compute $\mathbf{F}_h^{(n+1)}$ for the next iteration: $\mathbf{F}_h^{(n+1)} = \mathbf{F}_h^{(n)} - \eta \cdot \frac{\mathrm{d}\tilde{J}(\mathbf{F}_h^{(n)})}{\mathrm{d}\mathbf{F}_h^{(n)}}$;
12: Update counter $n = n + 1$;
13: **end while**
14: **return** Final prediction vector $\mathbf{F}_h^{(n+1)}$;

The runtime complexity of this algorithm is $O(\sum_{h \in D_h} t_h |D_h|^2)$ where t_h is the number of iterations to solve the subproblem over D_h. Although we do not know the upper bounds on the numbers of iterations of these two learning techniques, the runtime complexity can be reduced by blockwise gradient descent for two reasons: i) $\sum_{h \in D_h} |D_h| \leq m$ and ii) t_h has a large probability to be smaller than t due to the smaller number of data instances. This technique can be also viewed as optimizing Eq. (2) based on blockwise matrix computation.

Finally, for each $(x_i, y_i) \in D^U$, we predict that y_i is a hypernym of x_i if $F_i > \theta$ where $\theta \in (-1, 1)$ is a threshold tuned on the development set.

4 Experiments

In this section, we conduct experiments to evaluate our method. Section 4.1 to Section 4.5 report the experimental steps on Chinese datasets. We present the performance on English datasets in Section 4.6 and a discussion in Section 4.7.

4.1 Experimental Data

We have two collections of Chinese word/phase pairs as ground truth datasets. Each pair is labeled with an *is-a* or *not-is-a* tag. The first one (denoted as *FD*) is from Fu et al. (2014), containing 1,391 *is-a* pairs and 4,294 *not-is-a* pairs, which is the first publicly available dataset to evaluate this task. The second one (denoted as *BK*) is larger in size and crawled from Baidu Baike by ourselves, consisting of <entity, category> pairs. For each pair in *BK*, we ask multiple human annotators to label the tag and discard the pair with inconsistent labels by different annotators. In total, it contains 3,870 *is-a* pairs and 3,582 *not-is-a* pairs[4].

The Chinese text corpus is extracted from the contents of 1.2M entity pages from Baidu Baike[5], a Chinese online encyclopedia. It contains approximately 1.1B words. We use the open source toolkit *Ansj*[6] for Chinese word segmentation. Chinese words/phrases in our test sets may consist of multiple Chinese characters. We treat such word/phrase as a whole to learn embeddings, instead of using character-level embeddings.

In the following experiments, we use 60% of the data for training, 20% for development and 20% for testing, partitioned randomly. By rotating the 5-fold subsets of the datasets, we report the performance of each method on average.

4.2 Parameter Analysis

The word embeddings are pre-trained by ourselves on the Chinese corpus. In total, we obtain the 100-dimensional embedding vectors of 5.8M distinct words. The regularization parameters are set to $\lambda = 10^{-3}$ and $\mu_1 = \mu_2 = 10^{-4}$, fine tuned on the development set.

The choice of θ reflects the precision-recall trade-off in our model. A larger value of θ means we pay more attention to precision rather than recall. Figure 2 illustrates the precision-recall curves

on both datasets. It can be seen that the performance of our method is generally better in *BK* than *FD*. The most probable cause is that *BK* is a large dataset with more "balanced" numbers of positive and negative data. Finally, θ is set to 0.05 on *FD* and 0.1 on *BK*.

4.3 Performance

In a series of previous work (Fu et al., 2013, 2014; Wang and He, 2016), several pattern-based, inference-based and encyclopedia-based *is-a* relation extraction methods for English have been implemented for the Chinese language. As their experiments show, these methods achieve the F-measure of lower than 60% in most cases, which are not suggested to be strong baselines for Chinese hypernym prediction. Interested readers may refer to their papers for the experimental results.

To make the convincing conclusion, we employ two recent state-of-the-art approaches for Chinese *is-a* relation identification (Fu et al., 2014; Wang and He, 2016) as baselines. We also take the word embedding based classification approach (Mirza and Tonelli, 2016)[7] and Chinese Wikipedia based SVM model (Li et al., 2015) as baselines to predict *is-a* relations between words[8]. The experimental results are illustrated in Table 2.

For Fu et al. (2014), we test the performance using a linear projection model (denoted as S in Table 2) and piecewise projection models (P). It shows that the semantics of *is-a* relations are better modeled by multiple projection models, with a slight improvement in F-measure. By combining iterative projection models and pattern-based validation, the most recent approach (Wang and He, 2016) increases the F-measure by 4% and 2% in two datasets. In this method, the pattern-based statistics are calculated using the same corpus over which we train word embedding models. The main reason of the improvement may be that the projection models have a better generalization power by applying an iterative learning paradigm.

Mirza and Tonelli (2016) is implemented using three different strategies in combining the word vectors of a pair: i) concatenation $\mathbf{x}_i \oplus \mathbf{y}_i$ (de-

[7] Although the experiments in their paper are mostly related to temporal relations, the method can be applied to *is-a* relations without modification.

[8] Previously, these methods used different knowledge sources to train models and thus the results in their papers are not directly comparable with ours. To make fair comparison, we take the training data as the same knowledge source to train models for all methods.

Candidate Hypernym	P	T	Candidate Hypernym	P	T

noted as C), ii) addition $\mathbf{x}_i + \mathbf{y}_i$ (A) and iii) subtraction $\mathbf{x}_i - \mathbf{y}_i$ (S). As seen, the classification models using addition and subtraction have similar performance in two datasets, while the concatenation strategy outperforms previous two approaches. Although Li et al. (2015) achieve a high performance in their dataset, this method does not perform well in ours. The most likely cause is that the features in that work are designed specifically for the Chinese Wikipedia category system. Our initial model has a higher accuracy than all the baselines. By utilizing the transductive learning framework, we boost the F-measure by 1.7% and 2.1%, respectively. Therefore, our method is effective to predict hypernyms of Chinese entities. We further conduct statistical tests which show our method significantly ($p < 0.01$) improves the F-measure over the state-of-the-art method (Wang and He, 2016).

4.4 Effectiveness of Linguistic Rules

To illustrate the effectiveness of linguistic rules, we present the true positive (or negative) rate by using one positive (or negative) rule solely, shown in Table 4. These values serve as γ_is in the transductive learning stage. The results indicate that these rules have high precision (over 90%) over both datasets for our task.

We state that currently we only use a few handcraft linguistic rules in our work. The proposed approach is a general framework that can encode arbitrary numbers of rules and in any language.

4.5 Error Analysis and Case Studies

We analyze correct and error cases in the experiments. Some examples of prediction results are shown in Table 3. We can see that our method is generally effective. However, some mistakes occur mostly because it is difficult to distinguish strict *is-a* and *topic-of* relations. For example, the entity Nuclear Reactor is semantically close to Nuclear Energy. The error statistics show that such kind of errors account for approximately 80.2% and 78.6% in two test sets, respectively.

Based on the literature study, we find that such problem has been also reported in (Fu et al., 2013; Wang and He, 2016). To reduce such errors, we employ the Chinese thematic lexicon based on Li et al. (2015) in the transductive learning stage but the coverage is still limited. Two possible solutions are: i) adding more negative training data of this kind; and ii) constructing a large-scale thematic lexicon automatically from the Web.

4.6 Experiments on English Datasets

To examine how our method can benefit hypernym prediction for the English language, we use two standard datasets in this paper. The first one is a benchmark dataset for distributional semantic evaluation, i.e., *BLESS* (Baroni and Lenci, 2011). Because the number of pairs in *BLESS* is relatively small, we also use the *Shwartz* (Shwartz et al., 2016) dataset. In the experiments, we treat the HYPER relations as positive data (1,337 pairs) and randomly sample 30% of the RANDOM relations as negative data (3,754 pairs) in *BLESS*. To create a relatively balanced dataset, we take the random split of *Shwartz* as input and use only 30% of the negative pairs. The dataset contains 14,135 positive pairs and 16,956 negative pairs. We use English Wikipedia as the text corpus to estimate the

Dataset	BLESS			Shwartz		
Method	P	R	F	P	R	F
Lenci and Benotto (2012)	42.8	38.6	40.6	38.5	50.1	43.5
Santus et al. (2014)	59.2	52.3	55.4	51.2	71.5	59.6
Fu et al. (2014) (S)	65.3	62.4	63.8	65.6	66.1	65.8
Fu et al. (2014) (P)	68.1	64.2	66.1	62.3	71.9	67.3
Mirza and Tonelli (2016) (C)	79.4	**84.1**	81.7	79.3	**80.9**	**80.1**
Mirza and Tonelli (2016) (A)	80.7	72.3	76.3	79.1	79.6	79.4
Mirza and Tonelli (2016) (S)	78.0	81.2	79.6	**80.5**	77.5	79.0
Wang and He (2016)	76.2	75.4	75.8	75.1	76.3	75.6
Ours (Initial)	79.3	76.3	77.7	77.2	76.8	77.0
Ours	**84.4**	79.5	**81.9**	79.1	77.5	78.3

Table 5: Performance comparison on test sets for English hypernym prediction (%).

statistics, and the pre-trained embedding vectors of English words[9].

For comparison, we test all the baselines over English datasets except Li et al. (2015). This is because most features in Li et al. (2015) can only be used in the Chinese environment. To implement Wang and He (2016) for English, we use the original Hearst patterns (Hearst, 1992) to perform relation selection and do not consider *not-is-a* patterns. We also take two recent DSM based approaches (Lenci and Benotto, 2012; Santus et al., 2014) as baselines. As for our own method, we do not use linguistic rules in Table 1 for English. The results are illustrated in Table 5. As seen, our method is superior to all the baselines over *BLESS*, with an F-measure of 81.9%. In *Shwartz*, while the approach (Mirza and Tonelli, 2016) has the highest F-measure of 80.1%, our method is generally comparable to theirs and outperforms others. The results suggest that although our method is not necessarily the state-of-the-art for English hypernym prediction, it has several potential applications. Refer to Section 4.7 for discussion.

4.7 Discussion

From the experiments, we can see that the proposed approach outperforms the state-of-the-art methods for Chinese hypernym prediction. Although the English language is not our focus, our approach still has relatively high performance. Additionally, our work has potential values for the following applications:

- **Domain-specific or Context-sparse Relation Extraction.** If the task is to predict relations between words when it is related to a specific domain or the contexts are sparse, even for English, traditional pattern-based methods are likely to fail. Our method can predict the existence of relations without explicit textual patterns and requires a relatively small amount of pairs as training data.

- **Under-resourced Language Learning.** Our method can be adapted for relation extraction in languages with flexible expressions, few knowledge resources and/or low-performance NLP tools. Our method does not require deep NLP parsing of sentences in a text corpus and thus the performance is not affected by parsing errors.

5 Conclusion

In summary, this paper introduces a transuctive learning approach for Chinese hypernym prediction. By modeling linear projection models, linguistic rules and non-linear mappings, our method is able to identify Chinese hypernyms with high accuracy. Experiments show that the performance of our method outperforms previous approaches. We also discuss the potential applications of our method besides Chinese hypernym prediction. In our work, the candidate Chinese hyponyms and hypernyms are extracted from user generated categories. In the future, we will study how to construct a taxonomy from texts in Chinese.

Abstract

Reading comprehension (RC), aiming to understand natural texts and answer questions therein, is a challenging task. In this paper, we study the RC problem on the Stanford Question Answering Dataset (SQuAD). Observing from the training set that most correct answers are centered around constituents in the parse tree, we design a constituent-centric neural architecture where the generation of candidate answers and their representation learning are both based on constituents and guided by the parse tree. Under this architecture, the search space of candidate answers can be greatly reduced without sacrificing the coverage of correct answers and the syntactic, hierarchical and compositional structure among constituents can be well captured, which contributes to better representation learning of the candidate answers. On SQuAD, our method achieves the state of the art performance and the ablation study corroborates the effectiveness of individual modules.

1 Introduction

Reading comprehension (RC) aims to answer questions by understanding texts, which is a challenge task in natural language processing. Various RC tasks and datasets have been developed, including Machine Comprehension Test (Richardson et al., 2013) for multiple-choice question answering (QA) (Sachan et al., 2015; Wang and McAllester, 2015), Algebra (Hosseini et al., 2014) and Science (Clark and Etzioni, 2016) for passing standardized tests (Clark et al., 2016), CNN/Daily Mail (Hermann et al., 2015) and Children's Book Test (Hill et al., 2015) for cloze-style QA (Chen et al., 2016; Shen et al., 2016), WikiQA (Yang et al., 2015), Stanford Question Answering Dataset (SQuAD) (Rajpurkar et al., 2016) and Microsoft Machine Reading Comprehension (Nguyen et al., 2016) for open domain QA. In this paper, we are specifically interested in solving the SQuAD QA task (Figure 1 shows an example), in light of its following features: (1) large scale: 107,785 questions, 23,215 paragraphs; (2) non-synthetic: questions are generated by crowdworkers; (3) large search space of candidate answers.

> The most authoritative account at the time came from the medical faculty in Paris in a report to the king of France that blamed the heavens. This report became the first and most widely circulated of a series of plague tracts that sought to give advice to sufferers. That the plague was caused by bad air became the most widely accepted theory. Today, this is known as the Miasma theory.
>
> 1. Who was the medical report written for?
> the king of France
>
> 2. What is the newer, more widely accepted theory behind the spread of the plague?
> bad air
>
> 3. What is the bad air theory officially known as?
> Miasma theory

Figure 1: An example of the SQuAD QA task

We study two major problems: (1) how to generate candidate answers? Unlike in multiple-choice QA and cloze-style QA where a small amount of answer choices are given, an answer in SQuAD could be any span in the text, resulting in a large search space with size $O(n^2)$ (Rajpurkar et al., 2016), where n is the number of words in the sentence. This would incur a lot of noise, ambigu-

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1405–1414
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1129

ity and uncertainty, making it highly difficult to pick up the correct answer. (2) how to effectively represent the candidate answers? First, long-range semantics spanning multiple sentences need to be captured. As noted in (Rajpurkar et al., 2016), the answering of many questions requires multiple-sentence reasoning. For instance, in Figure 1, the last two sentences in the passages are needed to answer the third question. Second, local syntactic structure needs to be incorporated into representation learning. The study by (Rajpurkar et al., 2016) shows that syntax plays an important role in SQuAD QA: there are a wide range of syntactic divergence between a question and the sentence containing the answer; the answering of 64.1% questions needs to deal with syntactic variation; experiments show that syntactic features are the major contributing factors to good performance.

To tackle the first problem, motivated by the observation in (Rajpurkar et al., 2016) that the correct answers picked up by human are not arbitrary spans, but rather centered around constituents in the parse tree, we generate candidate answers based upon constituents, which significantly reduces the search space. Different from (Rajpurkar et al., 2016) who only consider exact constituents, we adopt a constituent expansion mechanism which greatly improves the coverage of correct answers.

For the representation learning of candidate answers which are sequences of constituents, we first encode individual constituents using a *chain-of-trees LSTM* (CT-LSTM) and tree-guided attention mechanism, then feed these encodings into a chain LSTM (Hochreiter and Schmidhuber, 1997) to generate representations for the constituent sequences. The CT-LSTM seamlessly integrates intra-sentence tree LSTMs (Tai et al., 2015) which capture the local syntactic properties of constituents and an inter-sentence chain LSTM which glues together the sequence of tree LSTMs such that the semantics of each sentence can be propagated to others. The tree-guided attention leverages the hierarchical relations among constituents to learn question-aware representations.

Putting these pieces together, we design a constituent-centric neural network (CCNN), which contains four layers: a chain-of-trees LSTM encoding layer, a tree-guided attention layer and a candidate-answer generation layer, a prediction layer. Evaluation on SQuAD demonstrates the effectiveness of CCNN.

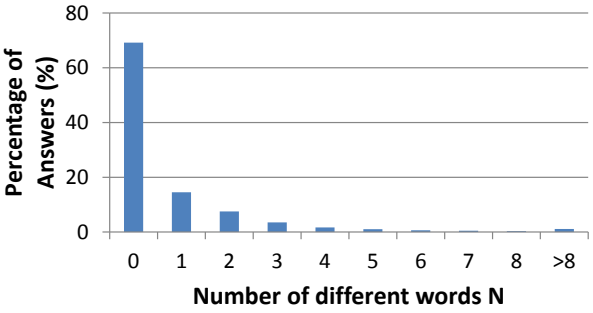

Figure 2: Percentage of answers that differ from their closest constituents by N words

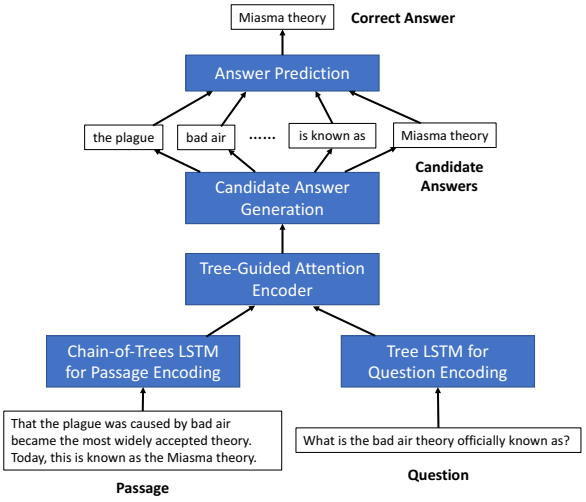

Figure 3: Constituent-centric neural network.

2 Constituent-Centric Neural Network for Reading Comprehension

2.1 Overall Architecture

As observed in (Rajpurkar et al., 2016), almost all correct answers are centered around the constituents. To formally confirm this, we compare the correct answers in the training set with constituents generated by the Stanford parser (Manning et al., 2014): for each correct answer, we find its "closest" constituent – the longest constituent that is a substring of the answer, and count how many words they differ from (let N denote this number). Figure 2 shows the percentage of answers whose N equals to $0, \cdots, 8$ and $N > 8$. As can be seen, $\sim$70% answers are exactly constituents ($N = 0$) and $\sim$97% answers differ from the closest constituents by less equal to 4 words. This observation motivates us to approach the

reading comprehension problem in a constituent-centric manner, where the generation of candidate answers and their representation learning are both based upon constituents.

Specifically, we design a Constituent-Centric Neural Network (CCNN) to perform end-to-end reading comprehension, where the inputs are the passage and question, and the output is a span in the passage that is mostly suitable to answer this question. As shown in Figure 3, the CCNN contains four layers. In the *encoding* layer, the chain-of-trees LSTM and tree LSTM encode the constituents in the passage and question respectively. The encodings are fed to the tree-guided *attention layer* to learn question-aware representations, which are passed to the *candidate-answer generation layer* to produce and encode the candidate answers based on constituent expansion. Finally, the *prediction layer* picks up the best answer from the candidates using a feed-forward network.

2.2 Encoding

Given the passages and questions, we first use the Stanford parser to parse them into constituent parse trees, then the encoding layer of CCNN learns representations for constituents in questions and passages, using tree LSTM (Tai et al., 2015) and chain-of-trees LSTM respectively. These LSTM encoders are able to capture the syntactic properties of constituents and long-range semantics across multiple sentences, which are crucial for SQuAD QA.

2.2.1 Tree LSTM for Question Encoding

Each question is a single sentence, having one constituent parse tree. Internal nodes in the tree represent constituents having more than one word and leaf nodes represent single-word constituent. Inspired by (Tai et al., 2015; Teng and Zhang, 2016), we build a bi-directional tree LSTM which consists of a bottom-up LSTM and a top-down LSTM, to encode these constituents (as shown in Figure 4). Each node (constituent) has two hidden states: $\mathbf{h}_\uparrow$ produced by the LSTM in bottom-up direction and $\mathbf{h}_\downarrow$ produced by the LSTM in top-down direction. Let T denote the maximum number of children an internal node could have. For each particular node, let L ($0 \leq L \leq T$) be the number of children it has, $\mathbf{h}_\uparrow^{(l)}$ and $\mathbf{c}_\uparrow^{(l)}$ be the bottom-up hidden state and memory cell of the l-th ($1 \leq l \leq L$) child (if any) respectively and $\mathbf{h}_\downarrow^{(p)}$

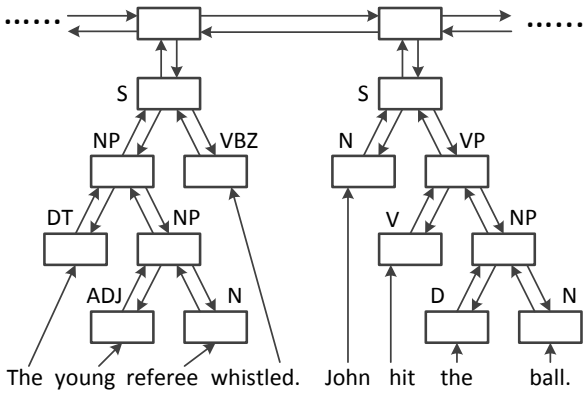

Figure 4: Chain-of-trees LSTM

and $\mathbf{c}_\downarrow^{(p)}$ be the top-down hidden state and memory cell of the parent.

In the bottom-up LSTM, each node has an input gate $\mathbf{i}_\uparrow$, L forget gates $\{\mathbf{f}_\uparrow^{(l)}\}_{l=1}^L$ corresponding to different children, an output gate $\mathbf{o}_\uparrow$ and a memory cell $\mathbf{c}_\uparrow$. For an internal node, the inputs are the hidden states and memory cells of its children and the transition equations are defined as:

$$
\begin{aligned}
&\mathbf{i}_\uparrow = \sigma(\textstyle\sum_{l=1}^{L} \mathbf{W}_\uparrow^{(i,l)} \mathbf{h}_\uparrow^{(l)} + \mathbf{b}_\uparrow^{(i)}) \\
&\forall l, \mathbf{f}_\uparrow^{(l)} = \sigma(\mathbf{W}_\uparrow^{(f,l)} \mathbf{h}_\uparrow^{(l)} + \mathbf{b}_\uparrow^{(f,l)}) \\
&\mathbf{o}_\uparrow = \sigma(\textstyle\sum_{l=1}^{L} \mathbf{W}_\uparrow^{(o,l)} \mathbf{h}_\uparrow^{(l)} + \mathbf{b}_\uparrow^{(o)}) \\
&\mathbf{u}_\uparrow = \tanh(\textstyle\sum_{l=1}^{L} \mathbf{W}_\uparrow^{(u,l)} \mathbf{h}_\uparrow^{(l)} + \mathbf{b}_\uparrow^{(u)}) \\
&\mathbf{c}_\uparrow = \mathbf{i}_\uparrow \odot \mathbf{u}_\uparrow + \textstyle\sum_{l=1}^{L} \mathbf{f}_\uparrow^{(l)} \odot \mathbf{c}_\uparrow^{(l)} \\
&\mathbf{h}_\uparrow = \mathbf{o}_\uparrow \odot \tanh(\mathbf{c}_\uparrow)
\end{aligned}
\tag{1}
$$

where the weight parameters $\mathbf{W}$ and bias parameters $\mathbf{b}$ with superscript l such as $\mathbf{W}_\uparrow^{(i,l)}$ are specific to the l-th child. For a leaf node which represents a single word, it has no forget gate and the input is the wording embedding (Pennington et al., 2014) of this word.

In the top-down direction, the gates, memory cell and hidden state are defined in a similar fashion as the bottom-up direction (Eq.(1)). For an internal node except the root, the inputs are the hidden state $\mathbf{h}_\downarrow^{(p)}$ and memory cell $\mathbf{c}_\downarrow^{(p)}$ of its parents. For a leaf node, in addition to $\mathbf{h}_\downarrow^{(p)}$ and $\mathbf{c}_\downarrow^{(p)}$, the inputs also contain the word embedding. For the root node, the top-down hidden state $\mathbf{h}_\downarrow^{(r)}$ is set to its bottom-up hidden state $\mathbf{h}_\uparrow^{(r)}$. $\mathbf{h}_\uparrow^{(r)}$ captures the semantics of all constituents, which is then replicated as $\mathbf{h}_\downarrow^{r}$ and propagated downwards to each individual constituent.

Concatenating the hidden states of two directions, we obtain the LSTM encoding for each node

$\mathbf{h} = [\mathbf{h}_\uparrow; \mathbf{h}_\downarrow]$ which will be the input of the attention layer. The bottom-up hidden state $\mathbf{h}_\uparrow$ composes the semantics of sub-constituents contained in this constituent and the top-down hidden state $\mathbf{h}_\downarrow$ captures the contextual semantics manifested in the entire sentence.

2.2.2 Chain-of-Trees LSTM for Passage Encoding

To encode the passage which contains multiple sentences, we design a chain-of-trees LSTM (Figure 4). A bi-directional tree LSTM is built for each sentence to capture the local syntactic structure and these tree LSTMs are glued together via a bi-directional chain LSTM (Graves et al., 2013) to capture long-range semantics spanning multiple sentences. The hidden states generated by the bottom-up tree LSTM serves as the input of the chain LSTM. Likewise, the chain LSTM states are fed to the top-down tree LSTM. This enables the encoding of every constituent to be propagated to all other constituents in the passage.

In the chain LSTM, each sentence t is treated as a unit. The input of this unit is generated by the tree LSTM of sentence t, which is the bottom-up hidden state $\mathbf{h}_{\uparrow t}$ at the root. Sentence t is associated with a forward hidden state $\overrightarrow{\mathbf{h}}_t$ and a backward state $\overleftarrow{\mathbf{h}}_t$. In the forward direction, the transition equations among the input gate $\overrightarrow{\mathbf{i}}_t$, forget gate $\overrightarrow{\mathbf{f}}_t$, output gate $\overrightarrow{\mathbf{o}}_t$ and memory cell $\overrightarrow{\mathbf{c}}_t$ are:

$$\begin{aligned}
\overrightarrow{\mathbf{i}}_t &= \sigma(\overrightarrow{\mathbf{W}}^{(i)}\mathbf{h}_{\uparrow t} + \overrightarrow{\mathbf{U}}^{(i)}\overrightarrow{\mathbf{h}}_{t-1} + \overrightarrow{\mathbf{b}}^{(i)}) \\
\overrightarrow{\mathbf{f}}_t &= \sigma(\overrightarrow{\mathbf{W}}^{(f)}\mathbf{h}_{\uparrow t} + \overrightarrow{\mathbf{U}}^{(f)}\overrightarrow{\mathbf{h}}_{t-1} + \overrightarrow{\mathbf{b}}^{(f)}) \\
\overrightarrow{\mathbf{o}}_t &= \sigma(\overrightarrow{\mathbf{W}}^{(o)}\mathbf{h}_{\uparrow t} + \overrightarrow{\mathbf{U}}^{(o)}\overrightarrow{\mathbf{h}}_{t-1} + \overrightarrow{\mathbf{b}}^{(o)}) \\
\overrightarrow{\mathbf{u}}_t &= \tanh(\overrightarrow{\mathbf{W}}^{(u)}\mathbf{h}_{\uparrow t} + \overrightarrow{\mathbf{U}}^{(u)}\overrightarrow{\mathbf{h}}_{t-1} + \overrightarrow{\mathbf{b}}^{(u)}) \\
\overrightarrow{\mathbf{c}}_t &= \overrightarrow{\mathbf{i}}_t \odot \overrightarrow{\mathbf{u}}_t + \overrightarrow{\mathbf{f}}_t \odot \overrightarrow{\mathbf{c}}_{t-1} \\
\overrightarrow{\mathbf{h}}_t &= \overrightarrow{\mathbf{o}}_t \odot \tanh(\overrightarrow{\mathbf{c}}_t)
\end{aligned} \tag{2}$$

The backward LSTM is defined in a similar way. Subsequently, $\overrightarrow{\mathbf{h}}_t$ and $\overleftarrow{\mathbf{h}}_t$, which encapsulate the semantics of all sentences, are inputted to the root of the top-down tree LSTM and propagated to all the constituents in sentence t.

To sum up, the CT-LSTM encodes a passage in the following way: (1) the bottom-up tree LSTMs compute hidden states $\mathbf{h}_\uparrow$ for each sentence and feed $\mathbf{h}_\uparrow$ of the root node into the chain LSTM; (2) the chain LSTM computes forward and backward states and feed them into the root of the top-down tree LSTMs; (3) the top-down tree LSTMs compute hidden states $\mathbf{h}_\downarrow$. At each constituent C, the bottom-up state $\mathbf{h}_\uparrow$ captures the semantics of sub-constituents in C and the top-down state $\mathbf{h}_\downarrow$ captures the semantics of the entire passage.

2.3 Tree-Guided Attention Mechanism

We propose a tree-guided attention (TGA) mechanism to learn a question-aware representation for each constituent in the passage, which consists of three ingredients: (1) constituent-level attention score computation; (2) tree-guided local normalization; (3) tree-guided attentional summarization. Given a constituent $\mathbf{h}^{(p)}$ in the passage, for each constituent $\mathbf{h}^{(q)}$ in the question, an unnormalized attention weight score a is computed as $a = \mathbf{h}^{(p)} \cdot \mathbf{h}^{(q)}$ which measures the similarity between the two constituents. Then we perform a tree-guided local normalization of these scores. At each internal node in the parse tree, where the unnormalized attention scores of its L children are $\{a_l\}_{l=1}^L$, a local normalization is performed using a softmax operation $\widetilde{a}_l = \exp(a_l)/\sum_{m=1}^L \exp(a_m)$ which maps these scores into a probabilistic simplex. This normalization scheme stands in contrast with the global normalization adopted in word-based attention (Wang and Jiang, 2016; Wang et al., 2016), where a single softmax is globally applied to the attention scores of all the words in the question.

Given these locally normalized attention scores, we merge the LSTM encodings of constituents in the question into an attentional representation in a recursive and bottom-up way. At each internal node, let $\mathbf{h}$ be its LSTM encoding, a and $\{a_l\}_{l=1}^L$ be the normalized attention scores of this node and its L children, and $\{\mathbf{b}_l\}_{l=1}^L$ be the attentional representations (which we will define later) generated at the children, then the attentional representation $\mathbf{b}$ of this node is defined as:

$$\mathbf{b} = a(\mathbf{h} + \sum_{l=1}^{L} a_l \mathbf{b}_l) \tag{3}$$

which takes the weighted representation $\sum_{l=1}^L a_l \mathbf{b}_l$ contributed from its children, adds in its own encoding $\mathbf{h}$, then performs a re-weighting using the attention score a. The attentional representation $\mathbf{b}^{(r)}$ at the root node acts as the final summarization of constituents in the question. We concatenate it to the LSTM encoding $\mathbf{h}^{(p)}$ of the passage constituent and obtain a *concatenated representation* $\mathbf{z} = [\mathbf{h}^{(p)}; \mathbf{b}^{(r)}]$ which will be the input of the candidate answer generation layer.

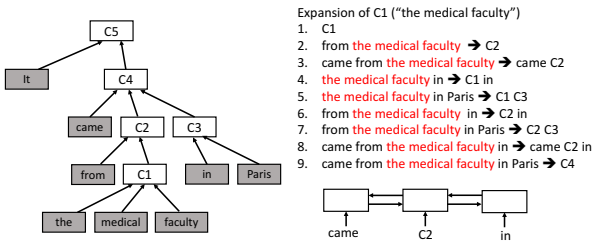

Figure 5: Constituent expansion. (Left) Parse tree of a sentence in the passage. (Top Right) Expansions of constituent C1 and their reductions (denoted by arrow). (Bottom Right) Learning the representation of an expansion using bidirectional chain-LSTM.

Unlike the word-based flat-structure attention mechanism (Wang and Jiang, 2016; Wang et al., 2016) where the attention scores are computed between words and normalized using a single global softmax, and the attentional summary is computed in a flat manner, the tree-guided attention calculates attention scores between constituents, normalizes them locally at each node in the parse tree and computes the attentional summary in a hierarchical way. Tailored to the parse tree, TGA is able to capture the syntactic, hierarchical and compositional structures among constituents and arguably generate better attentional representations, as we will validate in the experiments.

2.4 Candidate Answer Generation

As shown in Figure 2, while most correct answers in the training set are exactly constituents, some of them are not the case. To cover the non-constituent answers, we propose to expand each constituent by appending words adjacent to it. Let C denote a constituent and $S = \text{“}\cdots w_{i-1} w_i C w_j w_{j+1} \cdots\text{”}$ be the sentence containing C. We expand C by appending words preceding C (such as w_{i-1} and w_i) and words succeeding C (such as w_j and w_{j+1}) to C. We define an (l, r)-expansion of a constituent C as follows: append l words preceding C in the sentence to C; append r words succeeding C to C. Let M be the maximum expansion number that $l \leq M$ and $r \leq M$. Figure 5 shows an example. On the left is the constituent parse tree of the sentence “it came from the medical faculty in Paris”. On the upper right are the expansions of the constituent C1 – “the medical faculty”. To expand this constituent, we trace it back to the sentence and look up the M (M=2 in this case) words preceding C1 (which are “came” and “from”) and succeeding C1 (which are “in” and “Paris”). Then combinations of C1 and the preceding/succeeding words are taken to generate constituent expansions. On both the left and right side of C1, we have three choices of expansion: expanding 0,1,2 words. Taking combination of these cases, we obtain 9 expansions, including C1 itself ($(0, 0)$-expansion).

The next step is to perform reduction of constituent expansions. Two things need to be reduced. First, while expanding the current constituent, new constituents may come into being. For instance, in the expansion “came from C1 in Paris”, “in” and “Paris” form a constituent C3; “from” and C1 form a constituent C2; “came”, C2 and C3 form a constituent C4. Eventually, this expansion is reduced to C4. Second, the expansions generated from different constituents may have overlap and the duplicated expansions need to be removed. For example, the $(2, 1)$-expansion of C1 – “came from the medical faculty in” – can be reduced to “came C2 in”, which is the $(1, 1)$-expansion of C2. After reduction, each expansion is a sequence of constituents.

Next we encode these candidate answers and the encodings will be utilized in the prediction layer. In light of the fact that each expansion is a constituent sequence, we build a bi-directional chain LSTM (Figure 5, bottom right) to synthesize the representations of individual constituents therein. Let $E = C_1 \cdots C_n$ be an expansion consisting of n constituents. In the chain LSTM, the input of unit i is the combined representation of C_i. We concatenate the forward hidden state at C_n and backward state at C_1 as the final representation of E.

2.5 Answer Prediction and Parameter Learning

Given the representation of candidate answers, we use a feed-forward network $f : \mathbb{R}^d \to \mathbb{R}$ to predict the correct answer. The input of the network is the feature vector of a candidate answer and the output is a confidence score. The one with the largest score is chosen as the the correct answer.

For parameter learning, we normalize the confidence scores into a probabilistic simplex using softmax and define a cross entropy loss thereupon. Let J_k be the number of candidate answers produced from the k-th passage-question pair and

$\{\mathbf{z}_j^{(k)}\}_{j=1}^{J_k}$ be their representations. Let t_k be the index of the correct answer. Then the cross entropy loss of K pairs is defined as

$$\sum_{k=1}^{K}(-f(\mathbf{z}_{t_k}) + \log \sum_{j=1}^{J_k} \exp(f(\mathbf{z}_j^{(k)}))) \quad (4)$$

Model parameters are learned by minimizing this loss using stochastic gradient descent.

3 Experiments

3.1 Experimental Setup

The experiments are conducted on the Stanford Question Answering Dataset (SQuAD) v1.1, which contains 107,785 questions and 23,215 passages coming from 536 Wikipedia articles. The data was randomly partitioned into a training set (80%), a development set (10%) and an unreleased test set (10%). Rajpurkar et al. (2016) build a leaderboard to evaluate and publish results on the test set. Due to software copyright issues, we did not participate this online evaluation. Instead, we use the development set (which is untouched during model training) as test set. In training, if the correct answer is not in the candidate-answer set, we use the shortest candidate containing the correct answer as the target.

The Stanford parser is utilized to obtain the constituent parse trees for questions and passages. In the parse tree, any internal node which has one child is merged together with its child. For instance, in "(NP (NNS sufferers))", the parent "NP" has only one child "(NNS sufferers)", we merge them into "(NP sufferers)". We use 300-dimensional word embeddings from GloVe (Pennington et al., 2014) to initialize the model. Words not found in GloVe are initialized as zero vectors.

We use a feed-forward network with 2 hidden layers (both having the same amount of units) for answer prediction. The activation function is set to rectified linear. Hyperparameters in CCNN are tuned via 5-fold cross validation (CV) on the training set, summarized in Table 1. We use the ADAM (Kingma and Ba, 2014) optimizer to train the model with an initial learning rate 0.001 and a mini-batch size 100. An ensemble model is also trained, consisting of 10 training runs using the same hyperparameters. The performance is evaluated by two metrics (Rajpurkar et al., 2016): (1) exact match (EM) which measures the percentage of predictions that match any one of the ground truth answers exactly; (2) F1 score which measures the average overlap between the prediction and ground truth answer. In the development set each question has about three ground truth answers. F1 scores with the best matching answers are used to compute the average F1 score.

3.2 Results

Table 2 shows the performance of our model and previous approaches on the development set. CCNN (single model) achieves an EM score of 69.3% and an F1 score of 78.5%, significantly outperforming all previous approaches (single model). Through ensembling, the performance of CCNN is further improved and outperforms the baseline ensemble methods. The key difference between our method and previous approaches is that CCNN is constituent-centric where the generation and encoding of candidate answers are both based on constituents while the baseline approaches are mostly word-based where the candidate answer is an arbitrary span of words and the encoding is performed over individual words rather than at the constituent level. The constituent-centric model-design enjoys two major benefits. First, restricting the candidate answers from arbitrary spans to neighborhoods around the constituents greatly reduces the search space, which mitigates the ambiguity and uncertainty in picking up the correct answer. Second, the tree LSTMs and tree-guided attention mechanism encapsulate the syntactic, hierarchical and compositional structure among constituents, which leads to better representation learning of the candidate answers. We conjecture these are the primary reasons that CCNN outperforms the baselines and provide a validation in the next section.

3.3 Ablation Study

To further understand the individual modules in CCNN, we perform an ablation study. The results are shown in Table 2.

Tree LSTM To evaluate the effectiveness of tree LSTM in learning syntax-aware representations, we replace it with a syntax-agnostic chain LSTM. We build a bi-directional chain LSTM (denoted by A) over the entire passage to encode the individual words. Given a constituent $C = w_i \cdots w_j$, we build another bi-directional chain LSTM (denoted by B) over C where the inputs are the encodings of words $w_i, \cdots, w_j$ generated by LSTM

Parameter	Tuning Range	Best Choice
Maximum expansion number M in constituent expansion	$0, 1, 2, 3, 4, 5$	2
Size of hidden state in all LSTMs	$50, 100, 150, 200, 250, 300$	100
Size of hidden state in prediction network	100, 200, 300, 400, 500	400

Table 1: Hyperparameter Tuning

	Exact Match (EM,%)	F1 (%)
Single model		
Logistic Regression (Rajpurkar et al., 2016)	40.0	51.0
Fine Grained Gating (Yang et al., 2016)	60.0	71.3

CCNN (ensemble)	**74.1**	**82.6**

Table 2: Results on the development set

A. In LSTM B, the forward hidden state of w_j and backward state of w_i are concatenated to represent C. Note that the attention mechanism remains intact, which is still guided by the parse tree. This replacement cause 5.8% and 4.6% drop of the EM and F1 scores respectively, which demonstrates the necessity of incorporating syntactic structure (via tree LSTM) into representation learning.

Chain-of-Trees LSTM (CT-LSTM) We evaluate the effectiveness of CT-LSTM by comparing it with a bag of tree LSTMs: instead of using a chain LSTM to glue the tree LSTMs, we treat them as independent. Keeping the other modules intact and replacing CT-LSTM with a bag of independent tree LSTMs, the EM and F1 score drop 4.5% and 3.3% respectively. The advantage of CT-LSTM is that it enables the semantics of one sentence to be propagated to others, which makes multiple-sentence reasoning possible.

Tree-Guided Attention (TGA) Mechanism To evaluate the effectiveness of TGA, we performed two studies. First, we take it off from the architecture. Then constituents in the passage are solely represented by the chain-of-trees LSTM encodings and the question sentence is represented by the tree LSTM encoding at the root of the parse tree. At test time, we concatenate the encodings of a candidate answer and the question as inputs of the prediction network. Removing the attention layer decreases the EM and F1 by 5.4% and 4.2% respectively, demonstrating the effectiveness of attention mechanism for question-aware representation learning.

Second, we compare the tree-structured mech-

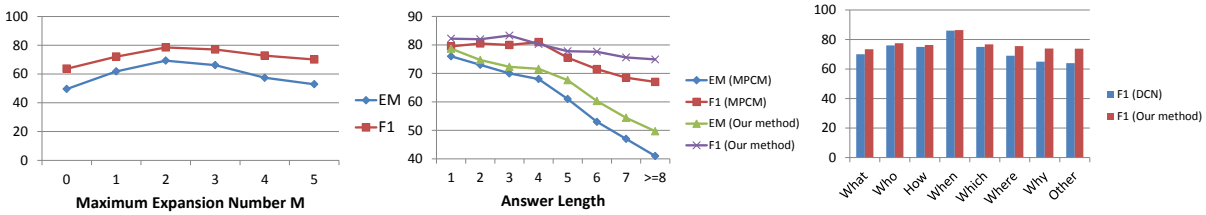

Figure 6: Performance for different (a) M (expansion number), (b) answer length, (c) question type.

anism in TGA with a flat-structure mechanism. For each constituent $\mathbf{h}_i^{(p)}$ in the passage, we compute its unnormalized score $a_{ij} = \mathbf{h}_i^{(p)} \cdot \mathbf{h}_j^{(q)}$ with every constituent $\mathbf{h}_j^{(q)}$ in the question (which has R constituents). Then a global softmax operation is applied to these scores, $\{\tilde{a}_{ij}\}_{j=1}^R = softmax(\{a_{ij}\}_{j=1}^R)$, to project them into a probabilistic simplex. Finally, a flat summarization $\sum_{j=1}^R \tilde{a}_{ij}\mathbf{h}_j^{(q)}$ is computed and appended to $\mathbf{h}_i^{(p)}$. Replacing TGA with flat-structure attention causes the EM and F1 to drop 3.7% and 2.6% respectively, which demonstrates the advantage of the tree-guided mechanism.

Constituent Expansion We study how the maximum expansion number M affects performance. If M is too small, many correct answers are not contained in the candidate set, which results in low recall. If M is too large, excessive candidates are generated, making it harder to pick up the correct one. Figure 6(a) shows how EM and F1 vary as M increases, from which we can see a value of M in the middle ground achieves the best tradeoff.

3.4 Analysis

In this section, we study how CCNN behaves across different answer length (number of words in the answer) and question types, which are shown in Figure 6(b) and (c). In Figure 6(b), we compare with the MPCM method (Wang et al., 2016). As answer length increases, the performance of both methods decreases. This is because for longer answers, it is more difficult to pinpoint the precise boundaries. The decreasing of F1 is slower than EM, because F1 is more elastic to small mismatches. Our method achieves larger improvement over MPCM at longer answers. We conjecture the reason is: longer answers have more complicated syntactic structure, which can be better captured by the tree LSTMs and tree-guided attention mechanism in our method. MPCM is built upon individual words and is syntax-agnostic.

In Figure 6(c), we compare with DCN (Xiong et al., 2016) on 8 question types. Our method achieves significant improvement over DCN on four types: "what", "where", "why" and "other". The answers of questions in these types are typically longer and have more complicated syntactic structure than the other four types where the answers are mostly entities (person, numeric, time, etc.). The syntax-aware nature of our method makes it outperform DCN whose model design does not explicitly consider syntactic structures.

4 Related Works

Several neural network based approaches have been proposed to solve the SQuAD QA problem, which we briefly review from three aspects: candidate answer generation, representation learning and attention mechanism.

Two ways were investigated for candidate answer generation: (1) chunking: candidates are preselected based on lexical and syntactic analysis, such as constituent parsing (Rajpurkar et al., 2016) and part-of-speech pattern (Yu et al., 2016); (2) directly predicting the start and end position of the answer span, using feed-forward neural network (Wang et al., 2016), LSTM (Seo et al., 2016), pointer network (Vinyals et al., 2015; Wang and Jiang, 2016), dynamic pointer decoder (Xiong et al., 2016).

The representation learning in previous approaches is conducted over individual words using the following encoders: LSTM in (Wang et al., 2016; Xiong et al., 2016); bi-directional gated recurrent unit (Chung et al., 2014) in (Yu et al., 2016); match-LSTM in (Wang and Jiang, 2016); bi-directional LSTM in (Seo et al., 2016).

In previous approaches, the attention (Bahdanau et al., 2014; Xu et al., 2015) mechanism is mostly word-based and flat-structured (Kadlec et al., 2016; Sordoni et al., 2016; Wang and Jiang,

2016; Wang et al., 2016; Yu et al., 2016): the attention scores are computed between individual words, are normalized globally and are used to summarize word-level encodings in a flat manner. Cui et al. (2016); Xiong et al. (2016) explored a coattention mechanism to learn question-to-passage and passage-to-question summaries. Seo et al. (2016) proposed to directly use the attention weights as augmented features instead of applying them for early summarization.

5 Conclusions and Future Work

To solve the SQuAD question answering problem, we design a constituent centric neural network (CCNN), where the generation and representation learning of candidate answers are both based on constituents. We use a constituent expansion mechanism to produce candidate answers, which can greatly reduce the search space without losing the recall of hitting the correct answer. To represent these candidate answers, we propose a chain-of-trees LSTM to encode constituents and a tree-guided attention mechanism to learn question-aware representations. Evaluations on the SQuAD dataset demonstrate the effectiveness of the constituent-centric neural architecture.

For future work, we will investigate the wider applicability of chain-of-trees LSTM as a general text encoder that can simultaneously capture local syntactic structure and long-range semantic dependency. It can be applied to named entity recognition, sentiment analysis, dialogue generation, to name a few. We will also apply the tree-guided attention mechanism to NLP tasks that need syntax-aware attention, such as machine translation, sentence summarization, textual entailment, etc. Another direction to explore is joint learning of syntactic parser and chain-of-trees LSTM. Currently, the two are separated, which may lead to suboptimal performance.

Cross-lingual Distillation for Text Classification

Abstract

Cross-lingual text classification(CLTC) is the task of classifying documents written in different languages into the same taxonomy of categories. This paper presents a novel approach to CLTC that builds on model distillation, which adapts and extends a framework originally proposed for model compression. Using soft probabilistic predictions for the documents in a label-rich language as the (induced) supervisory labels in a parallel corpus of documents, we train classifiers successfully for new languages in which labeled training data are not available. An adversarial feature adaptation technique is also applied during the model training to reduce distribution mismatch. We conducted experiments on two benchmark CLTC datasets, treating English as the source language and German, French, Japan and Chinese as the unlabeled target languages. The proposed approach had the advantageous or comparable performance of the other state-of-art methods.

1 Introduction

The availability of massive multilingual data on the Internet makes cross-lingual text classification (CLTC) increasingly important. The task is defined as to classify documents in different languages using the same taxonomy of predefined categories.

CLTC systems build on supervised machine learning require a sufficiently amount of labeled training data for every domain of interest in each language. But in reality, labeled data are not evenly distributed among languages and across domains. English, for example, is a label-rich language in the domains of news stories, Wikipedia pages and reviews of hotels, products, etc. But many other languages do not necessarily have such rich amounts of labeled data. This leads to an open challenge in CLTC, i.e., how can we effectively leverage the trained classifiers in a label-rich *source* language to help the classification of documents in other label-poor *target* languages?

Existing methods in CLTC use either a bilingual dictionary or a parallel corpus to bridge language barriers and to translate classification models (Xu et al., 2016) or text data(Zhou et al., 2016a). There are limitations and challenges in using either type of resources. Dictionary-based methods often ignore the dependency of word meaning and its context, and cannot leverage domain-specific disambiguation when the dictionary on hand is a general-purpose one. Parallel-corpus based methods, although more effective in deploying context (when combined with word embedding in particular), often have an issue of domain mismatch or distribution mismatch if the available source-language training data, the parallel corpus (human-aligned or machine-translation induced one) and the target documents of interest are not in exactly the same domain and genre(Duh et al., 2011). How to solve such domain/distribution mismatch problems is an open question for research.

This paper proposes a new parallel-corpus based approach, focusing on the reduction of domain/distribution matches in CLTC. We call this approach Cross-lingual Distillation with Feature Adaptation or CLDFA in short. It is inspired by the recent work in model compression (Hinton et al., 2015) where a large ensemble model is transformed to a compact (small) model. The assumption of knowledge distillation for model compression is that the knowledge learned by the large model can be viewed as a mapping from in-

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1415–1425
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1130

put space to output (label) space. Then, by training with the soft labels predicted by the large model, the small model can capture most of the knowledge from the large model. Extending this key idea to CLTC, if we see parallel documents as different instantiations of the same semantic concepts in different languages, a target-language classifier should gain the knowledge from a well-trained source classifier by training with the target-language part of the parallel corpus and the soft labels made by the source classifier on the source language side. More specifically, we propose to distillate knowledge from the source language to the target language in the following 2-step process:

- Firstly, we train a source-language classifier with both labeled training documents and adapt it to the unlabeled documents from the source-language side of the parallel corpus. The adaptation enforces our classifier to extract features that are: 1) discriminative for the classification task and 2) invariant with regard to the distribution shift between training and parallel data.

- Secondly, we use the trained source-language classifier to obtain the *soft* labels for a parallel corpus, and the target-language part of the parallel corpus to train a target classifier, which yields a similar category distribution over target-language documents as that over source-language documents. We also use unlabeled testing documents in the target language to adapt the feature extractor in this training step.

Intuitively, the first step addresses the potential domain/distribution mismatch between the labeled data and the unlabeled data in the source language. The second step addresses the potential mismatch between the target-domain training data (in the parallel corpus) and the test data (not in the parallel corpus). The soft-label based training of target classifiers makes our approach unique among parallel-corpus based CLTC methods (Section 2.1. The feature adaptation step makes our framework particularly robust in addressing the distributional difference between in-domain documents and parallel corpus, which is important for the success of CLTC with low-resource languages.

The main contributions in this paper are the following:

- We propose a novel framework (CLDFA) for knowledge distillation in CLTC through a parallel corpus. It has the flexibility to be built on a large family of existing monolingual text classification methods and enables the use of a large amount of unlabeled data from both source and target language.

- CLDFA has the same computational complexity as the plug-in text classification method and hence is very efficient and scalable with the proper choice of plug-in text classifier.

- Our evaluation on benchmark datasets shows that our method had a better or at least comparable performance than that of other state-of-art CLTC methods.

2 Related Work

Related work can be outlined with respect to the representative work in CLTC and the recent progress in deep learning for knowledge distillation.

2.1 CLTC Methods

One branch of CLTC methods is to use lexical level mappings to transfer the knowledge from the source language to the target language. The work by Bel et al. (Bel et al., 2003) was the first effort to solve CLTC problem. They translated the target-language documents to source language using a bilingual dictionary. The classifier trained in the source language was then applied on those translated documents. Similarly, Mihalcea et al. (Mihalcea et al., 2007) built cross-lingual classifier by translating subjectivity words and phrases in the source language into the target language. Shi et al. (Shi et al., 2010) also utilized a bilingual dictionary. Instead of translating the documents, they tried to translate the classification model from source language to target language. Prettenhofer and Stein. (Prettenhofer and Stein, 2010) also used the bilingual dictionary as a word translation oracle and built their CLTC system on structural correspondence learning, a theory for domain adaptation. A more recent work by (Xu et al., 2016) extended seminal bilingual dictionaries with unlabeled corpora in low-resource languages. Chen et al. (Chen et al., 2016) used bilingual word embedding to map documents in source and target

language into the same semantic space, and adversarial training was applied to enforce the trained classifier to be language-invariant.

Some recent efforts in CLTC focus on the use of automatic machine translation (MT) technology. For example, Wan (Wan, 2009) used machine translation systems to give each document a source-language and a target-language version, where one version is machine-translated from the another one. A co-training (Blum and Mitchell, 1998) algorithm was applied on two versions of both source and target documents to iterative train classifiers in both languages. MT-based CLTC also include the work on multi-view learning with different algorithms, such as majority voting(Amini et al., 2009), matrix completion(Xiao and Guo, 2013) and multi-view co-regularization(Guo and Xiao, 2012a).

Another branch of CLTC methods focuses on representation learning or the mapping of the induced representations in cross-language settings (Guo and Xiao, 2012b; Zhou et al., 2016a, 2015, 2016b; Xiao and Guo, 2013; Jagarlamudi et al., 2011; De Smet et al., 2011; Vinokourov et al., 2002; Platt et al., 2010; Littman et al., 1998). For example, Meng et al. (Meng et al., 2012) and Lu et al. (Lu et al., 2011) used a parallel corpus to learn word alignment probabilities in a pre-processing step. Some other work attempts to find a language-invariant (or interlingua) representation for words or documents in different languages using various techniques, such as latent semantic indexing (Littman et al., 1998), kernel canonical correlation analysis (Vinokourov et al., 2002), matrix completion(Xiao and Guo, 2013), principal component analysis (Platt et al., 2010) and Bayesian graphical models (De Smet et al., 2011).

2.2 Knowledge Distillation

The idea of distilling knowledge in a neural network was proposed by Hinton et al (Hinton et al., 2015), in which they introduced a student-teacher paradigm. Once the cumbersome teacher network was trained, the student network was trained according to soften predictions of the teacher network. In the field of computer vision, it has been empirically verified that student network trained by distillation performs better than the one trained with hard labels. (Hinton et al., 2015; Romero et al., 2014; Ba and Caruana, 2014). Gupta et al.(Gupta et al., 2015) transfers supervision between images from different modalities(e.g. from RGB image to depth image). There are also some recent works applied distillation in the field of natural language. For example, Lili et al. (Mou et al., 2015) distilled task specific knowledge from a set of high-dimensional embeddings to a low-dimensional space. Zhiting et al. used an iterative distillation method to transfer the structured information of logic rules into the weights of a neural network. Kim et al. (Kim and Rush, 2016) applied knowledge distillation approaches in the field of machine translation to reduce the size of neural machine translation model. Our framework shares the same purpose of existing works that transfer knowledge between models of different properties, such as model complexity, modality, and structured logic. However, our transfer happens between models working on different languages. To the best of knowledge, this is the first work using knowledge distillation to bridge the language gap for NLP tasks.

3 Preliminary

3.1 Task and Notation

CLTC aims to use the training data in the source language to build a model applicable in the target language. In our setting, we have labeled data in source language $L_{src} = \{x_i, y_i\}_{i=1}^{L}$, where x_i is the labeled document in source language and y_i is the label vector. We then have our test data in the target language, given by $T_{tgt} = \{x'_i\}_{i=1}^{T}$. Our framework can also use unlabeled documents from both languages in transductive learning settings. We use $U_{src} = \{x_i\}_{i=1}^{M}$ to denote source-language unlabeled documents,$U_{tgt} = \{x'_i\}_{i=1}^{N}$ to denote target-language unlabeled documents, and $U_{parl} = \{(x_i, x'_i)\}_{i=1}^{P}$ to denote a unlabeled bilingual parallel corpus where x_i and x'_i are paired document translations of each other. We assume that the unlabeled parallel corpus does not overlap with the source-language training documents and the target-language test documents.

3.2 Convolutional Neural Network (CNN) as a Plug-in Classifier

We use a state-of-the-art CNN-based neural network classifier (Kim, 2014) as the plug-in classifier in our framework. Instead of using a bag-of-words representation for each document, the CNN model concatenates the word embeddings (vertical vectors) of each input document into a $n \times k$

matrix, where n is the length (number of word occurrences) of the document, and k is the dimension of word embedding. Denoting by

$$\mathbf{x_{1:n}} = \mathbf{x_1} \oplus \mathbf{x_2} \oplus ... \oplus \mathbf{x_n}$$

as the resulted matrix, with $\oplus$ the concatenation operator. One-dimensional convolutional filter $\mathbf{w} \in R^{hk}$ with window size h operates on every consecutive h words, with non-linear function f and bias b. For window of size h started at index i, the feature after convolutional filter is given by:

$$c_i = f(\mathbf{w} \cdot \mathbf{x_{i:i+h-1}} + b)$$

A max-over-time pooling (Collobert et al., 2011) is applied on c over all possible positions such that each filter extracts one feature. The model uses multiple filters with different window sizes. The concatenated outputs from filters consist the feature of each document. We can see the convolutional filters and pooling layers as feature extractor $\mathbf{f} = G_f(x, \theta_f)$, where θ_f contains parameters for embedding layer and convolutional layer. Theses features are then passed to a fully connected softmax layer to produce probability distributions over labels. We see the final fully connected softmax layer as a label classifier $G_y(\mathbf{f}, \theta_y)$ that takes the output $\mathbf{f}$ from the feature extractor. The final output of model is given by $G_y(G_f(x, \theta_f), \theta_y)$, which is jointly parameterized by $\{\theta_f, \theta_y\}$

We want to emphasize that our choice of the plug-in classifier here is mainly for its simplicity and scalability to demonstrate our framework. There is a large family of neural classifiers for monolingual text classification that could be used in our framework as well, including other convolutional neural networks by (Johnson and Zhang, 2014), the recurrent neural networks by (Lai et al., 2015; Zhang et al., 2016; Johnson and Zhang, 2016; Sutskever et al., 2014; Dai and Le, 2015), the attention mechanism by (Yang et al., 2016), the deep dense network by (Iyyer et al., 2015), and more.

4 Proposed Framework

Let us introduce two versions of our model for cross-language knowledge distillation, i.e., the vanilla version and the full version with feature adaptation. Both are supported by the proposed framework. We denote the former by CLD-KCNN and the latter by CLDFA-KCNN.

4.1 Vanilla Distillation

Without loss of generality, assume we are learning a multi-class classifier for the target language. We have $y \in 1, 2, ..., |v|$ where v is the set of all possible classes. We assume the base classification network produces real number logits q_j for each class. For example, for the case of CNN text classifier, the logits can be produced by a linear transformation which takes features extracted max-pooling layer and outputs a vector of size $|v|$. The logits are converted into probabilities of classes through the softmax layer, by normalizing each q_j with all other logits.

$$p_j = \frac{\exp(q_j/T)}{\sum_{k=1}^{|v|} \exp(q_k/T)} \quad (1)$$

where T is a temperature and is normally set to 1. Using a higher value of T produces a softer probability distribution over classes.

The first step of our framework is to train the source-language classifier on labeled source documents L_{src}. We use standard temperature $T = 1$ and cross-entropy loss as the objective to minimize. For each example and its label (x_i, y_i) from the source training set, we have:

$$\mathcal{L}(\theta_{src}) = - \sum_{(x_i,y_i) \in L_{src}} \sum_{k=1}^{|v|} \mathbb{1}\{y_i = k\} \log p(y = k|x_i; \theta_{src}) \quad (2)$$

where $p(y = k|x; \theta_{src})$ is source model controlled by parameter θ_{src} and $\mathbb{1}\{\cdot\}$ is the indicator function.

In the second step, the knowledge captured in θ_{src} is transferred to the distilled model in the target language by training it on the parallel corpus. The intuition is that paired documents in parallel corpus should have the same distribution of class predicted by the source model and target model. In the simplest version of our framework, for each source-language document in the parallel corpus, we predict a soft class distribution by source model with high temperature. Then we minimize the cross-entropy between soft distribution produced by source model and the soft distribution produced by target model on the paired documents in the target language. More formally, we optimize θ_{tgt} according to the following loss

function for each document pair (x_i, x'_i) in parallel corpus.

$$\mathcal{L}(\theta_{tgt}) = -\sum_{(x_i,x'_i)\in U_{parl}} \sum_{k=1}^{|v|} p(y=k|x_i;\theta_{src}) \log p(y=k|x'_i;\theta_{tgt}) \quad (3)$$

During distillation, the same high temperature is used for training target model. After it has been trained, we set the temperature to 1 for testing.

We can show that under some assumptions, the two-step cross-lingual distillation is equivalent to distilling a target-language classifier in the target-language input space.

Lemma 1. *Assume the parallel corpus* $\{x_i, x'_i\} \in U_{parl}$ *is generated by* $x'_i \sim p(X';\eta)$ *and* $x_i = t(x'_i)$*, where* η *controls the marginal distribution of* x_i *and* t *is a differentiable translation function with integrable derivative. Let* $f_{\theta_{src}}(t(x'))$ *be the function that outputs soft labels of* $p(y = k|t(x');\theta_{src})$*. The distillation given by equation 3 can be interpreted as distillation of a target language classifier* $f_{\theta_{src}}(t(x'))$ *on target language documents sampled from* $p(X';\eta)$*.*

$f_{\theta_{src}}(t(x'))$ is the classifier that takes input of target documents, translates them into source documents through t and makes prediction using the source classifier. If we further assume the testing documents have the same marginal distribution $P(X';\eta)$, then the distilled classifier should have similar generalization power as $f_{\theta_{src}}(t(x'))$.

Theorem 2. *Let source training data* $x_i \in L_{src}$ *has marginal distribution* $p(X;\lambda)$*. Under the assumptions of lemma 1, further assume* $p(t(x');\lambda) = p(x';\eta)$*,* $p(y|t(x')) = p(y|x')$ *and* $t'(x') \approx C$*, where* C *is a constant. Then* $f_{\theta_{src}}(t(x'))$ *actually minimizes the expected loss in target language data* $E_{x'\sim p(X;\eta),y\sim p(Y|x')}[L\big(y, f(t(x'))\big)]$.

Proof. By definition of equation 2, $f_{\theta_{src}}(x)$ minimizes the expected loss $E_{x\sim p(X;\lambda),y\sim p(Y|x)}[L\big(y, f(x)\big)]$, where L is cross-entropy loss in our case. Then we can write

$$\begin{aligned}
&E_{x\sim p(X;\lambda),y\sim p(Y|x)}[L\big(y, f(x)\big)] \\
=&\int p(x;\lambda) \sum_y p(y|x) L\big(y, f(x)\big) dx \\
=&\int p(t(x');\lambda) \sum_y p(y|t(x')) L\big(y, f(t(x'))\big) t'(x') dx' \\
\approx& C \int p(x';\eta) \sum_y p(y|x') L\big(y, f(t(x'))\big) dx' \\
=& C E_{x'\sim p(X;\eta),y\sim p(Y|x')}[L\big(y, f(t(x'))\big)]
\end{aligned}$$

□

4.2 Distillation with Adversarial Feature Adaptation

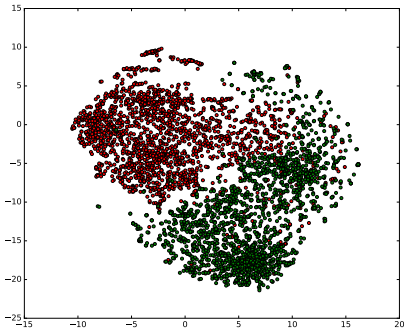

Figure 1: Extracted features for source-language documents in the English-Chinese Yelp Hotel Review dataset. Red dots represent features of the documents in L_{src} and green dots represent the features of documents in U_{parl}, which is a general-purpose parallel corpus.

Although vanilla distillation is intuitive and simple, it cannot handle distribution mismatch issues. For example, the marginal feature distributions of source-language documents in L_{src} and U_{parl} could be different, so are the distributions of target-language documents in U_{parl} and T_{tgt}. According to theorem 2, the vanilla distillation works for the best performance under unrealistic assumption: $p(t(x')|\lambda) = p(x'|\eta)$. To further illustrate our point, we trained a CNN classifier according to equation 2 and used the features extracted by G_f to present the source-language documents in both L_{src} and U_{parl}. Then we projected the high-dimensional features onto a 2-dimensional space via t-Distributed Stochastic Neighbor Embedding (t-SNE)(Maaten and Hinton, 2008). This resulted

the visualization of the project data in Figures 1 and 2.

It is quite obvious in Figure 1 that the general-purpose parallel corpus has a very different feature distribution from that of the labeled source training set. Even for machine-translated parallel data from the same domain, as shown in figure 2, there is still a non-negligible distribution shift from the source language to the target language for the extracted features. Our interpretation of this observation is that when the MT system (e.g. Google Translate) is a general-purpose one, it non-avoidably add translation ambiguities which would lead the distribution shift from the original domain. To address the distribution divergence brought by either a general-purpose parallel corpus or an imperfect MT system, we seek to adapt the features extraction part of our neural classifier such that the feature distributions on both sides should be close as possible in the newly induced feature space. We adapt the adversarial training method by (Ganin and Lempitsky, 2014) to the cross-lingual settings in our problems.

Given a set of training set of $L = \{x_i, y_i\}_{i=1,...,N}$ and an unlabeled set $U = \{x'_i\}_{i=1,...,M}$, our goal is to find a neural classifier $G_y(G_f(x, \theta_f), \theta_y)$, which has good discriminative performance on L and also extracts features which have similar distributions on L and U. One way to maximize the similarity of two distributions is to maximize the loss of a discriminative classifier whose job is to discriminate the two feature distributions. We denote this classifier by $G_d(\cdot, \theta_d)$, which is parameterized by θ_d.

At training time, we seek θ_f to minimize the loss of G_y and maximize the loss of G_d. Meanwhile, θ_y and θ_d are also optimized to minimize their corresponding loss. The overall optimization could be summarized as follows:

$$E(\theta_f, \theta_y, \theta_d) = \sum_{x_i, y_i \in L} L_y(y_i, G_y(G_f(x_i, \theta_f), \theta_y))$$
$$- \alpha \sum_{x_i \in L} L_d(0, G_d(G_f(x_i, \theta_f), \theta_d))$$
$$- \alpha \sum_{x_j \in U} L_d(1, G_d(G_f(x_j, \theta_f), \theta_d))$$

where L_y is the loss function for true labels y, L_d is loss function for binary labels indicating the source of data and α is the hyperparameter that controls the relative importance of two losses. We optimize θ_f, θ_y for minimizing E and optimize θ_d for maximizing E. We jointly optimize $\theta_f, \theta_y, \theta_d$ through the gradient reversal layer(Ganin and Lempitsky, 2014).

We use this feature adaptation technique to firstly adapt the source-language classifier to the source-language documents of the parallel corpus. When training the target-language classifier by matching soft labels on the parallel corpus, we also adapt the classifier to the target testing documents. We use cross-entropy loss functions as L_y and L_d for both feature adaptation.

5 Experiments and Discussions

5.1 Dataset

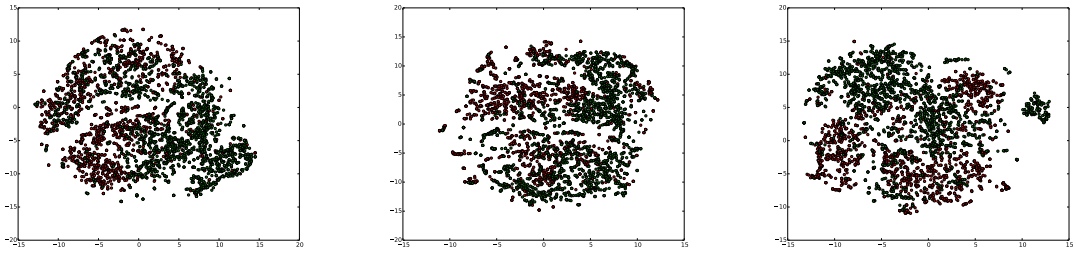
Our experiments used two benchmark datasets, as described below.

(1) Amazon Reviews

Language	Domain	# of Documents
English	book	50000
	DVD	30000
	music	25220
German	book	165470
	DVD	91516
	music	60392
French	book	32870
	DVD	9358
	music	15940
Japanese	book	169780
	DVD	68326
	music	55892

Table 1: Dataset Statistics for the Amazon reviews dataset

We used the multilingual multi-domain Amazon review dataset created by Prettenhofer and Stein (Prettenhofer and Stein, 2010). The dataset contains Amazon reviews in three domains: book, DVD and music. Each domain has the reviews in four different languages: English, German, French and Japanese. We treated English as the source language and the rest three as the target languages, respectively. This gives us 9 tasks (the product of the 3 domains and the 3 target languages) in total. For each task, there are 1000 positive and 1000 negative reviews in English and the target language, respectively. (Prettenhofer and Stein, 2010) also provides 2000 parallel reviews per task,



(a) Germany:DVD (b) French:Music (c) Japanese:Book

Figure 2: Extracted features for the source-language documents in the Amazon Reviews dataset. Red dots represent the features of the labeled training documents in L_{src}, and green dots represent the features of the documents in U_{parl}, which are the machine-translated documents from a target language. Below each figure is the target language and the domain of review (Section 5.1).

that were generated using Google Translate [1], and used by us for cross-language distillation. There are also several thousands of unlabeled reviews in each language. The statistics of unlabeled data is summarized in Table 1. All the reviews are tokenized using standard regular expressions except for Japanese, for which we used a publicly available segmenter [2].

(2) English-Chinese Yelp Hotel Reviews

This dataset was firstly used for CLTC by (Chen et al., 2016). The task is to make sentence-level sentiment classification with 5 labels(rating scale from 1 to 5), using English as the source language and Chinese as the target language. The labeled English data consists of balanced labels of 650k Yelp reviews from Zhang et al. (Zhang et al., 2015). The Chinese data includes 20k labeled Chinese hotel reviews and 1037k unlabeled ones from (Lin et al., 2015). Following the approach by (Chen et al., 2016), we use 10k of labeled Chinese data as validation set and another 10k hotel reviews as held-out test data. We a random sample of 500k parallel sentences from UM-courpus(Tian et al., 2014), which is a general-purpose corpus designed for machine translation.

5.2 Baselines

We compare the proposed method with other state-of-the-art methods as outlined below.

(1) Parallel-Corpus based CLTC Methods

Methods in this category all use an unlabeled parallel corpus. Methods named **PL-LSI** (Littman et al., 1998), **PL-OPCA** (Platt et al., 2010) and **PL-KCAA** (Vinokourov et al., 2002) learn latent document representations in a shared low-dimensional space by performing the Latent Semantic Indexing (LSI), the Oriented Principal Component Analysis (OPCA) and a kernel (namely KCAA) for the parallel text. **PL-MC** (Xiao and Guo, 2013) recovers missing features via matrix Completion, and also uses LSI to induce a latent space for parallel text. All these methods train a classifier in the shared feature space with labeled training data from both the source and target languages.

(2) MT-based CLTC Methods

The methods in this category all use an MT system to translate each test document in the target language to the source language in the testing phase. The prediction on each translated document is made by a source-language classifier, which can be a Logistic Regression model (**MT+LR**) (Chen et al., 2016) or a deep averaging network (**MT+DAN**) (Chen et al., 2016).

(3) Adversarial Deep Averaging Network

Similar to our approach, the adversarial Deep Averaging Network (**ADAN**) also exploits adversarial training for CLTC (Chen et al., 2016). However, it does not have the parallel-corpus based knowledge distillation part (which we do). Instead, it uses averaged bilingual embeddings of words as its input and adapts the feature extractor to produce similar features in both languages.

We also include the results of **mSDA** for the Yelp Hotel Reviews dataset. **mSDA** (Chen et al., 2012) is a domain adaptation method based on

stacked denoising autoencoders, which has been proved to be effective in cross-domain sentiment classification evaluations. We show the results reported by (Chen et al., 2012), where they used bilingual word embedding as input for mSDA.

5.3 Implementation Detail

We pre-trained both the source and target classifier with unlabeled data in each language. We ran word2vec(Mikolov et al., 2013) [3] on the tokenized unlabeled corpus. The learned word embeddings are used to initialize the word embedding look-up matrix, which maps input words to word embeddings and concatenates them into input matrix.

We fine-tuned the source-language classifier on the English training data with 5-fold cross-validation. For English-Chinese Yelp-hotel review dataset, the temperature T(Section 4.1) in distillation is tuned on validation set in the target language. For Amazon review dataset, since there is no default validation set, we set temperature from low to high in $\{1, 3, 5, 10\}$ and take the average among all predictions.

5.4 Main Results

In tables 2 and 3 we compare the results of our methods (the vanilla version CLD-KCNN and the full version CLDFA-KCNN) with those of other methods based on the published results in the literature. The baseline methods are different in these two tables as they were previously evaluated (by their authors) on different benchmark datasets. Clearly, CLDFA-KCNN outperformed the other methods on all except one task in these two datasets, showing that knowledge distillation is successfully carried out in our approach. Noticing that CLDFA-KCNN outperformed CLD-KCNN, showing the effectiveness of adversarial feature extraction in reducing the distribution mismatch between the parallel corpus and the train/test data in the target domain. We should also point out that in Table 2, the four baseline methods (PL-LSI, PL-KCCA, PL-OPCA and PL-MC) were evaluated under the condition of using additional 100 labeled target documents for training, according to the author's report (Xiao and Guo, 2013). On the other hand, our methods (CLD-KCNN and CLDFA-KCNN) were evaluated under a tougher condition, i.e., not using any labeled data in the target domains.

We also test our framework when a few training documents in the target language are available. A simple way to utilize the target-language supervision is to fit the target-language model with labeled target data after optimizing with our cross-lingual distillation framework. The performance of CLD-KCNN and CLDFA-KCNN trained with different sizes of labeled target-language data is shown in figure 3. We also compare the performance of training the same classifier using only

the target-language labels(**Target Only** in figure 3). As we can see, our framework can efficiently utilize the extra supervision and improve the performance over the training using only the target-language labels. The margin is most significant when the size of the target-language label is relatively small.

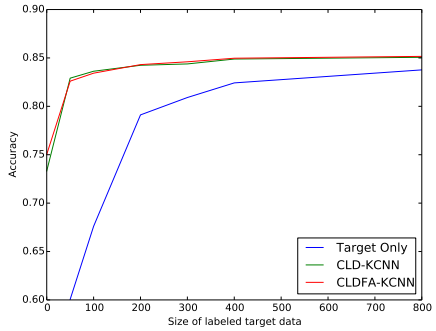

Figure 3: Accuracy scores of methods using varying sizes of target-language labeled data on the Amazon review dataset. The target language is German and the domain is music. The parallel corpus has a fixed size of 1000 and the size of the labeled target-language documents is shown on the x-axis

6 Conclusion

This work introduces a novel framework for distillation of discriminative knowledge across languages, providing effective and efficient algorithmic solutions for addressing domain/distribution mismatch issues in CLTC. The excellent performance of our approach is evident in our evaluation on two CLTC benchmark datasets, compared to that of other state-of-the-art methods.

Understanding and Predicting Empathic Behavior in Counseling Therapy

Abstract

Counselor empathy is associated with better outcomes in psychology and behavioral counseling. In this paper, we explore several aspects pertaining to counseling interaction dynamics and their relation to counselor empathy during motivational interviewing encounters. Particularly, we analyze aspects such as participants' engagement, participants' verbal and nonverbal accommodation, as well as topics being discussed during the conversation, with the final goal of identifying linguistic and acoustic markers of counselor empathy. We also show how we can use these findings alongside other raw linguistic and acoustic features to build accurate counselor empathy classifiers with accuracies of up to 80%.

1 Introduction

Behavioral counseling is an important tool to address public health issues such as mental health, substance abuse, and nutrition problems among others. This has motivated increased interest in the study of mechanisms associated with successful interventions. Among them, counselor empathy has been identified as a key intervention component that relates to positive therapy outcomes.

Displaying empathic behavior helps counselors to build rapport with their clients. Empathy levels experienced during counseling have a significant effect on treatment outcomes, as clients who perceive their counselor as empathic are more likely to improve than the ones who do not (Moyers and Miller, 2013).

In this paper, we apply quantitative approaches to understand the dynamics of the counseling interactions and their relation to counselor empathy. We focus our analysis on counseling conducted using Motivational Interviewing (MI), a well-established evidence-based counseling style, where counselor empathy is defined as the active interest and effort to understand the client's perspective (Miller and Rollnick, 2013).

We address four main research questions. First, are there differences in how the counselor and the client engage during empathic conversations? We explore this question by conducting turn-by-turn word frequency analyses of participant's interactions across the counseling conversations. Second, are there differences in verbal and vocal mimicry patterns occurring during high and low empathy interactions? We address this question by measuring the degree of language matching, verbal and nonverbal coordination, and power dynamics expressed during the interaction. Third, are there content differences in counselor discourse during high and low empathy interactions? We answer this question by applying topic modeling to identify the topics that are more salient in high and low empathy interventions (or in both). Finally, fourth, can we build accurate classifiers of counselor empathy? We show how the linguistic and acoustic empathy markers identified in our analyses, together with other raw features, can be used to construct classifiers able to predict counselor empathy with accuracies of up to 80%.

2 Related Work

There have been several efforts to study the role of empathy during counseling interactions. (Xiao et al., 2012) applied a text-based approach to discriminate empathic from non-empathic encounters using word-frequency analysis. They conducted a set of experiments aiming to predict empathy at the utterance and session level on a manually annotated dataset. Results showed that empathy can

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1426–1435
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1131

be predicted at reasonable accuracy levels, comparable to human assessments. (Gibson et al., 2015) presented a more refined approach for this task, which in addition to n-grams included features derived from the Linguistic Inquire Word Count, LIWC (Tausczik and Pennebaker, 2010) as well as psycholinguistic norms.

Other research has focused on exploring aspects related to counselor empathy skills, such as their ability to match the client language. (Lord et al., 2015) analyzed the language coordination between client and counselor using Language Style Synchrony (LSS), a measure of the degree of similarity in word usage among speakers in adjacent talking turns. They found that empathy scores are positively related to LSS, and that higher levels of LSS are likely to result in higher empathy scores.

Another line of work has explored the use of the acoustic component to predict empathy levels during counseling encounters. (Xiao et al., 2014) presented a study on the automatic evaluation of counselor empathy based on the analysis of correlation between prosody patterns and the degree of empathy showed by the therapist during the counseling interactions. More recently, (Xiao et al., 2015) addressed the empathy prediction task by deriving language models from transcripts obtained by an automatic speech recognition system, thus eliminating the need of human intervention during speaker segmentation and transcription.

Most of this previous research has focused on the prediction task, and explored a variety of linguistic and acoustic representations for this goal. While some of this work has explored the linguistic accommodation between speakers, previous methods have not fully explored the conversational aspects of the counseling interaction.

In this paper, we seek to explore how conversational aspects such as engagement, accommodation, and discourse topics are related to counselor empathy by using strategies such as turn-by-turn word frequency analysis, language coordination, power dynamics analysis, and topic modeling. Furthermore, we build accurate empathy classifiers that rely on acoustic and linguistic cues inspired by our conversational analyses.

3 Counseling Empathy Dataset

The dataset used in this study consists of 276 MI audio-recorded sessions from: two clinical research studies on smoking cessation and medication adherence (Catley et al., 2012; Goggin et al., 2013); recordings of MI students from a graduate-level MI course; wellness coaching phone calls; brief medical encounters in dental practice and student counseling. The dataset was obtained from a previous study conducted by the authors. Further details can be found in (Pérez-Rosas et al., 2016).

The counseling sessions target three behavior changes: diet changes (72 sessions), smoking cessation (95 sessions), medication adherence (93 sessions). In addition, there are 16 sessions on miscellaneous topics. The full set comprises 97.8 hours of audio with an average session length of 20.8 minutes with a standard deviation of 11.5 minutes.

3.1 Data Preprocessing

Before conducting our analysis on the collected dataset, we performed several preprocessing steps to ensure the confidentiality of the data and to enable automatic text and audio feature extraction.

First, all the counseling recordings were subjected to an anonymization process. This includes manually trimming the audio to remove introductions, and inserting silences to replace references to participant's name and location.

Next, 162 sessions for which transcripts were not readily available were transcribed via Mechanical Turk (Marge et al., 2010) using the following guidelines: 1) transcribe speech turn by turn, 2) clearly identify the speaker (either client or counselor), 3) include speech disfluencies, such as false starts, repetitions of whole words or parts of words, and fillers. Transcriptions were manually verified at random points to avoid spam and ensure their quality.

Since sessions were recorded in natural conditions, we applied speech enhancement methods to remove noise and improve the speech signal quality. We started by converting the audio signal from a stereo to a mono channel and to a uniform sample rate of 16k. We then applied the Mean Square Error estimation of spectral amplitude for audio denoising, as implemented in the Voicebox Speech Processing toolbox (Brookes, 2003). To allow for a turn-by-turn audio analysis of the counseling interaction, we processed the speech signal to separate client and counselor speech segments. To accomplish this task, we used on automatic speech-to-text forced alignment API.[1] We

[1] YouTube Data API

then used the automatically-obtained time stamps to segment the audio and derive speaker-specific speech segments for each counseling dyad.

3.2 Data Annotation

Empathy assessments were obtained using the Motivational Interviewing Treatment Integrity (MITI) coding scheme version 4.1 (Moyers, 2014). Each session was assigned an empathy score using a 5-point Likert scale, which measures the extent to which the clinician understands or makes an effort to grasp the client's perspective and feelings. The coding was conducted by two independent teams of three coders who had previous experience in MI and MI coding. Annotations were conducted using the session audio recording along with its transcript. The inter-rater reliability, measured in a random sample of 20 double coded sessions using the Intra-Class Correlation Coefficient was 0.60,[2] suggesting that the annotators showed moderate agreement on empathy assessments. The reported annotation agreement was calculated on the original 5-scale empathy score and it is within the ranges reported in previous Motivational Interviewing studies (0.60-0.62). Because of the skewed frequency distribution of the empathy scores in the dataset, we decided to conduct our analyses using empathy as a binary outcome, by classifying scores from 1 to 3 as low empathy, and scores of 4 and 5 as high empathy. This resulted in 179 high empathy sessions and 97 low empathy sessions.

4 Empathic vs Non-Empathic Interactions: Counselor Engagement

We start by exploring differences in verbal exchange length between low and high empathy encounters as an indirect measure of participants engagement during the conversation. In this analysis, we account for the time dimension by segmenting the conversation into five equal portions. First, we look at the ratio of words exchanged between the counselor and the client for the different fractions of the conversation.[3] As shown in Figure 1, low empathy interactions present noticeably

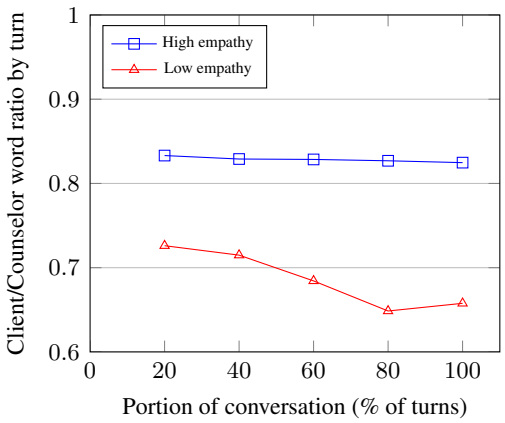

Figure 1: Word ratio by turn between clients and counselors as the conversation progresses.

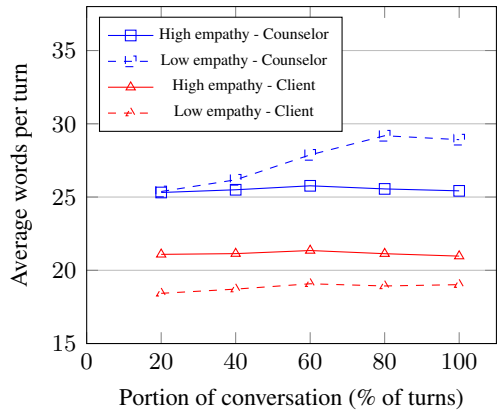

Figure 2: Average words per turn by counselors and clients as the conversation progresses.

lower ratio of words exchanged between counselors and clients across the interaction, while high empathy exchanges show consistently higher levels of interaction. This can be further observed in Figure 2, which shows that more empathic counselors speak considerably less than their clients, and that their less empathic counterparts. This is in line with findings in MI literature indicating that counselors who reduce the amount of time they talk with their clients are likely to allow more time for the patient to talk and explore their concerns, thus improving the perception of empathy and understanding.

5 The Role of Verbal and Nonverbal Accommodation in Empathy

Accommodation in health care communication involves counselor and client coordination including participation in communication and decision making, and shared understanding (D'Agostino

[2]ICC scores were obtained using a two-way mixed model with absolute agreement.

[3]This ratio is calculated for each pair of turns in the conversation, and it is simply measured as the number of words uttered by the counselor divided by the number of words uttered by the client. The turn-level word ratios are then averaged for all the turns included in a portion of the conversation.

and Bylund, 2014). We analyze the accommodation and its relation to empathy by exploring verbal and nonverbal behaviors exhibited by counseling participants during MI encounters. In addition to accommodation assessments, we explore the direction of the accommodation phenomena, i.e., whether the counselor is mirroring or leading the client.

5.1 Verbal Accommodation

In order to explore how verbal accommodation phenomena in our dataset relate to the MITI empathy assessments, we use two methods that are drawn from the Conversation Accommodation Theory. The first one is the Linguistic Style Matching (LSM) proposed in (Gonzales et al., 2009) to quantify to which extent one speaker, i.e., the counselor, matches the language of the other, i.e., the client. The second one is the Linguistic Style Coordination (LSC) metric proposed in (Danescu-Niculescu-Mizil et al., 2011), which quantifies the degree to which one individual immediately echoes the linguistic style of the person they are responding to. Both metrics are evaluated across eight linguistic markers from the LIWC dictionary (Tausczik and Pennebaker, 2010) (i.e., quantifiers, conjunctions, adverbs, auxiliary verbs, prepositions, articles, personal pronouns and impersonal pronouns).

LSM produces a score ranging between 0 and 1 indicating how much one person uses types of words comparable to the other person, while LSC generates a coordination score in the range of -1 to 1 indicating the degree of immediate coordination between speakers. While both measures are designed to analyze verbal synchrony, they can reveal different aspects of the counseling interaction. We use LSM to explore the potential match of language between counselors and clients across the counseling interaction, and we use LSC to quantify whether the counselor use of a specific linguistic marker in a given turn increases the probability of the client using the same marker during their reply. In addition, we use LSC to investigate power differences during the conversation based on the amount of coordination displayed by either counselor or client, under the assumption that the speaker who accommodates less holds the most power during the conversation (Danescu-Niculescu-Mizil et al., 2012).

Figure 3 shows the average LSM scores for

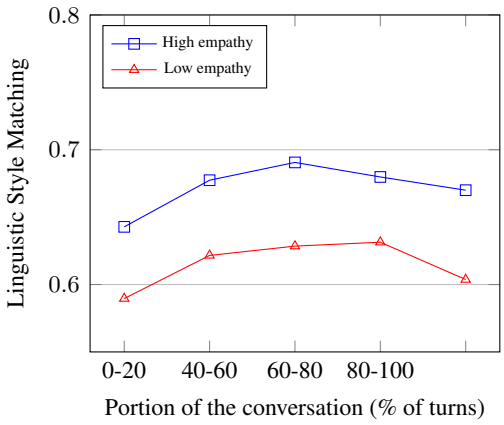

Figure 3: Linguistic style matching across five equal segments of the conversation duration.

eight linguistic markers measured on five equal segments of the conversation duration. As expected, we observe an increasing trend of language style matching during the counseling interaction in both high-empathic and low-empathic encounters, as people usually match their language unconsciously and regardless of the outcome of the conversation (Niederhoffer and Pennebaker, 2002). Interestingly, counselors and clients present a higher degree of language matching during high empathy encounters, while speakers in low empathy encounters show lower levels of style matching.

We evaluate the immediate LSC in two directions: coordination of counselors toward clients, and coordination of clients toward counselors. Results indicate low levels of immediate coordination in both cases, with values ranging between -0.06 and 0.1. Nonetheless, the results also suggest that clients coordinate more than counselors, with LSC(client,counselor)=-0.030 compared to LSC(counselor, client)=-0.038, which further suggests that counselors have more power (control) during the conversation.[4]

Analyses of the LSC levels from counselors to clients on different linguistic markers across high-empathic and low-empathic interactions provide interesting findings. While counselors generally show lower levels of coordination in the use of prepositions, auxiliary verbs, and personal pronouns (Figure 4), low-empathic counselors show higher LSC levels than their high-empathic counterparts. This can be attributed to the use of con-

[4]The differences in coordination showed during the analyses are statistically significant (two tailed t-test, p=0.0156)

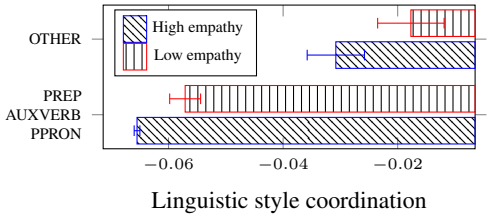

Figure 4: Linguistic style coordination from counselors to clients. OTHER include: quantifiers, conjunctions, adverbs, articles, and impersonal pronouns.

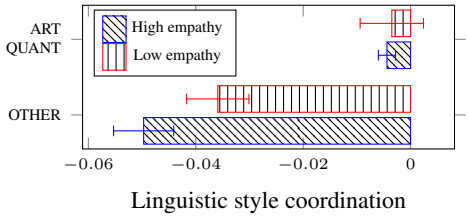

Figure 5: Linguistic style coordination from clients to counselors. OTHER include: conjunctions, adverbs, auxiliary verbs, prepositions, personal pronouns and impersonal pronouns.

frontational language (e.g., *I*, *could*, *should*, and *have*), which is often associated with low empathy. Similar analyses on the client side, shown in Figure 5, indicate significant differences in the use of linguistic markers by the client (except for articles and quantifiers). In particular, during low empathy encounters, clients coordinate more on the use of conjunctions, adverbs, auxiliary verbs, prepositions, personal pronouns, and impersonal pronouns.

5.2 Nonverbal Accommodation

Empathy is also shown through nonverbal channels such as visual and acoustics (Regenbogen et al., 2012). We explore the role of nonverbal mirroring in empathy by looking at vocal synchrony patterns shared between counselors and clients during the counseling interaction. We focus our analysis on vocal pitch, which is defined as the psychological perception of the voice frequency in terms of how high or how low it sounds. Pitch carries information about the speaker's emotional state, and has been shown to be related to the perception of empathy in psychotherapy (Reich et al., 2014).

We evaluate speech synchrony during turn-taking trajectories in the conversation. We consider two cases: sequences where the counselor replies to the client statements (e.g., rephrasing), and sequences where the counselor leads the interaction (e.g., asking questions). Starting with the turn-by-turn segmentation,[5] we extract pitch (F0) on each speaker-specific segment using OpenEar (Eyben et al., 2009).[6] We then measure the correlation of all pitch values during counselor following turns and during counselor leading turns across the entire therapy session.[7]

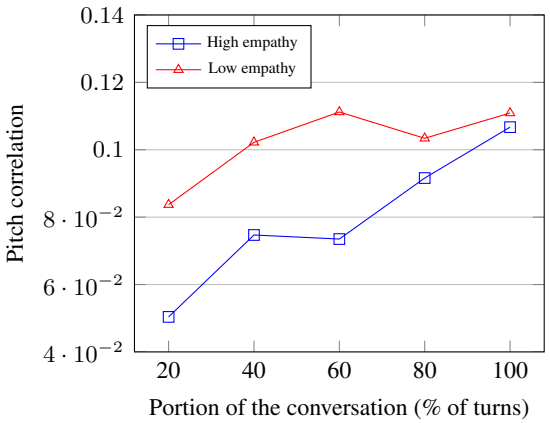

Figure 6: Pitch correlation among participants during counselor following turns as the conversation progresses.

Figures 6 and 7 show the trends in pitch synchrony across high-empathic and low-empathic encounters in the dataset. In the first figure, we observe that when replying to clients, counselors who are given low empathy scores show higher vocal synchrony levels than counselors who receive higher empathy scores. A potential explanation for this finding is that a counselor who mirrors the client pitch might amplify the emotional distress of the client, or may suggest the counselor's lack of confidence or knowledge (Reich et al., 2014).

On the other hand, we observe the opposite trend for the counselor leading sequences, where higher vocal synchrony levels are observed during high empathy interactions, which can be at-

[5]On average, there are approximately 40 counselor-client turns per conversation

[6]The feature extraction was done at audio-frame level every 10ms with a 25ms Hamming window.

[7]The terms of "counselor following" and "counselor leading" simply refer to how the correlation is computed. In "counselor following," we consider the set of counselor utterances and the previous client utterances; in "counselor leading," we consider the set of counselor utterances and the following client utterances.

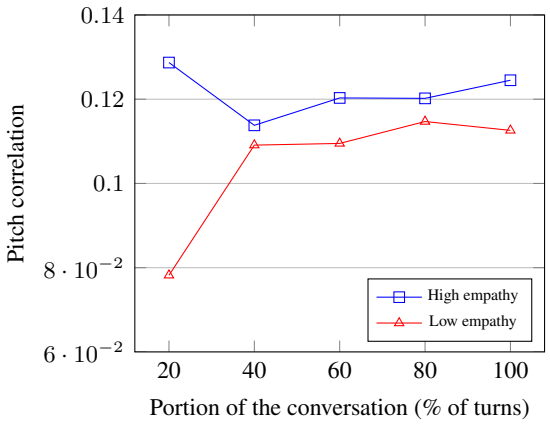

Figure 7: Pitch correlation among participants during counselor leading turns as the conversation progresses.

tributed to clients mirroring the counselor speech. The similarity is noticeably higher at the beginning of the conversation and gradually decreases as the conversation progresses. Moreover, the differences are not significant for the 40-100% turns, but results for the first 20% suggest significant differences at least in the beginning of the conversation ($p < 0.05$). This further confirm similarities during verbal and nonverbal accommodation, similar to how in section 5.1 we found that during high-empathic encounters, counselors hold control of the conversation and clients accommodate more than counselors.

6 Topics Discussed during Counseling Interaction and their Relation to Empathy

We also conduct content analysis on the counseling interactions, to identify themes discussed in high-empathic and low-empathic encounters. For this task, we employ the Meaning Extraction Method (MEM) (Chung and Pennebaker, 2008), a topic extraction method that identifies the most common words used in a set of documents, and clusters them into coherent themes by analyzing their co-occurrences. MEM has been used in the past in the psychotherapy domain to analyze salient topics in depression forums (Ramirez-Esparza et al., 2008) and also to investigate differences in topics discussed by patients given their therapy outcomes, i.e., therapeutic gain or unsuccessful therapy (Wolf et al., 2010).

Our analyses are conducted on counselor turns only, thus all the client turns are removed from each session transcript. We use the Meaning Extraction Helper tool (Boyd, 2016) to conduct the text preprocessing tasks, which include tokenizing and lemmatizing the words in each session, as well as removing function words. We keep only words who appear in at least 10% of the transcripts with a minimum frequency of 50. From the resulting list, we remove adjectives, adverbs, and verbs and keep only nouns as they usually refer to one definite class thus helping us to identify less ambiguous topics. Using the resulting noun list, with 339 entries, we generate a binary vector for each document, indicating the presence or absence of each noun in the document. We then run a Principal Component Analysis (PCA), followed by varimax rotation on the document matrix to find clusters of co-occurring nouns.

Behavior target	Sample words
Medication adherence	Adherence, dose, window, target, adherent, maintain, track
Smoking cessation	Cigarette, nicotine, risk, addiction, smoke, withdrawal
Weight management	diet, weight, eat, food, meal, lose, gain, cook, exercise

Table 1: Three behavior change targets in the dataset

The initial PCA shows that the first three components consist mainly of domain specific nouns. Notably, this accurately captures the presence of the three main behavior change targets discussed in the dataset, i.e., medication adherence, smoking cessation, and weight management; sample words from each component are shown in Table 1.

In order to identify topics potentially related to the counseling skill, we decided to remove the domain words from the analysis, which resulted in 250 nouns. Next, we use the same PCA configuration on the binary document matrix and rerun the experiment, which this time leads to 98 components. Following PCA literature recommendations (Velicer and Fava, 1998), we retain only components with at least three variables with loadings greater than 0.30, which leads to 14 components. We then re-run PCA forcing a 14 components solution; these components explain 35% of the total variance in the original matrix. Finally, we use the method proposed in (Wilson et al., 2016) to measure the degree to which a particular MEM topic (component) is used during high-empathic and low-emphatic encounters.

Topic	Sample nouns	Score
Concerns	Concern, scare, overwhelm, diagnose	2.52
Importance	Importance, reason, maintain, sense, increase	1.41
Inform	Information, schedule, discuss, read	1.14
Reflections	sound, start, look, mention, past, notice	1.19
Change	Health, past, experience, decision, realize, difficult, impact	1.27
Goals	Reach, choose, period, stick, idea, study, record	1.57
Motivation	Plan, motivate, routine, motivation, group, progress, fun	1.10
Support	Family, care, worry, job, lifestyle, job, focus, issue	0.92
Feelings	Worry, deal, stuck, struggle, leave	0.91
Guide	Stop, reduce, attempt, spend, replacement	0.79
Resistance	Trouble, barrier, fear, reach, involve, cover	073
Persuade	Routine, track, strategy, recommend, affect	0.64
Persuade	Stop, increase, decrease, benefit, consequences	0.455
Plan	Activity, strategy, barrier, couple	0.292

Table 2: Topics extracted by the MEM from MI sessions, along with sample nouns and salient topic scores.

Table 2 shows the scores assigned to each topic. In this table, scores greater than 1 correspond to topics salient in high empathy encounters while scores lower than 1 indicate topics salient in low empathy encounters. From this table, we can derive interesting observations. First, during high-empathic encounters, counselors seem to pay more attention to patient concerns, provide information, use reflective language, and talk about change. Second, during less empathic encounters, counselors seem to persuade and direct more, as well as focus on client's resistance to change. Interestingly, topics that are identified as dominant in less empathic interactions are also related to MI non-adherent behavior, which means the counselors are not following the MI strategy (Rollnick et al., 2008). Finally, regardless of the empathy shown during the encounter, counselors discuss patients' support system and feelings at similar rates (values closer to 1), which is expected when following the MI strategy.

7 Prediction of Counselor Empathy

In the previous sections, we provided evidence of important differences in linguistic and verbal behaviors exhibited by counselors and clients during high-empathic and low-empathic MI encounters. In this section, we explore the use of linguistic and acoustic cues to build a computational model that predicts counselor empathy during MI encounters.

The feature set consists of the cues identified during our exploratory analyses as potential indicators of counselor empathy, as well as additional text and audio features used during standard NLP and acoustic feature extraction.

The text-based features are extracted from the manual transcripts of the sessions, while the audio-based features are extracted from audio segments obtained by force-aligning each session transcript with its corresponding audio. However, as future work, we are considering to automatize this process by conducting automatic speaker diarization and transcription via automatic speech recognition.

During our experiments, we first explore the predictive power of each cue separately, followed by an integrated model that attempts to combine the linguistic and acoustic cues to improve the prediction of counselor empathy.

All the experiments are performed using a Random Forest (Breiman, 2001) classifier. Given the large number of features, we use feature selection based on information gain to identify the best set of features during each experiment. During this process we keep at least 20% of the features in each set. Evaluations are conducted using leave-one-session-out cross-validation. The feature selection algorithm is run on each training fold before the model is trained, and the final model includes the best subset of attributes. As a reference value, we use a majority class baseline, obtained by selecting high empathy as the default class, which corresponds to 64% accuracy.

7.1 Linguistic and Acoustic Features

Engagement: These features represent the participant's engagement during the conversation as described in Section 4. They are evaluated at 20% increments of the conversation duration and also at conversation (session) level. The features are listed in Table 3.

Linguistic accommodation: We measure the LSM and LSC metrics as described in section 5.2 over 74 LIWC categories and measured at 20% increments of the encounter duration.

[8]Calculated using the LSC metric

Feature	C	T
Counselor talk time based on syllable counting	✓	
Length of conversation setter, length of setter response, ratio between setter and response	✓	
Counselor turns, client turns	✓	✓
Average words during client and counselor turns	✓	✓
Ratio of counselor and client words in each turn	✓	✓
Rate of verbal mirroring on each LIWC category [8]	✓	

Table 3: Engagement features extracted at a) (C) conversation level, and b) (T) 20% increments of the conversation duration, in percentage of turns.

Nonverbal accommodation: This set includes the counselor-leading and counselor-following synchrony scores, calculated as described in section 5.2, and evaluated at 20% increments of the encounter duration.

Discourse topics: These features consist of the 14 topics identified in section 6 as frequently discussed during the MI encounters. The features are obtained by calculating the product of the principal components matrix and the binary document-term matrix.

Raw linguistic features: We extract a large set of linguistic features derived from the session transcript to model the counselor language. We include: unigrams and bigrams (ngrams), represented as a vector containing their frequencies in the session; psycholinguistic-inspired features that capture differences in semantic meaning (lexicons), represented as the total frequency counts of all the words in a lexicon-category that are present in the transcript; syntactic features that encode syntax patterns in the counselor statements (CFG), represented as a vector containing the frequency of lexicalized and unlexicalized production rules from the Context Free Grammar parse trees[9] of each transcript. The final linguistic features set consists of 13,648 features.

Raw acoustic features: This feature set includes a large number of speech features extracted with the OpenEar toolkit (Eyben et al., 2009). We use a predefined feature set, EmoLarge, which consists of a set of 6,552 features used for emotion recognition tasks. The features are derived from 25 low-level speech descriptors including intensity, loudness, 12 Mel frequency coefficients, pitch (F0), probability of voicing, F0 envelope, zero-crossing rate, and 8 line spectral frequencies.

[9]Extracted with the Stanford parser (Klein and Manning, 2003).

Feature set	Empathy		
		F-score	
	Acc.	HE	LE
Linguistic			
Engagement	71.01%	0.80	0.40
Ling Accom	73.19%	0.82	0.44
Topics	75.72%	0.83	0.57
N-grams	78.62%	0.86	0.58
Lexicons	76.09%	0.84	0.55
CFG	76.09%	0.84	0.53
All linguistic	**80.07%**	**0.87**	0.62
Acoustic			
Nonverb Accom	64.86%	0.79	0.00
Raw acoustic	73.91%	0.82	0.53
All acoustic	75.72%	0.83	0.56
Linguistic+ Acoustic			
Ling+acoustic (early)	76.81%	0.84	0.56
Ling+acoustic (late)	79.35%	0.86	**0.71**

Table 4: Overall prediction results and F-scores for high empathy (HE) and low empathy (LE) using linguistic and acoustic feature sets.

7.2 Classification Results

Classification results for each feature set are shown in Table 4. For the linguistic and acoustic modalities, almost all the feature sets provide classification accuracies above the baseline, with good F-scores for both high and low empathy. The only exception are the nonverbal accommodation features, which have an accuracy comparable to the baseline (64.86% vs. 64%).

When combining all the feature sets for each modality, we observe performance gains in the range of 10 to 15%, as compared to the models that use one feature set at a time.
