Preface: General Chair

Welcome to ACL 2017 in Vancouver, Canada! This is the 55th annual meeting of the Association for Computational Linguistics. A tremendous amount of knowledge has been presented at more than half a century's worth of our conferences. Hopefully, some of it is still relevant now that deep learning has solved language. We are anticipating one of the largest ACL conferences ever. We had a record number of papers submitted to the conference, and a record number of industry partners joining us as sponsors of the conference. We are on track to be one of the best attended ACL conferences to date. I hope that this year's conference is intellectually stimulating and that you take home many new ideas and techniques that will help extend your own research.

Each year, the ACL conference is organized by a dedicated team of volunteers. Please thank this year's organizers for their service to the community when you see them at the conference. Without these people, this conference would not happen: Regina Barzilay and Min-Yen Kan (Program Co-Chairs), Priscilla Rasmussen and Anoop Sarkar (Local Organizing Committee), Wei Xu and Jonathan Berant (Workshop Chairs), Maja Popović and Jordan Boyd-Graber (Tutorial Chairs), Wei Lu, Sameer Singh and Margaret Mitchell (Publication Chairs), Heng Ji and Mohit Bansal (Demonstration Chairs), Spandana Gella, Allyson Ettinger, and Matthieu Labeau (Student Research Workshop Organizers), Cecilia Ovesdotter Alm, Mark Dredze, and Marine Carpuat (Faculty Advisors to the Student Research Workshop), Charley Chan (Publicity Chair), Christian Federmann (Conference Handbook Chair), Maryam Siahbani (Student Volunteer Coordinator), and Nitin Madnani (Webmaster and Appmaster).

The organizers have been working for more than a year to put together the conference. Far more than a year in advance, the ACL 2017 Coordinating Committee helped to select the venue and to pick the General Chair and the Program Co-Chairs. This consisted of members from NAACL and ACL executive boards. Representing NAACL we had Hal Daumé III, Michael White, Joel Tetreault, and Emily Bender. Representing ACL we had Pushpak Bhattacharyya, Dragomir Radev, Graeme Hirst, Yejin Choi, and Priscilla Rasmussen. I would like to extend a personal thanks to Graeme and Priscilla who often serve as the ACL's institutional memory, and who have helped fill in many details along the way.

I would like to extend a special thanks to our Program Co-Chairs, Regina Barzilay and Min-Yen Kan. They documented their work creating the program by running a blog. They used their blog as a platform for engaging the ACL community in many of the decision making processes including soliciting suggestions for the conference's area chairs and invited speakers. They hosted discussions with Marti Hearst and Joakim Nivre about the value of publishing pre-prints of submitted paper on arXiv and how they relate to double blind reviewing. They even invited several prominent members of our community to provide last-minute writing advice. If you weren't following the blog in the lead-up to the conference, I highly recommend taking a look through it now. You can find it linked from the ACL 2017 web page.

This year's program looks like it will be excellent! We owe a huge thank you to Regina Barzilay and Min-Yen Kan. They selected this year's papers from 1,318 submissions with the help of 44 area chairs and more than 1,200 reviewers. Thanks to Regina, Min, the area chairs, the reviewers and the authors. Beyond the papers, we have talks by luminaries in the field of NLP, including ACL President Joakim Nivre, invited speakers Mirella Lapata and Noah Smith, and the recipient of this year's Lifetime Achievement Award. We also have an excellent set of workshops and tutorials. On the tutorial day, there will also be a special workshop on Women and Underrepresented Minorities in Natural Language Processing. Thank you to our workshop organizers and tutorial presenters.

This year's conference features two outreach activities that I would like to highlight. First, on Sunday, July 30, 2017, there will be a workshop on Women and Underrepresented Minorities in Natural Language Processing organized by Libby Barak, Isabelle Augenstein, Chloé Braud, He He, and Margaret Mitchell. The goals of the workshop are to increase awareness of the work women and underrepresented

groups do, support women and underrepresented groups in continuing to pursue their research, and motivate long-term resources for underrepresented groups within ACL. Second, for the first time ever, ACL is offering subsidized on-site childcare at the conference hotel. The goal of this is to allow ACL participants with children to more readily be able to attend the conference. Since childcare duties often fall disproportionately on women, our hope is that by having professional childcare on-site that we will allow more women to participate, and therefore to help promote their careers. My hope is that the childcare will be continued in future conferences.

I would like to thank our many sponsors for their generous contributions. Our platinum sponsors are Alibaba, Amazon, Apple, Baidu, Bloomberg, Facebook, Google, Samsung and Tencent. Our gold sponsors are eBay, Elsevier, IBM Research, KPMG, Maluuba, Microsoft, Naver Line, NEC, Recruit Institute of Technology, and SAP. Our silver sponsors are Adobe, Bosch, CVTE, Duolingo, Huawei, Nuance, Oracle, and Sogou. Our bronze sponsors are Grammarly, Toutiao, and Yandex. Our supporters include Newsela and four professional master's degree programs from Brandeis, Columbia, NYU and the University of Washington. We would like to acknowledge the generous support of the National Science Foundation which has awarded a $15,000 grant to the ACL Student Research Workshop. Finally, NVIDIA donated several Titan X GPU cards for us to raffle off during the conference.

Lastly, I would like to thank everyone else who helped to make this conference a success. Thank you to our area chairs, our army of reviewers, our workshop organizers, our tutorial presenters, our invited speakers, and our authors. Best regards to all of you.

Welcome to ACL 2017!

Chris Callison-Burch
General Chair

Preface: Program Committee Co-Chairs

Welcome to the 55th Annual Meeting of the Association for Computational Linguistics! This year, ACL received 751 long paper submissions and 567 short paper submissions[1]. Of the long papers, 195 were accepted for presentation at ACL — 117 as oral presentations and 78 as poster presentations (25% acceptance rate). 107 short papers were accepted — 34 as oral and 73 as poster presentations (acceptance rate of 18%). In addition, ACL will also feature 21 presentations of papers accepted in the *Transactions of the Association for Computational Linguistics* (TACL). Including the student research workshop and software demonstrations, the ACL program swells to a massive total of 367 paper presentations on the scientific program, representing the largest ACL program to date.

ACL 2017 will have two distinguished invited speakers: Noah A. Smith (Associate Professor of Computer Science and Engineering at the University of Washington) and Mirella Lapata (Professor in the School of Informatics at the University of Edinburgh). Both are well-renowned for their contributions to the field of computational linguistics and are excellent orators. We are honored that they have accepted our invitation to address the membership at this exciting juncture in our field's history, addressing key issues in representation learning and multimodal machine translation.

To manage the tremendous growth of our field, we introduced some changes to the conference. With the rotation of the annual meeting to the Americas, we anticipated a heavy load of submissions and early on we decided to have both the long and short paper deadlines merged to reduce reviewing load and to force authors to take a stand on their submissions' format. The joint deadline allowed us to only load our reviewers once, and also enabled us to have an extended period for more lengthy dialogue among authors, reviewers and area chairs.

In addition, oral presentations were shortened to fourteen (twelve) minutes for long (short) papers, plus time for questions. While this places a greater demand on speakers to be concise, we believe it is worth the effort, allowing far more work to be presented orally. We also took advantage of the many halls available and expanded the number of parallel talks to five during most of the conference sessions.

In keeping with changes introduced in the ACL community from last year, we continued the practice of recognizing outstanding papers at ACL. The 22 outstanding papers (15 long, 7 short, 1.6% of submissions) represent a broad spectrum of exciting contributions and have been specially placed on the final day of the main conference where the program is focused into two parallel sessions of these outstanding contributions. From these, a best paper and a best short paper those will be announced in the awards session on Wednesday afternoon.

Chris has already mentioned our introduction of the chairs' blog[2], where we strove to make the selection process of the internal workings of the scientific committee more transparent. We have publicly documented our calls for area chairs, reviewers and accepted papers selection process. Via the blog, we communicated several innovations in the conference organization workflow, of which we would call attention to two key ones here.

In the review process, we pioneered the use of the Toronto Paper Matching System, a topic model based approach to the assignment of reviewers to papers. We hope this decision will spur other program chairs to adopt the system, as increased coverage will better the reviewer/submission matching process, ultimately leading to a higher quality program.

For posterity, we also introduced the usage of hyperlinks in the bibliography reference sections of papers,

[1] These numbers exclude papers that were not reviewed due to formatting, anonymity, or double submission violations or that were withdrawn prior to review, which was unfortunately a substantial number.

[2] https://chairs-blog.acl2017.org/

and have worked with the ACL Anthology to ensure that digital object identifiers (DOIs) appear in the footer of each paper. These steps will help broaden the long-term impact of the work that our community has on the scientific world at large.

There are many individuals we wish to thank for their contributions to ACL 2017, some multiple times:

- The 61 area chairs who volunteered for our extra duty. They recruited reviewers, led discussions on each paper, replied to authors' direct comments to them and carefully assessed each submission. Their input was instrumental in guiding the final decisions on papers and selecting the outstanding papers.
- Our full program committee of BUG hard-working individuals who reviewed the conference's 1,318 submissions (including secondary reviewers).
- TACL editors-in-chief Mark Johnson, Lillian Lee, and Kristina Toutanova, for coordinating with us on TACL presentations at ACL.
- Noah Smith and Katrin Erk, program co-chairs of ACL 2016 and Ani Nenkova and Owen Rambow, program co-chairs of NAACL 2016, who we consulted several times on short order for help and advice.
- Wei Lu and Sameer Singh, our well-organized publication chairs, with direction and oversight from publication chair mentor Meg Mitchell. Also, Christian Federmann who helped with the local handbook.
- The responsive team at Softconf led by Rich Gerber, who worked quickly to resolve problems and who strove to integrate the use of the Toronto Paper Matching System (TPMS) for our use.
- Priscilla Rasmussen and Anoop Sarkar and the local organization team, especially webmaster Nitin Madnani.
- Christopher Calliston-Burch, our general chair, who kept us coordinated with the rest of the ACL 2017 team and helped us free our time to concentrate on the key duty of organizing the scientific program.
- Key-Sun Choi, Jing Jiang, Graham Neubig, Emily Pitler, and Bonnie Webber who carefully reviewed papers under consideration for best paper recognition.
- Our senior correspondents for the blog, who contributed guest posts and advice for writing and reviewing: Waleed Ammar, Yoav Artzi, Tim Baldwin, Marco Baroni, Claire Cardie, Xavier Carreras, Hal Daumé, Kevin Duh, Chris Dyer, Marti Hearst, Mirella Lapata, Emily M. Bender, Aurélien Max, Kathy McKeown, Ray Mooney, Ani Nenkova, Joakim Nivre, Philip Resnik, and Joel Tetreault. Without them, the participation of the community through the productive comments, and without you the readership, our blog for disseminating information about the decision processes would not have been possible and a success.

We hope that you enjoy ACL 2017 in Vancouver!

ACL 2017 program co-chairs
Regina Barzilay, Massachusetts Institute of Technology
Min-Yen Kan, National University of Singapore

Organizing Committee

General Chair:

Chris Callison-Burch, University of Pennsylvania

Program Co-Chairs:

Regina Barzilay, Massachusetts Institute of Technology
Min-Yen Kan, National University of Singapore

Local Organizing Committee:

Priscilla Rasmussen, ACL
Anoop Sarkar, Simon Fraser University

Workshop Chairs:

Wei Xu, Ohio State University
Jonathan Berant, Tel Aviv University

Tutorial Chairs:

Maja Popović, Humboldt-Universität zu Berlin
Jordan Boyd-Graber, University of Colorado, Boulder

Publication Chairs:

Wei Lu, Singapore University of Technology and Design
Sameer Singh, University of California, Irvine
Margaret Mitchell, Google (Advisory)

Demonstration Chairs:

Heng Ji, Rensselaer Polytechnic Institute
Mohit Bansal, University of North Carolina, Chapel Hill

Student Research Workshop Organizers:

Spandana Gella, University of Edinburgh
Allyson Ettinger, University of Maryland, College Park
Matthieu Labeau, Laboratoire d'Informatique pour la Mécanique et les Sciences de l'Ingénieur (LIMSI)

Faculty Advisors to the Student Research Workshop:

Cecilia Ovesdotter Alm, Rochester Institute of Technology
Mark Dredze, Johns Hopkins University
Marine Carpuat, University of Maryland, College Park

Publicity Chair:

Charley Chan, Bloomberg

Conference Handbook Chair:

Christian Federmann, Microsoft

Student Volunteer Coordinator:

Maryam Siahbani, University of the Fraser Valley

Webmaster and Appmaster:

Nitin Madnani, Educational Testing Service

Program Committee

Program Committee Co-Chairs

Regina Barzilay, Massachusetts Institute of Technology
Min-Yen Kan, National University of Singapore

Area Chairs

Mausam (Information Extraction and NLP Applications Area)
Omri Abend (Multilingual Area)
Eugene Agichtein (Information Extraction and NLP Applications Area)
Ron Artstein (Dialogue and Interactive Systems Area)
Alexandra Balahur (Sentiment Analysis and Opinion Mining Area)
Mohit Bansal (Vision, Robotics and Grounding Area)
Chia-Hui Chang (Information Extraction and NLP Applications Area)
Grzegorz Chrupała (Machine Learning Area)
Mona Diab (Multilingual Area)
Jason Eisner (Phonology, Morphology and Word Segmentation Area)
Manaal Faruqui (Semantics Area)
Raquel Fernandez (Dialogue and Interactive Systems Area)
Karën Fort (Multidisciplinary Area)
Amir Globerson (Machine Learning Area)
Hannaneh Hajishirzi (Semantics Area)
Chiori Hori (Speech Area)
Tommi Jaakkola (Machine Learning Area)
Yangfeng Ji (Discourse and Pragmatics Area)
Jing Jiang (Information Extraction and NLP Applications Area)
Sarvnaz Karimi (Information Extraction and NLP Applications Area)
Anna Korhonen (Semantics Area)
Zornitsa Kozareva (Information Extraction and NLP Applications Area)
Lun-Wei Ku (Sentiment Analysis and Opinion Mining Area)
Nate Kushman (Vision, Robotics and Grounding Area)
Chia-ying Lee (Speech Area)
Oliver Lemon (Dialogue and Interactive Systems Area)
Roger Levy (Cognitive Modeling and Psycholinguistics Area)
Sujian Li (Discourse and Pragmatics Area)
Wenjie Li (Summarization and Generation Area)
Kang Liu (Information Extraction and NLP Applications Area)
Tie-Yan Liu (Information Extraction and NLP Applications Area)
Yang Liu (Machine Translation Area)
Zhiyuan Liu (Social Media Area)
Minh-Thang Luong (Machine Translation Area)
Saif M Mohammad (Sentiment Analysis and Opinion Mining Area)
Alexander M Rush (Summarization and Generation Area)
Haitao Mi (Machine Translation Area)
Alessandro Moschitti (Information Extraction and NLP Applications Area)
Smaranda Muresan (Information Extraction and NLP Applications Area)
Preslav Nakov (Semantics Area)
Graham Neubig (Machine Translation Area)

Aurélie Névéol (Biomedical Area)
Shimei Pan (Social Media Area)
Michael Piotrowski (Multidisciplinary Area)
Emily Pitler (Tagging, Chunking, Syntax and Parsing Area)
Barbara Plank (Tagging, Chunking, Syntax and Parsing Area)
Sujith Ravi (Machine Learning Area)
Verena Rieser (Summarization and Generation Area)
Sophie Rosset (Resources and Evaluation Area)
Mehroosh Sadrzadeh (Semantics Area)
Hinrich Schütze (Phonology, Morphology and Word Segmentation Area)
Anders Søgaard (Cognitive Modeling and Psycholinguistics Area)
Karin Verspoor (Biomedical Area)
Aline Villavicencio (Semantics Area)
Svitlana Volkova (Social Media Area)
Bonnie Webber (Discourse and Pragmatics Area)
Deyi Xiong (Machine Translation Area)
William Yang Wang (Machine Learning Area)
Wajdi Zaghouani (Resources and Evaluation Area)
Yue Zhang (Tagging, Chunking, Syntax and Parsing Area)
Hai Zhao (Tagging, Chunking, Syntax and Parsing Area)

Primary Reviewers

Reviewers who are acknowledged by the program committee for providing one or more outstanding reviews are marked with "*".

Balamurali A R, Mourad Abbas, Omri Abend, Amjad Abu-Jbara, Gilles Adda, Heike Adel, Stergos Afantenos, Apoorv Agarwal, Eneko Agirre, Željko Agić, Alan Akbik, Ahmet Aker, Mohammed Alam, Hanan Aldarmaki, Enrique Alfonseca, Afra Alishahi, Laura Alonso Alemany, David Alvarez-Melis, Maxime Amblard, Maryam Aminian, Silvio Amir, Waleed Ammar, Daniel Andrade, Jacob Andreas*, Nicholas Andrews*, Ion Androutsopoulos, Galia Angelova, Jean-Yves Antoine*, Emilia Apostolova, Jun Araki, Yuki Arase, Lora Aroyo, Philip Arthur, Yoav Artzi*, Masayuki Asahara, Giuseppe Attardi, AiTi Aw, Ahmed Hassan Awadallah, Wilker Aziz

Outstanding Papers

With twin upward trends in the interest in computational linguistics and natural language processing and the size of our annual meeting, ACL has begun the practice of recognizing outstanding papers that represent a select cross-section of the entire field, as nominated by reviewers and vetted by the area chairs and program co-chairs. These papers have been centrally located in the program, on the last day of our meeting, in a more focused two parallel tracks format.

This year, we have nominated 15 long papers and 7 short papers, representing 1.8% of all submissions and approximately 5% of the accepted ACL program. Congratulations, authors!

(in alphabetical order by first author surname)

Long Papers

- Jan Buys and Phil Blunsom. *Robust Incremental Neural Semantic Graph Parsing.*
- Xinchi Chen, Zhan Shi, Xipeng Qiu and Xuanjing Huang. *Adversarial Multi-Criteria Learning for Chinese Word Segmentation.*
- Ryan Cotterell and Jason Eisner. *Probabilistic Typology: Deep Generative Models of Vowel Inventories.*
- Yanzhuo Ding, Yang Liu, Huanbo Luan and Maosong Sun. *Visualizing and Understanding Neural Machine Translation.*
- Milan Gritta, Mohammad Taher Pilehvar, Nut Limsopatham and Nigel Collier. *Vancouver Welcomes You! Minimalist Location Metonymy Resolution.*
- Daniel Hershcovich, Omri Abend and Ari Rappoport. *A Transition-Based Directed Acyclic Graph Parser for UCCA.*
- Shuhei Kurita, Daisuke Kawahara and Sadao Kurohashi. *Neural Joint Model for Transition-based Chinese Syntactic Analysis.*
- Ryan Lowe, Michael Noseworthy, Iulian Vlad Serban, Nicolas Angelard-Gontier, Yoshua Bengio and Joelle Pineau. *Towards an Automatic Turing Test: Learning to Evaluate Dialogue Responses.*
- Yasuhide Miura, Motoki Taniguchi, Tomoki Taniguchi and Tomoko Ohkuma. *Unifying Text, Metadata, and User Network Representations with a Neural Network for Geolocation Prediction.*
- Ramakanth Pasunuru and Mohit Bansal. *Multi-Task Video Captioning with Visual and Entailment Generation.*
- Maxim Rabinovich, Mitchell Stern and Dan Klein. *Abstract Syntax Networks for Code Generation and Semantic Parsing.*
- Ines Rehbein and Josef Ruppenhofer. *Detecting annotation noise in automatically labelled data.*
- Jiwei Tan, Xiaojun Wan and Jianguo Xiao. *Abstractive Document Summarization with a Graph-Based Attentional Neural Model.*
- Mingbin Xu, Hui Jiang and Sedtawut Watcharawittayakul. *A Local Detection Approach for Named Entity Recognition and Mention Detection.*
- Suncong Zheng, Feng Wang, Hongyun Bao, Yuexing Hao, Peng Zhou and Bo Xu. *Joint Extraction of Entities and Relations Based on a Novel Tagging Scheme.*

Short Papers

- Xinyu Hua and Lu Wang. *Understanding and Detecting Diverse Supporting Arguments on Controversial Issues.*
- Jindřich Libovický and Jindřich Helcl. *Attention Strategies for Multi-Source Sequence-to-Sequence Learning.*
- Bogdan Ludusan, Reiko Mazuka, Mathieu Bernard, Alejandrina Cristia and Emmanuel Dupoux. *The Role of Prosody and Speech Register in Word Segmentation: A Computational Modelling Perspective.*
- Afshin Rahimi, Trevor Cohn and Timothy Baldwin. *A Neural Model for User Geolocation and Lexical Dialectology.*
- Keisuke Sakaguchi, Matt Post and Benjamin Van Durme. *Error-repair Dependency Parsing for Ungrammatical Texts.*
- Alane Suhr, Mike Lewis, James Yeh and Yoav Artzi. *A Corpus of Compositional Language for Visual Reasoning.*
- Yizhong Wang, Sujian Li and Houfeng Wang. *A Two-stage Parsing Method for Text-level Discourse Analysis.*

Invited Talk: Squashing Computational Linguistics

Noah A. Smith

Paul G. Allen School of Computer Science and Engineering, University of Washington

Abstract

The computational linguistics and natural language processing community is experiencing an episode of deep fascination with representation learning. Like many other presenters at this conference, I will describe new ways to use representation learning in models of natural language. Noting that a data-driven model always assumes a theory (not necessarily a good one), I will argue for the benefits of language-appropriate inductive bias for representation-learning-infused models of language. Such bias often comes in the form of assumptions baked into a model, constraints on an inference algorithm, or linguistic analysis applied to data. Indeed, many decades of research in linguistics (including computational linguistics) put our community in a strong position to identify promising inductive biases. The new models, in turn, may allow us to explore previously unavailable forms of bias, and to produce findings of interest to linguistics. I will focus on new models of documents and of sentential semantic structures, and I will emphasize abstract, reusable components and their assumptions rather than applications.

Biography

Noah Smith is an Associate Professor in the Paul G. Allen School of Computer Science and Engineering at the University of Washington. Previously, he was an Associate Professor in the School of Computer Science at Carnegie Mellon University. He received his Ph.D. in Computer Science from Johns Hopkins University and his B.S. in Computer Science and B.A. in Linguistics from the University of Maryland. His research spans many topics in natural language processing, machine learning, and computational social science. He has served on the editorial boards of CL, JAIR, and TACL, as the secretary-treasurer of SIGDAT (2012–2015), and as program co-chair of ACL 2016. Alumni of his research group, Noah's ARK, are international leaders in NLP in academia and industry. Smith's work has been recognized with a UW Innovation award, a Finmeccanica career development chair at CMU, an NSF CAREER award, a Hertz Foundation graduate fellowship, numerous best paper nominations and awards, and coverage by NPR, BBC, CBC, the New York Times, the Washington Post, and Time.

Invited Talk: Translating from Multiple Modalities to Text and Back

Mirella Lapata

Professor, School of Informatics, University of Edinburgh

Abstract

Recent years have witnessed the development of a wide range of computational tools that process and generate natural language text. Many of these have become familiar to mainstream computer users in the from of web search, question answering, sentiment analysis, and notably machine translation. The accessibility of the web could be further enhanced with applications that not only translate between different languages (e.g., from English to French) but also within the same language, between different modalities, or different data formats. The web is rife with non-linguistic data (e.g., video, images, source code) that cannot be indexed or searched since most retrieval tools operate over textual data.

In this talk I will argue that in order to render electronic data more accessible to individuals and computers alike, new types of translation models need to be developed. I will focus on three examples, text simplification, source code generation, and movie summarization. I will illustrate how recent advances in deep learning can be extended in order to induce general representations for different modalities and learn how to translate between these and natural language.

Biography

Mirella Lapata is professor of natural language processing in the School of Informatics at the University of Edinburgh. Her research focuses on getting computers to understand, reason with, and generate. She is as an associate editor of the Journal of Artificial Intelligence Research and has served on the editorial boards of Transactions of the ACL and Computational Linguistics. She was the first recipient of the Karen Sparck Jones award of the British Computer Society, recognizing key contributions to NLP and information retrieval. She received two EMNLP best paper awards and currently holds a prestigious Consolidator Grant from the European Research Council.

Table of Contents

Conference Program

Monday, July 31st

10:30–11:45 Session 1A: Information Extraction 1 (NN)

10:30–10:48 *Adversarial Multi-task Learning for Text Classification*
Pengfei Liu, Xipeng Qiu and Xuanjing Huang

10:49–11:07 *Neural End-to-End Learning for Computational Argumentation Mining*
Steffen Eger, Johannes Daxenberger and Iryna Gurevych

11:08–11:26 *Neural Symbolic Machines: Learning Semantic Parsers on Freebase with Weak Supervision*
Chen Liang, Jonathan Berant, Quoc Le, Kenneth D. Forbus and Ni Lao

11:27–11:45 *Neural Relation Extraction with Multi-lingual Attention*
Yankai Lin, Zhiyuan Liu and Maosong Sun

Monday, July 31st

10:30–11:45 Session 1B: Semantics 1

10:30–10:48 *Learning Structured Natural Language Representations for Semantic Parsing*
Jianpeng Cheng, Siva Reddy, Vijay Saraswat and Mirella Lapata

10:49–11:07 *Morph-fitting: Fine-Tuning Word Vector Spaces with Simple Language-Specific Rules*
Ivan Vulić, Nikola Mrkšić, Roi Reichart, Diarmuid Ó Séaghdha, Steve Young and Anna Korhonen

11:08–11:26 *Skip-Gram - Zipf + Uniform = Vector Additivity*
Alex Gittens, Dimitris Achlioptas and Michael W. Mahoney

11:27–11:45 *The State of the Art in Semantic Representation*
Omri Abend and Ari Rappoport

Monday, July 31st

10:30–11:26 Session 1C: Discourse 1

10:30–10:48 *Joint Learning for Event Coreference Resolution*
Jing Lu and Vincent Ng

10:49–11:07 *Generating and Exploiting Large-scale Pseudo Training Data for Zero Pronoun Resolution*
Ting Liu, Yiming Cui, Qingyu Yin, Wei-Nan Zhang, Shijin Wang and Guoping Hu

11:08–11:26 *Discourse Mode Identification in Essays*
Wei Song, Dong Wang, Ruiji Fu, Lizhen Liu, Ting Liu and Guoping Hu

Monday, July 31st

10:30–11:07 Session 1D: Machine Translation 1

10:30–10:48 *A Convolutional Encoder Model for Neural Machine Translation*
Jonas Gehring, Michael Auli, David Grangier and Yann Dauphin

10:49–11:07 *Deep Neural Machine Translation with Linear Associative Unit*
Mingxuan Wang, Zhengdong Lu, Jie Zhou and Qun Liu

Monday, July 31st

10:30–11:45 Session 1E: Generation 1

10:30–10:48 *Neural AMR: Sequence-to-Sequence Models for Parsing and Generation*
Ioannis Konstas, Srinivasan Iyer, Mark Yatskar, Yejin Choi and Luke Zettlemoyer

10:49–11:07 *Program Induction by Rationale Generation: Learning to Solve and Explain Algebraic Word Problems*
Wang Ling, Dani Yogatama, Chris Dyer and Phil Blunsom

11:08–11:26 *Automatically Generating Rhythmic Verse with Neural Networks*
Jack Hopkins and Douwe Kiela

11:27–11:45 *Creating Training Corpora for NLG Micro-Planners*
Claire Gardent, Anastasia Shimorina, Shashi Narayan and Laura Perez-Beltrachini

Monday, July 31st

13:40–14:55 Session 2A: Question Answering 1

13:40–13:58 *Gated Self-Matching Networks for Reading Comprehension and Question Answering*
Wenhui Wang, Nan Yang, Furu Wei, Baobao Chang and Ming Zhou

13:59–14:17 *Generating Natural Answers by Incorporating Copying and Retrieving Mechanisms in Sequence-to-Sequence Learning*
Shizhu He, Cao Liu, Kang Liu and Jun Zhao

14:18–14:36 *Coarse-to-Fine Question Answering for Long Documents*
Eunsol Choi, Daniel Hewlett, Jakob Uszkoreit, Illia Polosukhin, Alexandre Lacoste and Jonathan Berant

14:37–14:55 *An End-to-End Model for Question Answering over Knowledge Base with Cross-Attention Combining Global Knowledge*
Yanchao Hao, Yuanzhe Zhang, Kang Liu, Shizhu He, Zhanyi Liu, Hua Wu and Jun Zhao

Monday, July 31st

13:40–14:55 Session 2B: Vision 1

13:40–13:58 *Translating Neuralese*
Jacob Andreas, Anca Dragan and Dan Klein

13:59–14:17 *Obtaining referential word meanings from visual and distributional information: Experiments on object naming*
Sina Zarrieß and David Schlangen

14:18–14:36 *FOIL it! Find One mismatch between Image and Language caption*
Ravi Shekhar, Sandro Pezzelle, Yauhen Klimovich, Aurélie Herbelot, Moin Nabi, Enver Sangineto and Raffaella Bernardi

14:37–14:55 *Verb Physics: Relative Physical Knowledge of Actions and Objects*
Maxwell Forbes and Yejin Choi

Monday, July 31st

13:40–14:36 Session 2C: Syntax 1

13:40–13:58 *A* CCG Parsing with a Supertag and Dependency Factored Model*
Masashi Yoshikawa, Hiroshi Noji and Yuji Matsumoto

13:59–14:17 *A Full Non-Monotonic Transition System for Unrestricted Non-Projective Parsing*
Daniel Fernández-González and Carlos Gómez-Rodríguez

14:18–14:36 *Aggregating and Predicting Sequence Labels from Crowd Annotations*
An Thanh Nguyen, Byron Wallace, Junyi Jessy Li, Ani Nenkova and Matthew Lease

Monday, July 31st

13:40–15:14 Session 2D: Machine Learning 1 (NN)

13:40–13:58 *Multi-space Variational Encoder-Decoders for Semi-supervised Labeled Sequence Transduction*
Chunting Zhou and Graham Neubig

13:59–14:17 *Scalable Bayesian Learning of Recurrent Neural Networks for Language Modeling*
Zhe Gan, Chunyuan Li, Changyou Chen, Yunchen Pu, Qinliang Su and Lawrence Carin

14:18–14:36 *Learning attention for historical text normalization by learning to pronounce*
Marcel Bollmann, Joachim Bingel and Anders Søgaard

14:37–14:55 *Deep Learning in Semantic Kernel Spaces*
Danilo Croce, Simone Filice, Giuseppe Castellucci and Roberto Basili

14:56–15:14 *Topically Driven Neural Language Model*
Jey Han Lau, Timothy Baldwin and Trevor Cohn

Monday, July 31st

13:40–14:55 Session 2E: Sentiment 1 (NN)

13:40–13:58 *Handling Cold-Start Problem in Review Spam Detection by Jointly Embedding Texts and Behaviors*
Xuepeng Wang, Kang Liu and Jun Zhao

13:59–14:17 *Learning Cognitive Features from Gaze Data for Sentiment and Sarcasm Classification using Convolutional Neural Network*
Abhijit Mishra, Kuntal Dey and Pushpak Bhattacharyya

14:18–14:36 *An Unsupervised Neural Attention Model for Aspect Extraction*
Ruidan He, Wee Sun Lee, Hwee Tou Ng and Daniel Dahlmeier

14:37–14:55 *Other Topics You May Also Agree or Disagree: Modeling Inter-Topic Preferences using Tweets and Matrix Factorization*
Akira Sasaki, Kazuaki Hanawa, Naoaki Okazaki and Kentaro Inui

Monday, July 31st

15:45–16:41 Session 3A: Information Extraction 2 / Biomedical 1

15:45–16:03 *Automatically Labeled Data Generation for Large Scale Event Extraction*
Yubo Chen, Shulin Liu, Xiang Zhang, Kang Liu and Jun Zhao

16:04–16:22 *Time Expression Analysis and Recognition Using Syntactic Token Types and General Heuristic Rules*
Xiaoshi Zhong, Aixin Sun and Erik Cambria

16:23–16:41 *Learning with Noise: Enhance Distantly Supervised Relation Extraction with Dynamic Transition Matrix*
Bingfeng Luo, Yansong Feng, Zheng Wang, Zhanxing Zhu, Songfang Huang, Rui Yan and Dongyan Zhao

Monday, July 31st

15:45–17:00 Session 3B: Semantics 2 (NN)

15:45–16:03 *A Syntactic Neural Model for General-Purpose Code Generation*
Pengcheng Yin and Graham Neubig

16:04–16:22 *Learning bilingual word embeddings with (almost) no bilingual data*
Mikel Artetxe, Gorka Labaka and Eneko Agirre

16:23–16:41 *Abstract Meaning Representation Parsing using LSTM Recurrent Neural Networks*
William Foland and James H. Martin

16:42–17:00 *Deep Semantic Role Labeling: What Works and What's Next*
Luheng He, Kenton Lee, Mike Lewis and Luke Zettlemoyer

Monday, July 31st

15:45–17:00 Session 3C: Speech 1 / Dialogue 1

15:45–16:03 *Towards End-to-End Reinforcement Learning of Dialogue Agents for Information Access*
Bhuwan Dhingra, Lihong Li, Xiujun Li, Jianfeng Gao, Yun-Nung Chen, Faisal Ahmed and Li Deng

16:04–16:22 *Sequential Matching Network: A New Architecture for Multi-turn Response Selection in Retrieval-Based Chatbots*
Yu Wu, Wei Wu, Chen Xing, Ming Zhou and Zhoujun Li

16:23–16:41 *Learning Word-Like Units from Joint Audio-Visual Analysis*
David Harwath and James Glass

16:42–17:00 *Joint CTC/attention decoding for end-to-end speech recognition*
Takaaki Hori, Shinji Watanabe and John Hershey

Monday, July 31st

15:45–16:22 Session 3D: Multilingual 1

15:45–16:03 *Found in Translation: Reconstructing Phylogenetic Language Trees from Translations*
Ella Rabinovich, Noam Ordan and Shuly Wintner

16:04–16:22 *Predicting Native Language from Gaze*
Yevgeni Berzak, Chie Nakamura, Suzanne Flynn and Boris Katz

Monday, July 31st

15:45–16:03 Session 3E: Phonology 1

15:45–16:03 *MORSE: Semantic-ally Drive-n MORpheme SEgment-er*
Tarek Sakakini, Suma Bhat and Pramod Viswanath

Tuesday, August 1st

10:30–11:45 Session 4A: Information Extraction 3 (NN)

10:30–10:48 *Deep Pyramid Convolutional Neural Networks for Text Categorization*
Rie Johnson and Tong Zhang

10:49–11:07 *Improved Neural Relation Detection for Knowledge Base Question Answering*
Mo Yu, Wenpeng Yin, Kazi Saidul Hasan, Cicero dos Santos, Bing Xiang and Bowen Zhou

11:08–11:26 *Deep Keyphrase Generation*
Rui Meng, Sanqiang Zhao, Shuguang Han, Daqing He, Peter Brusilovsky and Yu Chi

11:27–11:45 *Attention-over-Attention Neural Networks for Reading Comprehension*
Yiming Cui, Zhipeng Chen, Si Wei, Shijin Wang, Ting Liu and Guoping Hu

Tuesday, August 1st

10:30–11:26 Session 4B: Cognitive Modelling 1 / Vision 2

10:30–10:48 *Alignment at Work: Using Language to Distinguish the Internalization and Self-Regulation Components of Cultural Fit in Organizations*
Gabriel Doyle, Amir Goldberg, Sameer Srivastava and Michael Frank

10:49–11:07 *Representations of language in a model of visually grounded speech signal*
Grzegorz Chrupała, Lieke Gelderloos and Afra Alishahi

11:08–11:26 *Spectral Analysis of Information Density in Dialogue Predicts Collaborative Task Performance*
Yang Xu and David Reitter

Tuesday, August 1st

10:30–12:04 Session 4C: Dialogue 2

10:30–10:48 *Affect-LM: A Neural Language Model for Customizable Affective Text Generation*
Sayan Ghosh, Mathieu Chollet, Eugene Laksana, Louis-Philippe Morency and Stefan Scherer

10:49–11:07 *Domain Attention with an Ensemble of Experts*
Young-Bum Kim, Karl Stratos and Dongchan Kim

11:08–11:26 *Learning Discourse-level Diversity for Neural Dialog Models using Conditional Variational Autoencoders*
Tiancheng Zhao, Ran Zhao and Maxine Eskenazi

11:27–11:45 *Hybrid Code Networks: practical and efficient end-to-end dialog control with supervised and reinforcement learning*
Jason D Williams, Kavosh Asadi and Geoffrey Zweig

11:46–12:04 *Generating Contrastive Referring Expressions*
Martin Villalba, Christoph Teichmann and Alexander Koller

Tuesday, August 1st

10:30–11:07 Session 4D: Machine Translation 2

10:30–10:48 *Modeling Source Syntax for Neural Machine Translation*
Junhui Li, Deyi Xiong, Zhaopeng Tu, Muhua Zhu, Min Zhang and Guodong Zhou

10:49–11:07 *Sequence-to-Dependency Neural Machine Translation*
Shuangzhi Wu, Dongdong Zhang, Nan Yang, Mu Li and Ming Zhou

Tuesday, August 1st

10:30–11:45 Session 4E: Social Media 1

10:30–10:48 *Detect Rumors in Microblog Posts Using Propagation Structure via Kernel Learning*
Jing Ma, Wei Gao and Kam-Fai Wong

10:49–11:07 *EmoNet: Fine-Grained Emotion Detection with Gated Recurrent Neural Networks*
Muhammad Abdul-Mageed and Lyle Ungar

11:08–11:26 *Beyond Binary Labels: Political Ideology Prediction of Twitter Users*
Daniel Preoţiuc-Pietro, Ye Liu, Daniel Hopkins and Lyle Ungar

11:27–11:45 *Leveraging Behavioral and Social Information for Weakly Supervised Collective Classification of Political Discourse on Twitter*
Kristen Johnson, Di Jin and Dan Goldwasser

Tuesday, August 1st

13:49–14:39 Session 5A: Multidisciplinary 1

13:49–14:07 *A Nested Attention Neural Hybrid Model for Grammatical Error Correction*
Jianshu Ji, Qinlong Wang, Kristina Toutanova, Yongen Gong, Steven Truong and Jianfeng Gao

14:08–14:26 *TextFlow: A Text Similarity Measure based on Continuous Sequences*
Yassine Mrabet, Halil Kilicoglu and Dina Demner-Fushman

14:27–14:39 *Friendships, Rivalries, and Trysts: Characterizing Relations between Ideas in Texts*
Chenhao Tan, Dallas Card and Noah A. Smith

Tuesday, August 1st

13:30–14:26 Session 5B: Language and Resources 1

13:30–13:48 *Polish evaluation dataset for compositional distributional semantics models*
Alina Wróblewska and Katarzyna Krasnowska-Kieraś

13:49–14:07 *Automatic Annotation and Evaluation of Error Types for Grammatical Error Correction*
Christopher Bryant, Mariano Felice and Ted Briscoe

14:08–14:26 *Evaluation Metrics for Machine Reading Comprehension: Prerequisite Skills and Readability*
Saku Sugawara, Yusuke Kido, Hikaru Yokono and Akiko Aizawa

Tuesday, August 1st

13:30–14:26 Session 5C: Syntax 2 (NN)

13:30–13:48 *A Minimal Span-Based Neural Constituency Parser*
Mitchell Stern, Jacob Andreas and Dan Klein

13:49–14:07 *Semantic Dependency Parsing via Book Embedding*
Weiwei Sun, Junjie Cao and Xiaojun Wan

14:08–14:26 *Neural Word Segmentation with Rich Pretraining*
Jie Yang, Yue Zhang and Fei Dong

Tuesday, August 1st

13:30–14:07 Session 5D: Machine Translation 3 (NN)

13:30–13:48 *Neural Machine Translation via Binary Code Prediction*
Yusuke Oda, Philip Arthur, Graham Neubig, Koichiro Yoshino and Satoshi Nakamura

13:49–14:07 *What do Neural Machine Translation Models Learn about Morphology?*
Yonatan Belinkov, Nadir Durrani, Fahim Dalvi, Hassan Sajjad and James Glass

Tuesday, August 1st

13:30–14:07 Session 5E: Sentiment 2

13:30–13:48 *Context-Dependent Sentiment Analysis in User-Generated Videos*
Soujanya Poria, Erik Cambria, Devamanyu Hazarika, Navonil Majumder, Amir Zadeh and Louis-Philippe Morency

13:49–14:07 *A Multidimensional Lexicon for Interpersonal Stancetaking*
Umashanthi Pavalanathan, Jim Fitzpatrick, Scott Kiesling and Jacob Eisenstein

Tuesday, August 1st

15:25–16:21 Session 6A: Information Extraction 4

15:25–15:43 *Tandem Anchoring: a Multiword Anchor Approach for Interactive Topic Modeling*
Jeffrey Lund, Connor Cook, Kevin Seppi and Jordan Boyd-Graber

15:44–16:02 *Apples to Apples: Learning Semantics of Common Entities Through a Novel Comprehension Task*
Omid Bakhshandeh and James Allen

16:03–16:21 *Going out on a limb: Joint Extraction of Entity Mentions and Relations without Dependency Trees*
Arzoo Katiyar and Claire Cardie

Tuesday, August 1st

15:25–16:40 Session 6B: Semantics 2 (NN)

15:25–15:43 *Naturalizing a Programming Language via Interactive Learning*
Sida I. Wang, Samuel Ginn, Percy Liang and Christopher D. Manning

15:44–16:02 *Semantic Word Clusters Using Signed Spectral Clustering*
Joao Sedoc, Jean Gallier, Dean Foster and Lyle Ungar

16:03–16:21 *An Interpretable Knowledge Transfer Model for Knowledge Base Completion*
Qizhe Xie, Xuezhe Ma, Zihang Dai and Eduard Hovy

16:22–16:40 *Learning a Neural Semantic Parser from User Feedback*
Srinivasan Iyer, Ioannis Konstas, Alvin Cheung, Jayant Krishnamurthy and Luke Zettlemoyer

Tuesday, August 1st

15:25–17:00 Session 6C: Discourse 2 / Dialogue 3

15:25–15:43 *Joint Modeling of Content and Discourse Relations in Dialogues*
Kechen Qin, Lu Wang and Joseph Kim

15:44–16:02 *Argument Mining with Structured SVMs and RNNs*
Vlad Niculae, Joonsuk Park and Claire Cardie

16:03–16:21 *Neural Discourse Structure for Text Categorization*
Yangfeng Ji and Noah A. Smith

16:22–16:40 *Adversarial Connective-exploiting Networks for Implicit Discourse Relation Classification*
Lianhui Qin, Zhisong Zhang, Hai Zhao, Zhiting Hu and Eric Xing

16:41–17:00 *Don't understand a measure? Learn it: Structured Prediction for Coreference Resolution optimizing its measures*
Iryna Haponchyk and Alessandro Moschitti

Tuesday, August 1st

15:25–16:21 Session 6D: Machine Learning 2

15:25–15:43 *Bayesian Modeling of Lexical Resources for Low-Resource Settings*
Nicholas Andrews, Mark Dredze, Benjamin Van Durme and Jason Eisner

15:44–16:02 *Semi-Supervised QA with Generative Domain-Adaptive Nets*
Zhilin Yang, Junjie Hu, Ruslan Salakhutdinov and William Cohen

16:03–16:21 *From Language to Programs: Bridging Reinforcement Learning and Maximum Marginal Likelihood*
Kelvin Guu, Panupong Pasupat, Evan Liu and Percy Liang

Tuesday, August 1st

15:25–17:00 Session 6E: Summarization 1

15:25–15:43 *Diversity driven attention model for query-based abstractive summarization*
Preksha Nema, Mitesh M. Khapra, Anirban Laha and Balaraman Ravindran

15:44–16:02 *Get To The Point: Summarization with Pointer-Generator Networks*
Abigail See, Peter J. Liu and Christopher D. Manning

16:03–16:21 *Supervised Learning of Automatic Pyramid for Optimization-Based Multi-Document Summarization*
Maxime Peyrard and Judith Eckle-Kohler

16:22–16:40 *Selective Encoding for Abstractive Sentence Summarization*
Qingyu Zhou, Nan Yang, Furu Wei and Ming Zhou

16:41–17:00 *PositionRank: An Unsupervised Approach to Keyphrase Extraction from Scholarly Documents*
Corina Florescu and Cornelia Caragea

Wednesday, August 2nd

10:40–11:36 Session 7A: Outstanding Papers 1

10:40–10:58 *Towards an Automatic Turing Test: Learning to Evaluate Dialogue Responses*
Ryan Lowe, Michael Noseworthy, Iulian Vlad Serban, Nicolas Angelard-Gontier, Yoshua Bengio and Joelle Pineau

10:59–11:17 *A Transition-Based Directed Acyclic Graph Parser for UCCA*
Daniel Hershcovich, Omri Abend and Ari Rappoport

11:18–11:36 *Abstract Syntax Networks for Code Generation and Semantic Parsing*
Maxim Rabinovich, Mitchell Stern and Dan Klein

Wednesday, August 2nd

10:40–11:17 Session 7B: Outstanding Papers 2

10:40–10:58 *Visualizing and Understanding Neural Machine Translation*
Yanzhuo Ding, Yang Liu, Huanbo Luan and Maosong Sun

10:59–11:17 *Detecting annotation noise in automatically labelled data*
Ines Rehbein and Josef Ruppenhofer

Wednesday, August 2nd

15:00–16:34 Session 8A: Outstanding Papers 3

15:00–15:18 *Abstractive Document Summarization with a Graph-Based Attentional Neural Model*
Jiwei Tan, Xiaojun Wan and Jianguo Xiao

15:19–15:37 *Probabilistic Typology: Deep Generative Models of Vowel Inventories*
Ryan Cotterell and Jason Eisner

15:38–15:56 *Adversarial Multi-Criteria Learning for Chinese Word Segmentation*
Xinchi Chen, Zhan Shi, Xipeng Qiu and Xuanjing Huang

15:57–16:15 *Neural Joint Model for Transition-based Chinese Syntactic Analysis*
Shuhei Kurita, Daisuke Kawahara and Sadao Kurohashi

16:16–16:34 *Robust Incremental Neural Semantic Graph Parsing*
Jan Buys and Phil Blunsom

Wednesday, August 2nd

15:00–16:34 Session 8B: Outstanding Papers 4

15:00–15:18 *Joint Extraction of Entities and Relations Based on a Novel Tagging Scheme*
Suncong Zheng, Feng Wang, Hongyun Bao, Yuexing Hao, Peng Zhou and Bo Xu

15:19–15:37 *A Local Detection Approach for Named Entity Recognition and Mention Detection*
Mingbin Xu, Hui Jiang and Sedtawut Watcharawittayakul

15:38–15:56 *Vancouver Welcomes You! Minimalist Location Metonymy Resolution*
Milan Gritta, Mohammad Taher Pilehvar, Nut Limsopatham and Nigel Collier

15:57–16:15 *Unifying Text, Metadata, and User Network Representations with a Neural Network for Geolocation Prediction*
Yasuhide Miura, Motoki Taniguchi, Tomoki Taniguchi and Tomoko Ohkuma

16:16–16:34 *Multi-Task Video Captioning with Video and Entailment Generation*
Ramakanth Pasunuru and Mohit Bansal

Monday, July 31st

18:00–21:30 Session P1: Poster Session 1

Enriching Complex Networks with Word Embeddings for Detecting Mild Cognitive Impairment from Speech Transcripts
Leandro Santos, Edilson Anselmo Corrêa Júnior, Osvaldo Oliveira Jr, Diego Amancio, Letícia Mansur and Sandra Aluísio

Adversarial Adaptation of Synthetic or Stale Data
Young-Bum Kim, Karl Stratos and Dongchan Kim

Chat Detection in an Intelligent Assistant: Combining Task-oriented and Non-task-oriented Spoken Dialogue Systems
Satoshi Akasaki and Nobuhiro Kaji

A Neural Local Coherence Model
Dat Tien Nguyen and Shafiq Joty

Data-Driven Broad-Coverage Grammars for Opinionated Natural Language Generation (ONLG)
Tomer Cagan, Stefan L. Frank and Reut Tsarfaty

Learning to Ask: Neural Question Generation for Reading Comprehension
Xinya Du, Junru Shao and Claire Cardie

Joint Optimization of User-desired Content in Multi-document Summaries by Learning from User Feedback
Avinesh PVS and Christian M. Meyer

Flexible and Creative Chinese Poetry Generation Using Neural Memory
Jiyuan Zhang, Yang Feng, Dong Wang, Yang Wang, Andrew Abel, Shiyue Zhang and Andi Zhang

Learning to Generate Market Comments from Stock Prices

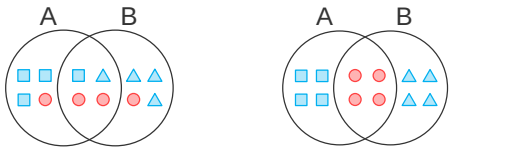
Abstract

Neural network models have shown their promising opportunities for multi-task learning, which focus on learning the shared layers to extract the common and task-invariant features. However, in most existing approaches, the extracted shared features are prone to be contaminated by task-specific features or the noise brought by other tasks. In this paper, we propose an adversarial multi-task learning framework, alleviating the shared and private latent feature spaces from interfering with each other. We conduct extensive experiments on 16 different text classification tasks, which demonstrates the benefits of our approach. Besides, we show that the shared knowledge learned by our proposed model can be regarded as off-the-shelf knowledge and easily transferred to new tasks. The datasets of all 16 tasks are publicly available at `http://nlp.fudan.edu.cn/data/`

1 Introduction

Multi-task learning is an effective approach to improve the performance of a single task with the help of other related tasks. Recently, neural-based models for multi-task learning have become very popular, ranging from computer vision (Misra et al., 2016; Zhang et al., 2014) to natural language processing (Collobert and Weston, 2008; Luong et al., 2015), since they provide a convenient way of combining information from multiple tasks.

However, most existing work on multi-task learning (Liu et al., 2016c,b) attempts to divide the features of different tasks into private and shared spaces, merely based on whether parameters of some components should be shared. As shown in Figure 1-(a), the general shared-private model introduces two feature spaces for any task: one is used to store task-dependent features, the other is used to capture shared features. The major limitation of this framework is that the shared feature space could contain some unnecessary task-specific features, while some sharable features could also be mixed in private space, suffering from feature redundancy.



(a) Shared-Private Model (b) Adversarial Shared-Private Model

Figure 1: Two sharing schemes for task A and task B. The overlap between two black circles denotes shared space. The blue triangles and boxes represent the task-specific features while the red circles denote the features which can be shared.

Taking the following two sentences as examples, which are extracted from two different sentiment classification tasks: Movie reviews and Baby products reviews.

*The **infantile** cart is simple and easy to use.*
*This kind of humour is **infantile** and boring.*

The word "`infantile`" indicates negative sentiment in Movie task while it is neutral in Baby task. However, the general shared-private model could place the task-specific word "`infantile`" in a shared space, leaving potential hazards for other tasks. Additionally, the capacity of shared space could also be wasted by some unnecessary features.

To address this problem, in this paper we propose an adversarial multi-task framework, in which the shared and private feature spaces are in-

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1–10
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1001

herently disjoint by introducing orthogonality constraints. Specifically, we design a generic shared-private learning framework to model the text sequence. To prevent the shared and private latent feature spaces from interfering with each other, we introduce two strategies: adversarial training and orthogonality constraints. The adversarial training is used to ensure that the shared feature space simply contains common and task-invariant information, while the orthogonality constraint is used to eliminate redundant features from the private and shared spaces.

The contributions of this paper can be summarized as follows.

1. Proposed model divides the task-specific and shared space in a more precise way, rather than roughly sharing parameters.
2. We extend the original binary adversarial training to multi-class, which not only enables multiple tasks to be jointly trained, but allows us to utilize unlabeled data.
3. We can condense the shared knowledge among multiple tasks into an off-the-shelf neural layer, which can be easily transferred to new tasks.

2 Recurrent Models for Text Classification

There are many neural sentence models, which can be used for text modelling, involving recurrent neural networks (Sutskever et al., 2014; Chung et al., 2014; Liu et al., 2015a), convolutional neural networks (Collobert et al., 2011; Kalchbrenner et al., 2014), and recursive neural networks (Socher et al., 2013). Here we adopt recurrent neural network with long short-term memory (LSTM) due to their superior performance in various NLP tasks (Liu et al., 2016a; Lin et al., 2017).

Long Short-term Memory Long short-term memory network (LSTM) (Hochreiter and Schmidhuber, 1997) is a type of recurrent neural network (RNN) (Elman, 1990), and specifically addresses the issue of learning long-term dependencies. While there are numerous LSTM variants, here we use the LSTM architecture used by (Jozefowicz et al., 2015), which is similar to the architecture of (Graves, 2013) but without peep-hole connections.

We define the LSTM *units* at each time step t to be a collection of vectors in $\mathbb{R}^d$: an *input gate* $\mathbf{i}_t$, a *forget gate* $\mathbf{f}_t$, an *output gate* $\mathbf{o}_t$, a *memory cell* $\mathbf{c}_t$ and a hidden state $\mathbf{h}_t$. d is the number of the LSTM units. The elements of the gating vectors $\mathbf{i}_t$, $\mathbf{f}_t$ and $\mathbf{o}_t$ are in $[0, 1]$.

The LSTM is precisely specified as follows.

$$\begin{bmatrix} \tilde{\mathbf{c}}_t \\ \mathbf{o}_t \\ \mathbf{i}_t \\ \mathbf{f}_t \end{bmatrix} = \begin{bmatrix} \tanh \\ \sigma \\ \sigma \\ \sigma \end{bmatrix} \left(\mathbf{W}_p \begin{bmatrix} \mathbf{x}_t \\ \mathbf{h}_{t-1} \end{bmatrix} + \mathbf{b}_p \right), \quad (1)$$

$$\mathbf{c}_t = \tilde{\mathbf{c}}_t \odot \mathbf{i}_t + \mathbf{c}_{t-1} \odot \mathbf{f}_t, \quad (2)$$

$$\mathbf{h}_t = \mathbf{o}_t \odot \tanh(\mathbf{c}_t), \quad (3)$$

where $\mathbf{x}_t \in \mathbb{R}^e$ is the input at the current time step; $\mathbf{W}_p \in \mathbb{R}^{4d \times (d+e)}$ and $\mathbf{b}_p \in \mathbb{R}^{4d}$ are parameters of affine transformation; σ denotes the logistic sigmoid function and $\odot$ denotes elementwise multiplication.

The update of each LSTM unit can be written precisely as follows:

$$\mathbf{h}_t = \mathbf{LSTM}(\mathbf{h}_{t-1}, \mathbf{x}_t, \theta_p). \quad (4)$$

Here, the function $\mathbf{LSTM}(\cdot, \cdot, \cdot, \cdot)$ is a shorthand for Eq. (1-3), and θ_p represents all the parameters of LSTM.

Text Classification with LSTM Given a text sequence $x = \{x_1, x_2, \cdots, x_T\}$, we first use a lookup layer to get the vector representation (embeddings) $\mathbf{x}_i$ of the each word x_i. The output at the last moment $\mathbf{h}_T$ can be regarded as the representation of the whole sequence, which has a fully connected layer followed by a softmax non-linear layer that predicts the probability distribution over classes.

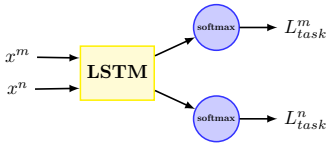
$$\hat{\mathbf{y}} = \text{softmax}(\mathbf{W}\mathbf{h}_T + \mathbf{b}) \quad (5)$$

where $\hat{\mathbf{y}}$ is prediction probabilities, $\mathbf{W}$ is the weight which needs to be learned, $\mathbf{b}$ is a bias term.

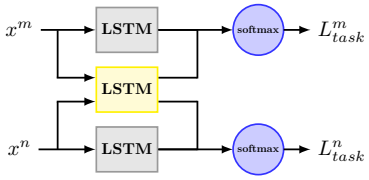
Given a corpus with N training samples (x_i, y_i), the parameters of the network are trained to minimise the cross-entropy of the predicted and true distributions.

$$L(\hat{y}, y) = -\sum_{i=1}^{N} \sum_{j=1}^{C} y_i^j \log(\hat{y}_i^j), \quad (6)$$

where y_i^j is the ground-truth label; $\hat{y}_i^j$ is prediction probabilities, and C is the class number.



(a) Fully Shared Model (FS-MTL)



(b) Shared-Private Model (SP-MTL)

Figure 2: Two architectures for learning multiple tasks. Yellow and gray boxes represent shared and private LSTM layers respectively.

3 Multi-task Learning for Text Classification

The goal of multi-task learning is to utilizes the correlation among these related tasks to improve classification by learning tasks in parallel. To facilitate this, we give some explanation for notations used in this paper. Formally, we refer to D_k as a dataset with N_k samples for task k. Specifically,

$$D_k = \{(x_i^k, y_i^k)\}_{i=1}^{N_k} \tag{7}$$

where x_i^k and y_i^k denote a sentence and corresponding label for task k.

3.1 Two Sharing Schemes for Sentence Modeling

The key factor of multi-task learning is the sharing scheme in latent feature space. In neural network based model, the latent features can be regarded as the states of hidden neurons. Specific to text classification, the latent features are the hidden states of LSTM at the end of a sentence. Therefore, the sharing schemes are different in how to group the shared features. Here, we first introduce two sharing schemes with multi-task learning: fully-shared scheme and shared-private scheme.

Fully-Shared Model (FS-MTL) In fully-shared model, we use a single shared LSTM layer to extract features for all the tasks. For example, given two tasks m and n, it takes the view that the features of task m can be totally shared by task n and vice versa. This model ignores the fact that some features are task-dependent. Figure 2a illustrates the fully-shared model.

Shared-Private Model (SP-MTL) As shown in Figure 2b, the shared-private model introduces two feature spaces for each task: one is used to store task-dependent features, the other is used to capture task-invariant features. Accordingly, we can see each task is assigned a private LSTM layer and shared LSTM layer. Formally, for any sentence in task k, we can compute its shared representation $\mathbf{s}_t^k$ and task-specific representation $\mathbf{h}_t^k$ as follows:

$$\mathbf{s}_t^k = \mathbf{LSTM}(x_t, \mathbf{s}_{t-1}^k, \theta_s), \tag{8}$$

$$\mathbf{h}_t^k = \mathbf{LSTM}(x_t, \mathbf{h}_{t-1}^m, \theta_k) \tag{9}$$

where $\mathbf{LSTM}(., \theta)$ is defined as Eq. (4).

The final features are concatenation of the features from private space and shared space.

3.2 Task-Specific Output Layer

For a sentence in task k, its feature $\mathbf{h}^{(k)}$, emitted by the deep muti-task architectures, is ultimately fed into the corresponding task-specific softmax layer for classification or other tasks.

The parameters of the network are trained to minimise the cross-entropy of the predicted and true distributions on all the tasks. The loss L_{task} can be computed as:

$$L_{Task} = \sum_{k=1}^{K} \alpha_k L(\hat{y}^{(k)}, y^{(k)}) \tag{10}$$

where α_k is the weights for each task k respectively. $L(\hat{y}, y)$ is defined as Eq. 6.

4 Incorporating Adversarial Training

Although the shared-private model separates the feature space into the shared and private spaces, there is no guarantee that sharable features can not exist in private feature space, or vice versa. Thus, some useful sharable features could be ignored in shared-private model, and the shared feature space is also vulnerable to contamination by some task-specific information.

Therefore, a simple principle can be applied into multi-task learning that a good shared feature space should contain more common information and no task-specific information. To address this problem, we introduce adversarial training into multi-task framework as shown in Figure 3 (ASP-MTL).

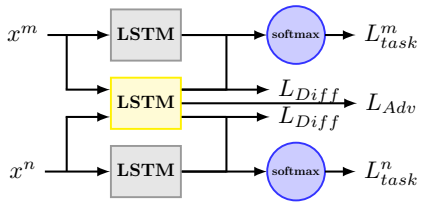


Figure 3: Adversarial shared-private model. Yellow and gray boxes represent shared and private LSTM layers respectively.

4.1 Adversarial Network

Adversarial networks have recently surfaced and are first used for generative model (Goodfellow et al., 2014). The goal is to learn a generative distribution $p_G(x)$ that matches the real data distribution $P_{data}(x)$ Specifically, GAN learns a generative network G and discriminative model D, in which G generates samples from the generator distribution $p_G(x)$. and D learns to determine whether a sample is from $p_G(x)$ or $P_{data}(x)$. This min-max game can be optimized by the following risk:

$$\phi = \min_G \max_D \Big(E_{x\sim P_{data}}[\log D(x)] + E_{z\sim p(z)}[\log(1 - D(G(z)))] \Big) \quad (11)$$

While originally proposed for generating random samples, adversarial network can be used as a general tool to measure equivalence between distributions (Taigman et al., 2016). Formally, (Ajakan et al., 2014) linked the adversarial loss to the H-divergence between two distributions and successfully achieve unsupervised domain adaptation with adversarial network. Motivated by theory on domain adaptation (Ben-David et al., 2010, 2007; Bousmalis et al., 2016) that a transferable feature is one for which an algorithm cannot learn to identify the domain of origin of the input observation.

4.2 Task Adversarial Loss for MTL

Inspired by adversarial networks (Goodfellow et al., 2014), we proposed an adversarial shared-private model for multi-task learning, in which a shared recurrent neural layer is working adversarially towards a learnable multi-layer perceptron, preventing it from making an accurate prediction about the types of tasks. This adversarial training encourages shared space to be more pure and ensure the shared representation not be contaminated by task-specific features.

Task Discriminator Discriminator is used to map the shared representation of sentences into a probability distribution, estimating what kinds of tasks the encoded sentence comes from.

$$D(\mathbf{s}^k_T, \theta_D) = \text{softmax}(\mathbf{b} + \mathbf{U}\mathbf{s}^k_T) \quad (12)$$

where $\mathbf{U} \in \mathbb{R}^{d\times d}$ is a learnable parameter and $\mathbf{b} \in \mathbb{R}^d$ is a bias.

Adversarial Loss Different with most existing multi-task learning algorithm, we add an extra task adversarial loss L_{Adv} to prevent task-specific feature from creeping in to shared space. The task adversarial loss is used to train a model to produce shared features such that a classifier cannot reliably predict the task based on these features. The original loss of adversarial network is limited since it can only be used in binary situation. To overcome this, we extend it to multi-class form, which allow our model can be trained together with multiple tasks:

$$L_{Adv} = \min_{\theta_s} \left(\lambda \max_{\theta_D} \left(\sum_{k=1}^{K} \sum_{i=1}^{N_k} d^k_i \log[D(E(\mathbf{x}^k))] \right) \right) \quad (13)$$

where d^k_i denotes the ground-truth label indicating the type of the current task. Here, there is a min-max optimization and the basic idea is that, given a sentence, the shared LSTM generates a representation to mislead the task discriminator. At the same time, the discriminator tries its best to make a correct classification on the type of task. After the training phase, the shared feature extractor and task discriminator reach a point at which both cannot improve and the discriminator is unable to differentiate among all the tasks.

Semi-supervised Learning Multi-task Learning We notice that the L_{Adv} requires only the input sentence x and does not require the corresponding label y, which makes it possible to combine our model with semi-supervised learning. Finally, in this semi-supervised multi-task learning framework, our model can not only utilize the data from related tasks, but can employ abundant unlabeled corpora.

4.3 Orthogonality Constraints

We notice that there is a potential drawback of the above model. That is, the task-invariant features can appear both in shared space and private space.

Motivated by recently work(Jia et al., 2010; Salzmann et al., 2010; Bousmalis et al., 2016)

Table 1: Statistics of the 16 datasets. The columns 2-5 denote the number of samples in training, development, test and unlabeled sets. The last two columns represent the average length and vocabulary size of corresponding dataset.

on shared-private latent space analysis, we introduce orthogonality constraints, which penalize redundant latent representations and encourages the shared and private extractors to encode different aspects of the inputs.

After exploring many optional methods, we find below loss is optimal, which is used by Bousmalis et al. (2016) and achieve a better performance:

$$L_{\text{diff}} = \sum_{k=1}^{K} \left\| \mathbf{S}^{k\top} \mathbf{H}^{k} \right\|_F^2 , \qquad (14)$$

where $\| \cdot \|_F^2$ is the squared Frobenius norm. $\mathbf{S}^k$ and $\mathbf{H}^k$ are two matrics, whose rows are the output of shared extractor $E_s(,;\theta_s)$ and task-specific extrator $E_k(,;\theta_k)$ of a input sentence.

4.4 Put It All Together

The final loss function of our model can be written as:

$$L = L_{Task} + \lambda L_{Adv} + \gamma L_{Diff} \qquad (15)$$

where λ and γ are hyper-parameter.

The networks are trained with backpropagation and this minimax optimization becomes possible via the use of a gradient reversal layer (Ganin and Lempitsky, 2015).

5 Experiment

5.1 Dataset

To make an extensive evaluation, we collect 16 different datasets from several popular review corpora.

The first 14 datasets are product reviews, which contain Amazon product reviews from different domains, such as Books, DVDs, Electronics, ect. The goal is to classify a product review as either positive or negative. These datasets are collected based on the raw data [1] provided by (Blitzer et al., 2007). Specifically, we extract the sentences and corresponding labels from the unprocessed original data [2]. The only preprocessing operation of these sentences is tokenized using the Stanford tokenizer [3].

The remaining two datasets are about movie reviews. The IMDB dataset[4] consists of movie reviews with binary classes (Maas et al., 2011). One key aspect of this dataset is that each movie review has several sentences. The MR dataset also consists of movie reviews from rotten tomato website with two classes [5](Pang and Lee, 2005).

All the datasets in each task are partitioned randomly into training set, development set and testing set with the proportion of 70%, 20% and 10% respectively. The detailed statistics about all the datasets are listed in Table 1.

5.2 Competitor Methods for Multi-task Learning

The multi-task frameworks proposed by previous works are various while not all can be applied to the tasks we focused. Nevertheless, we chose two most related neural models for multi-task learning and implement them as competitor methods.

- MT-CNN: This model is proposed by Collobert and Weston (2008) with convolutional layer, in which lookup-tables are shared partially while other layers are task-specific.

[1] https://www.cs.jhu.edu/~mdredze/datasets/sentiment/

[2] Blitzer et al. (2007) also provides two extra processed datasets with the format of Bag-of-Words, which are not proper for neural-based models.

Table 2: Error rates of our models on 16 datasets against typical baselines. The numbers in brackets represent the improvements relative to the average performance (Avg.) of three single task baselines.

- MT-DNN: The model is proposed by Liu et al. (2015b) with bag-of-words input and multi-layer perceptrons, in which a hidden layer is shared.

5.3 Hyperparameters

The word embeddings for all of the models are initialized with the 200d GloVe vectors ((Pennington et al., 2014)). The other parameters are initialized by randomly sampling from uniform distribution in $[-0.1, 0.1]$. The mini-batch size is set to 16.

For each task, we take the hyperparameters which achieve the best performance on the development set via an small grid search over combinations of the initial learning rate $[0.1, 0.01]$, $\lambda \in [0.01, 0.1]$, and $\gamma \in [0.01, 0.1]$. Finally, we chose the learning rate as 0.01, λ as 0.05 and γ as 0.01.

5.4 Performance Evaluation

Table 2 shows the error rates on 16 text classification tasks. The column of "Single Task" shows the results of vanilla LSTM, bidirectional LSTM (BiLSTM), stacked LSTM (sLSTM) and the average error rates of previous three models. The column of "Multiple Tasks" shows the results achieved by corresponding multi-task models. From this table, we can see that the performance of most tasks can be improved with a large margin with the help of multi-task learning, in which our model achieves the lowest error rates. More concretely, compared with SP-MTL, ASP-MTL achieves 4.1% average improvement surpassing SP-MTL with 1.0%, which indicates the importance of adversarial learning. It is noteworthy that for FS-MTL, the performances of some tasks are degraded, since this model puts all private and shared information into a unified space.

5.5 Shared Knowledge Transfer

With the help of adversarial learning, the shared feature extractor E_s can generate more pure task-invariant representations, which can be considered as off-the-shelf knowledge and then be used for unseen new tasks.

To test the transferability of our learned shared extractor, we also design an experiment, in which we take turns choosing 15 tasks to train our model M_S with multi-task learning, then the learned shared layer are transferred to a second network M_T that is used for the remaining one task. The parameters of transferred layer are **kept frozen**, and the rest of parameters of the network M_T are randomly initialized.

More formally, we investigate two mechanisms towards the transferred shared extractor. As shown in Figure 4. The first one Single Channel (SC) model consists of one shared feature extractor E_s from M_S, then the extracted representation will be sent to an output layer. By contrast, the Bi-Channel (BC) model introduces an extra LSTM layer to encode more task-specific information. To evaluate the effectiveness of our introduced adversarial training framework, we also make a compar-

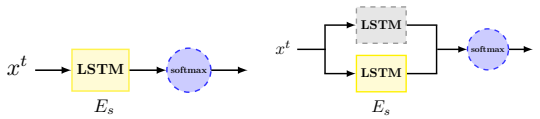
Table 3: Error rates of our models on 16 datasets against vanilla multi-task learning. ϕ (Books) means that we transfer the knowledge of the other 15 tasks to the target task Books.



(a) Single Channel (b) Bi-Channel

Figure 4: Two transfer strategies using a pre-trained shared LSTM layer. Yellow box denotes shared feature extractor E_s trained by 15 tasks.

ison with vanilla multi-task learning method.

Results and Analysis As shown in Table 3, we can see the shared layer from ASP-MTL achieves a better performance compared with SP-MTL. Besides, for the two kinds of transfer strategies, the Bi-Channel model performs better. The reason is that the task-specific layer introduced in the Bi-Channel model can store some private features. Overall, the results indicate that we can save the existing knowledge into a shared recurrent layer using adversarial multi-task learning, which is quite useful for a new task.

5.6 Visualization

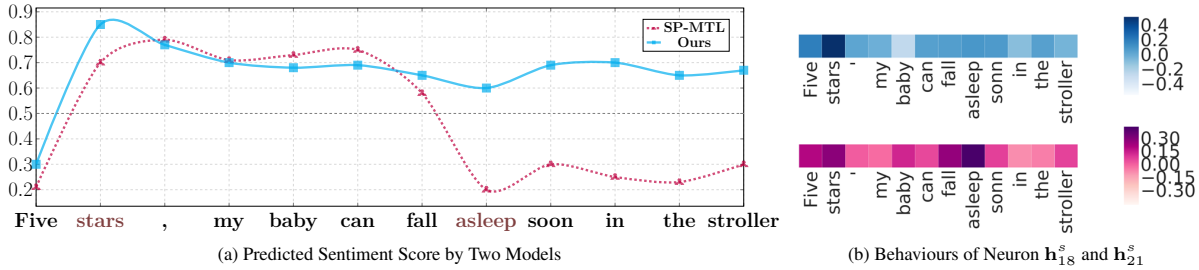
To get an intuitive understanding of how the introduced orthogonality constraints worked compared with vanilla shared-private model, we design an experiment to examine the behaviors of neurons from private layer and shared layer. More concretely, we refer to h_{tj} as the activation of the j-neuron at time step t, where $t \in \{1, \ldots, n\}$ and $j \in \{1, \ldots, d\}$. By visualizing the hidden state $\mathbf{h}_j$ and analyzing the maximum activation, we can find what kinds of patterns the current neuron focuses on.

Figure 5 illustrates this phenomenon. Here, we randomly sample a sentence from the validation set of Baby task and analyze the changes of the predicted sentiment score at different time steps, which are obtained by SP-MTL and our proposed model. Additionally, to get more insights into how neurons in shared layer behave diversely towards different input word, we visualize the activation of two typical neurons. For the positive sentence "`Five stars, my baby can fall asleep soon in the stroller`", both models capture the informative pattern "`Five stars`" [6]. However, SP-MTL makes a wrong prediction due to misunderstanding of the word "`asleep`".

By contrast, our model makes a correct prediction and the reason can be inferred from the activation of Figure 5-(b), where the shared layer of SP-MTL is so sensitive that many features related to other tasks are included, such as "`asleep`", which misleads the final prediction. This indicates the importance of introducing adversarial learning to prevent the shared layer from being contaminated by task-specific features.

We also list some typical patterns captured by

[6]For this case, the vanilla LSTM also give a wrong answer due to ignoring the feature "`Five stars`".



(a) Predicted Sentiment Score by Two Models

(b) Behaviours of Neuron $\mathbf{h}^s_{18}$ and $\mathbf{h}^s_{21}$

Figure 5: (a) The change of the predicted sentiment score at different time steps. Y-axis represents the sentiment score, while X-axis represents the input words in chronological order. The darker grey horizontal line gives a border between the positive and negative sentiments. (b) The purple heat map describes the behaviour of neuron $\mathbf{h}^s_{18}$ from shared layer of SP-MTL, while the blue one is used to show the behaviour of neuron $\mathbf{h}^s_{21}$, which belongs to the shared layer of our model.

Model	Shared Layer	Task-Movie	Task-Baby
SP-MTL	good, great bad, love, simple, cut, slow, cheap, infantile	good, great, well-directed, pointless, cut, cheap, infantile	love, bad, cute, safety, mild, broken simple
ASP-MTL	good, great, love, bad poor	well-directed, pointless, cut, cheap, infantile	cute, safety, mild, broken simple

Table 4: Typical patterns captured by shared layer and task-specific layer of SP-MTL and ASP-MTL models on Movie and Baby tasks.

neurons from shared layer and task-specific layer in Table 4, and we have observed that: 1) for SP-MTL, if some patterns are captured by task-specific layer, they are likely to be placed into shared space. Clearly, suppose we have many tasks to be trained jointly, the shared layer bear much pressure and must sacrifice substantial amount of capacity to capture the patterns they actually do not need. Furthermore, some typical task-invariant features also go into task-specific layer. 2) for ASP-MTL, we find the features captured by shared and task-specific layer have a small amount of intersection, which allows these two kinds of layers can work effectively.

6 Related Work

There are two threads of related work. One thread is multi-task learning with neural network. Neural networks based multi-task learning has been proven effective in many NLP problems (Collobert and Weston, 2008; Glorot et al., 2011).

Liu et al. (2016c) first utilizes different LSTM layers to construct multi-task learning framwork for text classification. Liu et al. (2016b) proposes a generic multi-task framework, in which different tasks can share information by an external memory and communicate by a reading/writing mechanism. These work has potential limitation of just learning a shared space solely on sharing parameters, while our model introduce two strategies to learn the clear and non-redundant shared-private space.

Another thread of work is adversarial network. Adversarial networks have recently surfaced as a general tool measure equivalence between distributions and it has proven to be effective in a variety of tasks. Ajakan et al. (2014); Bousmalis et al. (2016) applied adverarial training to domain adaptation, aiming at transferring the knowledge of one source domain to target domain. Park and Im (2016) proposed a novel approach for multi-modal representation learning which uses adversarial back-propagation concept.

Different from these models, our model aims to find task-invariant sharable information for multiple related tasks using adversarial training strategy. Moreover, we extend binary adversarial training to multi-class, which enable multiple tasks to be jointly trained.

7 Conclusion

In this paper, we have proposed an adversarial multi-task learning framework, in which the task-specific and task-invariant features are learned non-redundantly, therefore capturing the shared-private separation of different tasks. We have demonstrated the effectiveness of our approach by applying our model to 16 different text classification tasks. We also perform extensive qualitative

analysis, deriving insights and indirectly explaining the quantitative improvements in the overall performance.

Abstract

We investigate neural techniques for end-to-end computational argumentation mining (AM). We frame AM both as a token-based dependency parsing and as a token-based sequence tagging problem, including a multi-task learning setup. Contrary to models that operate on the argument component level, we find that framing AM as dependency parsing leads to subpar performance results. In contrast, less complex (local) tagging models based on BiLSTMs perform robustly across classification scenarios, being able to catch long-range dependencies inherent to the AM problem. Moreover, we find that jointly learning 'natural' subtasks, in a multi-task learning setup, improves performance.

1 Introduction

Computational argumentation mining (AM) deals with finding argumentation structures in text. This involves several subtasks, such as: (a) separating argumentative units from non-argumentative units, also called 'component segmentation'; (b) classifying argument components into classes such as "Premise" or "Claim"; (c) finding relations between argument components; (d) classifying relations into classes such as "Support" or "Attack" (Persing and Ng, 2016; Stab and Gurevych, 2017).

Thus, AM would have to detect claims and premises (reasons) in texts such as the following, where premise P supports claim C:

> Since it killed many marine lives$_P$, tourism has threatened nature$_C$.

Argument structures in real texts are typically much more complex, cf. Figure 1.

While different research has addressed different subsets of the AM problem (see below), the ultimate goal is to solve all of them, starting from unannotated plain text. Two recent approaches to this end-to-end learning scenario are Persing and Ng (2016) and Stab and Gurevych (2017). Both solve the end-to-end task by first training independent models for each subtask and then defining an integer linear programming (ILP) model that encodes global constraints such as that each premise has a parent, etc. Besides their pipeline architecture the approaches also have in common that they heavily rely on hand-crafted features.

Hand-crafted features pose a problem because AM is to some degree an "arbitrary" problem in that the notion of "argument" critically relies on the underlying argumentation theory (Reed et al., 2008; Biran and Rambow, 2011; Habernal and Gurevych, 2015; Stab and Gurevych, 2017). Accordingly, datasets typically differ with respect to their annotation of (often rather complex) argument structure. Thus, feature sets would have to be manually adapted to and designed for each new sample of data, a challenging task. The same critique applies to the designing of ILP constraints. Moreover, from a machine learning perspective, pipeline approaches are problematic because they solve subtasks independently and thus lead to error propagation rather than exploiting interrelationships between variables. In contrast to this, we investigate *neural* techniques for end-to-end learning in computational AM, which do not require the hand-crafting of features or constraints. The models we survey also all capture some notion of "joint"—rather than "pipeline"—learning. We investigate several approaches.

First, we frame the end-to-end AM problem as a dependency parsing problem. Dependency parsing may be considered a natural choice for AM, because argument structures often form trees,

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 11–22
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1002

or closely resemble them (see §3). Hence, it is not surprising that 'discourse parsing' (Muller et al., 2012) has been suggested for AM (Peldszus and Stede, 2015). What distinguishes our approach from these previous ones is that we operate on the *token* level, rather than on the level of components, because we address the end-to-end framework and, thus, do not assume that non-argumentative units have already been sorted out and/or that the boundaries of argumentative units are given.

Second, we frame the problem as a sequence tagging problem. This is a natural choice especially for component identification (segmentation and classification), which is a typical entity recognition problem for which BIO tagging is a standard approach, pursued in AM, e.g., by Habernal and Gurevych (2016). The challenge in the end-to-end setting is to also include relations into the tagging scheme, which we realize by coding the distances between linked components into the tag label. Since related entities in AM are oftentimes several dozens of tokens apart from each other, neural sequence tagging models are in principle ideal candidates for such a framing because they can take into account *long-range dependencies*—something that is inherently difficult to capture with traditional feature-based tagging models such as conditional random fields (CRFs).

Third, we frame AM as a *multi-task* (tagging) problem (Caruana, 1997; Collobert and Weston, 2008). We experiment with subtasks of AM—e.g., component identification—as auxiliary tasks and investigate whether this improves performance on the AM problem. Adding such subtasks can be seen as analogous to de-coupling, e.g., component identification from the full AM problem.

Fourth, we evaluate the model of Miwa and Bansal (2016) that combines sequential (entity) and tree structure (relation) information and is in principle applicable to any problem where the aim is to extract entities and their relations. As such, this model makes fewer assumptions than our dependency parsing and tagging approaches.

The contributions of this paper are as follows. (1) We present the *first neural end-to-end* solutions to computational AM. (2) We show that several of them perform better than the state-of-the-art joint ILP model. (3) We show that a framing of AM as a token-based dependency parsing problem is ineffective—in contrast to what has been proposed for systems that operate on the coarser component level and that (4) a standard neural sequence tagging model that encodes distance information between components performs robustly in different environments. Finally, (5) we show that a multi-task learning setup where natural subtasks of the full AM problem are added as auxiliary tasks improves performance.[1]

2 Related Work

AM has applications in legal decision making (Palau and Moens, 2009; Moens et al., 2007), document summarization, and the analysis of scientific papers (Kirschner et al., 2015). Its importance for the educational domain has been highlighted by recent work on writing assistance (Zhang and Litman, 2016) and essay scoring (Persing and Ng, 2015; Somasundaran et al., 2016).

Most works on AM address subtasks of AM such as locating/classifying components (Florou et al., 2013; Moens et al., 2007; Rooney et al., 2012; Knight et al., 2003; Levy et al., 2014; Rinott et al., 2015). Relatively few works address the full AM problem of component *and* relation identification. Peldszus and Stede (2016) present a corpus of microtexts containing only argumentatively relevant text of controlled complexity. To our best knowledge, Stab and Gurevych (2017) created the only corpus of attested high quality which annotates the AM problem in its entire complexity: it contains token-level annotations of components, their types, as well as relations and their types.

3 Data

We use the dataset of persuasive essays (PE) from Stab and Gurevych (2017), which contains student essays written in response to controversial topics such as "competition or cooperation—which is better?"

	Train	Test
Essays	322	80
Paragraphs	1786	449
Tokens	118648	29538

Table 1: Corpus statistics

As Table 1 details, the corpus consists of 402 essays, 80 of which are reserved for testing. The an-

[1] Scripts that document how we ran our experiments are available from https://github.com/UKPLab/acl2017-neural_end2end_AM.

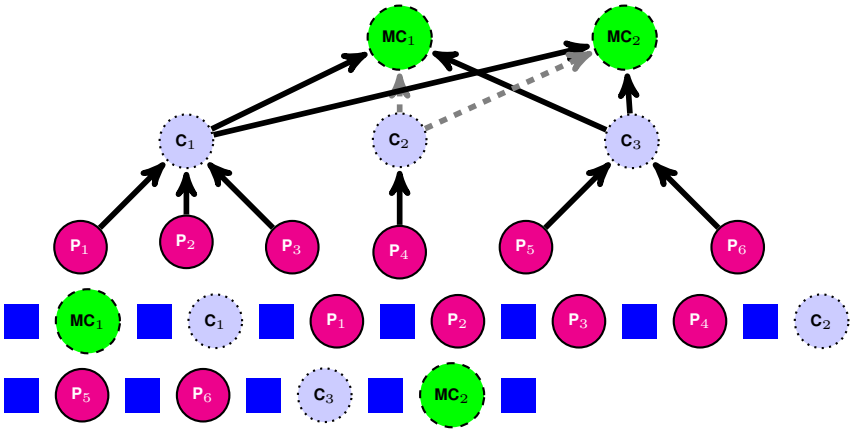

Figure 1: Bottom: Linear argumentation structure in a student essay. The essay is comprised of non-argumentative units (square) and argumentative units of different types: Premises (P), claims (C) and major claims (MC). Top: Relationsships between argumentative units. Solid arrows are support (for), dashed arrows are attack (against).

notation distinguishes between **major claims** (the central position of an author with respect to the essay's topic), **claims** (controversial statements that are either *for* or *against* the major claims), and **premises**, which give reasons for claims or other premises and either *support* or *attack* them. Overall, there are 751 major claims, 1506 claims, and 3832 premises. There are 5338 relations, most of which are supporting relations (>90%).

The corpus has a special structure, illustrated in Figure 1. First, major claims relate to no other components. Second, claims always relate to all other major claims.[2] Third, each premise relates to exactly one claim or premise. Thus, the argument structure in each essay is—almost—a tree. Since there may be several major claims, each claim potentially connects to multiple targets, violating the tree structure. This poses no problem, however, since we can "loss-lessly" re-link the claims to one of the major claims (e.g., the last major claim in a document) and create a special root node to which the major claims link. From this tree, the actual graph can be uniquely reconstructed.

There is another peculiarity of this data. Each essay is divided into paragraphs, of which there are 2235 in total. The argumentation structure is completely contained within a paragraph, except, possibly, for the relation from claims to major claims. Paragraphs have an average length of 66 tokens and are therefore much shorter than essays, which have an average length of 368 tokens. Thus, prediction on the paragraph level is easier than prediction on the essay level, because there are fewer components in a paragraph and hence fewer possibilities of source and target components in argument relations. The same is true for component classification: a paragraph can never contain premises only, for example, since premises link to other components.

[2] All MCs are considered as equivalent in meaning.

4 Models

This section describes our neural network framings for end-to-end AM.

Sequence Tagging is the problem of assigning each element in a stream of input tokens a label. In a neural context, the natural choice for tagging problems are recurrent neural nets (RNNs) in which a hidden vector representation $\mathbf{h}_t$ at time point t depends on the previous hidden vector representation $\mathbf{h}_{t-1}$ and the input $\mathbf{x}_t$. In this way, an infinite window ("long-range dependencies") around the current input token $\mathbf{x}_t$ can be taken into account when making an output prediction $\mathbf{y}_t$. We choose particular RNNs, namely, LSTMs (Hochreiter and Schmidhuber, 1997), which are popular for being able to address vanishing/exploding gradients problems. In addition to considering a left-to-right flow of information, bidirectional LSTMs (BL) also capture information to the right of the current input token.

The most recent generation of neural tagging models add label dependencies to BLs, so that successive output decisions are not made independently. This class of models is called BiLSTM-

CRF (BLC) (Huang et al., 2015). The model of Ma and Hovy (2016) adds convolutional neural nets (CNNs) on the character-level to BiLSTM-CRFs, leading to BiLSTM-CRF-CNN (BLCC) models. The character-level CNN may address problems of out-of-vocabulary words, that is, words not seen during training.

AM as Sequence Tagging: We frame AM as the following sequence tagging problem. Each input token has an associated label from $\mathcal{Y}$, where

$$\begin{aligned}\mathcal{Y} = \{(b,t,d,s) \,|\, & b \in \{\text{B},\text{I},\text{O}\}, t \in \{\text{P},\text{C},\text{MC},\perp\}, \\ & d \in \{\ldots,-2,-1,1,2,\ldots,\perp\}, \\ & s \in \{\text{Supp},\text{Att},\text{For},\text{Ag},\perp\}\}.\end{aligned} \quad (1)$$

In other words, $\mathcal{Y}$ consists of all four-tuples (b,t,d,s) where b is a BIO encoding indicating whether the current token is non-argumentative (O) or begins (B) or continues (I) a component; t indicates the *type* of the component (claim C, premise P, or major claim MC for our data). Moreover, d encodes the distance—measured in number of components—between the current component and the component it relates to. We encode the same d value for each token in a given component. Finally, s is the relation type ("stance") between two components and its value may be Support (Supp), Attack (Att), or For or Against (Ag). We also have a special symbol $\perp$ that indicates when a particular slot is not filled: e.g., a non-argumentative unit ($b = \text{O}$) has neither component type, nor relation, nor relation type. We refer to this framing as $\texttt{STag}_T$ (for "*S*imple *Tag*ging"), where T refers to the tagger used. For the example from §1, our coding would hence be:

Since (O,⊥,⊥,⊥)	it (B,P,1,Supp)	killed (I,P,1,Supp)	many (I,P,1,Supp)
marine (I,P,1,Supp)	lives (I,P,1,Supp)	, (O,⊥,⊥,⊥)	tourism (B,C,⊥,For)
has (I,C,⊥,For)	threatened (I,C,⊥,For)	nature (I,C,⊥,For)	. (O,⊥, ⊥, ⊥)

While the size of the label set $\mathcal{Y}$ is potentially infinite, we would expect it to be finite even in a potentially infinitely large data set, because humans also have only finite memory and are therefore expected to keep related components close in textual space. Indeed, as Figure 2 shows, in our PE essay data set about 30% of all relations between components have distance -1, that is, they follow the claim or premise that they attach to. Overall, around 2/3 of all relation distances d lie in $\{-2,-1,1\}$. However, the figure also illustrates that there are indeed long-range dependencies: distance values between -11 and $+10$ are observed in the data.

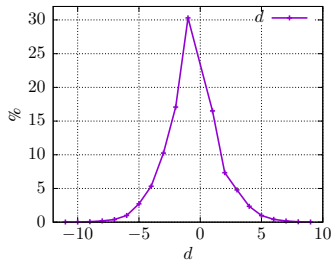

Figure 2: Distribution of distances d between components in PE dataset.

Multi-Task Learning Recently, there has been a lot of interest in so-called multi-task learning (MTL) scenarios, where several tasks are learned *jointly* (Søgaard and Goldberg, 2016; Peng and Dredze, 2016; Yang et al., 2016; Rusu et al., 2016; Héctor and Plank, 2017). It has been argued that such learning scenarios are closer to human learning because humans often transfer knowledge between several domains/tasks. In a neural context, MTL is typically implemented via weight sharing: several tasks are trained in the same network architecture, thereby sharing a substantial portion of network's parameters. This forces the network to learn *generalized* representations.

In the MTL framework of Søgaard and Goldberg (2016) the underlying model is a BiLSTM with several hidden layers. Then, given different tasks, each task k 'feeds' from one of the hidden layers in the network. In particular, the hidden states encoded in a specific layer are fed into a multiclass classifier f_k. The same work has demonstrated that this MTL protocol may be successful when there is a hierarchy between tasks and 'lower' tasks feed from lower layers.

AM as MTL: We use the same framework $\texttt{STag}_T$ for modeling AM as MTL. However, we in addition train auxiliary tasks in the network—each with a distinct label set $\mathcal{Y}'$.

Dependency Parsing methods can be classified into graph-based and transition-based approaches (Kiperwasser and Goldberg, 2016). *Transition-based* parsers encode the parsing problem as a sequence of configurations which may be modified by application of actions such as shift, reduce,

etc. The system starts with an initial configuration in which sentence elements are on a *buffer* and a *stack*, and a classifier successively decides which action to take next, leading to different configurations. The system terminates after a finite number of actions, and the parse tree is read off the terminal configuration. *Graph-based* parsers solve a structured prediction problem in which the goal is learning a scoring function over dependency trees such that correct trees are scored above all others.

Traditional dependency parsers used hand-crafted feature functions that look at "core" elements such as "word on top of the stack", "POS of word on top of the stack", and conjunctions of core features such as "word is X and POS is Y" (see McDonald et al. (2005)). Most neural parsers have not entirely abandoned feature engineering. Instead, they rely, for example, on encoding the core features of parsers as low-dimensional embedding vectors (Chen and Manning, 2014) but ignore feature combinations. Kiperwasser and Goldberg (2016) design a neural parser that uses only four features: the BiLSTM vector representations of the top 3 items on the stack and the first item on the buffer. In contrast, Dyer et al. (2015)'s neural parser associates each stack with a "stack LSTM" that encodes their contents. Actions are chosen based on the stack LSTM representations of the stacks, and no more feature engineering is necessary. Moreover, their parser has thus access to any part of the input, its history and stack contents.

AM as Dependency Parsing: To frame a problem as a dependency parsing problem, each instance of the problem must be encoded as a directed tree, where tokens have heads, which in turn are labeled. For end-to-end AM, we propose the framing illustrated in Figure 3. We highlight two design decisions, the remaining are analogous and/or can be read off the figure.

- The head of each non-argumentative text token is the document terminating token `END`, which is a punctuation mark in all our cases. The label of this link is O, the symbol for non-argumentative units.
- The head of each token in a premise is the *first* token of the claim or premise that it links to. The label of each of these links is $(b, \mathrm{P}, \mathrm{Supp})$ or $(b, \mathrm{P}, \mathrm{Att})$ depending on whether a premise "supports" or "attacks" a claim or premise; $b \in \{\mathrm{B}, \mathrm{I}\}$.

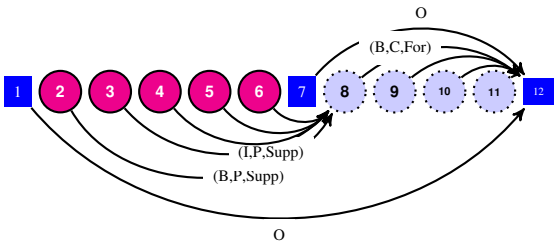

Figure 3: Dependency representation of sample sentence from §1. Links and selected labels.

LSTM-ER Miwa and Bansal (2016) present a neural end-to-end system for identifying both entities as well as relations between them. Their entity detection system is a BLC-type tagger and their relation detection system is a neural net that predicts a relation for each pair of detected entities. This relation module is a TreeLSTM model that makes use of dependency tree information. In addition to de-coupling entity and relation detection but jointly modeling them,[3] pretraining on entities and scheduled sampling (Bengio et al., 2015) is applied to prevent low performance at early training stages of entity detection and relation classification. To adapt LSTM-ER for the argument structure encoded in the PE dataset, we model three types of entities (premise, claim, major claim) and four types of relations (for, against, support, attack).

We use the **feature-based ILP model** from Stab and Gurevych (2017) as a comparison system. This system solves the subtasks of AM—component segmentation, component classification, relation detection and classification—independently. Afterwards, it defines an ILP model with various constraints to enforce valid argumentation structure. As features it uses structural, lexical, syntactic and context features, cf. Stab and Gurevych (2017) and Persing and Ng (2016).

Summarizing, we distinguish our framings in terms of *modularity* and in terms of their *constraints*. *Modularity*: Our dependency parsing framing and LSTM-ER are more modular than $\texttt{STag}_T$ because they de-couple relation information from entity information. However, (part of)

[3] By 'de-coupling', we mean that both tasks are treated separately rather than merging entity and relation information in the same tag label (output space). Still, a joint model like that of Miwa and Bansal (2016) de-couples the two tasks in such a way that many model parameters are shared across the tasks, similarly as in MTL.

this modularity can be regained by using $\texttt{STag}_T$ in an MTL setting. Moreover, since entity and relation information are considerably different, such a de-coupling may be advantageous. *Constraints*: LSTM-ER can, in principle, model any kind of—even many-to-many—relationships between detected entities. Thus, it is not guaranteed to produce trees, as we observe in AM datasets. $\texttt{STag}_T$ also does not need to produce trees, but it more severely restricts search space than does LSTM-ER: each token/component can only relate to one (and not several) other tokens/components. The same constraint is enforced by the dependency parsing framing. All of the tagging modelings, including LSTM-ER, are *local* models whereas our parsing framing is a *global* model: it globally enforces a tree structure on the token-level.

Further remarks: (1) part of the TreeLSTM modeling inherent to LSTM-ER is ineffective for our data because this modeling exploits dependency tree structures on the *sentence* level, while relationships between components are almost never on the sentence level. In our data, roughly 92% of all relationships are between components that appear in different sentences. Secondly, (2) that a model *enforces* a constraint does not necessarily mean that it is more suitable for a respective task. It has frequently been observed that models tend to produce output consistent with constraints in their training data in such situations (Zhang et al., 2017; Héctor and Plank, 2017); thus, they have *learned* the constraints.

5 Experiments

This section presents and discusses the empirical results for the AM framings outlined in §4. We relegate issues of *pre-trained word embeddings*, *hyperparameter optimization* and further *practical issues* to the supplementary material. Links to software used as well as some additional error analysis can also be found there.

Evaluation Metric We adopt the evaluation metric suggested in Persing and Ng (2016). This computes true positives TP, false positives FP, and false negatives FN, and from these calculates component and relation F_1 scores as $F_1 = \frac{2\text{TP}}{2\text{TP}+\text{FP}+\text{FN}}$. For space reasons, we refer to Persing and Ng (2016) for specifics, but to illustrate, for *components*, true positives are defined as the set of components in the gold standard for which there exists a predicted component with the same type that 'matches'. Persing and Ng (2016) define a notion of what we may term 'level α matching': for example, at the 100% level (exact match) predicted and gold components must have exactly the same spans, whereas at the 50% level they must only share at least 50% of their tokens (approximate match). We refer to these scores as C-F1 (100%) and C-F1 (50%), respectively. For *relations*, an analogous F1 score is determined, which we denote by R-F1 (100%) and R-F1 (50%). We note that R-F1 scores depend on C-F1 scores because correct relations must have correct arguments. We also define a 'global' F1 score, which is the F1-score of C-F1 and R-F1.

Most of our results are shown in Table 2.

(a) Dependency Parsing We show results for the two feature-based parsers MST (McDonald et al., 2005), Mate (Bohnet and Nivre, 2012) as well as the neural parsers by Dyer et al. (2015) (LSTM-Parser) and Kiperwasser and Goldberg (2016) (Kiperwasser). We train and test all parsers on the paragraph level, because training them on essay level was typically too memory-exhaustive.

MST mostly labels only non-argumentative units correctly, except for recognizing individual major claims, but never finds their exact spans (e.g., *"tourism can create negative impacts on"* while the gold major claim is *"international tourism can create negative impacts on the destination countries"*). Mate is slightly better and in particular recognizes several major claims correctly. Kiperwasser performs decently on the approximate match level, but not on exact level. Upon inspection, we find that the parser often predicts 'too large' component spans, e.g., by including following punctuation. The best parser by far is the LSTM-Parser. It is over 100% better than Kiperwasser on exact spans and still several percentage points on approximate spans.

How does performance change when we switch to the essay level? For the LSTM-Parser, the best performance on essay level is 32.84%/47.44% C-F1 (100%/50% level), and 9.11%/14.45% on R-F1, but performance result varied drastically between different parametrizations. Thus, the performance drop between paragraph and essay level is in any case immense.

Since the employed features of modern feature-based parsers are rather general—such as distance between words or word identities—we had expected them to perform much better. The mini-

	Paragraph level							Essay level						
	Acc.	C-F1		R-F1		F1		Acc.	C-F1		R-F1		F1	
		100%	50%	100%	50%	100%	50%		100%	50%	100%	50%	100%	50%
MST-Parser	31.23	0	6.90	0	1.29	0	2.17							
Mate	22.71	2.72	12.34	2.03	4.59	2.32	6.69							
Kiperwasser	52.80	26.65	61.57	15.57	34.25	19.65	44.01							
LSTM-Parser	55.68	58.86	68.20	35.63	40.87	44.38	51.11							
$\texttt{STag}_{\texttt{BLCC}}$	59.34	66.69	74.08	39.83	44.02	49.87	55.22	**60.46**	63.23	69.49	**34.82**	**39.68**	**44.90**	**50.51**
LSTM-ER	**61.67**	**70.83**	**77.19**	**45.52**	**50.05**	**55.42**	**60.72**	54.17	**66.21**	**73.02**	29.56	32.72	40.87	45.19
ILP	60.32	62.61	73.35	34.74	44.29	44.68	55.23							

Table 2: Performance of dependency parsers, $\texttt{STag}_{\texttt{BLCC}}$, LSTM-ER and ILP (from top to bottom). The ILP model operates on both levels. Best scores in each column in bold (signific. at $p < 0.01$; Two-sided Wilcoxon signed rank test, pairing F1 scores for documents). We also report token level accuracy.

mal feature set employed by Kiperwasser is apparently not sufficient for accurate AM but still a lot more powerful than the hand-crafted feature approaches. We hypothesize that the LSTM-Parser's good performance, relative to the other parsers, is due to its encoding of the *whole* stack history—rather than just the top elements on the stack as in Kiperwasser— which makes it aware of much larger 'contexts'. While the drop in performance from paragraph to essay level is expected, the LSTM-Parser's deterioration is much more severe than the other models' surveyed below. We believe that this is due to a mixture of the following: (1) 'capacity', i.e., model complexity, of the parsers—that is, risk of overfitting; and (2) few, but very long sequences on essay level—that is, little training data (trees), paired with a huge search space on each train/test instance, namely, the number of possible trees on n tokens. See also our discussions below, particularly, our stability analysis.

(b) Sequence Tagging For these experiments, we use the BLCC tagger from Ma and Hovy (2016) and refer to the resulting system as $\texttt{STag}_{\texttt{BLCC}}$. Again, we observe that paragraph level is considerably easier than essay level; e.g., for relations, there is ∼5% points increase from essay to paragraph level. Overall, $\texttt{STag}_{\texttt{BLCC}}$ is ∼13% better than the best parser for C-F1 and ∼11% better for R-F1 on the paragraph level. Our explanation is that taggers are simpler local models, and thus need less training data and are less prone to overfitting. Moreover, they can much better deal with the long sequences because they are largely invariant to length: e.g., it does in principle not matter, from a parameter estimation perspective, whether we train our taggers on two sequences of lengths n and m, respectively, or on one long sequence of length $n + m$.

(c) MTL As indicated, we use the MTL tagging framework from Søgaard and Goldberg (2016) for multi-task experiments. The underlying tagging framework is weaker than that of BLCC: there is no CNN which can take subword information into account and there are no dependencies between output labels: each tagging prediction is made independently of the other predictions. We refer to this system as $\texttt{STag}_{\texttt{BL}}$.

Accordingly, as Table 3 shows for the essay level (paragraph level omitted for space reasons), results are generally weaker: For exact match, C-F1 values are about ∼10% points below those of $\texttt{STag}_{\texttt{BLCC}}$, while approximate match performances are much closer. Hence, the independence assumptions of the BL tagger apparently lead to more 'local' errors such as exact argument span identification (cf. error analysis). An analogous trend holds for argument relations.

Additional Tasks: We find that when we train $\texttt{STag}_{\texttt{BL}}$ with only its main task—with label set $\mathcal{Y}$ as in Eq. (1)—the overall result is worst. In contrast, when we include the 'natural subtasks' "C" (label set $\mathcal{Y}_C$ consists of the projection on the coordinates (b, t) in $\mathcal{Y}$) and/or "R" (label set $\mathcal{Y}_R$ consists of the projection on the coordinates (d, s)), performance increases typically by a few percentage points. This indicates that complex sequence tagging may benefit when we train a "sub-labeler" in the same neural architecture, a finding that may be particularly relevant for morphological POS tagging (Müller et al., 2013). Unlike Søgaard and Goldberg (2016), we do not find that the optimal architecture is the one in which "lower" tasks (such as C or R) feed from lower layers. In fact, in one of the best parametrizations

the C task and the full task feed from the same layer in the deep BiLSTM. Moreover, we find that the C task is consistently more helpful as an auxiliary task than the R task.

	C-F1		R-F1		F1	
	100%	50%	100%	50%	100%	50%
$\mathcal{Y}$-3	49.59	65.37	26.28	37.00	34.35	47.25
$\mathcal{Y}$-3:$\mathcal{Y}_C$-1	54.71	66.84	28.44	37.35	37.40	47.92
$\mathcal{Y}$-3:$\mathcal{Y}_R$-1	51.32	66.49	26.92	37.18	35.31	47.69
$\mathcal{Y}$-3:$\mathcal{Y}_C$-3	**54.58**	67.66	**30.22**	**40.30**	**38.90**	**50.51**
$\mathcal{Y}$-3:$\mathcal{Y}_R$-3	53.31	66.71	26.65	35.86	35.53	46.64
$\mathcal{Y}$-3:$\mathcal{Y}_C$-1:$\mathcal{Y}_R$-2	52.95	**67.84**	27.90	39.71	36.54	50.09
$\mathcal{Y}$-3:$\mathcal{Y}_C$-3:$\mathcal{Y}_R$-3	54.55	67.60	28.30	38.26	37.26	48.86

Table 3: Performance of MTL sequence tagging approaches, essay level. Tasks separated by ":". Layers from which tasks feed are indicated by respective numbers.

On essay level, **(d) LSTM-ER** performs very well on component identification (+5% C-F1 compared to $\texttt{STag}_{\texttt{BLCC}}$), but rather poor on relation identification (-18% R-F1). Hence, its overall F1 on essay level is considerably below that of $\texttt{STag}_{\texttt{BLCC}}$. In contrast, LSTM-ER trained and tested on paragraph level substantially outperforms all other systems discussed, both for component as well as for relation identification.

We think that its generally excellent performance on components is due to LSTM-ER's de-coupling of component and relation tasks. Our findings indicate that a similar result can be achieved for $\texttt{STag}_T$ via MTL when components and relations are included as auxiliary tasks, cf. Table 3. For example, the improvement of LSTM-ER over $\texttt{STag}_{\texttt{BLCC}}$, for C-F1, roughly matches the increase for $\texttt{STag}_{\texttt{BL}}$ when including components and relations separately ($\mathcal{Y}$-3:$\mathcal{Y}_C$-3:$\mathcal{Y}_R$-3) over not including them as auxiliary tasks ($\mathcal{Y}$-3). Lastly, the better performance of LSTM-ER over $\texttt{STag}_{\texttt{BLCC}}$ for relations on paragraph level appears to be a consequence of its better performance on components. E.g., when both arguments are correctly predicted, $\texttt{STag}_{\texttt{BLCC}}$ has even higher chance of getting their relation correct than LSTM-ER (95.34% vs. 94.17%).

Why does LSTM-ER degrade so much on essay level for R-F1? As said, text sequences are much longer on essay level than on paragraph level—hence, there are on average many more entities on essay level. Thus, there are also many more possible relations between all entities discovered in a text—namely, there are $O(2^{m^2})$ possible relations between m discovered components. Due to its generality, LSTM-ER considers all these relations as plausible, while $\texttt{STag}_T$ does not (for any of choice of T): e.g., our coding explicitly constrains each premise to link to exactly *one* other component, rather than to $0, \ldots, m$ possible components, as LSTM-ER allows. In addition, our explicit coding of distance values d biases the learner T to reflect the distribution of distance values found in real essays—namely, that related components are typically close in terms of the number of components between them. In contrast, LSTM-ER only mildly prefers short-range dependencies over long-range dependencies, cf. Figure 4.

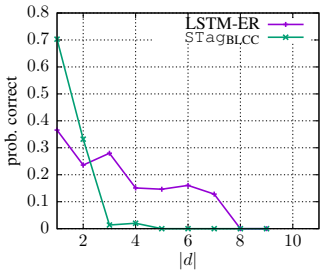

Figure 4: Probability of correct relation identification given true distance is $|d|$.

The **(e) ILP** has access to both paragraph and essay level information and thus has always more information than all neural systems compared to. Thus, it also knows in which paragraph in an essay it is. This is useful particularly for major claims, which always occur in first or last paragraphs in our data. Still, its performance is equal to or lower than that of LSTM-ER and $\texttt{STag}_{\texttt{BLCC}}$ when both are evaluated on paragraph level.

Stability Analysis

Table 4 shows averages and standard deviations of two selected models, namely, the $\texttt{STag}_{\texttt{BLCC}}$ tagging framework as well as the LSTM-Parser over several different runs (different random initializations as well as different hyperparameters as discussed in the supplementary material). These results detail that the taggers have lower standard deviations than the parsers. The difference is particularly striking on the essay level where the parsers often completely fail to learn, that is, their performance scores are close to 0%. As discussed above, we attribute this to the parsers' increased model capacity relative to the taggers, which makes them more prone to overfitting. Data scarcity is another very likely source of error in this context, as the parsers only observe 322 (though very rich) trees

in the training data, while the taggers are always roughly trained on 120K tokens. On paragraph level, they do observe more trees, namely, 1786.

	$\texttt{STag}_{\text{BLCC}}$	LSTM-Parser
Essay	60.62±3.54	9.40±13.57
Paragraph	64.74±1.97	56.24±2.87

Table 4: C-F1 (100%) in % for the two indicated systems; essay vs. paragraph level. Note that the mean performances are lower than the majority performances over the runs given in Table 2.

Error analysis

A systematic source of errors for all systems is detecting exact argument spans (segmentation). For instance, the ILP system predicts the following premise: *"As a practical epitome , students should be prepared to present in society after their graduation"*, while the gold premise omits the preceding discourse marker, and hence reads: *"students should be prepared to present in society after their graduation"*. On the one hand, it has been observed that even humans have problems exactly identifying such entity boundaries (Persing and Ng, 2016; Yang and Cardie, 2013). On the other hand, our results in Table 2 indicate that the neural taggers BLCC and BLC (in the LSTM-ER model) are much better at such exact identification than either the ILP model or the neural parsers. While the parsers' problems are most likely due to model complexity, we hypothesize that the ILP model's increased error rates stem from a weaker underlying tagging model (feature-based CRF vs. BiLSTM) and/or its features.[4] In fact, as Table 5 shows, the macro-F1 scores[5] on *only* the component segmentation tasks (BIO labeling) are substantially higher for both LSTM-ER and $\texttt{STag}_{\text{BLCC}}$ than for the ILP model. Noteworthy, the two neural systems even outperform the human upper bound (HUB) in this context, reported as 88.6% in Stab and Gurevych (2017).

6 Conclusion

We present the first study on neural end-to-end AM. We experimented with different *framings*, such as encoding AM as a dependency parsing problem, as a sequence tagging problem with particular label set, as a multi-task sequence tagging problem, and as a problem with both sequential and tree structure information. We show that (1) neural computational AM is as good or (substantially) better than a competing feature-based ILP formulation, while eliminating the need for manual feature engineering and costly ILP constraint designing. (2) BiLSTM taggers perform very well for component identification, as demonstrated for our $\texttt{STag}_T$ frameworks, for T = BLCC and T = BL, as well as for LSTM-ER (BLC tagger). (3) (Naively) coupling component and relation identification is not optimal, but both tasks should be treated separately, but modeled jointly. (4) Relation identification is more difficult: when there are few entities in a text ("short documents"), a more general framework such as that provided in LSTM-ER performs reasonably well. When there are many entities ("long documents"), a more restrained modeling is preferable. These are also our *policy recommendations*. Our work yields new state-of-the-art results in end-to-end AM on the PE dataset from Stab and Gurevych (2017).

Another possible framing, not considered here, is to frame AM as an encoder-decoder problem (Bahdanau et al., 2015; Vinyals et al., 2015). This is an even more general modeling than LSTM-ER. Its suitability for the end-to-end learning task is scope for future work, but its adequacy for component classification and relation identification has been investigated in Potash et al. (2016).

Abstract

Harnessing the statistical power of neural networks to perform language understanding and symbolic reasoning is difficult, when it requires executing efficient discrete operations against a large knowledge-base. In this work, we introduce a *Neural Symbolic Machine* (NSM), which contains (a) a neural "programmer", i.e., a sequence-to-sequence model that maps language utterances to programs and utilizes a *key-variable memory* to handle compositionality (b) a symbolic "computer", i.e., a Lisp interpreter that performs program execution, and helps find good programs by pruning the search space. We apply REINFORCE to directly optimize the task reward of this structured prediction problem. To train with weak supervision and improve the stability of REINFORCE we augment it with an *iterative maximum-likelihood* training process. NSM outperforms the state-of-the-art on the WEBQUESTIONSSP dataset when trained from question-answer pairs only, without requiring any feature engineering or domain-specific knowledge.

1 Introduction

Deep neural networks have achieved impressive performance in supervised classification and structured prediction tasks such as speech recognition (Hinton et al., 2012), machine translation (Bahdanau et al., 2014; Wu et al., 2016) and more. However, training neural networks for semantic parsing (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Liang et al., 2011) or program induction, where language is mapped to a symbolic representation that is executed by an executor, through weak supervision remains challenging. This is because the model must interact with a symbolic executor through non-differentiable operations to search over a large program space.

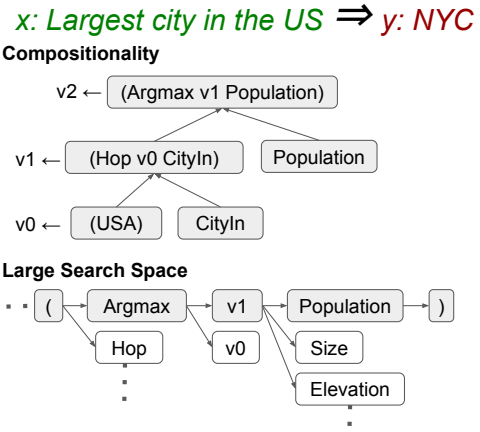

Figure 1: The main challenges of training a semantic parser from weak supervision: (a) *compositionality*: we use variables (v_0, v_1, v_2) to store execution results of intermediate generated programs. (b) *search*: we prune the search space and augment REINFORCE with pseudo-gold programs.

In semantic parsing, recent work handled this (Dong and Lapata, 2016; Jia and Liang, 2016) by training from manually annotated programs and avoiding program execution at training time. However, annotating programs is known to be expensive and scales poorly. In program induction, attempts to address this problem (Graves et al., 2014; Reed and de Freitas, 2016; Kaiser and Sutskever, 2015; Graves et al., 2016b; Andreas et al., 2016) either utilized low-level memory (Zaremba and Sutskever, 2015), or required memory to be differentiable (Neelakantan et al., 2015; Yin et al., 2015) so that the model can be trained with backpropagation. This makes it difficult to use the efficient discrete operations and memory of a traditional computer, and limited the application to synthetic or small knowledge bases.

In this paper, we propose to utilize the memory and discrete operations of a traditional com-

puter in a novel Manager-Programmer-Computer (MPC) framework for neural program induction, which integrates three components:

1. A **"manager"** that provides weak supervision (e.g., 'NYC' in Figure 1) through a reward indicating how well a task is accomplished. Unlike full supervision, weak supervision is easy to obtain at scale (Section 3.1).
2. A **"programmer"** that takes natural language as input and generates a program that is a sequence of tokens (Figure 2). The programmer learns from the reward and must overcome the hard search problem of finding correct programs (Section 2.2).
3. A **"computer"** that executes programs in a high level programming language. Its non-differentiable memory enables *abstract*, *scalable* and *precise* operations, but makes training more challenging (Section 2.3). To help the "programmer" prune the search space, it provides a friendly *neural computer interface*, which detects and eliminates invalid choices (Section 2.1).

Within this framework, we introduce the Neural Symbolic Machine (NSM) and apply it to semantic parsing. NSM contains a neural sequence-to-sequence (seq2seq) "programmer" (Sutskever et al., 2014) and a symbolic non-differentiable Lisp interpreter ("computer") that executes programs against a large knowledge-base (KB).

Our technical contribution in this work is threefold. First, to support language *compositionality*, we augment the standard seq2seq model with a *key-variable memory* to save and reuse intermediate execution results (Figure 1). This is a novel application of pointer networks (Vinyals et al., 2015) to compositional semantics.

Second, to alleviate the search problem of finding correct programs when training from question-answer pairs,we use the computer to execute partial programs and prune the programmer's search space by checking the syntax and semantics of generated programs. This generalizes the weakly supervised semantic parsing framework (Liang et al., 2011; Berant et al., 2013) by leveraging semantic denotations during structural search.

Third, to train from weak supervision and directly maximize the expected reward we turn to the REINFORCE (Williams, 1992) algorithm. Since learning from scratch is difficult for REINFORCE, we combine it with an *iterative maximum likelihood* (ML) training process, where beam search is used to find pseudo-gold programs, which are then used to augment the objective of REINFORCE.

On the WEBQUESTIONSSP dataset (Yih et al., 2016), NSM achieves new state-of-the-art results with weak supervision, significantly closing the gap between weak and full supervision for this task. Unlike prior works, it is trained end-to-end, and does not require feature engineering or domain-specific knowledge.

2 Neural Symbolic Machines

We now introduce NSM by first describing the "computer", a non-differentiable Lisp interpreter that executes programs against a large KB and provides code assistance (Section 2.1). We then propose a seq2seq model ("programmer") that supports compositionality using a key-variable memory to save and reuse intermediate results (Section 2.2). Finally, we describe a training procedure that is based on REINFORCE, but is augmented with pseudo-gold programs found by an iterative ML training procedure (Section 2.3).

Before diving into details, we define the *semantic parsing* task: given a knowledge base $\mathbb{K}$, and a question $x = (w_1, w_2, ..., w_m)$, produce a program or logical form z that when executed against $\mathbb{K}$ generates the right answer y. Let $\mathcal{E}$ denote a set of entities (e.g., ABELINCOLN),[1] and let $\mathcal{P}$ denote a set of properties (e.g., PLACEOFBIRTH). A knowledge base $\mathbb{K}$ is a set of assertions or triples $(e_1, p, e_2) \in \mathcal{E} \times \mathcal{P} \times \mathcal{E}$, such as (ABELINCOLN, PLACEOFBIRTH, HODGENVILLE).

2.1 Computer: Lisp Interpreter with Code Assistance

Semantic parsing typically requires using a set of operations to query the knowledge base and process the results. Operations learned with neural networks such as addition and sorting do not perfectly generalize to inputs that are larger than the ones observed in the training data (Graves et al., 2014; Reed and de Freitas, 2016). In contrast, operations implemented in high level programming languages are *abstract*, *scalable*, and *precise*, thus generalizes perfectly to inputs of arbitrary size. Based on this observation, we implement operations necessary for semantic parsing with an or-

[1] We also consider numbers (e.g., "1.33") and date-times (e.g., "1999-1-1") as entities.

dinary programming language instead of trying to learn them with a neural network.

We adopt a Lisp interpreter as the "computer". A program C is a list of expressions $(c_1...c_N)$, where each expression is either a special token "*Return*" indicating the end of the program, or a list of tokens enclosed by parentheses "$(FA_1...A_K)$". F is a function, which takes as input K arguments of specific types. Table 1 defines the semantics of each function and the types of its arguments (either a property p or a variable r). When a function is executed, it returns an entity list that is the expression's denotation in $\mathbb{K}$, and save it to a new variable.

By introducing variables that save the intermediate results of execution, the program naturally models *language compositionality* and describes from left to right a bottom-up derivation of the full meaning of the natural language input, which is convenient in a seq2seq model (Figure 1). This is reminiscent of the floating parser (Wang et al., 2015; Pasupat and Liang, 2015), where a derivation tree that is not grounded in the input is incrementally constructed.

The set of programs defined by our functions is equivalent to the subset of λ-calculus presented in (Yih et al., 2015). We did not use full Lisp programming language here, because constructs like control flow and loops are unnecessary for most current semantic parsing tasks, and it is simple to add more functions to the model when necessary.

To create a friendly *neural computer interface*, the interpreter provides code assistance to the programmer by producing a list of valid tokens at each step. First, a valid token should not cause a syntax error: e.g., if the previous token is "(", the next token must be a function name, and if the previous token is "*Hop*", the next token must be a variable. More importantly, a valid token should not cause a semantic (run-time) error: this is detected using the denotation saved in the variables. For example, if the previously generated tokens were "(*Hop* r", the next available token is restricted to properties $\{p \mid \exists e, e' : e \in r, (e, p, e') \in \mathbb{K}\}$ that are reachable from entities in r in the KB. These checks are enabled by the variables and can be derived from the definition of the functions in Table 1. The interpreter prunes the "programmer"'s search space by orders of magnitude, and enables learning from weak supervision on a large KB.

2.2 Programmer: Seq2seq Model with Key-Variable Memory

Given the "computer", the "programmer" needs to map natural language into a program, which is a sequence of tokens that reference operations and values in the "computer". We base our programmer on a standard seq2seq model with attention, but extend it with a key-variable memory that allows the model to learn to represent and refer to program variables (Figure 2).

Sequence-to-sequence models consist of two RNNs, an encoder and a decoder. We used a 1-layer GRU (Cho et al., 2014) for both the encoder and decoder. Given a sequence of words $w_1, w_2...w_m$, each word w_t is mapped to an embedding q_t (embedding details are in Section 3). Then, the encoder reads these embeddings and updates its hidden state step by step using $h_{t+1} = GRU(h_t, q_t, \theta_{Encoder})$, where $\theta_{Encoder}$ are the GRU parameters. The decoder updates its hidden states u_t by $u_{t+1} = GRU(u_t, c_{t-1}, \theta_{Decoder})$, where c_{t-1} is the embedding of last step's output token a_{t-1}, and $\theta_{Decoder}$ are the GRU parameters. The last hidden state of the encoder h_T is used as the decoder's initial state. We also adopt a dot-product attention similar to Dong and Lapata (2016). The tokens of the program $a_1, a_2...a_n$ are generated one by one using a softmax over the vocabulary of valid tokens at each step, as provided by the "computer" (Section 2.1).

To achieve compositionality, the decoder must learn to represent and refer to intermediate variables whose value was saved in the "computer" after execution. Therefore, we augment the model with a **key-variable memory**, where each entry has two components: a continuous embedding key v_i, and a corresponding variable token R_i referencing the value in the "computer" (see Figure 2). During encoding, we use an entity linker to link text spans (e.g., *"US"*) to KB entities. For each linked entity we add a memory entry where the key is the average of GRU hidden states over the entity span, and the variable token (R_1) is the name of a variable in the computer holding the linked entity (*m.USA*) as its value. During decoding, when a full expression is generated (i.e., the decoder generates ")"), it gets executed, and the result is stored as the value of a new variable in the "computer". This variable is keyed by the GRU hidden state at that step. When a new variable R_1 with key embedding v_1 is added into the key-variable memory,

$(\ \textit{Hop}\ r\ p\ ) \Rightarrow \{e_2 \mid e_1 \in r, (e_1, p, e_2) \in \mathbb{K}\}$
$(\ \textit{ArgMax}\ r\ p\ ) \Rightarrow \{e_1 \mid e_1 \in r, \exists e_2 \in \mathcal{E} : (e_1, p, e_2) \in \mathbb{K}, \forall e : (e_1, p, e) \in \mathbb{K}, e_2 \geq e\}$
$(\ \textit{ArgMin}\ r\ p\ ) \Rightarrow \{e_1 \mid e_1 \in r, \exists e_2 \in \mathcal{E} : (e_1, p, e_2) \in \mathbb{K}, \forall e : (e_1, p, e) \in \mathbb{K}, e_2 \leq e\}$
$(\ \textit{Filter}\ r_1\ r_2\ p\ ) \Rightarrow \{e_1 \mid e_1 \in r_1, \exists e_2 \in r_2 : (e_1, p, e_2) \in \mathbb{K}\}$

Table 1: Interpreter functions. r represents a variable, p a property in Freebase. $\geq$ and $\leq$ are defined on numbers and dates.

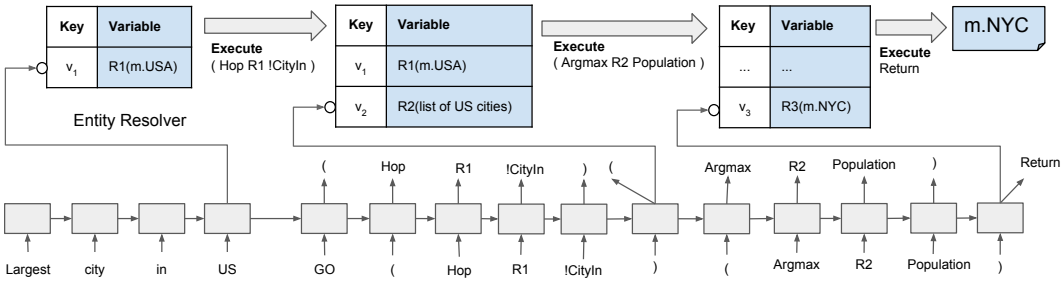

Figure 2: Semantic Parsing with NSM. The key embeddings of the key-variable memory are the output of the sequence model at certain encoding or decoding steps. For illustration purposes, we also show the values of the variables in parentheses, but the sequence model never sees these values, and only references them with the name of the variable ("R_1"). A special token "*GO*" indicates the start of decoding, and "*Return*" indicates the end of decoding.

the token R_1 is added into the decoder vocabulary with v_1 as its embedding. The final answer returned by the "programmer" is the value of the last computed variable.

Similar to pointer networks (Vinyals et al., 2015), the key embeddings for variables are dynamically generated for each example. During training, the model learns to represent variables by backpropagating gradients from a time step where a variable is selected by the decoder, through the key-variable memory, to an earlier time step when the key embedding was computed. Thus, the encoder/decoder learns to generate representations for variables such that they can be used at the right time to construct the correct program.

While the key embeddings are differentiable, the values referenced by the variables (lists of entities), stored in the "computer", are symbolic and non-differentiable. This distinguishes the key-variable memory from other memory-augmented neural networks that use continuous differentiable embeddings as the values of memory entries (Weston et al., 2014; Graves et al., 2016a).

2.3 Training NSM with Weak Supervision

NSM executes non-differentiable operations against a KB, and thus end-to-end backpropagation is not possible. Therefore, we base our training procedure on REINFORCE (Williams, 1992; Norouzi et al., 2016). When the reward signal is sparse and the search space is large, it is common to utilize some full supervision to pre-train REINFORCE (Silver et al., 2016). To train from weak supervision, we suggest an iterative ML procedure for finding pseudo-gold programs that will bootstrap REINFORCE.

REINFORCE We can formulate training as a reinforcement learning problem: given a question x, the state, action and reward at each time step $t \in \{0, 1, ..., T\}$ are (s_t, a_t, r_t). Since the environment is deterministic, the state is defined by the question x and the action sequence: $s_t = (x, a_{0:t-1})$, where $a_{0:t-1} = (a_0, ..., a_{t-1})$ is the history of actions at time t. A valid action at time t is $a_t \in A(s_t)$, where $A(s_t)$ is the set of valid tokens given by the "computer". Since each action corresponds to a token, the full history $a_{0:T}$ corresponds to a program. The reward $r_t = I[t = T] \cdot F_1(x, a_{0:T})$ is non-zero only at the last step of decoding, and is the F_1 score computed comparing the gold answer and the answer generated by executing the program $a_{0:T}$. Thus, the cumulative reward of a program $a_{0:T}$ is

$$R(x, a_{0:T}) = \sum_t r_t = F_1(x, a_{0:T}).$$

The agent's decision making procedure at each time is defined by a policy, $\pi_\theta(s, a) = P_\theta(a_t = a | x, a_{0:t-1})$, where θ are the model parameters. Since the environment is deterministic, the probability of generating a program $a_{0:T}$ is

$$P_\theta(a_{0:T}|x) = \prod_t P_\theta(a_t \mid x, a_{0:t-1}).$$

We can define our objective to be the expected cumulative reward and use policy gradient meth-

ods such as REINFORCE for training. The objective and gradient are:

$$J^{RL}(\theta) = \sum_x \mathbb{E}_{P_\theta(a_{0:T}|x)}[R(x, a_{0:T})],$$
$$\nabla_\theta J^{RL}(\theta) = \sum_x \sum_{a_{0:T}} P_\theta(a_{0:T} \mid x) \cdot [R(x, a_{0:T}) - B(x)] \cdot \nabla_\theta \log P_\theta(a_{0:T} \mid x),$$

where $B(x) = \sum_{a_{0:T}} P_\theta(a_{0:T} \mid x) R(x, a_{0:T})$ is a baseline that reduces the variance of the gradient estimation without introducing bias. Having a separate network to predict the baseline is an interesting future direction.

While REINFORCE assumes a stochastic policy, we use beam search for gradient estimation. Thus, in contrast with common practice of approximating the gradient by sampling from the model, we use the top-k action sequences (programs) in the beam with normalized probabilities. This allows training to focus on sequences with high probability, which are on the decision boundaries, and reduces the variance of the gradient.

Empirically (and in line with prior work), REINFORCE converged slowly and often got stuck in local optima (see Section 3). The difficulty of training resulted from the sparse reward signal in the large search space, which caused model probabilities for programs with non-zero reward to be very small at the beginning. If the beam size k is small, good programs fall off the beam, leading to zero gradients for all programs in the beam. If the beam size k is large, training is very slow, and the normalized probabilities of good programs when the model is untrained are still very small, leading to (1) near zero baselines, thus near zero gradients on "bad" programs (2) near zero gradients on good programs due to the low probability $P_\theta(a_{0:T} \mid x)$. To combat this, we present an alternative training strategy based on maximum-likelihood.

Iterative ML If we had gold programs, we could directly optimize their likelihood. Since we do not have gold programs, we can perform an iterative procedure (similar to hard Expectation-Maximization (EM)), where we search for good programs given fixed parameters, and then optimize the probability of the best program found so far. We do decoding on an example with a large beam size and declare $a^{best}_{0:T}(x)$ to be the pseudo-gold program, which achieved highest reward with shortest length among the programs decoded on x in all previous iterations. Then, we can optimize the ML objective:

$$J^{ML}(\theta) = \sum_x \log P_\theta(a^{best}_{0:T}(x) \mid x) \quad (1)$$

A question x is not included if we did not find any program with positive reward.

Training with iterative ML is fast because there is at most one program per example and the gradient is not weighted by model probability. while decoding with a large beam size is slow, we could train for multiple epochs after each decoding. This iterative process has a bootstrapping effect that a better model leads to a better program $a^{best}_{0:T}(x)$ through decoding, and a better program $a^{best}_{0:T}(x)$ leads to a better model through training.

Even with a large beam size, some programs are hard to find because of the large search space. A common solution to this problem is to use curriculum learning (Zaremba and Sutskever, 2015; Reed and de Freitas, 2016). The size of the search space is controlled by both the set of functions used in the program and the program length. We apply curriculum learning by gradually increasing both these quantities (see details in Section 3) when performing iterative ML.

Nevertheless, iterative ML uses only pseudo-gold programs and does not directly optimize the objective we truly care about. This has two adverse effects: (1) The best program $a^{best}_{0:T}(x)$ could be a spurious program that accidentally produces the correct answer (e.g., using the property PLACEOFBIRTH instead of PLACEOFDEATH when the two places are the same), and thus does not generalize to other questions. (2) Because training does not observe full negative programs, the model often fails to distinguish between tokens that are related to one another. For example, differentiating PARENTSOF vs. SIBLINGSOF vs. CHILDRENOF can be challenging. We now present learning where we combine iterative ML with REINFORCE.

Augmented REINFORCE To bootstrap REINFORCE, we can use iterative ML to find pseudo-gold programs, and then add these programs to the beam with a reasonably large probability. This is similar to methods from imitation learning (Ross et al., 2011; Jiang et al., 2012) that define a proposal distribution by linearly interpolating the model distribution and an oracle.

Algorithm 1 IML-REINFORCE

Input: question-answer pairs $\mathbb{D} = \{(x_i, y_i)\}$, mix ratio α, reward function $R(\cdot)$, training iterations N_{ML}, N_{RL}, and beam sizes B_{ML}, B_{RL}.
Procedure:
Initialize $C_x^* = \emptyset$ the best program so far for x
Initialize model θ randomly ▷ Iterative ML
for $n = 1$ to N_{ML} **do**
  for (x, y) in D **do**
    $\mathbb{C} \leftarrow$ Decode B_{ML} programs given x
    for j in $1...|\mathbb{C}|$ **do**
      if $R_{x,y}(C_j) > R_{x,y}(C_x^*)$ **then** $C_x^* \leftarrow C_j$
  $\theta \leftarrow$ ML training with $\mathbb{D}_{ML} = \{(x, C_x^*)\}$
Initialize model θ randomly ▷ REINFORCE
for $n = 1$ to N_{RL} **do**
  $\mathbb{D}_{RL} \leftarrow \emptyset$ is the RL training set
  for (x, y) in D **do**
    $\mathbb{C} \leftarrow$ Decode B_{RL} programs from x
    for j in $1...|\mathbb{C}|$ **do**
      if $R_{x,y}(C_j) > R_{x,y}(C_x^*)$ **then** $C_x^* \leftarrow C_j$
    $\mathbb{C} \leftarrow \mathbb{C} \cup \{C_x^*\}$
    for j in $1...|\mathbb{C}|$ **do**
      $\hat{p}_j \leftarrow (1-\alpha) \cdot \frac{p_j}{\sum_{j'} p_{j'}}$ where $p_j = P_\theta(C_j \mid x)$
      if $C_j = C_x^*$ **then** $\hat{p}_j \leftarrow \hat{p}_j + \alpha$
      $\mathbb{D}_{RL} \leftarrow \mathbb{D}_{RL} \cup \{(x, C_j, \hat{p}_j)\}$
  $\theta \leftarrow$ REINFORCE training with $\mathbb{D}_{RL}$

Algorithm 1 describes our overall training procedure. We first run iterative ML for N_{ML} iterations and record the best program found for every example x_i. Then, we run REINFORCE, where we normalize the probabilities of the programs in beam to sum to $(1-\alpha)$ and add α to the probability of the best found program $C^*(x_i)$. Consequently, the model always puts a reasonable amount of probability on a program with high reward during training. Note that we randomly initialized the parameters for REINFORCE, since initializing from the final ML parameters seems to get stuck in a local optimum and produced worse results.

On top of imitation learning, our approach is related to the common practice in reinforcement learning (Schaul et al., 2016) to replay rare successful experiences to reduce the training variance and improve training efficiency. This is also similar to recent developments (Wu et al., 2016) in machine translation, where ML and RL objectives are linearly combined, because anchoring the model to some high-reward outputs stabilizes training.

3 Experiments and Analysis

We now empirically show that NSM can learn a semantic parser from weak supervision over a large KB. We evaluate on WEBQUESTIONSSP, a challenging semantic parsing dataset with strong baselines. Experiments show that NSM achieves new state-of-the-art performance on WEBQUESTIONSSP with weak supervision, and significantly closes the gap between weak and full supervisions for this task.

3.1 The WEBQUESTIONSSP dataset

The WEBQUESTIONSSP dataset (Yih et al., 2016) contains full semantic parses for a subset of the questions from WEBQUESTIONS (Berant et al., 2013), because 18.5% of the original dataset were found to be "not answerable". It consists of 3,098 question-answer pairs for training and 1,639 for testing, which were collected using Google Suggest API, and the answers were originally obtained using Amazon Mechanical Turk workers. They were updated in (Yih et al., 2016) by annotators who were familiar with the design of Freebase and added semantic parses. We further separated out 620 questions from the training set as a validation set. For query pre-processing we used an in-house named entity linking system to find the entities in a question. The quality of the entity linker is similar to that of (Yih et al., 2015) at 94% of the gold root entities being included. Similar to Dong and Lapata (2016), we replaced named entity tokens with a special token "*ENT*". For example, the question "*who plays meg in family guy*" is changed to "*who plays ENT in ENT ENT*". This helps reduce overfitting, because instead of memorizing the correct program for a specific entity, the model has to focus on other context words in the sentence, which improves generalization.

Following (Yih et al., 2015) we used the last publicly available snapshot of Freebase (Bollacker et al., 2008). Since NSM training requires random access to Freebase during decoding, we pre-processed Freebase by removing predicates that are not related to world knowledge (starting with "*/common/*", "*/type/*", "*/freebase/*"),[2] and removing all text valued predicates, which are rarely the answer. Out of all 27K relations, 434 relations are removed during preprocessing. This results in a graph that fits in memory with 23K relations, 82M nodes, and 417M edges.

3.2 Model Details

For pre-trained word embeddings, we used the 300 dimension GloVe word embeddings trained on 840B tokens (Pennington et al., 2014). On the encoder side, we added a projection matrix to

[2] We kept "*/common/topic/notable_types*".

transform the embeddings into 50 dimensions. On the decoder side, we used the same GloVe embeddings to construct an embedding for each property using its Freebase id, and also added a projection matrix to transform this embedding to 50 dimensions. A Freebase id contains three parts: domain, type, and property. For example, the Freebase id for PARENTSOF is *"/people/person/parents"*. *"people"* is the domain, *"person"* is the type and *"parents"* is the property. The embedding is constructed by concatenating the average of word embeddings in the domain and type name to the average of word embeddings in the property name. For example, if the embedding dimension is 300, the embedding dimension for *"/people/person/parents"* will be 600. The first 300 dimensions will be the average of the embeddings for *"people"* and *"person"*, and the second 300 dimensions will be the embedding for *"parents"*.

The dimension of encoder hidden state, decoder hidden state and key embeddings are all 50. The embeddings for the functions and special tokens (e.g., "*UNK*", "*GO*") are randomly initialized by a truncated normal distribution with mean=0.0 and stddev=0.1. All the weight matrices are initialized with a uniform distribution in $[-\frac{\sqrt{3}}{d}, \frac{\sqrt{3}}{d}]$ where d is the input dimension. Dropout rate is set to 0.5, and we see a clear tendency for larger dropout rate to produce better performance, indicating overfitting is a major problem for learning.

3.3 Training Details

In iterative ML training, the decoder uses a beam of size $k = 100$ to update the pseudo-gold programs and the model is trained for 20 epochs after each decoding step. We use the Adam optimizer (Kingma and Ba, 2014) with initial learning rate 0.001. In our experiment, this process usually converges after a few (5-8) iterations.

For REINFORCE training, the best hyperparameters are chosen using the validation set. We use a beam of size $k = 5$ for decoding, and α is set to 0.1. Because the dataset is small and some relations are only used once in the whole training set, we train the model on the entire training set for 200 iterations with the best hyperparameters. Then we train the model with learning rate decay until convergence. Learning rate is decayed as $g_t = g_0 \times \beta^{\frac{\max(0, t-t_s)}{m}}$, where $g_0 = 0.001$, $\beta = 0.5$ $m = 1000$, and t_s is the number of training steps at the end of iteration 200.

Since decoding needs to query the knowledge base (KB) constantly, the speed bottleneck for training is decoding. We address this problem in our implementation by partitioning the dataset, and using multiple decoders in parallel to handle each partition. We use 100 decoders, which queries 50 KG servers, and one trainer. The neural network model is implemented in TensorFlow. Since the model is small, we didn't see a significant speedup by using GPU, so all the decoders and the trainer are using CPU only.

Inspired by the staged generation process in Yih et al. (2015), curriculum learning includes two steps. We first run iterative ML for 10 iterations with programs constrained to only use the "*Hop*" function and the maximum number of expressions is 2. Then, we run iterative ML again, but use both "*Hop*" and "*Filter*". The maximum number of expressions is 3, and the relations used by "*Hop*" are restricted to those that appeared in $a^{best}_{0:T}(q)$ in the first step.

3.4 Results and discussion

We evaluate performance using the offical evaluation script for WEBQUESTIONSSP. Because the answer to a question may contain multiple entities or values, precision, recall and F1 are computed based on the output of each individual question, and average F1 is reported as the main evaluation metric. Accuracy measures the proportion of questions that are answered exactly.

A comparison to STAGG, the previous state-of-the-art model (Yih et al., 2016, 2015), is shown in Table 2. Our model beats STAGG with weak supervision by a significant margin on all metrics, while relying on no feature engineering or handcrafted rules. When STAGG is trained with strong supervision it obtains an F1 of 71.7, and thus NSM closes half the gap between training with weak and full supervision.

Model	Prec.	Rec.	F1	Acc.
STAGG	67.3	73.1	66.8	58.8
NSM	70.8	76.0	**69.0**	59.5

Table 2: Results on the test set. Average F1 is the main evaluation metric and NSM outperforms STAGG with no domain-specific knowledge or feature engineering.

Four key ingredients lead to the final performance of NSM. The first one is the neural computer interface that provides code assistance by checking for syntax and semantic errors. We find

that semantic checks are very effective for open-domain KBs with a large number of properties. For our task, the average number of choices is reduced from 23K per step (all properties) to less than 100 (the average number of properties connected to an entity).

The second ingredient is augmented REINFORCE training. Table 3 compares augmented REINFORCE, REINFORCE, and iterative ML on the validation set. REINFORCE gets stuck in local optimum and performs poorly. Iterative ML training is not directly optimizing the F1 measure, and achieves sub-optimal results. In contrast, augmented REINFORCE is able to bootstrap using pseudo-gold programs found by iterative ML and achieves the best performance on both the training and validation set.

Settings	Train F1	Valid F1
Iterative ML	68.6	60.1
REINFORCE	55.1	47.8
Augmented REINFORCE	83.0	**67.2**

Table 3: Average F1 on the validation set for augmented REINFORCE, REINFORCE, and iterative ML.

The third ingredient is curriculum learning during iterative ML. We compare the performance of the best programs found with and without curriculum learning in Table 4. We find that the best programs found with curriculum learning are substantially better than those found without curriculum learning by a large margin on every metric.

Settings	Prec.	Rec.	F1	Acc.
No curriculum	79.1	91.1	78.5	67.2
Curriculum	88.6	96.1	89.5	79.8

Table 4: Evaluation of the programs with the highest F1 score in the beam ($a_{0:t}^{best}$) with and without curriculum learning.

The last important ingredient is reducing overfitting. Given the small size of the dataset, overfitting is a major problem for training neural network models. We show the contributions of different techniques for controlling overfitting in Table 5. Note that after all the techniques have been applied, the model is still overfitting with training F1@1=83.0% and validation F1@1=67.2%.

Among the programs generated by the model, a significant portion (36.7%) uses more than one expression. From Table 6, we can see that the performance doesn't decrease much as the compositional depth increases, indicating that the model is effective at capturing compositionality. We observe that programs with three expressions use a more limited set of properties, mainly focusing on answering a few types of questions such as "who plays meg in family guy", "what college did jeff corwin go to" and "which countries does russia border". In contrast, programs with two expressions use a more diverse set of properties, which could explain the lower performance compared to programs with three expressions.

Settings	Δ F1@1
−Pretrained word embeddings	−5.5
−Pretrained property embeddings	−2.7
−Dropout on GRU input and output	−2.4
−Dropout on softmax	−1.1
−Anonymize entity tokens	−2.0

Table 5: Contributions of different overfitting techniques on the validation set.

#Expressions	0	1	2	3
Percentage	0.4%	62.9%	29.8%	6.9%
F1	0.0	73.5	59.9	70.3

Table 6: Percentage and performance of model generated programs with different complexity (number of expressions).

Error analysis Error analysis on the validation set shows two main sources of errors:

1. **Search failure**: Programs with high reward are not found during search for pseudo-gold programs, either because the beam size is not large enough, or because the set of functions implemented by the interpreter is insufficient. The 89.5% F1 score in Table 4 indicates that at least 10% of the questions are of this kind.
2. **Ranking failure**: Programs with high reward exist in the beam, but are not ranked at the top during decoding. Because the training error is low, this is largely due to overfitting or spurious programs. The 67.2% F1 score in Table 3 indicates that about 20% of the questions are of this kind.

4 Related work

Among deep learning models for program induction, Reinforcement Learning Neural Turing Machines (RL-NTMs) (Zaremba and Sutskever, 2015) are the most similar to NSM, as a non-differentiable machine is controlled by a sequence

model. Therefore, both models rely on REINFORCE for training. The main difference between the two is the abstraction level of the programming language. RL-NTM uses lower level operations such as memory address manipulation and byte reading/writing, while NSM uses a high level programming language over a large knowledge base that includes operations such as following properties from entities, or sorting based on a property, which is more suitable for representing semantics. Earlier works such as OOPS (Schmidhuber, 2004) has desirable characteristics, for example, the ability to define new functions. These remain to be future improvements for NSM.

We formulate NSM training as an instance of reinforcement learning (Sutton and Barto, 1998) in order to directly optimize the task reward of the structured prediction problem (Norouzi et al., 2016; Li et al., 2016; Yu et al., 2017). Compared to imitation learning methods (Daume et al., 2009; Ross et al., 2011) that interpolate a model distribution with an oracle, NSM needs to solve a challenging search problem of training from weak supervisions in a large search space. Our solution employs two techniques (a) a symbolic "computer" helps find good programs by pruning the search space (b) an iterative ML training process, where beam search is used to find pseudo-gold programs. Wiseman and Rush (Wiseman and Rush, 2016) proposed a max-margin approach to train a sequence-to-sequence scorer. However, their training procedure is more involved, and we did not implement it in this work. MIXER (Ranzato et al., 2015) also proposed to combine ML training and REINFORCE, but they only considered tasks with full supervisions. Berant and Liang (Berant and Liang, 2015) applied imitation learning to semantic parsing, but still requires hand crafted grammars and features.

NSM is similar to Neural Programmer (Neelakantan et al., 2015) and Dynamic Neural Module Network (Andreas et al., 2016) in that they all solve the problem of semantic parsing from structured data, and generate programs using similar semantics. The main difference between these approaches is how an intermediate result (the memory) is represented. Neural Programmer and Dynamic-NMN chose to represent results as vectors of weights (row selectors and attention vectors), which enables backpropagation and search through all possible programs in parallel. However, their strategy is not applicable to a large KB such as Freebase, which contains about 100M entities, and more than 20k properties. Instead, NSM chooses a more scalable approach, where the "computer" saves intermediate results, and the neural network only refers to them with variable names (e.g., "R_1" for all cities in the US).

NSM is similar to the Path Ranking Algorithm (PRA) (Lao et al., 2011) in that semantics is encoded as a sequence of actions, and denotations are used to prune the search space during learning. NSM is more powerful than PRA by 1) allowing more complex semantics to be composed through the use of a key-variable memory; 2) controlling the search procedure with a trained neural network, while PRA only samples actions uniformly; 3) allowing input questions to express complex relations, and then dynamically generating action sequences. PRA can combine multiple semantic representations to produce the final prediction, which remains to be future work for NSM.

5 Conclusion

We propose the Manager-Programmer-Computer framework for neural program induction. It integrates neural networks with a symbolic *non-differentiable* computer to support *abstract*, *scalable* and *precise* operations through a friendly *neural computer interface*. Within this framework, we introduce the Neural Symbolic Machine, which integrates a neural sequence-to-sequence "programmer" with key-variable memory, and a symbolic Lisp interpreter with code assistance. Because the interpreter is non-differentiable and to directly optimize the task reward, we apply REINFORCE and use pseudo-gold programs found by an iterative ML training process to bootstrap training. NSM achieves new state-of-the-art results on a challenging semantic parsing dataset with weak supervision, and significantly closes the gap between weak and full supervision. It is trained end-to-end, and does not require any feature engineering or domain-specific knowledge.

Abstract

Relation extraction has been widely used for finding unknown relational facts from the plain text. Most existing methods focus on exploiting mono-lingual data for relation extraction, ignoring massive information from the texts in various languages. To address this issue, we introduce a multi-lingual neural relation extraction framework, which employs mono-lingual attention to utilize the information within mono-lingual texts and further proposes cross-lingual attention to consider the information consistency and complementarity among cross-lingual texts. Experimental results on real-world datasets show that our model can take advantage of multi-lingual texts and consistently achieve significant improvements on relation extraction as compared with baselines. The source code of this paper can be obtained from https://github.com/thunlp/MNRE

1 Introduction

People build many large-scale knowledge bases (KBs) to store structured knowledge about the real world, such as Wikidata[1] and DBpedia[2]. KBs are playing an important role in many AI and NLP applications such as information retrieval and question answering. The facts in KBs are typically organized in the form of triplets, e.g., (*New York*, `CityOf`, *United States*). Since existing KBs are far from complete and new facts are growing infinitely, meanwhile manual annotation of these knowledge is time-consuming and human-intensive, many works have been devoted to automated extraction of novel facts from various Web resources, where relation extraction (RE) from plain texts is one the most important knowledge sources.

Among various methods for relation extraction, distant supervision is the most promising approach (Mintz et al., 2009; Riedel et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012), which can automatically generate training instances via aligning KBs and texts to address the issue of lacking supervised data. As the development of deep learning, Zeng et al. (2015) introduce neural networks to extract relations with automatically learned features from training instances. To address the wrong labelling issue of distant supervision data, Lin et al. (2016) further employ sentence-level attention mechanism in neural relation extraction, and achieves the state-of-the-art performance.

However, most RE systems concentrate on extracting relational facts from mono-lingual data. In fact, people describe knowledge about the world using various languages. And people speaking different languages also share similar knowledge about the world due to the similarities of human experiences and human cognitive systems. For instance, though *New York* and *United States* are expressed as 纽约 and 美国 respectively in Chinese, both Americans and Chinese share the fact that "*New York* is a city of *USA*."

It is straightforward to build mono-lingual RE systems separately for each single language. But if so, it won't be able to take full advantage of diverse information hidden in the data of various languages. Multi-lingual data will benefit relation extraction for the following two reasons: **1. Consistency**. According to the distant supervision data in our experiments[3], we find that over half of Chinese

Relation	City in
English	1. **New York is a city** in the northeastern **United States**.
Chinese	1. **纽约**位于美国纽约州东南部大西洋沿岸，**是美国第一大城市**及第一大港. (**New York** is in the United States New York and on the Atlantic coast of the southeast Atlantic, **is the largest city** and largest port **in the United States**.) 2. **纽约是美国**人口最多**的城市**. (**New York is** the most populous **city in the United States**)

Table 1: An example of Chinese sentences and English sentence about the same relational fact (*New York*, `CityOf`, *United States*). Important parts are highlighted with bold face.

and English sentences are longer than 20 words, in which only several words are related to the relational facts. Take Table 1 for example. The first Chinese sentence has over 20 words, in which only "纽约" (New York) and "是美国第一大城市" (is the biggest city in the United States) actually directly reflect the relational fact `CityOf`. It is thus non-trivial to locate and learn these relational patterns from complicated sentences for relation extraction. Fortunately, a relational fact is usually expressed with certain patterns in various languages, and the correspondence of these patterns among languages is substantially consistent. The pattern consistency among languages provides us augmented clues to enhance relational pattern learning for relation extraction.

2. Complementarity. From our experiment data, we also find that 42.2% relational facts in English data and 41.6% ones in Chinese data are unique. Moreover, for nearly half of relations, the number of sentences expressing relational facts of these relations varies a lot in different languages. It is thus straightforward that the texts in different languages can be complementary to each other, especially from those resource-rich languages to resource-poor languages, and improve the overall performance of relation extraction.

To take full consideration of these issues, we propose **M**ulti-lingual Attention-based **N**eural **R**elation **E**xtraction (MNRE). We first employ a convolutional neural network (CNN) to embed the relational patterns in sentences into real-valued vectors. Afterwards, to consider the complementarity of all informative sentences in various languages and capture the consistency of relational patterns, we apply mono-lingual attention to select the informative sentences within each language and propose cross-lingual attention to take advantages of pattern consistency and complementarity among languages. Finally, we classify relations according to the global vector aggregated from all sentence vectors weighted by mono-lingual attention and cross-lingual attention.

In experiments, we build training instances via distant supervision by aligning Wikidata with Chinese Baidu Baike and English Wikipedia articles, and evaluate the performance of relation extraction in both English and Chinese. The experimental results show that our framework achieves significant improvement for relation extraction as compared to all baseline methods including both mono-lingual and multi-lingual ones. It indicates that our framework can take full advantages of sentences in different languages and better capture sophisticated patterns expressing relations.

2 Related Work

Recent years KBs have been widely used on various AI and NLP applications. As an important approach to enrich KBs, relation extraction from plain text has attracted many research interests. Relation extraction typically classifies each entity pair into various relation types according to supporting sentences that the both entities appear, which needs human-labelled relation-specific training instances. Many works have been invested to relation extraction including kernel-based model (Zelenko et al., 2003), embedding-based model (Gormley et al., 2015), CNN-based models (Zeng et al., 2014; dos Santos et al., 2015), and RNN-based model (Socher et al., 2012).

Nevertheless, these RE systems are insufficient due to the lack of training data. To address this issue, Mintz et al. (2009) align plain text with Freebase to automatically generate training instances following the distant supervision assumption. To further alleviate the wrong labelling problem, Riedel et al. (2010) model distant supervision for relation extraction as a multi-instance single-label learning problem, and Hoffmann et al. (2011); Surdeanu et al. (2012) regard it as a multi-instance multi-label learning problem. Recently, Zeng et al. (2015) attempt to connect neural networks with distant supervision following the expressed-at-least-once assumption. Lin

Baidu Baike and English Wikipedia articles, which will be introduced in details in the section of experiments.

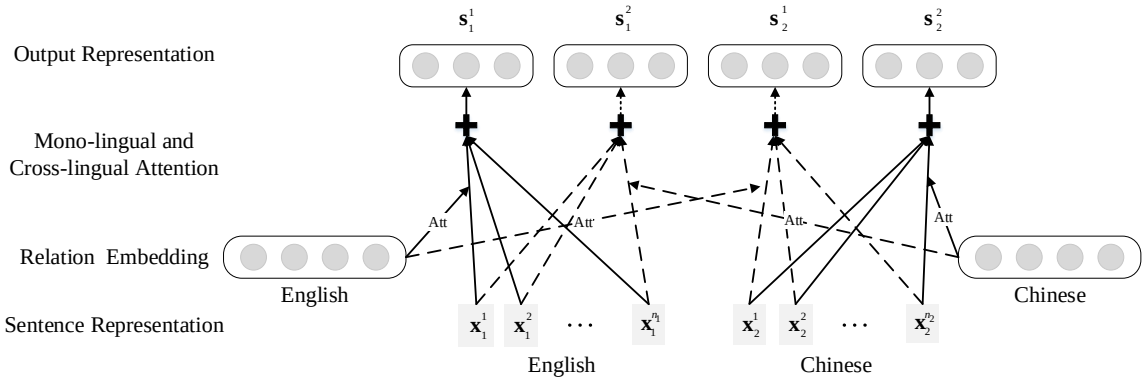

Figure 1: Overall architecture of our multi-lingual attention which contains two languages including English and Chinese. The solid lines indicates mono-lingual attention and the dashed lines indicates cross-lingual attention.

et al. (2016) further utilize sentence-level attention mechanism to consider all informative sentences jointly.

Most existing RE systems are absorbed in extracting relations from mono-lingual data, ignoring massive information lying in texts from multiple languages. In this area, Faruqui and Kumar (2015) present a language independent open domain relation extraction system, and Verga et al. (2015) further employ Universal Schema to combine OpenIE and link-prediction perspective for multi-lingual relation extraction. Both the works focus on multi-lingual transfer learning and learn a predictive model on a new language for existing KBs, by leveraging unified representation learning for cross-lingual entities. Different from these works, our framework aims to jointly model the texts in multiple languages to enhance relation extraction with distant supervision. To the best of our knowledge, this is the first effort to multi-lingual neural relation extraction.

The scope of multi-lingual analysis has been widely considered in many tasks besides relation extraction, such as sentiment analysis (Boiy and Moens, 2009), cross-lingual document summarization (Boudin et al., 2011), information retrieval in Web search (Dong et al., 2014) and so on.

3 Methodology

In this section, we describe our proposed MNRE framework in detail. The key motivation of MNRE is that, for each relational fact, the relation patterns in sentences of different languages should be substantially consistent, and MNRE can utilize the pattern consistency and complementarity among languages to achieve better results for relation extraction.

Formally, given two entities, their corresponding sentences in m different languages are defined as $T = \{S_1, S_2, \ldots, S_m\}$, where $S_j = \{x_j^1, x_j^2, \ldots, x_j^{n_j}\}$ corresponds to the sentence set in the jth language with n_j sentences. Our model measures a score $f(T, r)$ for each relation r, which is expected to be high when r is the valid one, otherwise low. The MNRE framework contains two main components:

1. Sentence Encoder. Given a sentence x and two target entities, we employ CNN to encode relation patterns in x into a distributed representation $\mathbf{x}$. The sentence encoder can also be implemented with GRU (Cho et al., 2014) or LSTM (Hochreiter and Schmidhuber, 1997). In experiments, we find CNN can achieve a better trade-off between computational efficiency and performance effectiveness. Thus, in this paper, we focus on CNN as the sentence encoder.

2. Multi-lingual Attention. With all sentences in various languages encoded into distributed vector representations, we apply mono-lingual and cross-lingual attentions to capture those informative sentences with accurate relation patterns. MNRE further aggregates these sentence vectors with weighted attentions into global representations for relation prediction.

We introduce the two components in detail as follows.

3.1 Sentence Encoder

The sentence encoder aims to transform a sentence x into its distributed representation $\mathbf{x}$ via CNN. First, it embeds the words in the input sentence

into dense real-valued vectors. Next, it employs convolutional, max-pooling and non-linear transformation layers to construct the distributed representation of the sentence, i.e., $\mathbf{x}$.

3.1.1 Input Representation

Following (Zeng et al., 2014), we transform each input word into the concatenation of two kinds of representations: (1) a word embedding which captures syntactic and semantic meanings of the word, and (2) a position embedding which specifies the position information of this word with respect to two target entities. In this way, we can represent the input sentence as a vector sequence $\mathbf{w} = \{\mathbf{w}_1, \mathbf{w}_2, \ldots\}$ with $\mathbf{w}_i \in \mathbb{R}^d$, where $d = d^a + d^b \times 2$. (d^a and d^b are the dimensions of word embeddings and position embeddings respectively)

3.1.2 Convolution, Max-pooling and Non-linear Layers

After encoding the input sentence, we use a convolutional layer to extract the local features, max-pooling, and non-linear layers to merge all local features into a global representation.

First, the convolutional layer extracts local features by sliding a window of length l over the sentence and perform a convolution within each sliding window. Formally, the output of convolutional layer for the ith sliding window is computed as:

$$\mathbf{p}_i = \mathbf{W}\mathbf{w}_{i-l+1:i} + \mathbf{b}, \tag{1}$$

where $\mathbf{w}_{i-l+1:i}$ indicates the concatenation of l word embeddings within the i-th window, $\mathbf{W} \in \mathbb{R}^{d^c \times (l \times d)}$ is the convolution matrix and $\mathbf{b} \in \mathbb{R}^{d^c}$ is the bias vector. (d^c is the dimension of output embeddings of the convolution layer)

After that, we combines all local features via a max-pooling operation and apply a hyperbolic tangent function to obtain a fixed-sized sentence vector for the input sentence. Formally, the ith element of the output vector $\mathbf{x} \in \mathbb{R}^{d^c}$ is calculated as:

$$[\mathbf{x}]_j = \tanh\big(\max_i(\mathbf{p}_{ij})\big). \tag{2}$$

The final vector $\mathbf{x}$ is expected to efficiently encode relation patterns about target entities from the input sentence.

Here, instead of max pooling operation, we can use piecewise max pooling operation adopted by PCNN (Zeng et al., 2015) which is a variation of CNN to better capture the relation patterns in the input sentence.

3.2 Multi-lingual Attention

To exploit the information of the sentences from all languages, our model adopts two kinds of attention mechanisms for multi-lingual relation extraction, including: (1) the mono-lingual attention which selects the informative sentences within one language and (2) the cross-lingual attention which measures the pattern consistency among languages.

3.2.1 Mono-lingual Attention

To address the wrong-labelling issue in distant supervision, we follow the idea of sentence-level attention (Lin et al., 2016) and set mono-lingual attention for MNRE. It is intuitive that each human language has its own characteristics. Hence we adopt different mono-lingual attentions to de-emphasize those noisy sentences within each language.

More specifically, for the j-th language and the sentence set S_j, we aim to aggregate all sentence vectors into a real-valued vector $\mathbf{S}_j$ for relation prediction. The mono-lingual vector $\mathbf{S}_j$ is computed as a weighted sum of those sentence vectors $\mathbf{x}_j^i$:

$$\mathbf{S}_j = \sum_i \alpha_j^i \mathbf{x}_j^i, \tag{3}$$

where α_j^i is the attention score of each sentence vector $\mathbf{x}_j^i$, defined as:

$$\alpha_j^i = \frac{\exp(e_j^i)}{\sum_k \exp(e_j^k)}, \tag{4}$$

where e_j^i is referred as a query-based function which scores how well the input sentence x_j^i reflects its labelled relation r. There are many ways to obtain e_j^i, and here we simply compute e_i as the inner product:

$$e_j^i = \mathbf{x}_j^i \cdot \mathbf{r}_j. \tag{5}$$

Here $\mathbf{r}_j$ is the query vector of the relation r with respect to the j-th language.

3.2.2 Cross-lingual Attention

Besides mono-lingual attention, we propose cross-lingual attention for neural relation extraction to better take advantages of multi-lingual data.

The key idea of cross-lingual attention is to emphasize those sentences which have strong consistency among different languages. On the basis of mono-lingual attention, cross-lingual attention

is capable of further removing unlikely sentences and resulting in more concentrated and informative sentences, with the factor of consistent correspondence of relation patterns among different languages.

Cross-lingual attention works similar to mono-lingual attention. Suppose j indicates a language and k is a another language ($k \neq j$). Formally, the cross-lingual representation $\mathbf{S}_{jk}$ is defined as a weighted sum of those sentence vectors $\mathbf{x}_j^i$ in the jth language:

$$\mathbf{S}_{jk} = \sum_i \alpha_{jk}^i \mathbf{x}_j^i, \tag{6}$$

where α_{jk}^i is the cross-lingual attention score of each sentence vector $\mathbf{x}_j^i$ with respect to the kth language. The cross-lingual attention α_{jk}^i is defined as:

$$\alpha_{jk}^i = \frac{\exp(e_{jk}^i)}{\sum_k \exp(e_{jk}^k)}, \tag{7}$$

where e_{jk}^i is referred as a query-based function which scores the consistency between the input sentence x_j^i in the jth language and the relation patterns in the kth language for expressing the semantic meanings of the labelled relation r. Similar to the mono-lingual attention, we compute e_{jk}^i as follows:

$$e_{jk}^i = \mathbf{x}_j^i \cdot \mathbf{r}_k, \tag{8}$$

where $\mathbf{r}_k$ is the query vector of the relation r with respect to the kth language.

Note that, for convenience, we denote those mono-lingual attention vectors $\mathbf{S}_j$ as $\mathbf{S}_{jj}$ in the remainder of this paper.

3.3 Prediction

For each entity pair and its corresponding sentence set T in m languages, we can obtain $m \times m$ vectors $\{\mathbf{S}_{jk} | j, k \in \{1, \ldots, m\}\}$ from the neural networks with multi-lingual attention. Those vectors with $j = k$ are mono-lingual attention vectors, and those with $j \neq k$ are cross-lingual attention vectors.

We take all vectors $\{\mathbf{S}_{jk}\}$ together and define the overall score function $f(T, r)$ as follows:

$$f(T, r) = \sum_{j,k \in \{1,\ldots,m\}} \log p(r|\mathbf{S}_{jk}, \theta), \tag{9}$$

where $p(r|\mathbf{S}_{jk}, \theta)$ is the probability of predicting the relation r conditional on $\mathbf{S}_{jk}$, computed using a softmax layer as follows:

$$p(r|\mathbf{S}_{jk}, \theta) = \text{softmax}(\mathbf{M}\mathbf{S}_{jk} + \mathbf{d}), \tag{10}$$

where $\mathbf{d} \in \mathbb{R}^{n_r}$ is a bias vector, n_r is the number of relation types and $\mathbf{M} \in \mathbb{R}^{n_r \times R^c}$ is a global relation matrix initialized randomly.

To better consider the characteristics of each human language, we further introduce $\mathbf{R}_k$ as the specific relation matrix of the kth language. Here we simply define $\mathbf{R}_k$ as composed by $\mathbf{r}_k$ in Eq. (8). Hence, Eq. (10) can be extended to:

$$p(r|\mathbf{S}_{jk}, \theta) = \text{softmax}[(\mathbf{R}_k + \mathbf{M})\mathbf{S}_{jk} + \mathbf{d}], \tag{11}$$

where $\mathbf{M}$ encodes global patterns for predicting relations and $\mathbf{R}_k$ encodes those language-specific characteristics.

Note that, in the training phase, the vectors $\{\mathbf{S}_{jk}\}$ are constructed using Eq. (3) and (6) using the labelled relation. In the testing phase, since the relation is not known in advance, we will construct different vectors $\{\mathbf{S}_{jk}\}$ for each possible relation r to compute $f(T, r)$ for relation prediction.

3.4 Optimization

Here we introduce the learning and optimization details of our MNRE framework. We define the objective function as follows:

$$J(\theta) = \sum_{i=1}^{s} f(T_i, r_i), \tag{12}$$

where s indicates the number of all entity pairs with each corresponding to a sentence set in different languages, and θ indicates all parameters of our framework.

To solve the optimization problem, we adopt mini-batch stochastic gradient descent (SGD) to minimize the objective function. For learning, we iterate by randomly selecting a mini-batch from the training set until converge.

4 Experiments

We first introduce the datasets and evaluation metrics used in the experiments. Next, we use a validation set to determine the best model parameters and choose the best model via early stopping. Afterwards, we show the effectiveness of our framework of considering pattern complementarity and consistency for multi-lingual relation extraction by quantitative and qualitative analysis. Finally, we compare the effect of two kinds of relation matrices in Eq. (11) used for prediction.

4.1 Datasets and Evaluation Metrics

We generate a new multi-lingual relation extraction dataset to evaluate our MNRE framework. Without loss of generality, the experiments focus on relation extraction from two languages including English and Chinese. In this dataset, the Chinese instances are generated by aligning Chinese Baidu Baike with Wikidata, and the English instances are generated by aligning English Wikipedia articles with Wikidata. The relational facts of Wikidata in this dataset are divided into three parts for training, validation and testing respectively. There are 176 relations including a special relation NA indicating there is no relation between entities. And we set both validation and testing sets for Chinese and English parts contain the same facts. We list the statistics about the dataset in Table 2.

Dataset		#Rel	#Sent	#Fact
English	Train	176	1,022,239	47,638
	Valid		80,191	2,192
	Test		162,018	4,326
Chinese	Train	176	940,595	42,536
	Valid		82,699	2,192
	Test		167,224	4,326

Table 2: Statistics of the dataset.

We follow previous works (Mintz et al., 2009) and investigate the performance of RE systems using the held-out evaluation, by comparing the relational facts discovered by RE systems from the testing set with those facts in KB. The evaluation method assumes that if a RE system accurately finds more relational facts in KBs from the testing set, it will achieve better performance for relation extraction. The held-out evaluation provides an approximate measure of RE performance without time-consuming human evaluation. In experiments, we report the precision/recall curves as the evaluation metric.

4.2 Experimental Settings

We tune the parameters of our MNRE framework by grid searching using validation set. For training, we set the iteration number over all the training data as 15. The best models were selected by early stopping using the evaluation results on the validation set. In Table 3 we show the best setting of all parameters used in our experiments.

Hyper-parameter	value
Window size w	3
Sentence embedding size d^c	230
Word dimension d^a	50
Position dimension d^b	5
Batch size B	160
Learning rate λ	0.001
Dropout probability p	0.5

Table 3: Parameter settings.

4.3 Effectiveness of Consistency

To demonstrate the effectiveness of considering pattern consistency among languages, we empirically compare different methods through held-out evaluation. We select CNN proposed in (Zeng et al., 2014) as our sentence encoder and implement it by ourselves which achieves comparable results as the authors reported on their experimental dataset NYT10[4]. And we compare the performance of our framework with the [P]CNN model trained with only English data ([P]CNN-En), only Chinese data ([P]CNN-Zh), a joint model ([P]CNN+joint) which predicts using [P]CNN-En and [P]CNN-Zh jointly, and another joint model with shared embeddings ([P]CNN+share) which trains [P]CNN-En and [P]CNN-Zh with common relation embedding matrices.

From Fig. 2, we have the following observations:

(1) Both [P]CNN+joint and [P]CNN+share achieve better performances as compared to [P]CNN-En and [P]CNN-Zh. It indicates that utilizing Chinese and English sentences jointly is beneficial to extracting novel relational facts. The reason is that those relational facts that are discovered from multiple languages are more reliable to be true.

(2) CNN+share only has similar performance as compared to CNN+joint, even through a bit worse when recall ranges from 0.1 to 0.2. Besides, PCNN+share performs worse than PCNN+joint nearly over the entire range of recall. It demonstrates that a simple combination of multiple languages by sharing relation embedding matrices cannot further capture more implicit correlations among various languages.

(3) Our MNRE model achieves the highest precision over the entire range of recall as compared to other methods including [P]CNN+joint and [P]CNN+share models. By grid searching of

CNN+Zh	CNN+En	MNRE	Sentence
—	Medium	Low	1. **Barzun** is a commune in the Pyrénées-Atlantiques department in the Nouvelle-Aquitaine region of south-western **France**.
—	Medium	High	2. **Barzun** was born in Créteil , France
Medium	—	Low	3. 作为从**法国**移民到美国来的顶尖知识分子，**巴尔赞**与莱昂内尔·特里林、德怀特·麦克唐纳等人一道，在冷战时期积极参与美国的公共知识生活 …(As a top intellectual immigrating from **France** to the United States, **Barzun**, together with Lionel Trilling and Dwight Macdonald, actively participated in public knowledge life in the United States during the cold war …)
Medium	—	High	4. **巴尔赞**于 1907 年出生于法国一个知识分子家庭，1920 年赴美。(**Barzun** was born in a **French** intellectual family in 1907 and went to America in 1920.)

Table 4: An example of our multi-lingual attention. Low, medium and high indicate the attention weights.

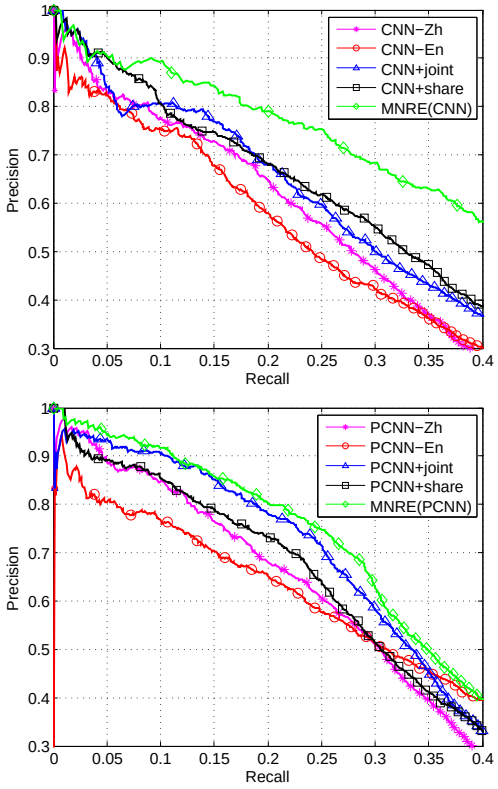

Figure 2: Top: Aggregated precision/recall curves of CNN-En, CNN-Zh, CNN+joint, CNN+share, and MNRE(CNN). Bottom: Aggregated precision/recall curves of PCNN-En, PCNN-Zh, PCNN+joint, PCNN+share, and MNRE(PCNN)

parameters for these baseline models, we can observe that both [P]CNN+joint and [P]CNN+share cannot achieve competitive results compared to MNRE even when increasing the size of the output layer. This indicates that no more useful information can be captured by simply increasing model size. On the contrary, our proposed MNRE model can successfully improve multi-lingual relation extraction by considering pattern consistency among languages.

We further give an example of cross-lingual attention in Table 4. It shows four sentences having the highest and lowest Chinese-to-English and English-to-Chinese attention weights respectively with respect to the relation `PlaceOfBirth` in MNRE. We highlight the entity pairs in bold face. For comparison, we also show their attention weights from CNN+Zh and CNN+En. From the table we find that, although all of the four sentences actually express the fact that Barzun was born in France, the first and third sentences contain much more noisy information that may confuse RE systems. By considering pattern consistency between sentences in two languages with cross-lingual attention, MNRE can identify the second and fourth sentences that unambiguously express the relation `PlaceOfBirth` with higher attention as compared to CNN+Zh and CNN+En.

4.4 Effectiveness of Complementarity

To demonstrate the effectiveness of considering pattern complementarity among languages, we empirically compare the following methods through held-out evaluation: MNRE for English (MNRE-En) and MNRE for Chinese (MNRE-Zh) which only use the mono-lingual vectors to predict relations, and [P]CNN-En and [P]CNN-Zh models.

Fig. 3 shows the aggregated precision/recall curves of the four models for both CNN and PCNN. From the figure, we find that:

(1) MNRE-En and MNRE-Zh outperform [P]CNN-En and [P]CNN-Zh almost in entire range of recall. It indicates that by jointly training with multi-lingual attention, both Chinese and English relation extractors are beneficial from those sentences from the other language.

(2) Although [P]CNN-En underperforms as compared to [P]CNN-Zh, MNRE-En is comparable to MNRE-Zh by jointly training through multi-lingual attention. It demonstrates that both Chi-

Relation	#Sent-En	#Sent-Zh	CNN-En	CNN-Zh	MNRE-En	MNRE-Zh
Contains	993	6984	17.95	69.87	73.72	75.00
HeadquartersLocation	1949	210	43.04	0.00	41.77	50.63
Father	1833	983	64.71	77.12	86.27	83.01
CountryOfCitizenship	25322	15805	95.22	93.23	98.41	98.21

Table 5: Detailed results (precision@1) of some specific relations. #Sent-En and #Sent-Zh indicate the numbers of English/Chinese sentences which are labelled with the relations.

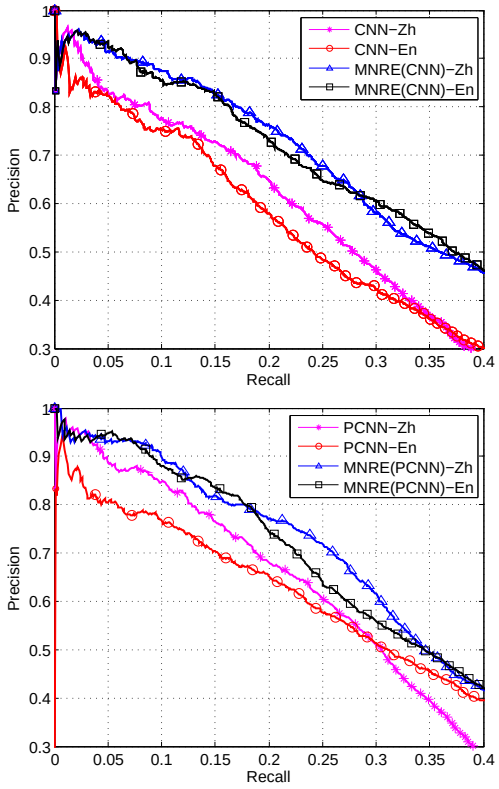

Figure 3: Top: Aggregate precision/recall curves of CNN-En, CNN-Zh, MNRE(CNN)-En and MNRE(CNN)-Zh. Bottom: Aggregate precision/recall curves of PCNN-En, PCNN-Zh, MNRE(PCNN)-En and MNRE(PCNN)-Zh.

nese and English relation extractors can take full advantages of texts in both languages via our propose multi-lingual attention scheme.

Table 5 shows the detailed results (in precision@1) of some specific relations of which the training instances are un-balanced on English and Chinese sides. From the table, we can see that:

(1) For the relation Contains of which the number of English training instances is only $1/7$ of Chinese ones, CNN-En gets much worse performance as compared to CNN-Zh due to the lack of training data. Nevertheless, by jointly training through multi-lingual attention, MNRE(CNN)-En is comparable to and slightly better than MNRE(CNN)-Zh.

(2) For the relation HeadquartersLocation of which the number of Chinese training instances is only $1/9$ of English ones, CNN-Zh even cannot predict any correct results. The reason is perhaps that, CNN-Zh of the relation is not sufficiently trained because there are only 210 Chinese training instances for this relation. Similarly, by jointly training through multi-lingual attention, MNRE(CNN)-En and MNRE(CNN)-Zh both achieve promising results.

(3) For the relations Father and CountryOfCitizenship of which the sentence number in English and Chinese are not so un-balanced, our MNRE can still improve the performance of relation extraction on both English and Chinese sides.

4.5 Comparison of Relation Matrix

For relation prediction, we use two kinds of relation matrices including: **M** that considers the global consistency of relations, and **R** that considers the specific characteristics of relations for each language. To measure the effect of the two relation matrices, we compare the performance of MNRE using the both matrices with those only using **M** (MNRE-M) and only using **R** (MNRE-R).

Fig. 4 shows the precision-recall curves for each method. From the figure, we observe that:t

(1) The performance of MNRE-M is much worse than both MNRE-R and MNRE. It indicates that we cannot just use global relation matrix for relation prediction. The reason is that each language has its own specific characteristics to express relation patterns, which cannot be well integrated into a single relation matrix.

(2) MNRE(CNN)-R has similar performance as compared to MNRE(CNN) when the recall is low. However, it has a sharp decline when the recall reaches 0.25. It suggests there also exists global consistency of relation patterns among languages which cannot be neglected. Hence, we should combine both **M** and **R** together for multi-lingual relation extraction, as proposed in our MNRE

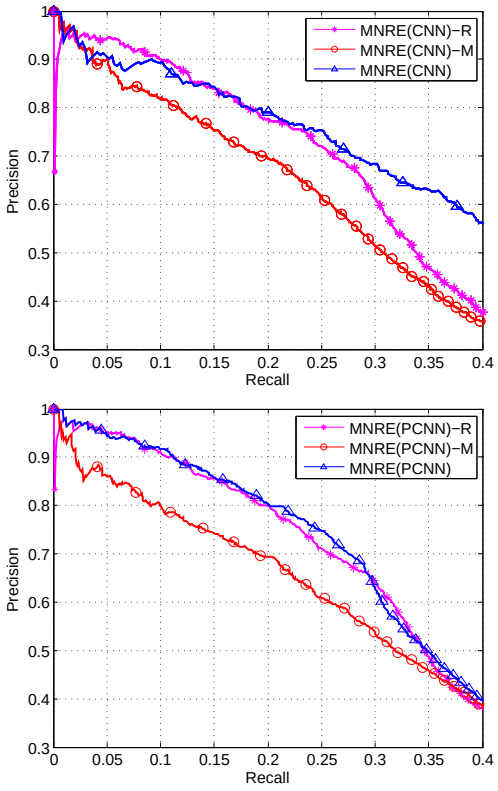

Figure 4: Top: Aggregated precion/recall curves of MNRE(CNN)-M, MNRE(CNN)-R and MNRE. Bottom: Aggregated precion/recall curves of MNRE(PCNN)-M, MNRE(PCNN)-R and MNRE(PCNN).

framework.

5 Conclusion

In this paper, we introduce a neural relation extraction framework with multi-lingual attention to take pattern consistency and complementarity among multiple languages into consideration. We evaluate our framework on multi-lingual relation extraction task, and the results show that our framework can effectively model relation patterns among languages and achieve state-of-the-art results.

We will explore the following directions as future work: (1) In this paper, we only consider sentence-level multi-lingual attention for relation extraction. In fact, we find that the word alignment information may be also helpful for capturing relation patterns. Hence, the word-level multi-lingual attention, which may discover implicit alignments between words in multiple languages, will further improve multi-lingual relation extraction. We will explore the effectiveness of word-level multi-lingual attention for relation extraction as our future work. (2) MNRE can be flexibly implemented in the scenario of multiple languages, and this paper focuses on two languages of English and Chinese. In future, we will extend MNRE to more languages and explore its significance.

Abstract

We introduce a neural semantic parser which is interpretable and scalable. Our model converts natural language utterances to intermediate, domain-general natural language representations in the form of predicate-argument structures, which are induced with a transition system and subsequently mapped to target domains. The semantic parser is trained end-to-end using annotated logical forms or their denotations. We achieve the state of the art on SPADES and GRAPHQUESTIONS and obtain competitive results on GEOQUERY and WEBQUESTIONS. The induced predicate-argument structures shed light on the types of representations useful for semantic parsing and how these are different from linguistically motivated ones.[1]

1 Introduction

Semantic parsing is the task of mapping natural language utterances to machine interpretable meaning representations. Despite differences in the choice of meaning representation and model structure, most existing work conceptualizes semantic parsing following two main approaches. Under the first approach, an utterance is parsed and grounded to a meaning representation *directly* via learning a task-specific grammar (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Wong and Mooney, 2006; Kwiatkowksi et al., 2010; Liang et al., 2011; Berant et al., 2013; Flanigan et al., 2014; Pasupat and Liang, 2015; Groschwitz et al., 2015). Under the second approach, the utterance is first parsed to an *intermediate* task-independent representation tied to a syntactic parser and then mapped to a grounded representation (Kwiatkowski et al., 2013; Reddy et al., 2016, 2014; Krishnamurthy and Mitchell, 2015; Gardner and Krishnamurthy, 2017). A merit of the two-stage approach is that it creates reusable intermediate interpretations, which potentially enables the handling of unseen words and knowledge transfer across domains (Bender et al., 2015).

The successful application of encoder-decoder models (Bahdanau et al., 2015; Sutskever et al., 2014) to a variety of NLP tasks has provided strong impetus to treat semantic parsing as a sequence transduction problem where an utterance is mapped to a target meaning representation in string format (Dong and Lapata, 2016; Jia and Liang, 2016; Kočiský et al., 2016). Such models still fall under the first approach, however, in contrast to previous work (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Liang et al., 2011) they reduce the need for domain-specific assumptions, grammar learning, and more generally extensive feature engineering. But this modeling flexibility comes at a cost since it is no longer possible to interpret how meaning composition is performed. Such knowledge plays a critical role in understand modeling limitations so as to build better semantic parsers. Moreover, without any task-specific prior knowledge, the learning problem is fairly unconstrained, both in terms of the possible derivations to consider and in terms of the target output which can be ill-formed (e.g., with extra or missing brackets).

In this work, we propose a neural semantic parser that alleviates the aforementioned problems. Our model falls under the second class of approaches where utterances are first mapped to an intermediate representation containing natural language predicates. However, rather than using an external parser (Reddy et al., 2014, 2016) or manually specified CCG grammars (Kwiatkowski et al., 2013), we induce intermediate representations in the form of predicate-argument structures

[1]Our code is available at https://github.com/cheng6076/scanner.

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 44–55
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1005

from data. This is achieved with a transition-based approach which by design yields recursive semantic structures, avoiding the problem of generating ill-formed meaning representations. Compared to most existing semantic parsers which employ a CKY style bottom-up parsing strategy (Krishnamurthy and Mitchell, 2012; Cai and Yates, 2013; Berant et al., 2013; Berant and Liang, 2014), the transition-based approach we proposed does not require feature decomposition over structures and thereby enables the exploration of rich, non-local features. The output of the transition system is then grounded (e.g., to a knowledge base) with a neural mapping model under the assumption that grounded and ungrounded structures are isomorphic.[2] As a result, we obtain a neural model that jointly learns to parse natural language semantics and induce a lexicon that helps grounding.

The whole network is trained end-to-end on natural language utterances paired with annotated logical forms or their denotations. We conduct experiments on four datasets, including GEOQUERY (which has logical forms; Zelle and Mooney 1996), SPADES (Bisk et al., 2016), WEBQUESTIONS (Berant et al., 2013), and GRAPHQUESTIONS (Su et al., 2016) (which have denotations). Our semantic parser achieves the state of the art on SPADES and GRAPHQUESTIONS, while obtaining competitive results on GEOQUERY and WEBQUESTIONS. A side-product of our modeling framework is that the induced intermediate representations can contribute to rationalizing neural predictions (Lei et al., 2016). Specifically, they can shed light on the kinds of representations (especially predicates) useful for semantic parsing. Evaluation of the induced predicate-argument relations against syntax-based ones reveals that they are interpretable and meaningful compared to heuristic baselines, but they sometimes deviate from linguistic conventions.

2 Preliminaries

Problem Formulation Let $\mathcal{K}$ denote a knowledge base or more generally a reasoning system, and x an utterance paired with a grounded meaning representation G or its denotation y. Our problem is to learn a semantic parser that maps x to G via an intermediate ungrounded representation U. When G is executed against $\mathcal{K}$, it outputs denotation y.

[2]We discuss the merits and limitations of this assumption in Section 5

Predicate	Usage	Sub-categories
answer	denotation wrapper	—
type	entity type checking	*stateid*, *cityid*, *riverid*, etc.
all	querying for an entire set of entities	—
aggregation	one-argument meta predicates for sets	*count*, *largest*, *smallest*, etc.
logical connectors	two-argument meta predicates for sets	*intersect*, *union*, *exclude*

Table 1: List of domain-general predicates.

Grounded Meaning Representation We represent grounded meaning representations in FunQL (Kate et al., 2005) amongst many other alternatives such as lambda calculus (Zettlemoyer and Collins, 2005), λ-DCS (Liang, 2013) or graph queries (Holzschuher and Peinl, 2013; Harris et al., 2013). FunQL is a variable-free query language, where each predicate is treated as a function symbol that modifies an argument list. For example, the FunQL representation for the utterance *which states do not border texas* is:

answer(*exclude*(*state(all)*, *next_to*(*texas*)))

where *next_to* is a domain-specific binary predicate that takes one argument (i.e., the entity *texas*) and returns a *set* of entities (e.g., the states bordering Texas) as its denotation. *all* is a special predicate that returns a collection of entities. *exclude* is a predicate that returns the difference between two input sets.

An advantage of FunQL is that the resulting *s*-expression encodes semantic compositionality and derivation of the logical forms. This property makes FunQL logical forms convenient to be predicted with recurrent neural networks (Vinyals et al., 2015; Choe and Charniak, 2016; Dyer et al., 2016). However, FunQL is less expressive than lambda calculus, partially due to the elimination of variables. A more compact logical formulation which our method also applies to is λ-DCS (Liang, 2013). In the absence of anaphora and composite binary predicates, conversion algorithms exist between FunQL and λ-DCS. However, we leave this to future work.

Ungrounded Meaning Representation We also use FunQL to express ungrounded meaning representations. The latter consist primarily of natural language predicates and domain-general predicates. Assuming for simplicity that domain-general predicates share the same vocabulary

in ungrounded and grounded representations, the ungrounded representation for the example utterance is:

answer(*exclude*(*states(all)*, *border*(*texas*)))

where *states* and *border* are natural language predicates. In this work we consider five types of domain-general predicates illustrated in Table 1. Notice that domain-general predicates are often implicit, or represent extra-sentential knowledge. For example, the predicate *all* in the above utterance represents all states in the domain which are not mentioned in the utterance but are critical for working out the utterance denotation. Finally, note that for certain domain-general predicates, it also makes sense to extract natural language rationales (e.g., *not* is indicative for *exclude*). But we do not find this helpful in experiments.

In this work we constrain ungrounded representations to be structurally isomorphic to grounded ones. In order to derive the target logical forms, all we have to do is replacing predicates in the ungrounded representations with symbols in the knowledge base.

3 Modeling

In this section, we discuss our neural model which maps utterances to target logical forms. The semantic parsing task is decomposed in two stages: we first explain how an utterance is converted to an intermediate representation (Section 3.1), and then describe how it is grounded to a knowledge base (Section 3.2).

3.1 Generating Ungrounded Representations

At this stage, utterances are mapped to intermediate representations with a transition-based algorithm. In general, the transition system generates the representation by following a derivation tree (which contains a set of applied rules) and some canonical generation order (e.g., depth-first). For FunQL, a simple solution exists since the representation itself encodes the derivation. Consider again *answer*(*exclude*(*states(all)*, *border*(*texas*))) which is tree structured. Each predicate (e.g., *border*) can be visualized as a non-terminal node of the tree and each entity (e.g., *texas*) as a terminal. The predicate *all* is a special case which acts as a terminal directly. We can generate the tree with a top-down, depth first transition system reminiscent of recurrent neural network grammars (RNNGs; Dyer et al. 2016). Similar to RNNG, our algorithm uses a buffer to store input tokens in the utterance and a stack to store partially completed trees. A major difference in our semantic parsing scenario is that tokens in the buffer are not fetched in a sequential order or removed from the buffer. This is because the lexical alignment between an utterance and its semantic representation is hidden. Moreover, some predicates cannot be clearly anchored to a token span. Therefore, we allow the generation algorithm to pick tokens and combine logical forms in arbitrary orders, conditioning on the entire set of sentential features. Alternative solutions in the traditional semantic parsing literature include a floating chart parser (Pasupat and Liang, 2015) which allows to construct logical predicates out of thin air.

Our transition system defines three actions, namely NT, TER, and RED, explained below.

NT(X) generates a Non-Terminal predicate. This predicate is either a natural language expression such as *border*, or one of the domain-general predicates exemplified in Table 1 (e.g., *exclude*). The type of predicate is determined by the placeholder X and once generated, it is pushed onto the stack and represented as a non-terminal followed by an open bracket (e.g., *'border('*). The open bracket will be closed by a reduce operation.

TER(X) generates a TERminal entity or the special predicate *all*. Note that the terminal choice does not include variable (e.g., $0, $1), since FunQL is a variable-free language which sufficiently captures the semantics of the datasets we work with. The framework could be extended to generate directly acyclic graphs by incorporating variables with additional transition actions for handling variable mentions and co-reference.

RED stands for REDuce and is used for subtree completion. It recursively pops elements from the stack until an open non-terminal node is encountered. The non-terminal is popped as well, after which a composite term representing the entire subtree, e.g., *border(texas)*, is pushed back to the stack. If a RED action results in having no more open non-terminals left on the stack, the transition system terminates. Table 2 shows the transition actions used to generate our running example.

The model generates the ungrounded representation U conditioned on utterance x by recursively calling one of the above three actions. Note that U is defined by a sequence of actions (denoted

Sentence: *which states do not border texas*
Non-terminal symbols in buffer: *which*, *states*, *do*, *not*, *border*
Terminal symbols in buffer: *texas*

Stack	**Action**	NT choice	TER choice
	NT	*answer*	
answer (	NT	*exclude*	
answer (*exclude* (	NT	*states*	
answer (*exclude* (*states* (	TER		*all*
answer (*exclude* (*states* (*all*	RED		
answer (*exclude* (*states* (*all*)	NT	*border*	
answer (*exclude* (*states* (*all*) , *border* (	TER		*texas*
answer (*exclude* (*states* (*all*) , *border* (*texas*	RED		
answer (*exclude* (*states* (*all*) , *border* (*texas*)	RED		
answer (*exclude* (*states* (*all*) , *border* (*texas*))	RED		
answer (*exclude* (*states* (*all*) , *border* (*texas*)))			

Table 2: Actions taken by the transition system for generating the ungrounded meaning representation of the example utterance. Symbols in red indicate domain-general predicates.

by a) and a sequence of term choices (denoted by u) as shown in Table 2. The conditional probability $p(U|x)$ is factorized over time steps as:

$$p(U|x) = p(a, u|x) = \prod_{t=1}^{T} p(a_t|a_{<t}, x)p(u_t|a_{<t}, x)^{\mathbb{I}(a_t \neq \text{RED})} \quad (1)$$

where $\mathbb{I}$ is an indicator function.

To predict the actions of the transition system, we encode the input buffer with a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) and the output stack with a stack-LSTM (Dyer et al., 2015). At each time step, the model uses the representation of the transition system e_t to predict an action:

$$p(a_t|a_{<t}, x) \propto \exp(W_a \cdot e_t) \quad (2)$$

where e_t is the concatenation of the buffer representation b_t and the stack representation s_t. While the stack representation s_t is easy to retrieve as the top state of the stack-LSTM, obtaining the buffer representation b_t is more involved. This is because we do not have an explicit buffer representation due to the non-projectivity of semantic parsing. We therefore compute at each time step an adaptively weighted representation of b_t (Bahdanau et al., 2015) conditioned on the stack representation s_t. This buffer representation is then concatenated with the stack representation to form the system representation e_t.

When the predicted action is either NT or TER, an ungrounded term u_t (either a predicate or an entity) needs to be chosen from the candidate list depending on the specific placeholder X. To select a domain-general term, we use the same representation of the transition system e_t to compute a probability distribution over candidate terms:

$$p(u_t^{\text{GENERAL}}|a_{<t}, x) \propto \exp(W_p \cdot e_t) \quad (3)$$

To choose a natural language term, we directly compute a probability distribution of all natural language terms (in the buffer) conditioned on the stack representation s_t and select the most relevant term (Jia and Liang, 2016):

$$p(u_t^{\text{NL}}|a_{<t}, x) \propto \exp(s_t) \quad (4)$$

When the predicted action is RED, the completed subtree is composed into a single representation on the stack. For the choice of composition function, we use a single-layer neural network as in Dyer et al. (2015), which takes as input the concatenated representation of the predicate and argument of the subtree.

3.2 Generating Grounded Representations

Since we constrain the network to learn ungrounded structures that are isomorphic to the target meaning representation, converting ungrounded representations to grounded ones becomes a simple lexical mapping problem. For simplicity, hereafter we do not differentiate natural language and domain-general predicates.

To map an ungrounded term u_t to a grounded term g_t, we compute the conditional probability

of g_t given u_t with a bi-linear neural network:

$$p(g_t|u_t) \propto \exp \vec{u_t} \cdot W_{ug} \cdot \vec{g_t}^\top \quad (5)$$

where $\vec{u_t}$ is the contextual representation of the ungrounded term given by the bidirectional LSTM, $\vec{g_t}$ is the grounded term embedding, and W_{ug} is the weight matrix.

The above grounding step can be interpreted as learning a lexicon: the model exclusively relies on the intermediate representation U to predict the target meaning representation G without taking into account any additional features based on the utterance. In practice, U may provide sufficient contextual background for closed domain semantic parsing where an ungrounded predicate often maps to a single grounded predicate, but is a relatively impoverished representation for parsing large open-domain knowledge bases like Freebase. In this case, we additionally rely on a discriminative reranker which ranks the grounded representations derived from ungrounded representations (see Section 3.4).

3.3 Training Objective

When the target meaning representation is available, we directly compare it against our predictions and back-propagate. When only denotations are available, we compare surrogate meaning representations against our predictions (Reddy et al., 2014). Surrogate representations are those with the correct denotations. When there exist multiple surrogate representations,[3] we select one randomly and back-propagate. The global effect of the above update rule is close to maximizing the marginal likelihood of denotations, which differs from recent work on weakly-supervised semantic parsing based on reinforcement learning (Neelakantan et al., 2017).

Consider utterance x with ungrounded meaning representation U, and grounded meaning representation G. Both U and G are defined with a sequence of transition actions (same for U and G) and a sequence of terms (different for U and G). Recall that $a = [a_1, \cdots, a_n]$ denotes the transition action sequence defining U and G; let $u = [u_1, \cdots, u_k]$ denote the ungrounded terms (e.g., predicates), and $g = [g_1, \cdots, g_k]$ the grounded terms. We aim to maximize the likelihood of the grounded meaning representation $p(G|x)$ over all training examples. This likelihood can be decomposed into the likelihood of the grounded action sequence $p(a|x)$ and the grounded term sequence $p(g|x)$, which we optimize separately.

For the grounded action sequence (which by design is the same as the ungrounded action sequence and therefore the output of the transition system), we can directly maximize the log likelihood $\log p(a|x)$ for all examples:

$$\mathcal{L}_a = \sum_{x \in \mathcal{T}} \log p(a|x) = \sum_{x \in \mathcal{T}} \sum_{t=1}^{n} \log p(a_t|x) \quad (6)$$

where $\mathcal{T}$ denotes examples in the training data.

For the grounded term sequence g, since the intermediate ungrounded terms are latent, we maximize the expected log likelihood of the grounded terms $\sum_u [p(u|x) \log p(g|u, x)]$ for all examples, which is a lower bound of the log likelihood $\log p(g|x)$:

$$\begin{aligned} \mathcal{L}_g &= \sum_{x \in \mathcal{T}} \sum_{u} [p(u|x) \log p(g|u, x)] \\ &= \sum_{x \in \mathcal{T}} \sum_{u} \left[p(u|x) \sum_{t=1}^{k} \log p(g_t|u_t) \right] \end{aligned} \quad (7)$$

The final objective is the combination of $\mathcal{L}_a$ and $\mathcal{L}_g$, denoted as $\mathcal{L}_G = \mathcal{L}_a + \mathcal{L}_g$. We optimize this objective with the method described in Lei et al. (2016).

3.4 Reranker

As discussed above, for open domain semantic parsing, solely relying on the ungrounded representation would result in an impoverished model lacking sentential context useful for disambiguation decisions. For all Freebase experiments, we followed previous work (Berant et al., 2013; Berant and Liang, 2014; Reddy et al., 2014) in additionally training a discriminative ranker to re-rank grounded representations globally.

The discriminative ranker is a maximum-entropy model (Berant et al., 2013). The objective is to maximize the log likelihood of the correct answer y given x by summing over all grounded candidates G with denotation y (i.e.,$[\![G]\!]_{\mathcal{K}} = y$):

$$\mathcal{L}_y = \sum_{(x,y) \in \mathcal{T}} \log \sum_{[\![G]\!]_{\mathcal{K}} = y} p(G|x) \quad (8)$$

$$p(G|x) \propto \exp\{f(G, x)\} \quad (9)$$

where $f(G, x)$ is a feature function that maps pair (G, x) into a feature vector. We give details on the features we used in Section 4.2.

[3] The average Freebase surrogate representations obtained with highest denotation match (F1) is 1.4.

4 Experiments

In this section, we verify empirically that our semantic parser derives useful meaning representations. We give details on the evaluation datasets and baselines used for comparison. We also describe implementation details and the features used in the discriminative ranker.

4.1 Datasets

We evaluated our model on the following datasets which cover different domains, and use different types of training data, i.e., pairs of natural language utterances and grounded meanings or question-answer pairs.

GEOQUERY (Zelle and Mooney, 1996) contains 880 questions and database queries about US geography. The utterances are compositional, but the language is simple and vocabulary size small. The majority of questions include at most one entity. SPADES (Bisk et al., 2016) contains 93,319 questions derived from CLUEWEB09 (Gabrilovich et al., 2013) sentences. Specifically, the questions were created by randomly removing an entity, thus producing sentence-denotation pairs (Reddy et al., 2014). The sentences include two or more entities and although they are not very compositional, they constitute a large-scale dataset for neural network training. WEBQUESTIONS (Berant et al., 2013) contains 5,810 question-answer pairs. Similar to SPADES, it is based on Freebase and the questions are not very compositional. However, they are real questions asked by people on the Web. Finally, GRAPHQUESTIONS (Su et al., 2016) contains 5,166 question-answer pairs which were created by showing 500 Freebase graph queries to Amazon Mechanical Turk workers and asking them to paraphrase them into natural language.

4.2 Implementation Details

Amongst the four datasets described above, GEOQUERY has annotated logical forms which we directly use for training. For the other three datasets, we treat surrogate meaning representations which lead to the correct answer as gold standard. The surrogates were selected from a subset of candidate Freebase graphs, which were obtained by entity linking. Entity mentions in SPADES have been automatically annotated with Freebase entities (Gabrilovich et al., 2013). For WEBQUESTIONS and GRAPHQUESTIONS, we follow the procedure described in Reddy et al. (2016). We identify potential entity spans using seven handcrafted part-of-speech patterns and associate them with Freebase entities obtained from the Freebase/KG API.[4] We use a structured perceptron trained on the entities found in WEBQUESTIONS and GRAPHQUESTIONS to select the top 10 non-overlapping entity disambiguation possibilities. We treat each possibility as a candidate input utterance, and use the perceptron score as a feature in the discriminative reranker, thus leaving the final disambiguation to the semantic parser.

Apart from the entity score, the discriminative ranker uses the following basic features. The first feature is the likelihood score of a grounded representation aggregating all intermediate representations. The second set of features include the embedding similarity between the relation and the utterance, as well as the similarity between the relation and the question words. The last set of features includes the answer type as indicated by the last word in the Freebase relation (Xu et al., 2016).

We used the Adam optimizer for training with an initial learning rate of 0.001, two momentum parameters [0.99, 0.999], and batch size 1. The dimensions of the word embeddings, LSTM states, entity embeddings and relation embeddings are $[50, 100, 100, 100]$. The word embeddings were initialized with Glove embeddings (Pennington et al., 2014). All other embeddings were randomly initialized.

4.3 Results

Experimental results on the four datasets are summarized in Tables 3–6. We present comparisons of our system which we call SCANNER (as a shorthand for **S**ymboli**C** me**A**ni**N**g r**E**p**R**esentation) against a variety of models previously described in the literature.

GEOQUERY results are shown in Table 5. The first block contains symbolic systems, whereas neural models are presented in the second block. We report accuracy which is defined as the proportion of the utterance that are correctly parsed to their gold standard logical forms. All previous neural systems (Dong and Lapata, 2016; Jia and Liang, 2016) treat semantic parsing as a sequence transduction problem and use LSTMs to directly map utterances to logical forms. SCANNER yields performance improvements over these

systems when using comparable data sources for training. Jia and Liang (2016) achieve better results with synthetic data that expands GEOQUERY; we could adopt their approach to improve model performance, however, we leave this to future work.

Table 6 reports SCANNER's performance on SPADES. For all Freebase related datasets we use average F1 (Berant et al., 2013) as our evaluation metric. Previous work on this dataset has used a semantic parsing framework similar to ours where natural language is converted to an intermediate syntactic representation and then grounded to Freebase. Specifically, Bisk et al. (2016) evaluate the effectiveness of four different CCG parsers on the semantic parsing task when varying the amount of supervision required. As can be seen, SCANNER outperforms all CCG variants (from unsupervised to fully supervised) without having access to any manually annotated derivations or lexicons. For fair comparison, we also built a neural baseline that encodes an utterance with a recurrent neural network and then predicts a grounded meaning representation directly (Ture and Jojic, 2016; Yih et al., 2016). Again, we observe that SCANNER outperforms this baseline.

Results on WEBQUESTIONS are summarized in Table 3. SCANNER obtains performance on par with the best symbolic systems (see the first block in the table). It is important to note that Bast and Haussmann (2015) develop a question answering system, which contrary to ours cannot produce meaning representations whereas Berant and Liang (2015) propose a sophisticated agenda-based parser which is trained borrowing ideas from imitation learning. SCANNER is conceptually similar to Reddy et al. (2016) who also learn a semantic parser via intermediate representations which they generate based on the output of a dependency parser. SCANNER performs competitively despite not having access to any linguistically-informed syntactic structures. The second block in Table 3 reports the results of several neural systems. Xu et al. (2016) represent the state of the art on WEBQUESTIONS. Their system uses Wikipedia to prune out erroneous candidate answers extracted from Freebase. Our model would also benefit from a similar post-processing step. As in previous experiments, SCANNER outperforms the neural baseline, too.

Finally, Table 4 presents our results on GRAPHQUESTIONS. We report F1 for SCANNER, the neural baseline model, and three symbolic systems presented in Su et al. (2016). SCANNER achieves a new state of the art on this dataset with a gain of 4.23 F1 points over the best previously reported model.

4.4 Analysis of Intermediate Representations

Since a central feature of our parser is that it learns intermediate representations with natural language predicates, we conducted additional experiments in order to inspect their quality. For GEOQUERY

Metrics	Accuracy
Exact match	79.3
Structure match	89.6
Token match	96.5

Table 7: GEOQUERY evaluation of ungrounded meaning representations. We report accuracy against a manually created gold standard.

which contains only 280 test examples, we manually annotated intermediate representations for the test instances and evaluated the learned representations against them. The experimental setup aims to shows how humans can participate in improving the semantic parser with feedback at the intermediate stage. In terms of evaluation, we use three metrics shown in Table 7. The first row shows the percentage of exact matches between the predicted representations and the human annotations. The second row refers to the percentage of structure matches, where the predicted representations have the same structure as the human annotations, but may not use the same lexical terms. Among structurally correct predictions, we additionally compute how many tokens are correct, as shown in the third row. As can be seen, the induced meaning representations overlap to a large extent with the human gold standard.

We also evaluated the intermediate representations created by SCANNER on the other three (Freebase) datasets. Since creating a manual gold standard for these large datasets is time-consuming, we compared the induced representations against the output of a syntactic parser. Specifically, we converted the questions to event-argument structures with EASYCCG (Lewis and Steedman, 2014), a high coverage and high accuracy CCG parser. EASYCCG extracts predicate-argument structures with a labeled F-score of 83.37%. For further comparison, we built a simple baseline which identifies predicates based on the output of the Stanford POS-tagger (Manning et al., 2014) following the ordering VBD $\gg$ VBN $\gg$ VB $\gg$ VBP $\gg$ VBZ $\gg$ MD.

As shown in Table 8, on SPADES and WEBQUESTIONS, the predicates learned by our model match the output of EASYCCG more closely than the heuristic baseline. But for GRAPHQUESTIONS which contains more compositional questions, the mismatch is higher. However, since the key idea of our model is to capture salient meaning for the task at hand rather than strictly obey syntax, we would not expect the

Dataset	SCANNER	Baseline
SPADES	51.2	45.5
–*conj* (1422)	56.1	66.4
–*control* (132)	28.3	40.5
–*pp* (3489)	46.2	23.1
–*subord* (76)	37.9	52.9
WEBQUESTIONS	42.1	25.5
GRAPHQUESTIONS	11.9	15.3

Table 8: Evaluation of predicates induced by SCANNER against EASYCCG. We report F1(%) across datasets. For SPADES, we also provide a breakdown for various utterance types.

predicates induced by our system to entirely agree with those produced by the syntactic parser. To further analyze how the learned predicates differ from syntax-based ones, we grouped utterances in SPADES into four types of linguistic constructions: coordination (*conj*), control and raising (*control*), prepositional phrase attachment (*pp*), and subordinate clauses (*subord*). Table 8 also shows the breakdown of matching scores per linguistic construction, with the number of utterances in each type. In Table 9, we provide examples of predicates identified by SCANNER, indicating whether they agree or not with the output of EASYCCG. As a reminder, the task in SPADES is to predict the entity masked by a *blank* symbol (_).

As can be seen in Table 8, the matching score is relatively high for utterances involving coordination and prepositional phrase attachments. The model will often identify informative predicates (e.g., nouns) which do not necessarily agree with linguistic intuition. For example, in the utterance *wilhelm_maybach and his son _ started maybach in 1909* (see Table 9), SCANNER identifies the predicate-argument structure *son(wilhelm_maybach)* rather than *started(wilhelm_maybach)*. We also observed that the model struggles with control and subordinate constructions. It has difficulty distinguishing control from raising predicates as exemplified in the utterance *ceo john_thain agreed to leave _* from Table 9, where it identifies the raising predicate *agreed*. For subordinate clauses, SCANNER tends to take shortcuts identifying as predicates words closest to the *blank* symbol.

5 Discussion

We presented a neural semantic parser which converts natural language utterances to grounded meaning representations via intermediate predicate-argument structures. Our model

essentially jointly learns how to parse natural language semantics and the lexicons that help grounding. Compared to previous neural semantic parsers, our model is more interpretable as the intermediate structures are useful for inspecting what the model has learned and whether it matches linguistic intuition.

An assumption our model imposes is that ungrounded and grounded representations are structurally isomorphic. An advantage of this assumption is that tokens in the ungrounded and grounded representations are strictly aligned. This allows the neural network to focus on parsing and lexical mapping, sidestepping the challenging structure mapping problem which would result in a larger search space and higher variance. On the negative side, the structural isomorphism assumption restricts the expressiveness of the model, especially since one of the main benefits of adopting a two-stage parser is the potential of capturing domain-independent semantic information via the intermediate representation. While it would be challenging to handle drastically non-isomorphic structures in the current model, it is possible to perform local structure matching, i.e., when the mapping between natural language and domain-specific predicates is many-to-one or one-to-many. For instance, Freebase does not contain a relation representing *daughter*, using instead two relations representing *female* and *child*. Previous work (Kwiatkowski et al., 2013) models such cases by introducing collapsing (for many-to-one mapping) and expansion (for one-to-many mapping) operators. Within our current framework, these two types of structural mismatches can be handled with semi-Markov assumptions (Sarawagi and Cohen, 2005; Kong et al., 2016) in the parsing (i.e., predicate selection) and the grounding steps, respectively. Aside from relaxing strict isomorphism, we would also like to perform cross-domain semantic parsing where the first stage of the semantic parser is shared across domains.

Acknowledgments We would like to thank three anonymous reviewers, members of the Edinburgh ILCC and the IBM Watson, and Abulhair Saparov for feedback. The support of the European Research Council under award number 681760 "Translating Multiple Modalities into Text" is gratefully acknowledged.

Abstract

Morphologically rich languages accentuate two properties of distributional vector space models: 1) the difficulty of inducing accurate representations for low-frequency word forms; and 2) insensitivity to distinct lexical relations that have similar distributional signatures. These effects are detrimental for language understanding systems, which may infer that *inexpensive* is a rephrasing for *expensive* or may not associate *acquire* with *acquires*. In this work, we propose a novel *morph-fitting* procedure which moves past the use of curated semantic lexicons for improving distributional vector spaces. Instead, our method injects morphological constraints generated using simple language-specific rules, pulling *inflectional* forms of the same word close together and pushing *derivational antonyms* far apart. In intrinsic evaluation over four languages, we show that our approach: **1)** improves low-frequency word estimates; and **2)** boosts the semantic quality of the entire word vector collection. Finally, we show that morph-fitted vectors yield large gains in the downstream task of *dialogue state tracking*, highlighting the importance of morphology for tackling long-tail phenomena in language understanding tasks.

1 Introduction

Word representation learning has become a research area of central importance in natural language processing (NLP), with its usefulness demonstrated across many application areas such as parsing (Chen and Manning, 2014; Johannsen et al., 2015), machine translation (Zou et al., 2013), and many others (Turian et al., 2010; Collobert et al., 2011). Most prominent word representation techniques are grounded in the *distributional hypothesis* (Harris, 1954), relying on word co-occurrence information in large textual corpora (Curran, 2004; Turney and Pantel, 2010; Mikolov et al., 2013; Mnih and Kavukcuoglu, 2013; Levy and Goldberg, 2014; Schwartz et al., 2015, i.a.).

Morphologically rich languages, in which "substantial grammatical information... is expressed at word level" (Tsarfaty et al., 2010), pose specific challenges for NLP. This is not always considered when techniques are evaluated on languages such as English or Chinese, which do not have rich morphology. In the case of distributional vector space models, morphological complexity brings two challenges to the fore:

1. Estimating Rare Words: A single lemma can have many different surface realisations. Naively treating each realisation as a separate word leads to sparsity problems and a failure to exploit their shared semantics. On the other hand, lemmatising the entire corpus can obfuscate the differences that exist between different word forms even though they share some aspects of meaning.

2. Embedded Semantics: Morphology can encode semantic relations such as antonymy (e.g. *literate* and *illiterate*, *expensive* and *inexpensive*) or (near-)synonymy (*north*, *northern*, *northerly*).

In this work, we tackle the two challenges jointly by introducing a *resource-light* vector space fine-tuning procedure termed *morph-fitting*. The proposed method does not require curated knowledge bases or gold lexicons. Instead, it makes use of the observation that morphology implicitly encodes semantic signals pertaining to synonymy (e.g., German word inflections *katalanisch, katalanischem, katalanischer* denote the same semantic concept in different grammatical roles), and antonymy (e.g., *mature* vs. *immature*), capitalising on the

Table 1: The nearest neighbours of three example words (*expensive*, *slow* and *book*) in English, German and Italian before (top) and after (bottom) morph-fitting.

proliferation of word forms in morphologically rich languages. Formalised as an instance of the post-processing *semantic specialisation* paradigm (Faruqui et al., 2015; Mrkšić et al., 2016), morph-fitting is steered by a set of linguistic constraints derived from simple language-specific rules which describe (a subset of) morphological processes in a language. The constraints emphasise similarity on one side (e.g., by extracting *morphological* synonyms), and antonymy on the other (by extracting *morphological* antonyms), see Fig. 1 and Tab. 2.

The key idea of the fine-tuning process is to pull synonymous examples described by the constraints closer together in the transformed vector space, while at the same time pushing antonymous examples away from each other. The explicit post-hoc injection of morphological constraints enables: **a)** the estimation of more accurate vectors for low-frequency words which are linked to their high-frequency forms by the constructed constraints;[1] this tackles the data sparsity problem; and **b)** specialising the distributional space to distinguish between similarity and relatedness (Kiela et al., 2015), thus supporting language understanding applications such as *dialogue state tracking* (DST).[2]

As a post-processor, morph-fitting allows the integration of morphological rules with any distributional vector space in any language: it treats an input distributional word vector space as a black box and fine-tunes it so that the transformed space reflects the knowledge coded in the input morphological constraints (e.g., Italian words *rispettoso* and *irrispetosa* should be far apart in the transformed vector space, see Fig. 1). Tab. 1 illustrates the effects of morph-fitting by qualitative examples in three languages: the vast majority of nearest neighbours are "morphological" synonyms.

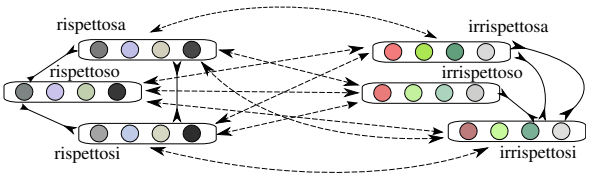

Figure 1: *Morph-fitting* in Italian. Representations for *rispettoso*, *rispettosa*, *rispettosi* (EN: *respectful*), are pulled closer together in the vector space (solid lines; ATTRACT constraints). At the same time, the model pushes them away from their antonyms (dashed lines; REPEL constraints) *irrispettoso*, *irrispettosa*, *irrispettosi* (EN: *disrespectful*), obtained through morphological affix transformation captured by language-specific rules (e.g., adding the prefix *ir-* typically negates the base word in Italian)

We demonstrate the efficacy of morph-fitting in four languages (English, German, Italian, Russian), yielding large and consistent improvements on benchmarking word similarity evaluation sets such as SimLex-999 (Hill et al., 2015), its multilingual extension (Leviant and Reichart, 2015), and SimVerb-3500 (Gerz et al., 2016). The improvements are reported for all four languages, and with a variety of input distributional spaces, verifying the robustness of the approach.

We then show that incorporating morph-fitted vectors into a state-of-the-art neural-network DST model results in improved tracking performance, especially for morphologically rich languages. We report an improvement of 4% on Italian, and 6% on German when using *morph-fitted* vectors instead of the distributional ones, setting a new state-of-the-art DST performance for the two datasets.[3]

[1] For instance, the vector for the word *katalanischem* which occurs only 9 times in the German Wikipedia will be pulled closer to the more reliable vectors for *katalanisch* and *katalanischer*, with frequencies of 2097 and 1383 respectively.

[2] Representation models that do not distinguish between synonyms and antonyms may have grave implications in downstream language understanding applications such as spoken dialogue systems: a user looking for *'an affordable Chinese restaurant in west Cambridge'* does not want a recommendation for *'an expensive Thai place in east Oxford'*.

[3] There are no readily available DST datasets for Russian.

2 Morph-fitting: Methodology

Preliminaries In this work, we focus on four languages with varying levels of morphological complexity: English (EN), German (DE), Italian (IT), and Russian (RU). These correspond to languages in the Multilingual SimLex-999 dataset. Vocabularies W_{en}, W_{de}, W_{it}, W_{ru} are compiled by retaining all word forms from the four Wikipedias with word frequency over 10, see Tab. 3. We then extract sets of linguistic constraints from these (large) vocabularies using a set of simple language-specific *if-then-else* rules, see Tab. 2.[4] These constraints (Sect. 2.2) are used as input for the vector space post-processing ATTRACT-REPEL algorithm (outlined in Sect. 2.1).

2.1 The ATTRACT-REPEL Model

The ATTRACT-REPEL model, proposed by Mrkšić et al. (2017b), is an extension of the PARAGRAM procedure proposed by Wieting et al. (2015). It provides a generic framework for incorporating *similarity* (e.g. *successful* and *accomplished*) and *antonymy* constraints (e.g. *nimble* and *clumsy*) into pre-trained word vectors. Given the initial vector space and collections of ATTRACT and REPEL constraints A and R, the model gradually modifies the space to bring the designated word vectors closer together or further apart. The method's cost function consists of three terms. The first term pulls the ATTRACT examples $(x_l, x_r) \in A$ closer together. If B_A denotes the current mini-batch of ATTRACT examples, this term can be expressed as:

$$A(\mathcal{B}_A) = \sum_{(x_l,x_r)\in\mathcal{B}_A} \left(ReLU\left(\delta_{att} + \mathbf{x}_l\mathbf{t}_l - \mathbf{x}_l\mathbf{x}_r\right)\right. \\ \left. + \; ReLU\left(\delta_{att} + \mathbf{x}_r\mathbf{t}_r - \mathbf{x}_l\mathbf{x}_r\right)\right)$$

where δ_{att} is the similarity margin which determines how much closer synonymous vectors should be to each other than to each of their respective negative examples. $ReLU(x) = \max(0, x)$ is the standard rectified linear unit (Nair and Hinton, 2010). The 'negative' example $\mathbf{t}_i$ for each word x_i in any ATTRACT pair is the word vector *closest* to $\mathbf{x}_i$ among the examples in the current mini-batch (distinct from its target synonym and $\mathbf{x}_i$ itself). This means that this term forces synonymous words from the in-batch ATTRACT constraints to be closer to one another than to any other word in the current mini-batch.

The second term pushes antonyms away from each other. If $(x_l, x_r) \in B_R$ is the current mini-batch of REPEL constraints, this term can be expressed as follows:

$$R(\mathcal{B}_R) = \sum_{(x_l,x_r)\in\mathcal{B}_R} \left(ReLU\left(\delta_{rpl} + \mathbf{x}_l\mathbf{x}_r - \mathbf{x}_l\mathbf{t}_r\right)\right. \\ \left. + \; ReLU\left(\delta_{rpl} + \mathbf{x}_l\mathbf{x}_r - \mathbf{x}_r\mathbf{t}_r\right)\right)$$

In this case, each word's 'negative' example is the (in-batch) word vector furthest away from it (and distinct from the word's target antonym). The intuition is that we want antonymous words from the input REPEL constraints to be *further away* from each other than from any other word in the current mini-batch; δ_{rpl} is now the *repel* margin.

The final term of the cost function serves to retain the abundance of semantic information encoded in the starting distributional space. If $\mathbf{x}_i^{init}$ is the initial distributional vector and $V(\mathcal{B})$ is the set of all vectors present in the given mini-batch, this term (per mini-batch) is expressed as follows:

$$R(\mathcal{B}_A, \mathcal{B}_R) = \sum_{\mathbf{x}_i\in V(\mathcal{B}_A\cup\mathcal{B}_R)} \lambda_{reg} \left\|\mathbf{x}_i^{init} - \mathbf{x}_i\right\|_2$$

where λ_{reg} is the L2 regularisation constant.[5] This term effectively *pulls* word vectors towards their initial (distributional) values, ensuring that relations encoded in initial vectors persist as long as they do not contradict the newly injected ones.

English	German	Italian

Table 2: Example synonymous (inflectional; top) and antonymous (derivational; bottom) constraints.

2.2 Language-Specific Rules and Constraints

Semantic Specialisation with Constraints The fine-tuning ATTRACT-REPEL procedure is entirely driven by the input ATTRACT and REPEL sets of

[4] A native speaker can easily come up with these sets of morphological rules (or at least with a reasonable subset of them) without any linguistic training. What is more, the rules for DE, IT, and RU were created by non-native, non-fluent speakers with a limited knowledge of the three languages, exemplifying the simplicity and portability of the approach.

[5] We use hyperparameter values $\delta_{att} = 0.6$, $\delta_{rpl} = 0.0$, $\lambda_{reg} = 10^{-9}$ from prior work without fine-tuning. We train all models for 10 epochs with AdaGrad (Duchi et al., 2011).

	$\|W\|$	$\|A\|$	$\|R\|$
English	1,368,891	231,448	45,964
German	1,216,161	648,344	54,644
Italian	541,779	278,974	21,400
Russian	950,783	408,400	32,174

Table 3: Vocabulary sizes and counts of ATTRACT (A) and REPEL (R) constraints.

constraints. These can be extracted from a variety of semantic databases such as WordNet (Fellbaum, 1998), the Paraphrase Database (Ganitkevitch et al., 2013; Pavlick et al., 2015), or BabelNet (Navigli and Ponzetto, 2012; Ehrmann et al., 2014) as done in prior work (Faruqui et al., 2015; Wieting et al., 2015; Mrkšić et al., 2016, i.a.). In this work, we investigate another option: extracting constraints *without* curated knowledge bases in a spectrum of languages by exploiting inherent language-specific properties related to linguistic morphology. This relaxation ensures a wider portability of ATTRACT-REPEL to languages and domains without readily available or adequate resources.

Extracting ATTRACT Pairs The core difference between *inflectional* and *derivational morphology* can be summarised in a few lines as follows: the former refers to a set of processes through which the word form expresses meaningful syntactic information, e.g., verb tense, without any change to the semantics of the word. On the other hand, the latter refers to the formation of new words with semantic shifts in meaning (Schone and Jurafsky, 2001; Haspelmath and Sims, 2013; Lazaridou et al., 2013; Zeller et al., 2013; Cotterell and Schütze, 2017).

For the ATTRACT constraints, we focus on *inflectional* rather than on *derivational morphology* rules as the former preserve the full meaning of a word, modifying it only to reflect grammatical roles such as verb tense or case markers (e.g., *(en_read, en_reads)* or *(de_katalanisch, de_katalanischer)*). This choice is guided by our intent to fine-tune the original vector space in order to improve the embedded semantic relations.

We define two rules for English, widely recognised as morphologically simple (Avramidis and Koehn, 2008; Cotterell et al., 2016b). These are: **(R1)** *if* $w_1, w_2 \in W_{en}$, where $w_2 = w_1$ + *ing/ed/s*, *then* add (w_1, w_2) and (w_2, w_1) to the set of ATTRACT constraints A. This rule yields pairs such as *(look, looks), (look, looking), (look, looked)*.

If $w[:-1]$ is a function which strips the last character from word w, the second rule is: **(R2)** *if* w_1 ends with the letter *e and* $w_1 \in W_{en}$ *and* $w_2 \in W_{en}$, where $w_2 = w_1[:-1]$ + *ing/ed*, *then* add (w_1, w_2) and (w_2, w_1) to A. This creates pairs such as *(create, creating)* and *(create, created)*. Naturally, introducing more sophisticated rules is possible in order to cover for other special cases and morphological irregularities (e.g., *sweep / swept*), but in all our EN experiments, A is based on the two simple EN rules R1 and R2.

The other three languages, with more complicated morphology, yield a larger number of rules. In Italian, we rely on the sets of rules spanning: (1) regular formation of plural (*libro / libri*); (2) regular verb conjugation (*aspettare / aspettiamo*); (3) regular formation of past participle (*aspettare / aspettato*); and (4) rules regarding grammatical gender (*bianco / bianca*). Besides these, another set of rules is used for German and Russian: (5) regular declension (e.g., *asiatisch / asiatischem*).

Extracting REPEL Pairs As another source of implicit semantic signals, W also contains words which represent *derivational antonyms*: e.g., two words that denote concepts with opposite meanings, generated through a derivational process. We use a standard set of EN "antonymy" prefixes: AP_{en} = *{dis, il, un, in, im, ir, mis, non, anti}* (Fromkin et al., 2013). *If* $w_1, w_2 \in W_{en}$, where w_2 is generated by adding a prefix from AP_{en} to w_1, *then* (w_1, w_2) and (w_2, w_1) are added to the set of REPEL constraints R. This rule generates pairs such as *(advantage, disadvantage)* and *(regular, irregular)*. An additional rule replaces the suffix *-ful* with *-less*, extracting antonyms such as *(careful, careless)*.

Following the same principle, we use AP_{de} = *{un, nicht, anti, ir, in, miss}*, AP_{it} = *{in, ir, im, anti}*, and AP_{ru} = *{*не, анти*}*. For instance, this generates an IT pair *(rispettoso, irrispettoso)* (see Fig. 1). For DE, we use another rule targeting suffix replacement: *-voll* is replaced by *-los*.

We further expand the set of REPEL constraints by transitively combining antonymy pairs from the previous step with inflectional ATTRACT pairs. This step yields additional constraints such as *(rispettosa, irrispettosi)* (see Fig. 1). The final A and R constraint counts are given in Tab. 3. The full sets of rules are available as supplemental material.

3 Experimental Setup

Training Data and Setup For each of the four languages we train the skip-gram with negative sampling (SGNS) model (Mikolov et al., 2013)

on the latest Wikipedia dump of each language. We induce 300-dimensional word vectors, with the frequency cut-off set to 10. The vocabulary sizes $|W|$ for each language are provided in Tab. 3.[6] We label these collections of vectors SGNS-LARGE.

Other Starting Distributional Vectors We also analyse the impact of *morph-fitting* on other collections of well-known EN word vectors. These vectors have varying vocabulary coverage and are trained with different architectures. We test standard distributional models: Common-Crawl GloVe (Pennington et al., 2014), SGNS vectors (Mikolov et al., 2013) with various contexts (*BOW* = bag-of-words; *DEPS* = dependency contexts), and training data (*PW* = Polyglot Wikipedia from Al-Rfou et al. (2013); *8B* = 8 billion token `word2vec` corpus), following (Levy and Goldberg, 2014) and (Schwartz et al., 2015). We also test the symmetric-pattern based vectors of Schwartz et al. (2016) (*SymPat-Emb*), count-based PMI-weighted vectors reduced by SVD (Baroni et al., 2014) (*Count-SVD*), a model which replaces the context modelling function from CBOW with bidirectional LSTMs (Melamud et al., 2016) (*Context2Vec*), and two sets of EN vectors trained by injecting multilingual information: *BiSkip* (Luong et al., 2015) and *MultiCCA* (Faruqui and Dyer, 2014).

We also experiment with standard well-known distributional spaces in other languages (IT and DE), available from prior work (Dinu et al., 2015; Luong et al., 2015; Vulić and Korhonen, 2016a).

Morph-fixed Vectors A baseline which utilises an equal amount of knowledge as morph-fitting, termed *morph-fixing*, fixes the vector of each word to the distributional vector of its most frequent inflectional synonym, tying the vectors of low-frequency words to their more frequent inflections. For each word w_1, we construct a set of $M+1$ words $W_{w_1} = \{w_1, w'_1, \ldots, w'_M\}$ consisting of the word w_1 itself and all M words which co-occur with w_1 in the ATTRACT constraints. We then choose the word w'_{max} from the set W_{w_1} with the maximum frequency in the training data, and fix all other word vectors in W_{w_1} to its word vector. The morph-fixed vectors (MFIX) serve as our primary baseline, as they outperformed another straightforward baseline based on *stemming* across all of our intrinsic and extrinsic experiments.

Morph-fitting Variants We analyse two variants of morph-fitting: (1) using ATTRACT constraints only (MFIT-A), and (2) using both ATTRACT and REPEL constraints (MFIT-AR).

4 Intrinsic Evaluation: Word Similarity

Evaluation Setup and Datasets The first set of experiments intrinsically evaluates *morph-fitted* vector spaces on word similarity benchmarks, using Spearman's rank correlation as the evaluation metric. First, we use the SimLex-999 dataset, as well as SimVerb-3500, a recent EN verb pair similarity dataset providing similarity ratings for 3,500 verb pairs.[7] SimLex-999 was translated to DE, IT, and RU by Leviant and Reichart (2015), and they crowdsourced similarity scores from native speakers. We use this dataset for our multilingual evaluation.[8]

Morph-fitting EN Word Vectors As the first experiment, we morph-fit a wide spectrum of EN distributional vectors induced by various architectures (see Sect. 3). The results on SimLex and SimVerb are summarised in Tab. 4. The results with EN SGNS-LARGE vectors are shown in Fig. 3a. Morph-fitted vectors bring consistent improvement across all experiments, regardless of the quality of the initial distributional space. This finding confirms that the method is robust: its effectiveness does not depend on the architecture used to construct the initial space. To illustrate the improvements, note that the best score on SimVerb for a model trained on running text is achieved by *Context2vec* ($\rho = 0.388$); injecting morphological constraints into this vector space results in a gain of 7.1 ρ points.

Experiments on Other Languages We next extend our experiments to other languages, testing both morph-fitting variants. The results are summarised in Tab. 5, while Fig. 3a-3d show results for the morph-fitted SGNS-LARGE vectors. These scores confirm the effectiveness and robustness of morph-fitting across languages, suggesting that the idea of fitting to morphological constraints is indeed language-agnostic, given the set of language-specific rule-based constraints. Fig. 3 also demon-

[6] Other SGNS parameters were set to standard values (Baroni et al., 2014; Vulić and Korhonen, 2016b): 15 epochs, 15 negative samples, global learning rate: .025, subsampling rate: $1e-4$. Similar trends in results persist with $d = 100, 500$.

[7] Unlike other gold standard resources such as WordSim-353 (Finkelstein et al., 2002) or MEN (Bruni et al., 2014), SimLex and SimVerb provided explicit guidelines to discern between semantic similarity and association, so that related but non-similar words (e.g. *cup* and *coffee*) have a low rating.

[8] Since Leviant and Reichart (2015) re-scored the original EN SimLex, we use their EN SimLex version for consistency.

Vectors	Evaluation	
	SimLex-999	SimVerb-3500
1. SG-BOW2-PW (300) (Mikolov et al., 2013)	.339 → **.439**	.277 → **.381**
2. GloVe-6B (300) (Pennington et al., 2014)	.324 → **.438**	.286 → **.405**
3. Count-SVD (500) (Baroni et al., 2014)	.267 → **.360**	.199 → **.301**
4. SG-DEPS-PW (300) (Levy and Goldberg, 2014)	.376 → **.434**	.313 → **.418**

Table 5: Results on multilingual SimLex-999 (EN, DE, and IT) with two morph-fitting variants.

strates that the morph-fitted vector spaces consistently outperform the morph-fixed ones.

The comparison between MFIT-A and MFIT-AR indicates that both sets of constraints are important for the fine-tuning process. MFIT-A yields consistent gains over the initial spaces, and (consistent) further improvements are achieved by also incorporating the antonymous REPEL constraints. This demonstrates that both types of constraints are useful for semantic specialisation.

Comparison to Other Specialisation Methods We also tried using other post-processing specialisation models from the literature in lieu of ATTRACT-REPEL using the same set of "morphological" synonymy and antonymy constraints. We compare ATTRACT-REPEL to the retrofitting model

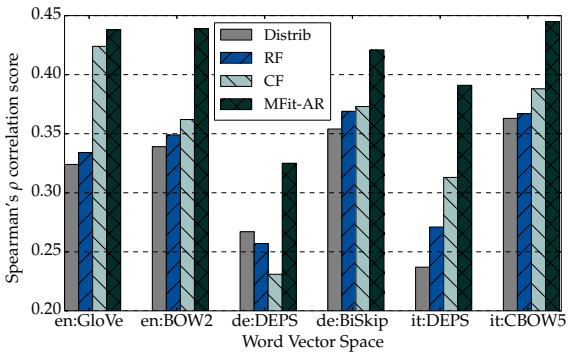

Figure 2: A comparison of morph-fitting (the MFIT-AR variant) with two other standard specialisation approaches using the same set of morphological constraints: Retrofitting (RF) (Faruqui et al., 2015) and Counter-fitting (CF) (Mrkšić et al., 2016). Spearman's ρ correlation scores on the multilingual SimLex-999 dataset for the same six distributional spaces from Tab. 5.

of (Faruqui et al., 2015) and counter-fitting (Mrkšić et al., 2017a). The two baselines were trained for 20 iterations using suggested settings. The results for EN, DE, and IT are summarised in Fig. 2. They clearly indicate that MFIT-AR outperforms the two other post-processors for each language. We hypothesise that the difference in performance mainly stems from context-sensitive vector space updates performed by ATTRACT-REPEL. Conversely, the other two models perform pairwise updates which do not consider what effect each update has on the example pair's relation to other word vectors (for a detailed comparison, see (Mrkšić et al., 2017b)).

Besides their lower performance, the two other specialisation models have additional disadvantages compared to the proposed morph-fitting model. First, retrofitting is able to incorporate only synonymy/ATTRACT pairs, while our results demonstrate the usefulness of both types of constraints, both for intrinsic evaluation (Tab. 5) and downstream tasks (see later Fig. 3). Second, counter-fitting is computationally intractable with SGNS-LARGE vectors, as its regularisation term involves the computation of all pairwise distances between words in the vocabulary.

Further Discussion The simplicity of the used language-specific rules does come at a cost of occasionally generating incorrect linguistic constraints such as *(tent, intent)*, *(prove, improve)* or *(press, impress)*. In future work, we will study how to fur-

ther refine extracted sets of constraints. We also plan to conduct experiments with gold standard morphological lexicons on languages for which such resources exist (Sylak-Glassman et al., 2015; Cotterell et al., 2016b), and investigate approaches which learn morphological inflections and derivations in different languages automatically as another potential source of morphological constraints (Soricut and Och, 2015; Cotterell et al., 2016a; Faruqui et al., 2016; Kann et al., 2017; Aharoni and Goldberg, 2017, i.a.).

5 Downstream Task: Dialogue State Tracking (DST)

Goal-oriented dialogue systems provide conversational interfaces for tasks such as booking flights or finding restaurants. In *slot-based* systems, application domains are specified using *ontologies* that define the search constraints which users can express. An ontology consists of a number of *slots* and their assorted *slot values*. In a *restaurant search* domain, sets of slot-values could include PRICE = [*cheap, expensive*] or FOOD = [*Thai, Indian, ...*].

The DST model is the first component of modern dialogue pipelines (Young, 2010). It serves to capture the intents expressed by the user at each dialogue turn and update the *belief state*. This probability distribution over the possible dialogue states (defined by the domain ontology) is the system's internal estimate of the user's goals. It is used by the downstream *dialogue manager* component to choose the subsequent system response (Su et al., 2016). The following example shows the true dialogue state in a multi-turn dialogue:

User: What's good in the southern part of town?
`inform(area=south)`
System: Vedanta is the top-rated Indian place.
User: How about something cheaper?
`inform(area=south, price=cheap)`
System: Seven Days is very popular. Great hot pot.
User: What's the address?
`inform(area=south, price=cheap); request(address)`
System: Seven Days is at 66 Regent Street.

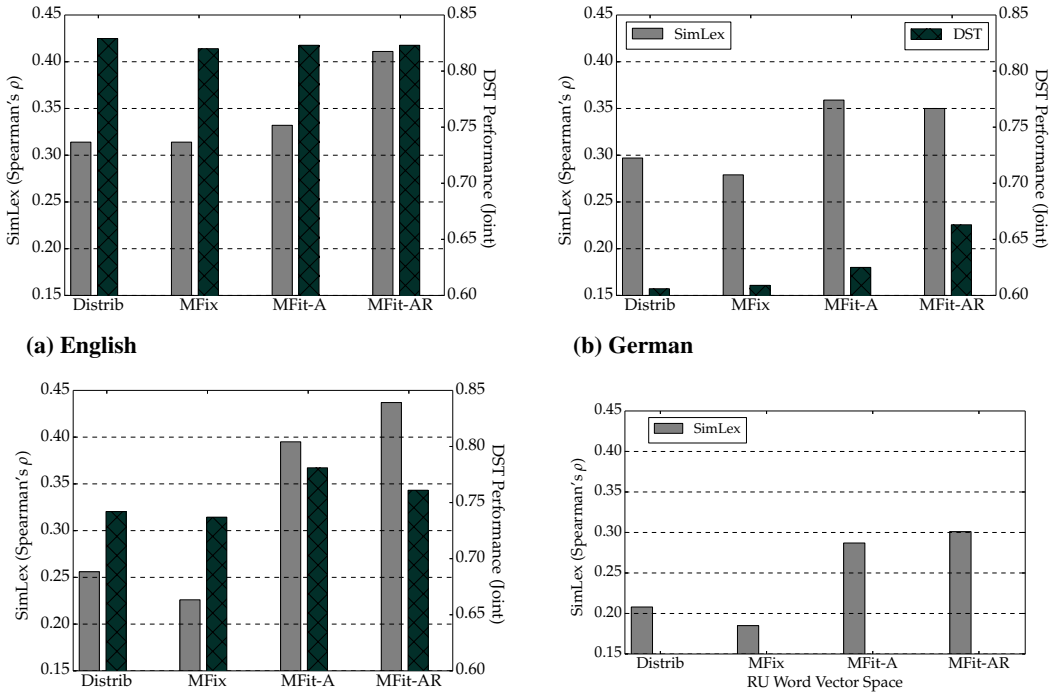
The Dialogue State Tracking Challenge (DSTC) shared task series formalised the evaluation and provided labelled DST datasets (Henderson et al., 2014a,b; Williams et al., 2016). While a plethora of DST models are available based on, e.g., handcrafted rules (Wang et al., 2014) or conditional random fields (Lee and Eskenazi, 2013), the recent DST methodology has seen a shift towards neural-network architectures (Henderson et al., 2014c,d; Zilka and Jurcicek, 2015; Mrkšić et al., 2015; Perez and Liu, 2017; Liu and Perez, 2017; Vodolán et al., 2017; Mrkšić et al., 2017a, i.a.).

Model: Neural Belief Tracker To detect intents in user utterances, most existing models rely on either (or both): **1)** Spoken Language Understanding models which require large amounts of annotated training data; or **2)** hand-crafted, domain-specific lexicons which try to capture lexical and morphological variation. The Neural Belief Tracker (NBT) is a novel DST model which overcomes both issues by reasoning purely over pre-trained word vectors (Mrkšić et al., 2017a). The NBT learns to compose these vectors into intermediate utterance and context representations. These are then used to decide which of the ontology-defined intents (goals) have been expressed by the user. The NBT model keeps word vectors *fixed* during training, so that unseen, yet related words can be mapped to the right intent at test time (e.g. *northern* to *north*).

Data: Multilingual WOZ 2.0 Dataset Our DST evaluation is based on the WOZ dataset, released by Wen et al. (2017). In this Wizard-of-Oz setup, two Amazon Mechanical Turk workers assumed the role of the user and the system asking/providing information about restaurants in Cambridge (operating over the same ontology and database used for DSTC2 (Henderson et al., 2014a)). Users typed instead of speaking, removing the need to deal with noisy speech recognition. In DSTC datasets, users would quickly adapt to the system's inability to deal with complex queries. Conversely, the WOZ setup allowed them to use sophisticated language. The WOZ 2.0 release expanded the dataset to 1,200 dialogues (Mrkšić et al., 2017a). In this work, we use translations of this dataset to Italian and German, released by Mrkšić et al. (2017b).

Evaluation Setup The principal metric we use to measure DST performance is the *joint goal accuracy*, which represents the proportion of test set dialogue turns where all user goals expressed up to that point of the dialogue were decoded correctly (Henderson et al., 2014a). The NBT models for EN, DE and IT are trained using four variants of the SGNS-LARGE vectors: **1)** the initial distributional vectors; **2)** *morph-fixed* vectors; **3)** and **4)** the two variants of *morph-fitted* vectors (see Sect. 3).

As shown by Mrkšić et al. (2017b), *semantic specialisation* of the employed word vectors ben-



(a) English **(b) German**

(c) Italian **(d) Russian**

Figure 3: An overview of the results (Spearman's ρ correlation) for four languages on SimLex-999 (grey bars, left y axis) and the downstream DST performance (dark bars, right y axis) using SGNS-LARGE vectors ($d = 300$), see Tab. 3 and Sect. 3. The left y axis measures the intrinsic word similarity performance, while the right y axis provides the scale for the DST performance (there are no DST datasets for Russian).

efits DST performance across all three languages. However, large gains on SimLex-999 do not always induce correspondingly large gains in downstream performance. In our experiments, we investigate the extent to which *morph-fitting* improves DST performance, and whether these gains exhibit stronger correlation with intrinsic performance.

Results and Discussion The dark bars (against the right axes) in Fig. 3 show the DST performance of NBT models making use of the four vector collections. IT and DE benefit from both kinds of *morph-fitting*: IT performance increases from $74.1 \rightarrow 78.1$ (MFIT-A) and DE performance rises even more: $60.6 \rightarrow 66.3$ (MFIT-AR), setting a new state-of-the-art score for both datasets. The *morph-fixed* vectors do not enhance DST performance, probably because fixing word vectors to their highest frequency inflectional form eliminates useful semantic content encoded in the original vectors. On the other hand, morph-fitting makes use of this information, supplementing it with semantic relations between different morphological forms. These conclusions are in line with the SimLex gains, where morph-fitting outperforms both distributional and *morph-fixed* vectors.

English performance shows little variation across the four word vector collections investigated here. This corroborates our intuition that, as a morphologically simpler language, English stands to gain less from fine-tuning the morphological variation for downstream applications. This result again points at the discrepancy between intrinsic and extrinsic evaluation: the considerable gains in SimLex performance do not necessarily induce similar gains in downstream performance. Additional discrepancies between SimLex and downstream DST performance are detected for German and Italian. While we observe a slight drop in SimLex performance with the DE MFIT-AR vectors compared to the MFIT-A ones, their relative performance is reversed in the DST task. On the other hand, we see the opposite trend in Italian, where the MFIT-A vectors score lower than the MFIT-AR vectors on SimLex, but higher on the DST task. In summary, we believe these results show that SimLex is not a perfect proxy for downstream performance in language understanding tasks. Regardless, its performance does correlate with downstream performance to a large extent, providing a useful indicator for the usefulness of specific word vector

spaces for extrinsic tasks such as DST.

6 Related Work

Semantic Specialisation A standard approach to incorporating external information into vector spaces is to pull the representations of similar words closer together. Some models integrate such constraints into the training procedure, modifying the prior or the regularisation (Yu and Dredze, 2014; Xu et al., 2014; Bian et al., 2014; Kiela et al., 2015), or using a variant of the SGNS-style objective (Liu et al., 2015; Osborne et al., 2016). Another class of models, popularly termed *retrofitting*, injects lexical knowledge from available semantic databases (e.g., WordNet, PPDB) into pre-trained word vectors (Faruqui et al., 2015; Jauhar et al., 2015; Wieting et al., 2015; Nguyen et al., 2016; Mrkšić et al., 2016). Morph-fitting falls into the latter category. However, instead of resorting to curated knowledge bases, and experimenting solely with English, we show that the *morphological richness* of any language can be exploited as a source of inexpensive supervision for fine-tuning vector spaces, at the same time specialising them to better reflect true semantic similarity, and learning more accurate representations for low-frequency words.

Word Vectors and Morphology The use of morphological resources to improve the representations of morphemes and words is an active area of research. The majority of proposed architectures encode morphological information, provided either as gold standard morphological resources (Sylak-Glassman et al., 2015) such as CELEX (Baayen et al., 1995) or as an external analyser such as Morfessor (Creutz and Lagus, 2007), along with distributional information jointly at *training* time in the language modelling (LM) objective (Luong et al., 2013; Botha and Blunsom, 2014; Qiu et al., 2014; Cotterell and Schütze, 2015; Bhatia et al., 2016, i.a.). The key idea is to learn a morphological composition function (Lazaridou et al., 2013; Cotterell and Schütze, 2017) which synthesises the representation of a word given the representations of its constituent morphemes. Contrary to our work, these models typically coalesce all lexical relations.

Another class of models, operating at the character level, shares a similar methodology: such models compose token-level representations from subcomponent embeddings (subwords, morphemes, or characters) (dos Santos and Zadrozny, 2014; Ling et al., 2015; Cao and Rei, 2016; Kim et al., 2016; Wieting et al., 2016; Verwimp et al., 2017, i.a.).

In contrast to prior work, our model *decouples* the use of morphological information, now provided in the form of inflectional and derivational rules transformed into constraints, from the actual training. This pipelined approach results in a simpler, more portable model. In spirit, our work is similar to Cotterell et al. (2016b), who formulate the idea of post-training specialisation in a generative Bayesian framework. Their work uses gold morphological lexicons; we show that competitive performance can be achieved using a non-exhaustive set of simple rules. Our framework facilitates the inclusion of *antonyms* at no extra cost and naturally extends to constraints from other sources (e.g., WordNet) in future work. Another practical difference is that we focus on similarity and evaluate morph-fitting in a well-defined downstream task where the artefacts of the distributional hypothesis are known to prompt statistical system failures.

7 Conclusion and Future Work

We have presented a novel *morph-fitting* method which injects morphological knowledge in the form of linguistic constraints into word vector spaces. The method makes use of implicit semantic signals encoded in inflectional and derivational rules which describe the morphological processes in a language. The results in intrinsic word similarity tasks show that *morph-fitting* improves vector spaces induced by distributional models across four languages. Finally, we have shown that the use of *morph-fitted* vectors boosts the performance of downstream language understanding models which rely on word representations as features, especially for morphologically rich languages such as German.

Future work will focus on other potential sources of morphological knowledge, porting the framework to other morphologically rich languages and downstream tasks, and on further refinements of the post-processing specialisation algorithm and the constraint selection.

Abstract

In recent years word-embedding models have gained great popularity due to their remarkable performance on several tasks, including word analogy questions and caption generation. An unexpected "side-effect" of such models is that their vectors often exhibit compositionality, i.e., *adding* two word-vectors results in a vector that is only a small angle away from the vector of a word representing the semantic composite of the original words, e.g., "man" + "royal" = "king".

This work provides a theoretical justification for the presence of additive compositionality in word vectors learned using the Skip-Gram model. In particular, it shows that additive compositionality holds in an even stricter sense (small distance rather than small angle) under certain assumptions on the process generating the corpus. As a corollary, it explains the success of vector calculus in solving word analogies. When these assumptions do not hold, this work describes the correct non-linear composition operator.

Finally, this work establishes a connection between the Skip-Gram model and the Sufficient Dimensionality Reduction (SDR) framework of Globerson and Tishby: the parameters of SDR models can be obtained from those of Skip-Gram models simply by adding information on symbol frequencies. This shows that Skip-Gram embeddings are optimal in the sense of Globerson and Tishby and, further, implies that the heuristics commonly used to approximately fit Skip-Gram models can be used to fit SDR models.

1 Introduction

The strategy of representing words as vectors has a long history in computational linguistics and machine learning. The general idea is to find a map from words to vectors such that word-similarity and vector-similarity are in correspondence. Whilst vector-similarity can be readily quantified in terms of distances and angles, quantifying word-similarity is a more ambiguous task. A key insight in that regard is to posit that the meaning of a word is captured by "the company it keeps" (Firth, 1957) and, therefore, that two words that keep company with similar words are likely to be similar themselves.

In the simplest case, one seeks vectors whose inner products approximate the co-occurrence frequencies. In more sophisticated methods co-occurrences are reweighed to suppress the effect of more frequent words (Rohde et al., 2006) and/or to emphasize pairs of words whose co-occurrence frequency maximally deviates from the independence assumption (Church and Hanks, 1990).

An alternative to seeking word-embeddings that reflect co-occurrence statistics is to extract the vectorial representation of words from non-linear statistical language models, specifically neural networks. (Bengio et al., 2003) already proposed (i) associating with each vocabulary word a *feature vector*, (ii) expressing the *probability function* of word sequences in terms of the feature vectors of the words in the sequence, and (iii) learning *simultaneously* the vectors and the parameters of the probability function. This approach came into prominence recently through works of Mikolov et al. (see below) whose main departure from (Bengio et al., 2003) was to follow the suggestion of (Mnih and Hinton, 2007) and trade-away the expressive capacity of general neural-network models for the scalability (to very large

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 69–76
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1007

corpora) afforded by (the more restricted class of) log-linear models.

An unexpected side effect of deriving word-embeddings via neural networks is that the word-vectors produced appear to enjoy (approximate) *additive compositionality*: adding two word-vectors often results in a vector whose nearest word-vector belongs to the word capturing the composition of the added words, e.g., "man" + "royal" = "king" (Mikolov et al., 2013c). This unexpected property allows one to use these vectors to answer word-analogy questions *algebraically*, e.g., answering the question "Man is to king as woman is to ___" by returning the word whose word-vector is nearest to the vector

$$\mathbf{v}(\text{king}) - \mathbf{v}(\text{man}) + \mathbf{v}(\text{woman}).$$

In this work we focus on explaining the source of this phenomenon for the most prominent such model, namely the Skip-Gram model introduced in (Mikolov et al., 2013a). The Skip-Gram model learns vector representations of words based on their patterns of co-occurrence in the training corpus as follows: it assigns to each word c in the vocabulary V, a "context" and a "target" vector, respectively $\mathbf{u}_c$ and $\mathbf{v}_c$, which are to be used in order to predict the words that appear around each occurrence of c within a window of Δ tokens. Specifically, the log probability of any target word w to occur at any position within distance Δ of a context word c is taken to be proportional to the inner product between u_c and v_w, i.e., letting $n = |V|$,

$$p(w|c) = \frac{\mathrm{e}^{\mathbf{u}_c^T \mathbf{v}_w}}{\sum_{i=1}^{n} \mathrm{e}^{\mathbf{u}_c^T \mathbf{v}_i}} \quad . \tag{1}$$

Further, Skip-Gram assumes that the conditional probability of each possible set of words in a window around a context word c factorizes as the product of the respective conditional probabilities:

$$p(w_{-\Delta}, \ldots, w_{\Delta}|c) = \prod_{\substack{\delta=-\Delta \\ \delta \neq 0}}^{\Delta} p(w_\delta|c). \tag{2}$$

(Mikolov et al., 2013a) proposed learning the Skip-Gram parameters on a training corpus by using maximum likelihood estimation under (1) and (2). Thus, if w_i denotes the i-th word in the training corpus and T the length of the corpus, we seek the word vectors that maximize

$$\frac{1}{T} \sum_{i=1}^{T} \sum_{\substack{\delta=-\Delta \\ \delta \neq 0}}^{\Delta} \log p(w_{i+\delta}|w_i) \quad . \tag{3}$$

As mentioned, the normalized context vectors obtained from maximizing (3) under (1) and (2) exhibit additive compositionality. For example, the cosine distance between the sum of the context vectors of the words "Vietnam" and "capital" and the context vector of the word "Hanoi" is small.

While there has been much interest in using algebraic operations on word vectors to carry out semantic operations like composition, and mathematically-flavored explanations have been offered (e.g., in the recent work (Paperno and Baroni, 2016)), the only published work which attempts a rigorous theoretical understanding of this phenomenon is (Arora et al., 2016). This work guarantees that word vectors can be recovered by factorizing the so-called PMI matrix, and that algebraic operations on these word vectors can be used to solve analogies, under certain conditions on the process that generated the training corpus. Specifically, the word vectors must be known *a priori, before their recovery, and to have been generated by randomly scaling uniformly sampled vectors from the unit sphere*[1]. Further, the ith word in the corpus must have been selected with probability proportional to $\mathrm{e}^{\mathbf{u}_w^T \mathbf{c}_i}$, where the "discourse" vector $\mathbf{c}_i$ governs the topic of the corpus at the ith word. Finally, the discourse vector is assumed to evolve according to a random walk on the unit sphere that has a uniform stationary distribution.

By way of contrast, our results assume nothing *a priori* about the properties of the word vectors. In fact, the connection we establish between the Skip-Gram and the Sufficient Dimensionality Reduction model of (Globerson and Tishby, 2003) shows that the word vectors learned by Skip-Gram are information-theoretically optimal. Further, the context word c in the Skip-Gram model essentially serves the role that the discourse vector does in the PMI model of (Arora et al., 2016): the words neighboring c are selected with probability proportional to $\mathrm{e}^{\mathbf{u}_c^T \mathbf{v}_w}$. We find the exact non-linear composition operator when no assumptions are made on the context word. When an analogous assumption to that of (Arora et al., 2016) is made, that the

[1] More generally, it suffices that the word vectors have certain properties consistent with this sampling process.

context words are uniformly distributed, we prove that the composition operator reduces to vector addition.

While our primary motivation has been to provide a better theoretical understanding of word compositionality in the popular Skip-Gram model, our connection with the SDR method illuminates a much more general point about the practical applicability of the Skip-Gram model. In particular, it addresses the question of whether, for a given corpus, fitting a Skip-Gram model will give good embeddings. Even if we are making reasonable linguistic assumptions about how to model words and the interdependencies of words in a corpus, it's not clear that these have to hold universally on all corpuses to which we apply Skip-Gram. However, the fact that when we fit a Skip-Gram model we are fitting an SDR model (up to frequency information), and the fact that SDR models are information-theoretically optimal in a certain sense, argues that regardless of whether the Skip-Gram assumptions hold, Skip-Gram always gives us optimal features in the following sense: the learned context embeddings and target embeddings preserve the maximal amount of mutual information between any pair of random variables X and Y consistent with the observed co-occurence matrix, where Y is the target word and X is the predictor word (in a min-max sense, since there are many ways of coupling X and Y, each of which may have different amounts of mutual information). Importantly, this statement requires no assumptions on the distribution $P(X, Y)$.

2 Compositionality of Skip-Gram

In this section, we first give a mathematical formulation of the intuitive notion of compositionality of words. We then prove that the composition operator for the Skip-Gram model in full generality is a non-linear function of the vectors of the words being composed. Under a single simplifying assumption, the operator *linearizes* and reduces to the addition of the word vectors. Finally, we explain how linear compositionality allows for solving word analogies with vector algebra.

A natural way of capturing the compositionality of words is to say that the *set* of context words $c_1, \ldots, c_m$ has the same meaning as the single word c if for every other word w,

$$p(w|c_1, \ldots, c_m) = p(w|c) \ .$$

Although this is an intuitively satisfying definition, we never expect it to hold exactly; instead, we replace exact equality with the minimization of KL-divergence. That is, we state that the best candidate for having the same meaning as the set of context words C is the word

$$\arg\min_{c \in V} \mathrm{D}_{\mathrm{KL}}(p(\cdot|C) \,|\, p(\cdot|c)) \ . \tag{4}$$

We refer to any vector that minimizes (4) as a *paraphrase* of the set of words C.

There are two natural concerns with (4). The first is that, in general, it is not clear how to define $p(\cdot|C)$. The second is that KL-divergence minimization is a hard problem, as it involves optimization over many high dimensional probability distributions. Our main result shows that both of these problems go away for any language model that satisfies the following two assumptions:

A1. For every word c, there exists Z_c such that for every word w,

$$p(w|c) = \frac{1}{Z_c} \exp(\mathbf{u}_c^T \mathbf{v}_w) \ . \tag{5}$$

A2. For every set of words $C = \{c_1, c_2, \ldots, c_m\}$, there exists Z_C such that for every word w,

$$p(w|C) = \frac{p(w)^{1-m}}{Z_C} \prod_{i=1}^{m} p(w|c_i) \ . \tag{6}$$

Clearly, the Skip-Gram model satisfies A1 by definition. We prove that it also satisfies A2 when $m \leq \Delta$ (Lemma 1). Next, we state a theorem that holds for any model satisfying assumptions A1 and A2, including the Skip-Gram model when $m \leq \Delta$.

Theorem 1. *In every word model that satisfies A1 and A2, for every set of words $C = \{c_1, \ldots, c_m\}$, any paraphase c of C satisfies*

$$\sum_{w \in V} p(w|c)\mathbf{v}_w = \sum_{w \in V} p(w|C)\mathbf{v}_w \ . \tag{7}$$

Theorem 1 characterizes the composition operator for any language model which satisfies our two assumptions; in general, this operator is *not* addition. Instead, a paraphrase c is a vector such that the average word vector under $p(\cdot|c)$ matches that under $p(\cdot|C)$. When the expectations in (7) can be computed, the composition operator can be implemented by solving a non-linear system of equations to find a vector $\mathbf{u}$ for which the left-hand side of (7) equals the right-hand side.

Our next result proves that although the composition operator is nontrivial in the general case, to recover vector addition as the composition operator, it suffices to assume that the word frequency is *uniform*.

Theorem 2. *In every word model that satisfies A1, A2, and where $p(w) = 1/|V|$ for every $w \in V$, the paraphrase of $C = \{c_1, \ldots, c_m\}$ is*

$$\mathbf{u}_1 + \ldots + \mathbf{u}_m \ .$$

As word frequencies are typically much closer to a Zipf distribution (Piantadosi, 2014), the uniformity assumption of Theorem 2 is not realistic. That said, we feel it is important to point out that, as reported in (Mikolov et al., 2013b), additivity captures compositionality *more* accurately when the training set is manipulated so that the prior distribution of the words is made *closer* to uniform.

Using composition to solve analogies. It has been observed that word vectors trained using nonlinear models like Skip-Gram tend to encode semantic relationships between words as linear relationships between the word vectors (Mikolov et al., 2013b; Pennington et al., 2014; Levy and Goldberg, 2014). In particular, analogies of the form "man:woman::king:?" can often be solved by taking ? to be the word in the vocabulary whose context vector has the smallest angle with $\mathbf{u}_{\text{woman}} + (\mathbf{u}_{\text{king}} - \mathbf{u}_{\text{man}})$. Theorems 1 and 2 offer insight into the solution such analogy questions.

We first consider solving an analogy of the form "m:w::k:?"" in the case where the composition operator is nonlinear. The fact that m and w share a relationship means m is a paraphrase of the set of words $\{w, R\}$, where R is a set of words encoding the relationship between m and w. Similarly, the fact that k and ? share the same relationship means k is a paraphrase of the set of words $\{?, R\}$. By Theorem 1, we have that R and ? must satisfy

$$\sum_{\ell \in V} p(\ell|m) v_\ell = \sum_{\ell \in V} p(\ell|w, R) v_\ell \quad \text{and}$$
$$\sum_{\ell \in V} p(\ell|k) v_\ell = \sum_{\ell \in V} p(\ell|?, R) v_\ell .$$

We see that solving analogies when the composition operator is nonlinear requires the solution of two highly nonlinear systems of equations. In sharp contrast, when the composition operator is linear, the solution of analogies delightfully reduces to elementary vector algebra. To see this, we again begin with the assertion that the fact that m and w share a relationship means m is a paraphrase of the set of words $\{w, R\}$; Similarly, k is a paraphrase of $\{?, R\}$. By Theorem 2,

$$\mathbf{u}_m = \mathbf{u}_w + \mathbf{u}_r \quad \text{and}$$
$$\mathbf{u}_k = \mathbf{u}_? + \mathbf{u}_r,$$

which gives the expected relationship

$$\mathbf{u}_? = \mathbf{u}_k + (\mathbf{u}_w - \mathbf{u}_m).$$

Note that because this expression for $\mathbf{u}_?$ is in terms of k, w, and m, there is actually no need to assume that R is a set of actual words in V.

2.1 Proofs

Proof of Theorem 1. Note that $p(w|C)$ equals

$$\frac{p(w)^{1-m}}{Z_C} \prod_{i=1}^{m} p(w|c_i)$$
$$= \frac{p(w)^{1-m}}{Z_C} \exp\left(\sum_{i=1}^{m} \mathbf{u}_{c_i}^T \mathbf{v}_w - \sum_{i=1}^{m} \log Z_{c_i} \right)$$
$$= \frac{1}{Z} p(w)^{1-m} \exp(\mathbf{u}_C^T \mathbf{v}_w) \ ,$$

where $Z = Z_C \prod_{i=1}^m Z_i$, and $\mathbf{u}_C = \sum_{i=1}^m \mathbf{u}_i$.

Minimizing the KL-divergence

$$\mathrm{D}_{\mathrm{KL}}(p(\cdot|c_1, \ldots, c_m) \| p(\cdot|c))$$

as a function of c is equivalent to maximizing the negative cross-entropy as a function of $\mathbf{u}_c$, i.e., as maximizing

$$Q(\mathbf{u}_c) = Z \sum_w \frac{\exp(\mathbf{u}_C^T \mathbf{v}_w)}{p(w)^{m-1}} (\mathbf{u}_c^T \mathbf{v}_w - \log Z_c) \ .$$

Since Q is concave, the maximizers occur where its gradient vanishes. As $\nabla_{\mathbf{u}_c} Q$ equals

$$Z \sum_w \frac{\exp(\mathbf{u}_C^T \mathbf{v}_w)}{p(w)^{m-1}} \left[\mathbf{v}_w - \frac{\sum_{\ell=1}^n \exp(\mathbf{u}_c^T \mathbf{v}_\ell) \mathbf{v}_\ell}{\sum_{k=1}^n \exp(\mathbf{u}_c^T \mathbf{v}_k)} \right]$$
$$= \frac{\sum_{\ell=1}^n \exp(\mathbf{u}_c^T \mathbf{v}_\ell) \mathbf{v}_\ell}{\sum_{k=1}^n \exp(\mathbf{u}_c^T \mathbf{v}_k)} - Z \sum_w \frac{\exp(\mathbf{u}_C^T \mathbf{v}_w) \mathbf{v}_w}{p(w)^{m-1}}$$
$$= \sum_{w \in V} p(w|c) \mathbf{v}_w - \sum_{w \in V} p(w|c_1, \ldots, c_m) \mathbf{v}_w \ ,$$

we see that (7) follows. □

Proof of Theorem 2. Recall that $\mathbf{u}_C = \sum_{i=1}^m \mathbf{u}_i$. When $p(w) = 1/|V|$ for all $w \in V$, the negative cross-entropy simplifies to

$$Q(\mathbf{u}_c) = Z \sum_w \exp\left(\mathbf{u}_C^T \mathbf{v}_w\right) \left(\mathbf{u}_c^T \mathbf{v}_w - \log Z_c\right) \ ,$$

and its gradient $\nabla_{\mathbf{u}_c} Q$ to

$$Z \sum_w \exp({\mathbf{u}_C}^T \mathbf{v}_w) \left[\mathbf{v}_w - \frac{\sum_{\ell=1}^n \exp(\mathbf{u}_c^T \mathbf{v}_\ell) \mathbf{v}_\ell}{\sum_{k=1}^n \exp(\mathbf{u}_c^T \mathbf{v}_k)} \right]$$
$$= Z \sum_w \exp({\mathbf{u}_C}^T \mathbf{v}_w) \mathbf{v}_w - \sum_w \exp(\mathbf{u}_c^T \mathbf{v}_w) \mathbf{v}_w \ .$$

Thus, $\nabla Q(\mathbf{u}_C) = 0$ and since Q is concave, $\mathbf{u}_C$ is its unique maximizer. □

Lemma 1. *The Skip-Gram model satisfies assumption A2 when $m \leq \Delta$.*

Proof of Lemma 1. First, assume that $m = \Delta$. In the Skip-Gram model target words are conditionally independent given a context word, i.e.,

$$p(c_1, \ldots, c_m | w) = \prod_{i=1}^m p(c_i | w).$$

Applying Baye's rule,

$$\begin{aligned} p(w | c_1, \ldots, c_m) &= \frac{p(c_1, \ldots, c_m | w) p(w)}{p(c_1, \ldots, c_m)} \\ &= \frac{p(w)}{p(c_1, \ldots, c_m)} \prod_{i=1}^m p(c_i | w) \\ &= \frac{p(w)}{p(c_1, \ldots, c_m)} \prod_{i=1}^m \frac{p(w | c_i) p(c_i)}{p(w)} \\ &= \frac{p(w)^{1-m}}{Z_C} \prod_{i=1}^m p(w | c_i) \ , \qquad (8) \end{aligned}$$

where $Z_C = 1/\left(\prod_{i=1}^m p(c_i)\right)$. This establishes the result when $m = \Delta$. The cases $m < \Delta$ follow by marginalizing out $\Delta - m$ context words in the equality (8). □

Projection of paraphrases onto the vocabulary Theorem 2 states that if there is a word c in the vocabulary V whose context vector equals the sum of the context vectors of the words $c_1, \ldots, c_m$, then c has the same "meaning", in the sense of (4), as the composition of the words $c_1, \ldots, c_m$. For any given set of words $C = \{c_1, \ldots, c_m\}$, it is unlikely that there exists a word $c \in V$ whose context vector is exactly equal to the sum of the context vectors of the words $c_1, \ldots, c_m$. Similarly, in Theorem 1, the solution(s) to (7) will most likely not equal the context vector of any word in V. In both cases, we thus need to project the vector(s) onto words in our vocabulary in some manner.

Since Theorem 1 holds for any prior over V, in theory, we could enumerate all words in V and find the word(s) that minimize the difference of the left hand side of (7) from the right hand side. In practice, it turns out that the *angle* between the context vector of a word $w \in V$ and solution-vector(s) is a good proxy and one gets very good experimental results by selecting as the paraphrase of a collection of words, the word that minimizes the angle to the paraphrase vector.

Minimizing the angle has been empirically successful at capturing composition in multiple log-linear word models. One way to understand the success of this approach is to recall that each word c is characterized by a categorical distribution over all other words w, as stated in (1). The peaks of this categorical distribution are precisely the words with which c co-occurs most often. These words characterize c more than all the other words in the vocabulary, so it is reasonable to expect that a word c' whose categorical distribution has similar peaks as the categorical distribution of c is similar in meaning to c. Note that the location of the peaks of $p(\cdot|c)$ are immune to the scaling of $\mathbf{u}_c$ (athough the values of $p(\cdot|c)$ may change); thus, the words w which best characterize c are those for which $\mathbf{v}_w$ has a high inner product with $\mathbf{u}_c / \|\mathbf{u}_c\|_2$. Since

$$\left| \frac{\mathbf{u}_c^T \mathbf{v}_w}{\|\mathbf{u}_c\|_2} - \frac{\mathbf{u}_{c'}^T \mathbf{v}_w}{\|\mathbf{u}_{c'}\|_2} \right| \leq \sqrt{2\left(1 - \frac{\mathbf{u}_c^T \mathbf{u}_{c'}}{\|\mathbf{u}_c\|_2 \|\mathbf{u}_{c'}\|_2}\right)} \|\mathbf{v}_w\|_2,$$

it is clear that if the angle between the context representations of c and c' is small, the distributions $p(w|c)$ and $p(w|c')$ will tend to have similar peaks.

3 Skip-Gram learns a Sufficient Dimensionality Reduction Model

The Skip-Gram model assumes that the distribution of the neighbors of a word follows a specific exponential parametrization of a categorical distribution. There is empirical evidence that this model generates features that are useful for NLP tasks, but there is no *a priori* guarantee that the training corpus was generated in this manner. In this section, we provide theoretical support for the usefulness of the features learned even when the Skip-Gram model is misspecified.

To do so, we draw a connection between Skip-Gram and the Sufficient Dimensionality Reduction (SDR) factorization of Globerson and Tishby (Globerson and Tishby, 2003). The SDR model

learns optimal[2] embeddings for discrete random variables X and Y *without assuming any parametric form on the distributions* of X and Y, and it is useful in a variety of applications, including information retrieval, document classification, and association analysis (Globerson and Tishby, 2003). As it turns out, these embeddings, like Skip-Gram, are obtained by learning the parameters of an exponentially parameterized distribution. In Theorem 3 below, we show that if a Skip-Gram model is fit to the cooccurence statistics of X and Y, then the output can be trivially modified (by adding readily-available information on word frequencies) to obtain the parameters of an SDR model.

This connection is significant for two reasons: first, the original algorithm of (Globerson and Tishby, 2003) for learning SDR embeddings is expensive, as it involves information projections. Theorem 3 shows that if one can efficiently fit a Skip-Gram model, then one can efficiently fit an SDR model. This implies that Skip-Gram specific approximation heuristics like negative-sampling, hierarchical softmax, and Glove, which are believed to return high-quality approximations to Skip-Gram parameters (Mikolov et al., 2013b; Pennington et al., 2014), can be used to efficiently approximate SDR model parameters. Second, (Globerson and Tishby, 2003) argues for the optimality of the SDR embedding in any domain where the training information on X and Y consists of their coocurrence statistics; this optimality and the Skip-Gram/SDR connection argues for the use of Skip-Gram approximations in such domains, and supports the positive experimental results that have been observed in applications in network science (Grover and Leskovec, 2016), proteinomics (Asgari and Mofrad, 2015), and other fields.

As stated above, the SDR factorization solves the problem of finding information-theoretically optimal features, given co-occurrence statistics for a pair of discrete random variables X and Y. Associate a vector $\mathbf{w}_i$ to the ith state of X, a vector $\mathbf{h}_j$ to the jth state of Y, and let $\mathbf{W} = [\mathbf{w}_1^T \cdots \mathbf{w}_{|X|}^T]^T$ and $\mathbf{H}$ be defined similarly. Globerson and Tishby show that such optimal features can be obtained from a low-rank factorization of the matrix $\mathbf{G}$ of co-occurence measurements: G_{ij} counts the number of times state i of X has been observed to co-occur with state j of Y. The loss of this factorization is measured using the KL-divergence, and so the optimal features are obtained from solving the problem

$$\arg\min_{\mathbf{W},\mathbf{H}} \mathrm{D}_{\mathrm{KL}} \left(\frac{\mathbf{G}}{Z_{\mathbf{G}}} \middle\| \frac{1}{Z_{\mathbf{W},\mathbf{H}}} \mathrm{e}^{\mathbf{W}\mathbf{H}^T} \right).$$

Here, $Z_{\mathbf{G}} = \sum_{ij} G_{ij}$ normalizes $\mathbf{G}$ into an estimate of the joint pmf of X and Y, and similarly $Z_{\mathbf{W},\mathbf{H}}$ is the constant that normalizes $\mathrm{e}^{\mathbf{W}\mathbf{H}^T}$ into a joint pmf. The expression $\mathrm{e}^{\mathbf{W}\mathbf{H}^T}$ denotes entry-wise exponentiation of $\mathbf{W}\mathbf{H}^T$.

Now we revisit the Skip-Gram training objective, and show that it differs from the SDR objective only slightly. Whereas the SDR objective measures the distance between the pmfs given by (normalized versions of) $\mathbf{G}$ and $\mathrm{e}^{\mathbf{W}\mathbf{H}^T}$, the Skip-Gram objective measures the distance between the pmfs given by (normalized versions of) *the rows* of $\mathbf{G}$ and $\mathrm{e}^{\mathbf{W}\mathbf{H}^T}$. That is, SDR emphasizes fitting the entire pmfs, while Skip-Gram emphasizes fitting conditional distributions.

Before presenting our main result, we state and prove the following lemma, which is of independent interest and is used in the proof of our main theorem. Recall that Skip-Gram represents each word c as a multinomial distribution over all other words w, and it learns the parameters for these distributions by a maximum likelihood estimation. It is known that learning model parameters by maximum likelihood estimation is equivalent to minimizing the KL-divergence of the learned model from the empirical distribution; the following lemma establishes the KL-divergence that Skip-Gram minimizes.

Lemma 2. *Let $\mathbf{G}$ be the word co-occurrence matrix constructed from the corpus on which a Skip-Gram model is trained, in which case G_{cw} is the number of times word w occurs as a neighboring word of c in the corpus. For each word c, let g_c denote the empirical frequency of the word in the corpus, so that*

$$g_c = \sum_w G_{cw} / \sum_{t,w} G_{t,w}.$$

Given a positive vector $\mathbf{x}$, let $\hat{\mathbf{x}} = \mathbf{x}/\|\mathbf{x}\|_1$. Then, the Skip-Gram model parameters $\mathbf{U} = \begin{bmatrix} \mathbf{u}_1 & \cdots & \mathbf{u}_{|V|} \end{bmatrix}^T$ and $\mathbf{V} = \begin{bmatrix} \mathbf{v}_1 & \cdots & \mathbf{u}_{|V|} \end{bmatrix}^T$

[2] Optimal in an information-theoretic sense: they preserve the maximal mutual information between any pair of random variables with the observed coocurrence statistics, without regard to the underlying joint distribution.

minimize the objective

$$\sum_c g_c \mathrm{D_{KL}}(\hat{\mathbf{g}^c} \,\|\, \widehat{\mathrm{e}^{\mathbf{u}_c^T \mathbf{V}^T}}),$$

where $\mathbf{g}^c$ *is the cth row of* G.

Proof. Recall that Skip-Gram chooses $\mathbf{U}$ and $\mathbf{V}$ to maximize

$$Q = \frac{1}{T} \sum_{i=1}^{T} \sum_{\substack{\delta=-C \\ \delta \neq 0}}^{C} \log p(w_{i+\delta}|w_i) \ ,$$

where

$$p(w|c) = \frac{\mathrm{e}^{\mathbf{u}_c^T \mathbf{v}_w}}{\sum_{i=1}^{n} \mathrm{e}^{\mathbf{u}_c^T \mathbf{v}_i}} \ .$$

This objective can be rewritten using the pairwise cooccurence statistics as

$$\begin{aligned}
Q &= \frac{1}{T} \sum_{c,w} G_{cw} \log p(w|c) \\
&= \frac{1}{T} \sum_c \left[\left(\sum_t G_{ct} \right) \sum_w \frac{G_{cw}}{\sum_t G_{ct}} \log p(w|c) \right] \\
&\propto \frac{1}{T} \sum_c \left[\frac{(\sum_t G_{ct})}{(\sum_{tw} G_{tw})} \sum_w \frac{G_{cw}}{\sum_t G_{ct}} \log p(w|c) \right] \\
&= \sum_c g_c \left(\sum_w \left(\hat{\mathbf{g}^c}\right)_w \log p(w|c) \right) \\
&= \sum_c g_c \left(-\mathrm{D_{KL}}(\hat{\mathbf{g}^c} \,\|\, p(\cdot|c)) - H(\hat{\mathbf{g}^c}) \right),
\end{aligned}$$

where $H(\cdot)$ denotes the entropy of a distribution. It follows that since Skip-Gram maximizes Q, it minimizes

$$\sum_c g_c \mathrm{D_{KL}}(\hat{\mathbf{g}^c} \,\|\, p(\cdot|c)) = \sum_c g_c \mathrm{D_{KL}}(\hat{\mathbf{g}^c} \,\|\, \widehat{\mathrm{e}^{\mathbf{u}_c^T \mathbf{V}^T}}).$$

□

We now prove our main theorem of this section, which states that SDR parameters can be obtained by augmenting the Skip-Gram embeddings to account for word frequencies.

Theorem 3. *Let* $\mathbf{U}, \mathbf{V}$ *be the results of fitting a Skip-Gram model to* $\mathbf{G}$*, and consider the augmented matrices*

$$\tilde{\mathbf{U}} = [\mathbf{U} \,|\, \boldsymbol{\alpha}] \text{ and } \tilde{\mathbf{V}} = [\mathbf{V} \,|\, \mathbf{1}],$$

where

$$\alpha_c = \log \left(\frac{g_c}{\sum_w \mathrm{e}^{\mathbf{u}_c^T \mathbf{v}_w}} \right) \text{ and } g_c = \frac{\sum_w G_{c,w}}{\sum_{t,w} G_{t,w}}.$$

Then, the features $(\tilde{\mathbf{U}}, \tilde{\mathbf{V}})$ *constitute a sufficient dimensionality reduction of* $\mathbf{G}$.

Proof. For convenience, let $\overline{\mathbf{G}}$ denote the joint pdf matrix $\mathbf{G}/Z_{\mathbf{G}}$, and let $\widehat{\mathbf{G}}$ denote the matrix obtained by normalizing each row of $\mathbf{G}$ to be a probability distribution. Then, it suffices to show that $D_{KL}(\overline{\mathbf{G}} \,\|\, q_{\mathbf{W},\mathbf{H}})$ is minimized over the set of probability distributions

$$\left\{ q_{\mathbf{W},\mathbf{H}} \,\middle|\, q_{\mathbf{W},\mathbf{H}}(w,c) = \frac{1}{Z} \left(\mathrm{e}^{\mathbf{W}\mathbf{H}^T} \right)_{cw} \right\},$$

when $\mathbf{W} = \tilde{\mathbf{U}}$ and $\mathbf{H} = \tilde{\mathbf{V}}$.

To establish this result, we use a chain rule for the KL-divergence. Recall that if we denote the expected KL-divergence between two marginal pmfs by

$$\begin{aligned}
&D_{KL}(p(\cdot|c) \| q(\cdot|c)) \\
&\quad = \sum_c p(c) \left(\sum_w p(w|c) \log \left(\frac{p(w|c)}{q(w|c)} \right) \right),
\end{aligned}$$

then the KL-divergence satisfies the chain rule:

$$\begin{aligned}
&D_{KL}(p(w,c) \| q(w,c)) \\
&\quad = D_{KL}(p(c) \| q(c)) + D_{KL}(p(w|c) \| q(w|c)).
\end{aligned}$$

Using this chain rule, we get

$$\begin{aligned}
&D_{KL}(\overline{\mathbf{G}} \,\|\, q_{\mathbf{W},\mathbf{H}}(w,c)) \qquad (9) \\
&\quad = D_{KL}(\mathbf{g} \,\|\, q_{\mathbf{W},\mathbf{H}}(c)) + D_{KL}(\widehat{\mathbf{G}} \| q_{\mathbf{W},\mathbf{H}}(w|c)).
\end{aligned}$$

Note that the second term in this sum is, in the notation of Lemma 2,

$$D_{KL}(\widehat{\mathbf{G}} \| q_{\mathbf{W},\mathbf{H}}(w|c)) = \sum_c g_c \mathrm{D_{KL}}(\hat{\mathbf{g}^c} \,\|\, \widehat{\mathrm{e}^{\mathbf{w}_c^T \mathbf{H}^T}}),$$

so the matrices $\mathbf{U}$ and $\mathbf{V}$ that are returned by fitting the Skip-Gram model minimize the second term in this sum. We now show that the augmented matrices $\mathbf{W} = \tilde{\mathbf{U}}$ and $\mathbf{H} = \tilde{\mathbf{V}}$ also minimize this second term, and in addition they make the first term vanish.

To see that the first of these claims holds, i.e., that the augmented matrices make the second term in (9) vanish, note that

$$q_{\tilde{\mathbf{U}},\tilde{\mathbf{V}}}(w|c) \propto \mathrm{e}^{\tilde{\mathbf{u}}_c^T \tilde{\mathbf{v}}_w} = \mathrm{e}^{\mathbf{u}_c^T \mathbf{v}_w + \alpha_c} \propto q_{\mathbf{U},\mathbf{V}}(w|c),$$

and the constant of proportionality is independent of w. It follows that $q_{\tilde{\mathbf{U}},\tilde{\mathbf{V}}}(w|c) = q_{\mathbf{U},\mathbf{V}}(w|c)$ and

$$D_{KL}(\widehat{\mathbf{G}} \,\|\, q_{\tilde{\mathbf{U}},\tilde{\mathbf{V}}}(w|c)) = D_{KL}(\widehat{\mathbf{G}} \,\|\, q_{\mathbf{U},\mathbf{V}}(w|c)).$$

Thus, the choice $\mathbf{W} = \tilde{\mathbf{U}}$ and $\mathbf{H} = \tilde{\mathbf{V}}$ minimizes the second term in (9).

To see that the augmented matrices make the first term in (9) vanish, observe that when $\mathbf{W} = \tilde{\mathbf{U}}$ and $\mathbf{H} = \tilde{\mathbf{V}}$, we have that $q_{\tilde{\mathbf{U}},\tilde{\mathbf{V}}}(c) = \mathbf{g}$ by construction. This can be verified by calculation:

$$
\begin{aligned}
q_{\tilde{\mathbf{U}},\tilde{\mathbf{V}}}(c) &= \frac{\sum_w q_{\tilde{\mathbf{U}},\tilde{\mathbf{V}}}(w,c)}{\sum_{w,t} q_{\tilde{\mathbf{U}},\tilde{\mathbf{V}}}(w,t)} = \frac{\sum_w \mathrm{e}^{\mathbf{u}_c^T \mathbf{v}_w + \alpha_c}}{\sum_{w,t} \mathrm{e}^{\mathbf{u}_t^T \mathbf{v}_w + \alpha_t}} \\
&= \frac{\left(\sum_w \mathrm{e}^{\mathbf{u}_c^T \mathbf{v}_w}\right) \mathrm{e}^{\alpha_c}}{\sum_t \left(\sum_w \mathrm{e}^{\mathbf{u}_t^T \mathbf{v}_w}\right) \mathrm{e}^{\alpha_t}} \\
&= \frac{\left[(\mathrm{e}^{\mathbf{U}\mathbf{V}^T}\mathbf{1}) \odot \mathrm{e}^{\boldsymbol{\alpha}}\right]_c}{\mathbf{1}^T \left[(\mathrm{e}^{\mathbf{U}\mathbf{V}^T}\mathbf{1}) \odot \mathrm{e}^{\boldsymbol{\alpha}}\right]}.
\end{aligned}
$$

Here, the notation $\mathbf{x} \odot \mathbf{y}$ denotes entry-wise multiplication of vectors.

Since $\alpha_c = \log(g_c) - \log\left(\left(\mathrm{e}^{\mathbf{U}\mathbf{V}^T}\mathbf{1}\right)_c\right)$, we have

$$
q_{\tilde{\mathbf{U}},\tilde{\mathbf{V}}}(c) = \frac{\left[(\mathrm{e}^{\mathbf{U}\mathbf{V}^T}\mathbf{1}) \odot \mathrm{e}^{\boldsymbol{\alpha}}\right]_c}{\mathbf{1}^T \left[(\mathrm{e}^{\mathbf{U}\mathbf{V}^T}\mathbf{1}) \odot \mathrm{e}^{\boldsymbol{\alpha}}\right]} = \frac{g_c}{\sum_t g_t} = g_c.
$$

The choice $\mathbf{W} = \tilde{\mathbf{U}}$ and $\mathbf{H} = \tilde{\mathbf{V}}$ makes the first term in (9) vanish, and it also minimizes the second term in (9). Thus, it follows that the features $(\tilde{\mathbf{U}}, \tilde{\mathbf{V}})$ constitute a sufficient dimensionality reduction of $\mathbf{G}$. □

The State of the Art in Semantic Representation

Omri Abend **Ari Rappoport**

Department of Computer Science, The Hebrew University of Jerusalem
{oabend|arir}@cs.huji.ac.il

Abstract

Semantic representation is receiving growing attention in NLP in the past few years, and many proposals for semantic schemes (e.g., AMR, UCCA, GMB, UDS) have been put forth. Yet, little has been done to assess the achievements and the shortcomings of these new contenders, compare them with syntactic schemes, and clarify the general goals of research on semantic representation. We address these gaps by critically surveying the state of the art in the field.

1 Introduction

Schemes for Semantic Representation of Text (SRT) aim to reflect the meaning of sentences and texts in a transparent way. There has recently been an influx of proposals for semantic representations and corpora, e.g. GMB (Basile et al., 2012), AMR (Banarescu et al., 2013), UCCA (Abend and Rappoport, 2013b) and Universal Decompositional Semantics (UDS; White et al., 2016). Nevertheless, no detailed assessment of the relative merits of the different schemes has been carried out, nor their comparison to previous sentential analysis schemes, notably syntactic ones. An understanding of the achievements and gaps of semantic analysis in NLP is crucial to its future prospects.

In this paper we begin to chart the various proposals for semantic schemes according to the **content** they support. As not many semantic queries on texts can at present be answered with near human-like reliability without using manual symbolic annotation, we will mostly focus on schemes that represent semantic distinctions explicitly.[1]

We begin by discussing the goals of SRT in Section 2. Section 3 surveys major represented meaning components, including predicate-argument relations, discourse relations and logical structure. Section 4 details the various concrete proposals for SRT schemes and annotated resources, while Sections 5 and 6 discuss criteria for their evaluation and their relation to syntax, respectively.

We find that despite the major differences in terms of formalism and interface with syntax, in terms of their content there is a great deal of convergence of SRT schemes. Principal differences between schemes are mostly related to their ability to abstract away from formal and syntactic variation, namely to assign similar structures to different constructions that have a similar meaning, and to assign different structures to constructions that have different meanings, despite their surface similarity. Other important differences are in the level of training they require from their annotators (e.g., expert annotators vs. crowd-sourcing) and in their cross-linguistic generality. We discuss the complementary strengths of different schemes, and suggest paths for future integration.

2 Defining Semantic Representation

The term *semantics* is used differently in different contexts. For the purposes of this paper we define a semantic representation as one that reflects the meaning of the text as it is understood by a language speaker. A semantic representation should thus be paired with a method for extracting information from it that can be directly evaluated by humans. The extraction process should be reliable and computationally efficient.

[1] Note that even a string representation of text can be regarded as semantic given a reliable enough parser.

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 77–89
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1008

We stipulate that a fundamental component of the content conveyed by SRTs is argument structure – who did what to whom, where, when and why, i.e., events, their participants and the relations between them. Indeed, the fundamental status of argument structure has been recognized by essentially all approaches to semantics both in theoretical linguistics (Levin and Hovav, 2005) and in NLP, through approaches such as Semantic Role Labeling (SRL; Gildea and Jurafsky, 2002), formal semantic analysis (e.g., Bos, 2008), and Abstract Meaning Representation (AMR; Banarescu et al., 2013). Many other useful meaning components have been proposed, and are discussed at a greater depth in Section 3.

Another approach to defining an SRT is through external (extra-textual) criteria or applications. For instance, a semantic representation can be defined to support inference, as in textual entailment (Dagan et al., 2006) or natural logic (Angeli and Manning, 2014). Other examples include defining a semantic representation in terms of supporting knowledge base querying (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005), or defining semantics through a different modality, for instance interpreting text in terms of images that correspond to it (Kiros et al., 2014), or in terms of embodied motor and perceptual schemas (Feldman et al., 2010).

A different approach to SRT is taken by Vector Space Models (VSM), which eschew the use of symbolic structures, instead modeling all linguistic elements as vectors, from the level of words to phrases and sentences. Proponents of this approach generally invoke neural network methods, obtaining impressive results on a variety of tasks including lexical tasks such as cross-linguistic word similarity (Ammar et al., 2016), machine translation (Bahdanau et al., 2015), and dependency parsing (Andor et al., 2016). VSMs are also attractive in being flexible enough to model non-local and gradient phenomena (e.g., Socher et al., 2013). However, more research is needed to clarify the scope of semantic phenomena that such models are able to reliably capture. We therefore only lightly touch on VSMs in this survey.

Finally, a major consideration in semantic analysis, and one of its great potential advantages, is its cross-linguistic universality. While languages differ in terms of their form (e.g., in their phonology, lexicon, and syntax), they have often been assumed to be much closer in terms of their semantic content (Bar-Hillel, 1960; Fodor, 1975). See Section 5 for further discussion.

A terminological note: within formal linguistics, semantics is often the study of the relation between symbols (e.g., words, syntactic constructions) and what they signify. In this sense, semantics is the study of the aspects of meaning that are overtly expressed by the lexicon and grammar of a language, and is thus tightly associated with a theory of the syntax-semantics interface. We note that this definition of semantics is somewhat different from the one intended here, which defines semantic schemes as theories of meaning.

3 Semantic Content

We turn to discussing the main content types encoded by semantic representation schemes. Due to space limitations, we focus only on text semantics, which studies the meaning relationships between lexical items, rather than the meaning of the lexical items themselves.[2] We also defer discussion of more targeted semantic distinctions, such as sentiment, to future work.

We will use the following as a running example:

(1) Although Ann was leaving, she gave the present to John.

Events. Events (sometimes called frames, propositions or scenes) are the basic building blocks of argument structure representations. An event includes a predicate (main relation, frame-evoking element), which is the main determinant of what the event is about. It also includes arguments (participants, core elements) and secondary relations (modifiers, non-core elements). Example 1 is usually viewed as having two events, evoked by "leaving" and "gave".

Schemes commonly provide an ontology or a lexicon of event types (also a predicate lexicon), which categorizes semantically similar events evoked by different lexical items. For instance, FrameNet defines frames as schematized story fragments evoked by a set of conceptually similar predicates. In (1), the frames evoked by "leaving" and "gave" are DEPARTING and GIVING, but DEPARTING may also be evoked by "depart" and "exit", and GIVING by "donate" and "gift".

[2] We use the term "Text Semantics", rather than the commonly used "Sentence Semantics" to include inter-sentence semantic relations as well.

The events discussed here should not be confused with events as defined in Information Extraction and related tasks such as event coreference (Humphreys et al., 1997), which correspond more closely to the everyday notion of an event, such as a political or financial event, and generally consist of multiple events in the sense discussed here. The representation of such events is recently receiving considerable interest within NLP, e.g. the Richer Event Descriptions framework (RED; Ikuta et al., 2014).

Predicates and Arguments. While predicate-argument relations are universally recognized as fundamental to semantic representation, the interpretation of the terms varies across schemes. Most SRL schemes cover a wide variety of verbal predicates, but differ in which nominal and adjectival predicates are covered. For example, PropBank (Palmer et al., 2005), one of the major resources for SRL, covers verbs, and in its recent versions also eventive nouns and multi-argument adjectives. FrameNet (Ruppenhofer et al., 2016) covers all these, but also covers relational nouns that do not evoke an event, such as "president". Other lines of work address semantic arguments that appear outside sentence boundaries, or that do not explicitly appear anywhere in the text (Gerber and Chai, 2010; Roth and Frank, 2015).

Core and Non-core Arguments. Perhaps the most common distinction between argument types is between core and non-core arguments (Dowty, 2003). While it is possible to define the distinction distributionally as one between obligatory and optional arguments, here we focus on the semantic dimension, which distinguishes arguments whose meaning is predicate-specific and are necessary components of the described event (core), and those which are predicate-general (non-core). For example, FrameNet defines core arguments as conceptually necessary components of a frame, that make the frame unique and different from other frames, and peripheral arguments as those that introduce additional, independent or distinct relations from that of the frame such as time, place, manner, means and degree (Ruppenhofer et al., 2016, pp. 23-24).

Semantic Roles. Semantic roles are categories of arguments. Many different semantic role inventories have been proposed and used in NLP over the years, the most prominent being FrameNet (where roles are shared across predicates that evoke the same frame type, such as "leave" and "depart"), and PropBank (where roles are verb-specific). PropBank's role sets were extended by subsequent projects such as AMR. Another prominent semantic role inventory is VerbNet (Kipper et al., 2008) and subsequent projects (Bonial et al., 2011; Schneider et al., 2015), which define a closed set of abstract semantic roles (such as AGENT, PATIENT and INSTRUMENT) that apply to all predicate arguments.

Co-reference and Anaphora. Co-reference allows to abstract away from the different ways to refer to the same entity, and is commonly included in semantic resources. Coreference interacts with argument structure annotation, as in its absence each argument is arbitrarily linked to one of its textual instances. Most SRL schemes would mark "Ann" in (1) as an argument of "leaving" and "she" as an argument of "gave", although on semantic grounds "Ann" is an argument of both.

Some SRTs distinguish between the cases of argument sharing which is encoded by the syntax and is thus explicit (e.g., in "John went home and took a shower", "John" is both an argument of "went home" and of "took a shower"), and cases where the sharing of arguments is inferred (as in (1)). This distinction may be important for text understanding, as the inferred cases tend to be more ambiguous ("she" in (1) might not refer to "Ann"). Other schemes, such as AMR, eschew this distinction and use the same terms to represent all cases of coreference.

Temporal Relations. Most temporal semantic work in NLP has focused on temporal relations between events, either by timestamping them according to time expressions found in the text, or by predicting their relative order in time. Important resources include TimeML, a specification language for temporal relations (Pustejovsky et al., 2003), and the TempEval series of shared tasks and annotated corpora (Verhagen et al., 2009, 2010; UzZaman et al., 2013). A different line of work explores scripts: schematic, temporally ordered sequences of events associated with a certain scenario (Chambers and Jurafsky, 2008, 2009; Regneri et al., 2010). For instance, going to a restaurant includes sitting at a table, ordering, eating and paying, generally in this order.

Related to temporal relations, are causal relations between events, which are ubiquitous in language, and central for a variety of applications,

including planning and entailment. See (Mirza et al., 2014) and (Dunietz et al., 2015) for recently proposed annotation schemes for causality and its sub-types. Mostafazadeh et al. (2016) integrated causal and TimeML-style temporal relations into a unified representation.

The internal temporal structure of events has been less frequently tackled. Moens and Steedman (1988) defined an ontology for the temporal components of an event, such as its preparatory process (e.g., "climbing a mountain"), or its culmination ("reaching its top"). Statistical work on this topic is unfortunately scarce, and mostly focuses on lexical categories such as aspectual classes (Siegel and McKeown, 2000; Palmer et al., 2007; Friedrich et al., 2016; White et al., 2016), and tense distinctions (Elson and McKeown, 2010). Still, casting events in terms of their temporal components, characterizing an annotation scheme for doing so and rooting it in theoretical foundations, is an open challenge for NLP.

Spatial Relations. The representation of spatial relations is pivotal in cognitive theories of meaning (e.g., Langacker, 2008), and in application domains such as geographical information systems or robotic navigation. Important tasks in this field include Spatial Role Labeling (Kordjamshidi et al., 2012) and the more recent SpaceEval (Pustejovsky et al., 2015). The tasks include the identification and classification of spatial elements and relations, such as places, paths, directions and motions, and their relative configuration.

Discourse Relations encompass any semantic relation between events or larger semantic units. For example, in (1) the leaving and the giving events are sometimes related through a discourse relation of type CONCESSION, evoked by "although". Such information is useful, often essential for a variety of NLP tasks such as summarization, machine translation and information extraction, but is commonly overlooked in the development of such systems (Webber and Joshi, 2012).

The Penn Discourse Treebank (PeDT; Miltsakaki et al., 2004) annotates discourse units, and classifies the relations between them into a hierarchical, closed category set, including high-level relation types like TEMPORAL, COMPARISON and CONTINGENCY and finer-grained ones such as JUSTIFICATION and EXCEPTION. Another commonly used resource is the RST Discourse Treebank (Carlson et al., 2003), which places more focus on higher-order discourse structures, resulting in deeper hierarchical structures than the PeDT's, which focuses on local discourse structure.

Another discourse information type explored in NLP is discourse segmentation, where texts are partitioned into shallow structures of discourse units categorized either according to their topic or according to their function within the text. An example is the segmentation of scientific papers into functional segments and their labeling with categories such as BACKGROUND and DISCUSSION (Liakata et al., 2010). See (Webber et al., 2011) for a survey of discourse structure in NLP.

Discourse relations beyond the scope of a single sentence are often represented by specialized semantic resources and not by general ones, despite the absence of a clear boundary line between them. This, however, is beginning to change with some schemes, e.g., GMB and UCCA, already supporting cross-sentence semantic relations.[3]

Logical Structure. Logical structure, including quantification, negation, coordination and their associated scope distinctions, is the cornerstone of semantic analysis in much of theoretical linguistics, and has attracted much attention in NLP as well. Common representations are often based on variants of predicate calculus, and are useful for applications that require mapping text into an external, often executable, formal language, such as a querying language (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005) or robot instructions (Artzi and Zettlemoyer, 2013). Logical structures are also useful for recognizing entailment relations between sentences, as some entailments can be computed from the text's logical structure by formal provers (Bos and Markert, 2005; Lewis and Steedman, 2013).

Inference and Entailment. A primary motivation for many semantic schemes is their ability to support inference and entailment. Indeed, means for predicting logical entailment are built into many forms of semantic representations. A different approach was taken in the tasks of Recognizing Textual Entailment (Dagan et al., 2013), and Natural Logic (van Eijck, 2005), which considers an inference valid if a reasonable annotator would find the hypothesis likely to hold given

[3] AMR will also support discourse structure in its future versions (N. Schneider; personal communication).

the premise, even if it cannot be deduced from it. See (Manning, 2006) for a discussion of this point. Such inference relations are usually not included in semantic treebanks, but annotated in specialized resources (e.g., Dagan et al., 2006; Bowman et al., 2015).

4 Semantic Schemes and Resources

This section briefly surveys the different schemes and resources for SRT. We focus on design principles rather than specific features, as the latter are likely to change as the schemes undergo continuous development. In general, schemes discussed in Section 3 are not repeated here.

Semantic Role Labeling. SRL schemes diverge in their event types, the type of predicates they cover, their granularity, their cross-linguistic applicability, their organizing principles and their relation with syntax. Most SRL schemes define their annotation relative to some syntactic structure, such as parse trees of the PTB in the case of PropBank, or specialized syntactic categories defined for SRL purposes in the case of FrameNet. Other than PropBank, FrameNet and VerbNet discussed above, other notable resources include Semlink (Loper et al., 2007) that links corresponding entries in different resources such as PropBank, FrameNet, VerbNet and WordNet, and the Preposition Supersenses project (Schneider et al., 2015), which focuses on roles evoked by prepositions. See (Palmer et al., 2010, 2013) for a review of SRL schemes and resources. SRL schemes are often termed "shallow semantic analysis" due to their focus on argument structure, leaving out other relations such as discourse events, or how predicates and arguments are internally structured.

AMR. AMR covers predicate-argument relations, including semantic roles (adapted from PropBank) that apply to a wide variety of predicates (including verbal, nominal and adjectival predicates), modifiers, co-reference, named entities and some time expressions.

AMR does not currently support relations above the sentence level, and is admittedly English-centric, which results in an occasional conflation of semantic phenomena that happen to be similarly realized in English, into a single semantic category. AMR thus faces difficulties when assessing the invariance of its structures across translations (Xue et al., 2014). As an example, consider the sentences "I happened to meet Jack in the office", and "I asked to meet Jack in the office". While the two have similar syntactic forms, the first describes a single "meeting" event, where "happened" is a modifier, while the second describes two distinct events: asking and meeting. AMR annotates both in similar terms, which may be suitable for English, where aspectual relations are predominantly expressed as subordinating verbs (e.g., "begin", "want"), and are syntactically similar to primary verbs that take an infinitival complement (such as "ask to meet" or "learn to swim"). However, this approach is less suitable cross-linguistically. For instance, when translating the sentences to German, the divergence between the semantics of the two sentences is clear: in the first "happened" is translated to an adverb: "Ich habe Jack im Büro zufällig getroffen" (lit. "I have Jack in-the office by-chance met"), and in the second "asked" is translated to a verb: "Ich habe gebeten, Jack im Büro zu treffen" (lit. "I have asked, Jack in-the office to meet").

UCCA. UCCA (Universal Conceptual Cognitive Annotation) (Abend and Rappoport, 2013a,b) is a cross-linguistically applicable scheme for semantic annotation, building on typological theory, primarily on Basic Linguistic Theory (Dixon, 2010). UCCA's foundational layer of categories focuses on argument structures of various types and relations between them. In its current state, UCCA is considerably more coarse-grained than the above mentioned schemes (e.g., it does not include semantic role information). However, its distinctions tend to generalize well across languages (Sulem et al., 2015). For example, unlike AMR, it distinguishes between primary and aspectual verbs, so cases such as "happened to meet" are annotated similarly to cases such as "met by chance", and differently from "asked to meet".

Another design principle UCCA evokes is support for annotation by non-experts. To do so the scheme reformulates some of the harder distinctions into more intuitive ones. For instance, the core/non-core distinction is replaced in UCCA with the distinction between pure relations (Adverbials) and those evoking an object (Participants), which has been found easier for annotators to apply.

UDS. Universal Decompositional Semantics (White et al., 2016) is a multi-layered scheme, which currently includes semantic role anno-

tation, word senses and aspectual classes (e.g., realis/irrealis). UDS emphasizes accessible distinctions, which can be collected through crowd-sourcing. However, the skeletal structure of UDS representations is derived from syntactic dependencies, and only includes verbal argument structures that can be so extracted. Notably, many of the distinctions in UDS are defined using feature bundles, rather than mutually exclusive categories. For instance, a semantic role may be represented as having the features +VOLITION and +AWARENESS, rather than as having the category AGENT.

The Prague Dependency Treebank (PDT) Tectogrammatical Layer (PDT-TL) (Sgall, 1992; Böhmová et al., 2003) covers a rich variety of functional and semantic distinctions, such as argument structure (including semantic roles), tense, ellipsis, topic/focus, co-reference, word sense disambiguation and local discourse information. The PDT-TL results from an abstraction over PDT's syntactic layers, and its close relation with syntax is apparent. For instance, the PDT-TL encodes the distinction between a governing clause and a dependent clause, which is primarily syntactic in nature, so in the clauses "John came just as we were leaving" and "We were leaving just as John came" the governing and dependent clause are swapped, despite their semantic similarity.

CCG-based Schemes. CCG (Steedman, 2000) is a lexicalized grammar (i.e., nearly all semantic content is encoded in the lexicon), which defines a theory of how lexical information is composed to form the meaning of phrases and sentences (see Section 6.2), and has proven effective in a variety of semantic tasks (Zettlemoyer and Collins, 2005, 2007; Kwiatkowski et al., 2010; Artzi and Zettlemoyer, 2013, *inter alia)*. Several projects have constructed logical representations by associating CCG with semantic forms (by assigning logical forms to the leaves). For example, Boxer (Bos, 2008) and GMB, which builds on Boxer, use Discourse Representation Structures (Kamp and Reyle, 1993), while Lewis and Steedman (2013) used Davidsonian-style λ-expressions, accompanied by lexical categorization of the predicates. These schemes encode events with their argument structures, and include an elaborate logical structure, as well as lexical and discourse information.

HPSG-based Schemes. Related to CCG-based schemes are SRTs based on Head-driven Phrase Structure Grammar (HPSG; Pollard and Sag, 1994), where syntactic and semantic features are represented as feature bundles, which are iteratively composed through unification rules to form composite units. HPSG-based SRT schemes commonly use the Minimal Recursion Semantics (Copestake et al., 2005) formalism. Annotated corpora and manually crafted grammars exist for multiple languages (Flickinger, 2002; Oepen et al., 2004; Bender and Flickinger, 2005, *inter alia)*, and generally focus on argument structural and logical semantic phenomena. The Broad-coverage Semantic Dependency Parsing shared task and corpora (Oepen et al., 2014, 2015) include corpora annotated with the PDT-TL, and dependencies extracted from the HPSG grammars Enju (Miyao, 2006) and the LinGO English Reference Grammar (ERG; Flickinger, 2002).

Like the PDT-TL, projects based on CCG, HPSG, and other expressive grammars such as LTAG (Joshi and Vijay-Shanker, 1999) and LFG (Kaplan and Bresnan, 1982) (e.g., GlueTag (Frank and van Genabith, 2001)), yield semantic representations that are coupled with syntactic ones. While this approach provides powerful tools for inference, type checking, and mapping into external formal languages, it also often results in difficulties in abstracting away from some syntactic details. For instance, the dependencies derived from ERG in the SDP corpus use the same label for different senses of the English possessive construction, regardless of whether they correspond to ownership (e.g., "John's dog") or to a different meaning, such as marking an argument of a nominal predicate (e.g., "John's kick"). See Section 6.

OntoNotes is a useful resource with multiple inter-linked layers of annotation, borrowed from different schemes. The layers include syntactic, SRL, co-reference and word sense disambiguation content. Some properties of the predicate, such as which nouns are eventive, are encoded as well.

To summarize, while SRT schemes differ in the types of content they support, schemes evolve to continuously add new content types, making these differences less consequential. The fundamental difference between the schemes is the extent that they abstract away from syntax. For instance, AMR and UCCA abstract away from syntax as part of their design, while in most other schemes syntax and semantics are more tightly coupled.

Schemes also differ in other aspects discussed in Sections 5 and 6.

5 Evaluation

Human evaluation is the ultimate criterion for validating an SRT scheme given our definition of semantics as meaning as it is understood by a language speaker. Determining how well an SRT scheme corresponds to human interpretation of a text is ideally carried out by asking annotators to make some semantic prediction or annotation according to pre-specified guidelines, and to compare this to the information extracted from the SRT. Question Answering SRL (QASRL; He et al., 2015) is an SRL scheme which solicits non-experts to answer mostly wh-questions, converting their output to an SRL annotation. Hartshorne et al. (2013) and Reisinger et al. (2015) use crowdsourcing to elicit semantic role features, such as whether the argument was volitional in the described event, in order to evaluate proposals for semantic role sets.

Another evaluation approach is task-based evaluation. Many semantic representations in NLP are defined with an application in mind, making this type of evaluation natural. For instance, a major motivation for AMR is its applicability to machine translation, making MT a natural (albeit hitherto unexplored) testbed for AMR evaluation. Another example is using question answering to evaluate semantic parsing into knowledge-base queries.

Another common criterion for evaluating a semantic scheme is *invariance*, where semantic analysis should be similar across paraphrases or translation pairs (Xue et al., 2014; Sulem et al., 2015). For instance, most SRL schemes abstract away from the syntactic divergence between the sentences (1) "He gave a present to John" and (2) "It was John who was given a present" (although a complete analysis would reflect the difference of focus between them).

Importantly, these evaluation criteria also apply in cases where the representation is automatically induced, rather than manually defined. For instance, vector space representations are generally evaluated either through task-based evaluation, or in terms of semantic features computed from them, whose validity is established by human annotators (e.g., Agirre et al., 2013, 2014).

Finally, where semantic schemes are induced through manual annotation (and not through automated procedures), a common criterion for determining whether the guidelines are sufficiently clear, and whether the categories are well-defined is to measure agreement between annotators, by assigning them the same texts and measuring the similarity of the resulting structures. Measures include the SMATCH measure for AMR (Cai and Knight, 2013), and the PARSEVAL F-score (Black et al., 1991) adapted for DAGs for UCCA.

SRT schemes diverge in the background and training they require from their annotators. Some schemes require extensive training (e.g., AMR), while others can be (at least partially) collected by crowdsourcing (e.g., UDS). Other examples include FrameNet, which requires expert annotators for creating new frames, but employs less trained in-house annotators for applying existing frames to texts; QASRL, which employs non-expert annotators remotely; and UCCA, which uses in-house non-experts, demonstrating no advantage to expert over non-expert annotators after an initial training period. Another approach is taken by GMB, which uses online collaboration where expert collaborators participate in manually correcting automatically created representations. They further employ gamification strategies for collecting some aspects of the annotation.

Universality. One of the great promises of semantic analysis (over more surface forms of analysis) is its cross-linguistic potential. However, while the theoretical and applicative importance of universality in semantics has long been recognized (Goddard, 2011), the nature of universal semantics remains unknown. Recently, projects such as BabelNet (Ehrmann et al., 2014), UBY (Gurevych et al., 2012) and Open Multilingual Wordnet[4], constructed huge multi-lingual semantic nets, by linking resources such as Wikipedia and WordNet and processing them using modern NLP. However, such projects currently focus on lexical semantic and encyclopedic information rather than on text semantics.

Symbolic SRT schemes such as SRL schemes and AMR have also been studied for their cross-linguistic applicability (Padó and Lapata, 2009; Sun et al., 2010; Xue et al., 2014), indicating partial portability across languages. Translated versions of PropBank and FrameNet have been constructed for multiple languages (e.g., Akbik et al., 2016; Hartmann and Gurevych, 2013). How-

[4] http://compling.hss.ntu.edu.sg/omw/

ever, as both PropBank and FrameNet are lexicalized schemes, and as lexicons diverge wildly across languages, these schemes require considerable adaptation when ported across languages (Kozhevnikov and Titov, 2013). Ongoing research tackles the generalization of VerbNet's unlexicalized roles to a universally applicable set (e.g., Schneider et al., 2015). Few SRT schemes place cross-linguistically applicability as one of their main criteria, examples include UCCA, and the LinGO Grammar Matrix (Bender and Flickinger, 2005), both of which draw on typological theory.

Vector space models, which embed words and sentences in a vector space, have also been applied to induce a shared cross-linguistic space (Klementiev et al., 2012; Rajendran et al., 2015; Wu et al., 2016). However, further evaluation is required in order to determine what aspects of meaning these representations reflect reliably.

6 Syntax and Semantics

6.1 Syntactic and Semantic Generalization

Syntactic distinctions are generally guided by a combination of semantic and distributional considerations, where emphasis varies across schemes.

Consider phrase-based syntactic structures, common examples of which, such as the Penn Treebank for English (Marcus et al., 1993) and the Penn Chinese Treebank (Xue et al., 2005), are adaptations of X-bar theory. Constituents are commonly defined in terms of distributional criteria, such as whether they can serve as conjuncts, be passivized, elided or fronted (Carnie, 2002, pp. 50-53). Moreover, phrase categories are defined according to the POS category of their headword, such as Noun Phrase, Verb Phrase or Preposition Phrase, which are also at least partly distributional, motivated by their similar morphological and syntactic distribution. In contrast, SRT schemes tend to abstract away from these realizational differences and directly reflect the argument structure of the sentence using the same set of categories, irrespective of the POS of the predicate, or the case marking of its arguments.

Distributional considerations are also apparent with functional syntactic schemes (the most commonly used form of which in NLP are lexicalist dependency structures), albeit to a lesser extent. A prominent example is Universal Dependencies (UD; Nivre et al., 2016), which aims at producing a cross-linguistically consistent dependency-based annotation, and whose categories are motivated by a combination of distributional and semantic considerations. For example, UD would distinguish between the dependency type between "John" and "brother" in "John, my brother, arrived" and "John, who is my brother, arrived", despite their similar semantics. This is due to the former invoking an apposition, and the latter a relative clause, which are different in their distribution.

As an example of the different categorization employed by UD and by purely semantic schemes such as AMR and UCCA consider (1) "founding of the school", (2) "president of the United States" and (3) "United States president". UD is faithful to the syntactic structure and represents (1) and (2) similarly, while assigning a different structure to (3). In contrast, AMR and UCCA perform a semantic generalization and represents examples (2) and (3) similarly and differently from (1).

6.2 The Syntax-Semantics Interface

A common assumption on the interface between syntax and semantics is that semantics of phrases and sentences is compositional – it is determined recursively by the meaning of its immediate constituents and their syntactic relationships, which are generally assumed to form a closed set (Montague, 1970, and much subsequent work). Thus, the interpretation of a sentence can be computed bottom-up, by establishing the meaning of individual words, and recursively composing them, to obtain the full sentential semantics. The order and type of these compositions are determined by the syntactic structure.

Compositionality is employed by linguistically expressive grammars, such as those based on CCG and HPSG, and has proven to be a powerful method for various applications. See (Bender et al., 2015) for a recent discussion of the advantages of compositional SRTs. Nevertheless, a compositional account meets difficulties when faced with multi-word expressions and in accounting for cases like "he sneezed the napkin off the table", where it is difficult to determine whether "sneezed" or "off" account for the constructional meaning. Construction Grammar (Fillmore et al., 1988; Goldberg, 1995) answers these issues by using an open set of construction-specific compositional operators, and supporting lexical en-

tries of varying lengths. Several ongoing projects address the implementation of the principles of Construction Grammar into explicit grammars, including Sign-based Construction Grammar (Fillmore et al., 2012), Embodied Construction Grammar (Feldman et al., 2010) and Fluid Construction Grammar (Steels and de Beules, 2006).

The achievements of machine learning methods in many areas, and optimism as to its prospects, have enabled the approaches to semantics discussed in this paper. Machine learning allows to define semantic structures on purely semantic grounds and to let algorithms identify how these distinctions are mapped to surface/distributional forms. Some of the schemes discussed in this paper take this approach in its pure form (e.g., AMR and UCCA).

7 Conclusion

Semantic representation in NLP is undergoing rapid changes. Traditional semantic work has either used shallow methods that focus on specific semantic phenomena, or adopted formal semantic theories which are coupled with a syntactic scheme through a theory of the syntax-semantics interface. Recent years have seen increasing interest in an alternative approach that defines semantic structures independently from any syntactic or distributional criteria, much due to the availability of semantic treebanks that implement this approach.

Semantic schemes diverge in whether they are anchored in the words and phrases of the text (e.g., all types of semantic dependencies and UCCA) or not (e.g., AMR and logic-based representations). We do not view this as a major difference, because most unanchored representations (including AMR) retain their close affinity with the words of the sentence, possibly because of the absence of a workable scheme for lexical decomposition, while dependency structures can be converted into logic-based representations (Reddy et al., 2016). In practice, anchoring facilitates parsing, while unanchored representations are more flexible to use where words and semantic components are not in a one-to-one correspondence.

Our survey concludes that the main distinguishing factors between schemes are their relation to syntax, their degree of universality, and the expertise and training they require from annotators, an important factor in addressing the annotation bottleneck. We hope this survey of the state of the art in semantic representation will promote discussion, expose more researchers to the most pressing questions in semantic representation, and lead to the wide adoption of the best components from each scheme.

Joint Learning for Event Coreference Resolution

Jing Lu and **Vincent Ng**
Human Language Technology Research Institute
University of Texas at Dallas
Richardson, TX 75083-0688
{ljwinnie,vince}@hlt.utdallas.edu

Abstract

While joint models have been developed for many NLP tasks, the vast majority of event coreference resolvers, including the top-performing resolvers competing in the recent TAC KBP 2016 Event Nugget Detection and Coreference task, are pipeline-based, where the propagation of errors from the trigger detection component to the event coreference component is a major performance limiting factor. To address this problem, we propose a model for jointly learning event coreference, trigger detection, and event anaphoricity. Our joint model is novel in its choice of tasks and its features for capturing cross-task interactions. To our knowledge, this is the first attempt to train a mention-ranking model and employ event anaphoricity for event coreference. Our model achieves the best results to date on the KBP 2016 English and Chinese datasets.

1 Introduction

Within-document event coreference resolution is the task of determining which event mentions in a text refer to the same real-world event. Compared to entity coreference resolution, event coreference resolution is not only much less studied, but it is arguably more challenging. The challenge stems in part from the fact that an event coreference resolver typically lies towards the end of the standard information extraction pipeline, assuming as input the noisy outputs of its upstream components. One such component is the trigger detection system, which is responsible for identifying event triggers and determining their event subtypes.

As is commonly known, trigger detection is another challenging task that is far from being solved. In fact, in the recent TAC KBP 2016 Event Nugget Detection and Coreference task, trigger detection (a.k.a. event nugget detection in KBP) is deliberately made more challenging by focusing only on detecting the 18 subtypes of triggers on which the KBP 2015 participating systems' performances were the poorest (Mitamura et al., 2016). The best-performing KBP 2016 system on English trigger detection achieved only an F-score of 47 (Lu and Ng, 2016).[1]

Given the difficulty of trigger detection, it is conceivable that many errors will propagate from the trigger detection component to the event coreference component in any pipeline architecture where trigger detection precedes event coreference resolution. These trigger detection errors could severely harm event coreference performance. For instance, two event mentions could be wrongly posited as coreferent if the underlying triggers were wrongly predicted to have the same subtype. Nevertheless, the top-performing systems in the KBP 2016 event coreference task all adopted the aforementioned pipeline architecture (Liu et al., 2016; Lu and Ng, 2016; Nguyen et al., 2016). Their performances are not particularly impressive, however: the best English event coreference F-score (averaged over four scoring metrics) is only around 30%.

To address this error propagation problem, we describe a joint model of trigger detection, event coreference, and event anaphoricity in this paper. Our choice of these three tasks is motivated in part by their inter-dependencies. As mentioned above, it is well-known that trigger detection performance has a huge impact on event coreference performance. Though largely under-investigated, event coreference could also improve

[1] This is the best English nugget *type* result in KBP 2016. In this paper, we will not be concerned with *realis* classification, as it does not play any role in event coreference.

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 90–101
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1009

trigger detection. For instance, if two event mentions are posited as coreferent, then the underlying triggers must have the same event subtype. While the use of anaphoricity information for entity coreference has been extensively studied (see Ng (2010)), to our knowledge there has thus far been no attempt to explicitly model event anaphoricity for event coreference.[2] Although the mention-ranking model we employ for event coreference also allows an event mention to be posited as non-anaphoric (by resolving it to a *null* candidate antecedent), our decision to train a separate anaphoricity model and integrate it into our joint model is motivated in part by the recent successes of Wiseman et al. (2015), who showed that there are benefits in jointly training a noun phrase anaphoricity model and a mention-ranking model for entity coreference resolution. Finally, event anaphoricity and trigger detection can also mutually benefit each other. For instance, any verb posited as a non-trigger cannot be anaphoric, and any verb posited as anaphoric must be a trigger. Note that in our joint model, anaphoricity serves as an *auxiliary* task: its intended use is to improve trigger detection and event coreference, potentially mediating the interaction between trigger detection and event coreference.

Being a structured conditional random field, our model encompasses two types of factors. Unary factors encode the features specific for each task. Binary and ternary factors capture the interaction between each pair of tasks in a soft manner, enabling the learner to learn which combinations of values of the output variables are more probable. For instance, the learner should learn that it is not a good idea to classify a verb both as anaphoric and as a non-trigger. Our model is similar in spirit to Durrett and Klein's (2014) joint model for *entity* analysis, which performs joint learning for entity coreference, entity linking and semantic typing via the use of interaction features.

Our contributions are two-fold. First, we present a joint model of event coreference, trigger detection, and anaphoricity that is novel in terms of the choice of tasks and the features used to capture cross-task interactions. Second, our model achieves the best results to date on the KBP 2016 English and Chinese event coreference tasks.

[2]Following the entity coreference literature, we overload the term *anaphoricity*, saying that an event mention is anaphoric if it is coreferent with a preceding mention in the associated text.

2 Definitions, Task, and Corpora

2.1 Definitions

We employ the following definitions in our discussion of trigger detection and event coreference:

- An **event mention** is an explicit occurrence of an event consisting of a textual trigger, arguments or participants (if any), and the event type/subtype.
- An **event trigger** is a string of text that most clearly expresses the occurrence of an event, usually a word or a multi-word phrase
- An **event argument** is an argument filler that plays a certain role in an event.
- An **event coreference chain** (a.k.a. an **event hopper**) is a group of event mentions that refer to the same real-world event. They must have the same event (sub)type.

To understand these definitions, consider the example in Table 1, which contains two coreferent event mentions, $ev1$ and $ev2$. *left* is the trigger for $ev1$ and *departed* is the trigger for $ev2$. Both triggers have subtype Movement.Transport-Person. $ev1$ has three arguments, *Georges Cipriani*, *prison*, and *Wednesday* with roles *Person*, *Origin*, and *Time* respectively. $ev2$ also has three arguments, *He*, *Ensisheim*, and *police vehicle* with roles *Person*, *Origin*, and *Instrument* respectively.

2.2 Task

The version of the event coreference task we focus on in this paper is the Event Nugget Detection and Coreference task in the TAC KBP 2016 Event Track. While we discuss the role played by event arguments in event coreference in the previous subsection, KBP 2016 addresses event argument detection as a separate shared task. In other words, the KBP 2016 Event Nugget Detection and Coreference task focuses solely on trigger detection and event coreference.

It is worth mentioning that the KBP Event Nugget Detection and Coreference task, which started in 2015, aims to address a major weakness of the ACE 2005 event coreference task. Specifically, ACE 2005 adopts a strict notion of event identity, with which two event mentions were annotated as coreferent if and only if "they had the same agent(s), patient(s), time, and location" (Song et al., 2015), and their event attributes (polarity, modality, genericity, and tense) were not incompatible. In contrast, KBP adopts a more relaxed definition of event coreference, allowing two

Georges Cipriani$_{[Person]}$, {left}$_{ev1}$ the prison$_{[Origin]}$ in Ensisheim in northern France on parole on Wednesday$_{[Time]}$. He$_{[Person]}$ {departed}$_{ev2}$ Ensisheim$_{[Origin]}$ in a police vehicle$_{[Instrument]}$ bound for an open prison near Strasbourg.

Table 1: Event coreference resolution example.

event mentions to be coreferent as long as they *intuitively* refer to the same real-world event. Under this definition, two event mentions can be coreferent even if their time and location arguments are not coreferent. In our example in Table 1, $ev1$ and $ev2$ are coreferent in KBP because they both refer to the same event of Cipriani leaving the prison. However, they are *not* coreferent in ACE because their *Origin* arguments are not coreferent (one Origin argument involves a prison in Ensisheim while the other involves the city Ensisheim).

2.3 Corpora

Given our focus on the KBP 2016 Event Nugget Detection and Coreference task, we employ the English and Chinese corpora used in this task for evaluation, referring to these corpora as the KBP 2016 English and Chinese corpora for brevity. There are no official training sets: the task organizers simply made available a number of event coreference-annotated corpora for training. For English, we use LDC2015E29, E68, E73, and E94 for training. These corpora are composed of two types of documents, newswire documents and discussion forum documents. Together they contain 648 documents with 18739 event mentions distributed over 9955 event coreference chains. For Chinese, we use LDC2015E78, E105, and E112 for training. These corpora are composed of discussion forum documents only. Together they contain 383 documents with 4870 event mentions distributed over 3614 event coreference chains.

The test set for English consists of 169 newswire and discussion forum documents with 4155 event mentions distributed over 3191 event coreference chains. The test set for Chinese consists of 167 newswire and discussion forum documents with 2518 event mentions distributed over 1912 event coreference chains. Note that these test sets contain only annotations for event triggers and event coreference (i.e., there are no event argument annotations). While some of the training sets additionally contain event argument annotations, we do not make use of event argument annotations in model training to ensure a fairer comparison to the teams participating in the KBP 2016 Event Nugget Detection and Coreference task.

3 Model

3.1 Overview

Our model, which is a structured conditional random field, operates at the document level. Specifically, given a test document, we first extract from it (1) all single-word nouns and verbs and (2) all words and phrases that have appeared at least once as a trigger in the training data. We treat each of these extracted words and phrases as a candidate event mention.[3] The goal of the model is to make joint predictions for the candidate event mentions in a document. Three predictions will be made for each candidate event mention that correspond to the three tasks in the model: its trigger subtype, its anaphoricity, and its antecedent.

Given this formulation, we define three types of output variables:

- Event subtype variables $\mathbf{t} = (t_1, \ldots, t_n)$. Each t_i takes a value in the set of 18 event subtypes defined in KBP 2016 or NONE, which indicates that the event mention is not a trigger.
- Anaphoricity variables $\mathbf{a} = (a_1, \ldots, a_n)$. Each a_i is either ANAPHORIC or NOT ANAPHORIC.
- Coreference variables $\mathbf{c} = (c_1, \ldots, c_n)$, where $c_i \in \{1, \ldots, i-1, \text{NEW}\}$. In other words, the value of each c_i is the id of its antecedent, which can be one of the preceding event mentions or NEW (if the event mention underlying c_i starts a new cluster).

Each candidate event mention is associated with exactly one coreference variable, one event subtype variable, and one anaphoricity variable. Our model induces the following log-linear probability distribution over these variables:

$$p(\mathbf{t}, \mathbf{a}, \mathbf{c}|x; \Theta) \propto \exp(\sum_i \theta_i f_i(\mathbf{t}, \mathbf{a}, \mathbf{c}, x))$$

[3] According to the KBP annotation guidelines, each word may trigger multiple event mentions (e.g., *murder* can trigger two event mentions with subtypes Life.Die and Conflict.Attack). Hence, our treating each extracted word as a candidate event mention effectively prevents a word from triggering multiple event mentions. Rather than complicate model design by relaxing this simplifying assumption, we present an alternative, though partial, solution to this problem wherein we allow each event mention to be associated with multiple event subtypes. See the Appendix for details.

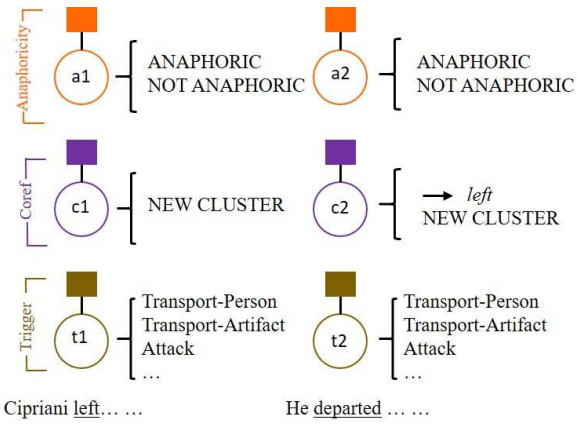

Figure 1: Unary factors for the three tasks, the variables they are connected to, and the possible values of the variables. Unary factors encode task-specific features. Each factor is connected to the corresponding output node. The features associated with a factor are used to predict the value of the output node it is connected to when a model is run independently of other models.

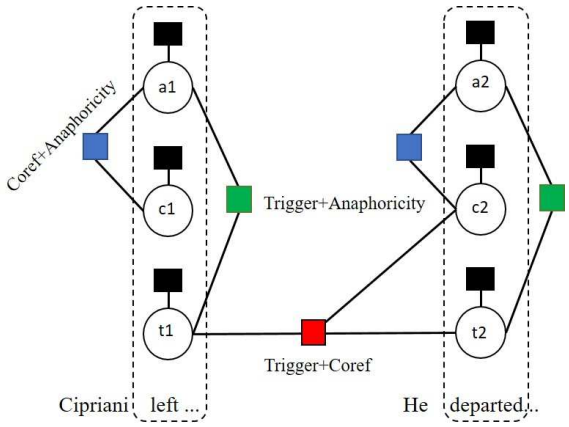

Figure 2: Binary and ternary factors. These higher-order factors capture cross-task interactions. The binary anaphoricity and trigger factors encourage anaphoric mentions to be triggers. The binary anaphoricity and coreference factors encourage non-anaphoric mentions to start a NEW coreference cluster. The ternary trigger and coreference factors encourage coreferent mentions to be triggers.

where $\theta_i \in \Theta$ is the weight associated with feature function f_i and x is the input document.

3.2 Features

Given that our model is a structured conditional random field, the features can be divided into two types: (1) task-specific features, and (2) cross-task features, which capture the interactions between a pair of tasks. We express these two types of features in factor graph notation. The task-specific features are encoded in unary factors, each of which is connected to the corresponding variable (Figure 1). The cross-task features are encoded in binary or ternary factors, each of which couples the output variables from two tasks (Figure 2). Next, we describe these two types of features. Each feature is used to train models for both English and Chinese unless otherwise stated.

3.2.1 Task-Specific Features

We begin by describing the task-specific features, which are encoded in unary factors, as well as each of the three independent models.

3.2.1.1 Trigger Detection

When applied in isolation, our trigger detection model returns a distribution over possible subtypes given a candidate trigger. Each candidate trigger t is represented using t's word, t's lemma, word bigrams formed with a window size of three from t, as well as feature conjunctions created by pairing t's lemma with each of the following features: the head word of the entity syntactically closest to t, the head word of the entity textually closest to t, the entity type of the entity that is syntactically closest to t, and the entity type of the entity that is textually closest to t.[4] In addition, for event mentions with verb triggers, we use the head words and the entity types of their subjects and objects as features, where the subjects and objects are extracted from the dependency parse trees obtained using Stanford CoreNLP (Manning et al., 2014). For event mentions with noun triggers, we create the same features that we did for verb triggers, except that we replace the subjects and verbs with heuristically extracted agents and patients. Finally, for the Chinese trigger detector, we additionally create two features from each character in t, one encoding the character itself and the other encoding the entry number of the corresponding character in a Chinese synonym dictionary.[5]

3.2.1.2 Event Coreference

We employ a mention-ranking model for event coreference that selects the most probable antecedent for a mention to be resolved (or NEW if the mention is non-anaphoric) from its set of candidate antecedents. When applied in isolation, the model is trained to maximize the condi-

[4] We train a CRF-based entity extraction model for jointly identifying the entity mentions and their types. Details can be found in Lu et al. (2016).

[5] The dictionary is available from http://ir.hit.edu.cn/. An entry number in this dictionary conceptually resembles a synset id in WordNet (Fellbaum, 1998).

tional likelihood of collectively resolving the mentions to their correct antecedents in the training texts (Durrett and Klein, 2013). Below we describe the features used to represent the candidate antecedents for the mention to be resolved, m_j.

Features representing the NULL candidate antecedent: Besides m_j's word and m_j's lemma, we employ feature conjunctions given their usefulness in entity coreference (Fernandes et al., 2014). Specifically, we create a conjunction between m_j's lemma and the number of sentences preceding m_j, as well as a conjunction between m_j's lemma and the number of mentions preceding m_j in the document.

Features representing a non-NULL candidate antecedent, m_i: m_i's word, m_i's lemma, whether m_i and m_j have the same lemma, and feature conjunctions including: (1) m_i's word paired with m_j's word, (2) m_i's lemma paired with m_j's lemma, (3) the sentence distance between m_i and m_j paired with m_i's lemma and m_j's lemma, (4) the mention distance between m_i and m_j paired with m_i's lemma and m_j's lemma, (5) a quadruple consisting of m_i and m_j's subjects and their lemmas, and (6) a quadruple consisting of m_i and m_j's objects and their lemmas.

3.2.1.3 Anaphoricity Determination

When used in isolation, the anaphoricity model returns the probability that the given event mention is anaphoric. To train the model, we represent each event mention m_j using the following features: (1) the head word of each candidate antecedent paired with m_j's word, (2) whether at least one candidate antecedent has the same lemma as that of m_j, and (3) the probability that m_j is anaphoric in the training data (if m_j never appears in the training data, this probability is set to 0.5).

3.2.2 Cross-Task Interaction Features

Cross-task interaction features are associated with the binary and ternary factors.

3.2.2.1 Trigger Detection and Anaphoricity

We fire features that conjoin each candidate event mention's event subtype, the lemma of its trigger and its anaphoricity.

3.2.2.2 Trigger Detection and Coreference

We define our joint coreference and trigger detection factors such that the features defined on subtype variables t_i and t_j are fired only if current mention m_j is coreferent with preceding mention m_i. These features are: (1) the pair of m_i and m_j's subtypes, (2) the pair of m_j's subtype and m_i's word, and (3) the pair of m_i's subtype and m_j's word.

3.2.2.3 Coreference and Anaphoricity

We fire a feature that conjoins event mention m_j's anaphoricity and whether or not a non-NULL antecedent is selected for m_j.

3.3 Training

We learn the model parameters Θ from a set of d training documents, where document i contains content x_i, gold triggers $\mathbf{t_i^*}$ and gold event coreference partition C_i^*. Before learning, there are a couple of issues we need to address.

First, we need to derive gold anaphoricity labels $\mathbf{a_i^*}$ from C_i^*. This is straightforward: the first mention of each coreference chain is NOT ANAPHORIC, whereas the rest are ANAPHORIC.

Second, we employ gold event mentions for model training, but training models only on gold mentions is not sufficient: for instance, a trigger detector trained solely on gold mentions will not be able to classify a candidate event mention as NONE during testing. To address this issue, we additionally train the models on candidate event mentions corresponding to non-triggers. We create these candidate event mentions as follows. For each word w that appears as a true trigger at least once in the training data, we create a candidate event mention from each occurrence of w in the training data that is not annotated as a true trigger.

Third, since our model produces event coreference output in the form of an antecedent vector (with one antecedent per event mention), it needs to be trained on antecedent vectors. However, since the coreference annotation for each document i is provided in the form of a clustering C_i^*, we follow previous work on entity coreference resolution (Durrett and Klein, 2013): we sum over all antecedent structures $A(C_i^*)$ that are *consistent* with C_i^* (i.e., the first mention of a cluster has antecedent NEW, whereas each of the subsequent mentions can select any of the preceding mentions in the same cluster as its antecedent).

Next, we learn the model parameters to maximize the following conditional likelihood of the training data with L1 regularization:

$$L(\Theta) = \sum_{i=1}^{d} \log \sum_{\mathbf{c}^* \in A(C_i^*)} p'(\mathbf{t_i^*}, \mathbf{a_i^*}, \mathbf{c}^* | x_i; \Theta) + \lambda \|\Theta\|_1$$

In this objective, p' is obtained by augmenting the distribution p (defined in Section 3.1) with task-specific parameterized loss functions:

$$p'(\mathbf{t}, \mathbf{a}, \mathbf{c}|x_i; \Theta) \propto p(\mathbf{t}, \mathbf{a}, \mathbf{c}|x_i; \Theta) \exp[\alpha_t l_t(\mathbf{t}, \mathbf{t}^*) + \alpha_a l_a(\mathbf{a}, \mathbf{a}^*) + \alpha_c l_c(\mathbf{c}, C^*)]$$

where l_t, l_a and l_c are task-specific loss functions, and α_t, α_a and α_c are the associated weight parameters that specify the relative importance of the three tasks in the objective function.

Softmax-margin, the technique of integrating task-specific loss functions into the objective function, was introduced by Gimpel and Smith (2010) and subsequently used by Durrett and Klein (2013, 2014). By encoding task-specific knowledge, these loss functions can help train a model that places less probability mass on less desirable output configurations.

Our loss function for event coreference, l_c, is motivated by the one Durrett and Klein (2013) developed for entity coreference. It is a weighted sum of the counts of three error types:

$$l_c(\mathbf{c}, C^*) = \alpha_{c,FA} FA(\mathbf{c}, C^*) + \alpha_{c,FN} FN(\mathbf{c}, C^*) + \alpha_{c,WL} WL(\mathbf{c}, C^*)$$

where $FA(\mathbf{c}, C^*)$ is the number of non-anaphoric mentions misclassified as anaphoric, $FN(\mathbf{c}, C^*)$ is the number of anaphoric mentions misclassified as non-anaphoric, and $WL(\mathbf{c}, C^*)$ is the number of incorrectly resolved anaphoric mentions.

Our loss function for trigger detection, l_t, is parameterized in a similar way, having three parameters associated with three error types: $\alpha_{t,FT}$ is associated with the number of non-triggers misclassified as triggers, $\alpha_{t,FN}$ is associated with the number of triggers misclassified as non-triggers, and $\alpha_{t,WL}$ is associated with the number of triggers labeled with the wrong subtype.

Finally, our loss function for anaphoricity determination, l_a, is also similarly parameterized, having two parameters: $\alpha_{a,FA}$ and $\alpha_{a,FN}$ are associated with the number of false anaphors and the number of false non-anaphors, respectively.

Following Durrett and Klein (2014), we use AdaGrad (Duchi et al., 2011) to optimize our objective with $\lambda = 0.001$ in our experiments.

3.4 Inference

Inference, which is performed during training and decoding, involves computing the marginals for a variable or a set of variables to which a factor connects. For efficiency, we perform approximate inference using belief propagation rather than exact inference. Given that convergence can typically be reached within five iterations of belief propagation, we employ five iterations in all experiments.

Performing inference using belief propagation on the full factor graph defined in Section 3.1 can still be computationally expensive, however. One reason is that the number of ternary factors grows quadratically with the number of event mentions in a document. To improve scalability, we restrict the domains of the coreference variables. Rather than allow the domain of coreference variable c_j to be of size j, we allow a preceding mention m_i to be a candidate antecedent of mention m_j if (1) the sentence distance between the two mentions is less than an empirically determined threshold and (2) either they are coreferent at least once in the training data or their head words have the same lemma. Doing so effectively enables us to prune the unlikely candidate antecedents for each event mention. As Durrett and Klein (2014) point out, such pruning has the additional benefit of reducing "the memory footprint and time needed to build a factor graph", as we do not need to create any factor between m_i and m_j and its associated features if m_i is pruned. To further reduce the memory footprint, we additionally restrict the domains of the event subtype variables. Given a candidate event mention created from word w, we allow the domain of its subtype variable to include only NONE as well as those subtypes that w is labeled with at least once in the training data.

For decoding, we employ minimum Bayes risk, which computes the marginals of each variable w.r.t. the joint model and derives the most probable assignment to each variable.

4 Evaluation

4.1 Experimental Setup

We perform training and evaluation on the KBP 2016 English and Chinese corpora. For English, we train models on 509 of the training documents, tune parameters on 139 training documents, and report results on the official KBP 2016 English test set.[6] For Chinese, we train models on 302 of the training documents, tune parameters on 81 training documents, and report results on the official

[6]The parameters to be tuned are the α's multiplying the loss functions and those inside the loss functions.

Table 2: Results of all three tasks on the KBP 2016 evaluation sets. The KBP2016 results are those achieved by the best-performing coreference resolver in the official KBP 2016 evaluation. Δ is the performance difference between the JOINT model and the corresponding INDEP. model. All results are expressed in terms of F-score.

KBP 2016 Chinese test set.

Results of event coreference and trigger detection are obtained using version 1.7.2 of the official scorer provided by the KBP 2016 organizers. To evaluate event coreference performance, the scorer employs four scoring measures, namely MUC (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998), CEAF_e (Luo, 2005) and BLANC (Recasens and Hovy, 2011), as well as the unweighted average of their F-scores (AVG-F). The scorer reports event mention detection performance in terms of F-score, considering a mention correctly detected if it has an exact match with a gold mention in terms of boundary, event type, and event subtype. In addition, we report anaphoricity determination performance in terms of the F-score computed over anaphoric mentions, counting an extracted anaphoric mention as a true positive if it has an exact match with a gold anaphoric mention in terms of boundary.

4.2 Results and Discussion

Results are shown in Table 2 where performance on all three tasks (event coreference, trigger detection, and anaphoricity determination) is expressed in terms of F-score. The top half of the table shows the results on the English evaluation set. Specifically, row 1 shows the performance of the best event coreference system participating in KBP 2016 (Lu and Ng, 2016). This system adopts a pipeline architecture. It first uses an ensemble of one-nearest-neighbor classifiers for trigger detection. Using the extracted triggers, it then applies a pipeline of three sieves, each of which is a one-nearest-neighbor classifier, for event coreference. As we can see, this system achieves an AVG-F of 30.08 for event coreference and an F-score of 46.99 for trigger detection.

Row 2 shows the performance of the independent models, each of which is trained independently of the other models. Specifically, each independent model is trained using only the unary factors associated with it. As we can see, the independent models outperform the top KBP 2016 system by 1.2 points in AVG-F for event coreference and 1.83 points for trigger detection.

Results of our joint model are shown in row 3. The absolute performance differences between the joint model and the independent models are shown in row 4. As we can see, the joint model outperforms the independent models for all three tasks: by 1.80 points for event coreference, 0.48 points for trigger detection and 4.59 points for anaphoricity determination. Most encouragingly, the joint model outperforms the top KBP 2016 system for both event coreference and trigger detection. For event coreference, it outperforms the top KBP system w.r.t. all scoring metrics, yielding an improvement of 3 points in AVG-F. For trigger detection, it outperforms the top KBP system by 2.31 points.

The bottom half of Table 2 shows the results on the Chinese evaluation set. The top KBP 2016 event coreference system on Chinese is also the Lu and Ng (2016) system. While the top KBP system outperforms the independent models for both tasks (by 0.59 points in AVG-F for event coreference and 0.19 points for trigger detection), our joint model outperforms the independent models

	English			Chinese

JOINT−CorefAnaph	+0.63	+0.66	+1.46	+1.50	+0.88	+0.28
JOINT−TriggerAnaph	+1.89	+0.50	+4.01	+1.65	+0.50	+1.79
JOINT	+1.80	+0.48	+4.59	+1.95	+0.71	+4.02

Table 3: Results of model ablations on the KBP 2016 evaluation sets. Each row of ablation results is obtained by either adding one type of interaction factor to the INDEP. model or deleting one type of interaction factor from the JOINT model. For each column, the results are expressed in terms of changes to the INDEP. model's F-score shown in row 1.

for all three tasks: by 1.95 points for event coreference, 4.02 points for anaphoricity determination, and 0.71 points for trigger detection. Like its English counterpart, our Chinese joint model outperforms the top KBP system for both event coreference and trigger detection. For event coreference, it outperforms the top KBP system w.r.t. all but the CEAF_e metric, yielding an absolute improvement of 1.36 points in AVG-F. For trigger detection, it outperforms the top KBP system by 0.52 points.

For both datasets, the joint model's superior performance to the independent coreference model stems primarily from considerable improvements in MUC F-score. As MUC is a link-based measure, these results provide suggestive evidence that joint modeling has enabled more event coreference links to be discovered.

4.3 Model Ablations

To evaluate the importance of each of the three types of joint factors in the joint model, we perform ablation experiments.[7] Table 3 shows the results on the English and Chinese datasets when we add each type of joint factors to the independent model and remove each type of joint factors from the full joint model. The results of each task are expressed in terms of changes to the corresponding independent model's F-score.

[7] Chen and Ng (2013) also performed ablation on their ACE-style Chinese event coreference resolver. However, given the differences in the tasks involved (e.g., they did not model event anaphoricity, but included tasks such as event argument extraction and role classification, entity coreference, and event mention attribute value computation) and the ablation setup (e.g., they ablated individual tasks/components in their pipeline-based system in an incremental fashion, whereas we ablate interaction factors rather than tasks), a direct comparison of their observations and ours is difficult.

Coref-Trigger interactions. Among the three types of factors, this one contributes the most to coreference performance, regardless of whether it is applied in isolation or in combination with the other two types of factors to the independent coreference model. In addition, it is the most effective type of factor for improving trigger detection. When applied in combination, it also improves anaphoricity determination, although less effectively than the other two types of factors.

Coref-Anaphoricity interactions. When applied in isolation to the independent models, this type of factor improves coreference resolution but has a mixed impact on anaphoricity determination. When applied in combination with other types of factors, it improves both tasks, particularly anaphoricity determination. Its impact on trigger detection, however, is generally negative.

Trigger-Anaphoricity interactions. When applied in isolation to the independent models, this type of factor improves both trigger detection and anaphoricity determination. When applied in combination with other types of factors, it still improves anaphoricity determination (particularly on Chinese), but has a mixed effect on trigger detection. Among the three types of factors, it has the least impact on coreference resolution.

4.4 Error Analysis

Next, we conduct an analysis of the major sources of error made by our joint coreference model.

4.4.1 Two Major Types of Precision Error

Erroneous and mistyped triggers. Our trigger model tends to assign the same subtype to event mentions triggered by the same word. As a result, it often assigns the wrong subtype to triggers that

possess different subtypes in different contexts. For the same reason, words that are only sometimes used as triggers are often wrongly posited as triggers when they are not. These two types of triggers have in turn led to the establishment of incorrect coreference links.[8]

Failure to extract arguments. In the absence of an annotated corpus for training an argument classifier, we exploit dependency relations for argument extraction. Doing so proves inadequate, particularly for noun triggers, owing to the absence of dependency relations that can be used to reliably extract their arguments. Moreover, using dependency relations does not allow the extraction of arguments that do not appear in the same sentence as their trigger. Since the presence of incompatible arguments is an important indicator of non-coreference, our model's failure to extract arguments has resulted in incorrect coreference links.

4.4.2 Three Major Types of Recall Error

Missing triggers. Our trigger model fails to identify trigger words that are unseen or rarely-occurring in the training data. As a result, many coreference links cannot be established.

Lack of entity coreference information. Entity coreference information is useful for event coreference because the corresponding arguments of two event mentions are typically coreferent. Since our model does not exploit entity coreference information, it treats two lexically different event arguments as non-coreferent/unrelated. This in turn weakens its ability to determine whether two event mentions are coreferent. This issue is particularly serious in discussion forum documents, where it is not uncommon to see pronouns serve as subjects and objects of event mentions. The situation is further aggravated in Chinese documents, where zero pronouns are prevalent.

Lack of contextual understanding. Our model only extracts features from the sentence in which an event mention appears. However, additional contextual information present in neighboring sentences may be needed for correct coreference resolution. This is particularly true in discussion forum documents, where the same event may be described differently by different people. For example, when describing the fact that Tim Cook will attend Apple's Istanbul store opening, one person said "Cook is expected to return to Turkey for the store opening", and another person described this event as "Tim travels abroad YET AGAIN to be feted by the not-so-high-and-mighty". It is by no means easy to determine that *return* and *travel* trigger two coreferent mentions in these sentences.

[8] In our joint model, mentions that are posited as coreferent are encouraged to have the same subtype. While it can potentially fix the errors involving coreferent mentions that have different subtypes, it cannot fix the errors in which the two mentions involved have the same erroneous subtype.

5 Related Work

Existing event coreference resolvers have been evaluated on different corpora, such as MUC (e.g., Humphreys et al. (1997)), ACE (e.g., Ahn (2006), Chen and Ji (2009), McConky et al. (2012), Sangeetha and Arock (2012), Chen and Ng (2015, 2016), Krause et al. (2016)), OntoNotes (e.g., Chen et al. (2011)), the Intelligence Community corpus (e.g., Cybulska and Vossen (2012), Araki et al. (2014), Liu et al. (2014)), the ECB corpus (e.g., Lee et al. (2012), Bejan and Harabagiu (2014)) and its extension ECB+ (e.g., Yang et al. (2015)), and ProcessBank (e.g., Araki and Mitamura (2015)). The newest event coreference corpora are the ones used in the KBP 2015 and 2016 Event Nugget Detection and Coreference shared tasks, in which the best performers in 2015 and 2016 are RPI's system (Hong et al., 2015) and UTD's system (Lu and Ng, 2016), respectively. The KBP 2015 corpus has recently been used to evaluate Peng et al.'s (2016) minimally supervised approach and Lu et al.'s (2016) joint inference approach to event coreference. With the rarest exceptions (e.g., Lu et al. (2016)), existing resolvers have adopted a pipeline architecture in which trigger detection is performed prior to coreference resolution.

6 Conclusion

We proposed a joint model of event coreference resolution, trigger detection, and event anaphoricity determination. The model is novel in its choice of tasks and the cross-task interaction features. When evaluated on the KBP 2016 English and Chinese corpora, our model not only outperforms the independent models but also achieves the best results to date on these corpora.

Appendix: Handling Words that Trigger Multiple Event Mentions

In KBP, a word can trigger multiple event mentions. However, since we create exactly one candidate event mention from each extracted word in each test document, our model effectively prevents a word from triggering multiple event mentions. This poses a problem: each word cannot be associated with more than one event subtype. This appendix describes how we (partially) address this issue that involves allowing each event mention to be associated with multiple event subtypes.

To address this problem, we preprocess the *gold trigger annotations* in the *training* data as follows. First, for each word triggering multiple event mentions (with different event subtypes), we merge their event mentions into one event mention having the combined subtype. In principle, we can add each of these combined subtypes into our event subtype inventory and allow our model to make predictions using them. However, to avoid over-complicating the prediction task (by having a large subtype inventory), we only add the three most frequently occurring combined subtypes in the training data to the inventory. Merged mentions whose combined subtype is not among the most frequent three will be unmerged in order to recover the original mentions so that the model can still be trained on them.

To train our joint model, however, the trigger annotations and the event coreference annotations in the training data must be consistent. Since we modified the trigger annotations (by merging event mentions and allowing combined subtypes), we make two modifications to the event coreference annotations to ensure consistency between the two sets of annotations. First, let C_1 and C_2 be two event coreference chains in a training document such that the set of words triggering the event mentions in C_1 (with subtype t_1) is the same as that triggering the event mentions in C_2 (with subtype t_2). If each of the event mentions in C_1 was merged with the corresponding event mention in C_2 during the aforementioned preprocessing of the trigger annotations (because combining t_1 and t_2 results in one of the three most frequent combined subtypes), then we delete one of the two coreference chains, and assign the combined subtype to the remaining chain. Finally, we remove any remaining event mentions that were merged during the preprocessing of trigger annotations from their respective coreference chains and create a singleton cluster for each of the merged mentions.

Generating and Exploiting Large-scale Pseudo Training Data for Zero Pronoun Resolution

Abstract

Most existing approaches for zero pronoun resolution are heavily relying on annotated data, which is often released by shared task organizers. Therefore, the lack of annotated data becomes a major obstacle in the progress of zero pronoun resolution task. Also, it is expensive to spend manpower on labeling the data for better performance. To alleviate the problem above, in this paper, we propose a simple but novel approach to automatically generate large-scale pseudo training data for zero pronoun resolution. Furthermore, we successfully transfer the cloze-style reading comprehension neural network model into zero pronoun resolution task and propose a two-step training mechanism to overcome the gap between the pseudo training data and the real one. Experimental results show that the proposed approach significantly outperforms the state-of-the-art systems with an absolute improvements of 3.1% F-score on OntoNotes 5.0 data.

1 Introduction

Previous works on zero pronoun (ZP) resolution mainly focused on the supervised learning approaches (Han, 2006; Zhao and Ng, 2007; Iida et al., 2007; Kong and Zhou, 2010; Iida and Poesio, 2011; Chen and Ng, 2013). However, a major obstacle for training the supervised learning models for ZP resolution is the lack of annotated data. An important step is to organize the shared task on anaphora and coreference resolution, such as the ACE evaluations, SemEval-2010 shared task on Coreference Resolution in Multiple Languages (Marta Recasens, 2010) and CoNLL-2012 shared task on Modeling Multilingual Unrestricted Coreference in OntoNotes (Sameer Pradhan, 2012). Following these shared tasks, the annotated evaluation data can be released for the following researches. Despite the success and contributions of these shared tasks, it still faces the challenge of spending manpower on labeling the extended data for better training performance and domain adaptation.

To address the problem above, in this paper, we propose a simple but novel approach to automatically generate large-scale pseudo training data for zero pronoun resolution. Inspired by data generation on cloze-style reading comprehension, we can treat the zero pronoun resolution task as a special case of reading comprehension problem. So we can adopt similar data generation methods of reading comprehension to the zero pronoun resolution task. For the noun or pronoun in the document, which has the frequency equal to or greater than 2, we randomly choose one position where the noun or pronoun is located on, and replace it with a specific symbol $\langle blank \rangle$. Let query $\mathcal{Q}$ and answer $\mathcal{A}$ denote the sentence that contains a $\langle blank \rangle$, and the noun or pronoun which is replaced by the $\langle blank \rangle$, respectively. Thus, a pseudo training sample can be represented as a triple:

$$\langle \mathcal{D}, \mathcal{Q}, \mathcal{A} \rangle \quad (1)$$

For the zero pronoun resolution task, a $\langle blank \rangle$ represents a zero pronoun (ZP) in query $\mathcal{Q}$, and $\mathcal{A}$ indicates the corresponding antecedent of the ZP. In this way, tremendous pseudo training samples can be generated from the various documents, such as news corpus.

Towards the shortcomings of the previous approaches that are based on feature engineering, we propose a neural network architecture, which is an attention-based neural network model, for zero pronoun resolution. Also we propose a two-step

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 102–111
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1010

training method, which benefit from both large-scale pseudo training data and task-specific data, showing promising performance.

To sum up, the contributions of this paper are listed as follows.

- To our knowledge, this is the first time that utilizing reading comprehension neural network model into zero pronoun resolution task.
- We propose a two-step training approach, namely pre-training-then-adaptation, which benefits from both the large-scale automatically generated pseudo training data and task-specific data.
- Towards the shortcomings of the feature engineering approaches, we first propose an attention-based neural network model for zero pronoun resolution.

2 The Proposed Approach

In this section, we will describe our approach in detail. First, we will describe our method of generating large-scale pseudo training data for zero pronoun resolution. Then we will introduce two-step training approach to alleviate the gaps between pseudo and real training data. Finally, the attention-based neural network model as well as associated unknown words processing techniques will be described.

2.1 Generating Pseudo Training Data

In order to get large quantities of training data for neural network model, we propose an approach, which is inspired by (Hermann et al., 2015), to automatically generate large-scale pseudo training data for zero pronoun resolution. However, our approach is much more simple and general than that of (Hermann et al., 2015). We will introduce the details of generating the pseudo training data for zero pronoun resolution as follows.

First, we collect a large number of documents that are relevant (or homogenous in some sense) to the released OntoNote 5.0 data for zero pronoun resolution task in terms of its domain. In our experiments, we used large-scale news data for training.

Given a certain document $\mathcal{D}$, which is composed by a set of sentences $\mathcal{D} = \{s_1, s_2, ..., s_n\}$, we randomly choose an answer word $\mathcal{A}$ in the document. Note that, we restrict $\mathcal{A}$ to be either a noun or pronoun, where the part-of-speech is identified using LTP Toolkit (Che et al., 2010), as well as the answer word should appear at least twice in the document. Second, after the answer word $\mathcal{A}$ is chosen, the sentence that contains $\mathcal{A}$ is defined as a query $\mathcal{Q}$, in which the answer word $\mathcal{A}$ is replaced by a specific symbol $\langle blank \rangle$. In this way, given the query $\mathcal{Q}$ and document $\mathcal{D}$, the target of the prediction is to recover the answer $\mathcal{A}$. That is quite similar to the zero pronoun resolution task. Therefore, the automatically generated training samples is called ***pseudo*** training data. Figure 1 shows an example of a pseudo training sample.

In this way, we can generate tremendous triples of $\langle \mathcal{D}, \mathcal{Q}, \mathcal{A} \rangle$ for training neural network, without making any assumptions on the nature of the original corpus.

2.2 Two-step Training

It should be noted that, though we have generated large-scale pseudo training data for neural network training, there is still a gap between pseudo training data and the real zero pronoun resolution task in terms of the query style. So we should do some adaptations to our model to deal with the zero pronoun resolution problems ideally.

In this paper, we used an effective approach to deal with the mismatch between pseudo training data and zero pronoun resolution task-specific data. Generally speaking, in the first stage, we use a large amount of the pseudo training data to train a fundamental model, and choose the best model according to the validation accuracy. Then we continue to train from the previous best model using the zero pronoun resolution task-specific training data, which is exactly the same domain and query type as the standard zero pronoun resolution task data.

The using of the combination of proposed pseudo training data and task-specific data, i.e. zero pronoun resolution task data, is far more effective than using either of them alone. Though there is a gap between these two data, they share many similar characteristics to each other as illustrated in the previous part, so it is promising to utilize these two types of data together, which will compensate to each other.

The two-step training procedure can be concluded as,

Document:

1 ||| welcome both of you to the studio to participate in our program ,
欢迎 两 位 呢 来 演播室 参与 我们 的 节目 ,

2 ||| it happened that i was going to have lunch with a friend at noon .
正好 因为 我 也 和 朋友 这个 , 这个 中午 一起 吃饭 。

3 ||| after that , i received an sms from 1860 .
然后 我 就 收到 1860 的 短信 。

4 ||| uh-huh , it was by sms .
嗯 , 是 通过 短信 的 方式 ,

5 ||| uh-huh , that means , er , you knew about the accident through the source of radio station .
嗯 , 就是说 呃 你 是 通过 台 里面 的 一 个 信息 的 渠道 知道 这儿 出 了 这样 的 事故 。

6 ||| although we live in the west instead of the east part , and it did not affect us that much ,
虽然 我们 生活 在 西部 不 是 在 东部 , 对 我们 影响 不 是 很 大 ,

7 ||| but i think it is very useful to inform people using sms .
但是 呢 , 我 觉得 有 这样 一 个 短信 告诉 大家 呢 是 非常 有用 的 啊 。

Query:

8 ||| some car owners said that **<blank>** was very good。
有 车主 表示 , 说 这 **<blank>** 非常 的 好。

Answer:

sms
短信

Figure 1: Example of pseudo training sample for zero pronoun resolution system. (The original data is in Chinese, we translate this sample into English for clarity)

- Pre-training stage: by using large-scale training data to train the neural network model, we can learn richer word embeddings, as well as relatively reasonable weights in neural networks than just training with a small amount of zero pronoun resolution task training data;
- Adaptation stage: after getting the best model that is produced in the previous step, we continue to train the model with task-specific data, which can force the previous model to adapt to the new data, without losing much knowledge that has learned in the previous stage (such as word embeddings).

As we will see in the experiment section that the proposed two-step training approach is effective and brings significant improvements.

2.3 Attention-based Neural Network Model

Our model is primarily an attention-based neural network model, which is similar to *Attentive Reader* proposed by (Hermann et al., 2015). Formally, when given a set of training triple $\langle \mathcal{D}, \mathcal{Q}, \mathcal{A} \rangle$, we will construct our network in the following way.

Firstly, we project one-hot representation of document $\mathcal{D}$ and query $\mathcal{Q}$ into a continuous space with the shared embedding matrix W_e. Then we input these embeddings into different bi-directional RNN to get their contextual representations respectively. In our model, we used the bidirectional Gated Recurrent Unit (GRU) as RNN implementation (Cho et al., 2014).

$$e(x) = W_e \cdot x, \ where \ \ x \in \mathcal{D}, \mathcal{Q} \tag{2}$$

$$\overrightarrow{h_s} = \overrightarrow{GRU}(e(x)); \overleftarrow{h_s} = \overleftarrow{GRU}(e(x)) \tag{3}$$

$$h_s = [\overrightarrow{h_s}; \overleftarrow{h_s}] \tag{4}$$

For the query representation, instead of concatenating the final forward and backward states as its representations, we directly get an averaged representations on all bi-directional RNN slices, which can be illustrated as

$$h_{query} = \frac{1}{n} \sum_{t=1}^{n} h_{query}(t) \tag{5}$$

For the document, we place a soft attention over all words in document (Bahdanau et al., 2014), which indicate the degree to which part of document is attended when filling the blank in the query sentence. Then we calculate a weighted sum of all document tokens to get the attended representation of document.

$$m(t) = \tanh(W \cdot h_{doc}(t) + U \cdot h_{query}) \tag{6}$$

$$\alpha(t) = \frac{\exp(W_s \cdot m(t))}{\sum_{j=1}^{n} \exp(W_s \cdot m(j))} \tag{7}$$

$$h_{doc\_att} = h_{doc} \cdot \alpha \tag{8}$$

where variable $\alpha(t)$ is the normalized attention weight at tth word in document, h_{doc} is a matrix that concatenate all $h_{doc}(t)$ in sequence.

$$h_{doc} = concat[h_{doc}(1), h_{doc}(2), ..., h_{doc}(t)] \tag{9}$$

Then we use attended document representation and query representation to estimate the final answer, which can be illustrated as follows, where V

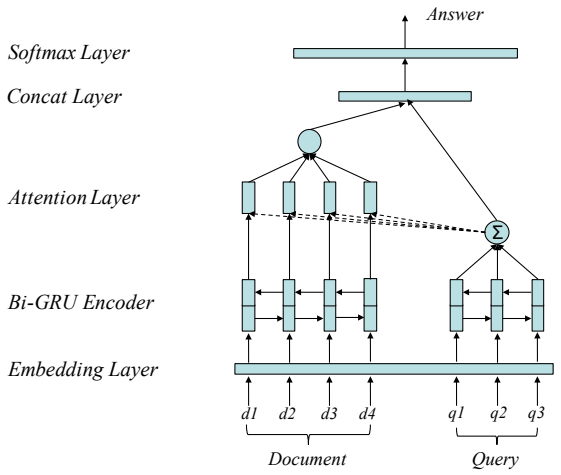

Figure 2: Architecture of attention-based neural network model for zero pronoun resolution task.

is the vocabulary,

$$r = concat[h_{doc\_att}, h_{query}] \tag{10}$$

$$P(\mathcal{A}|\mathcal{D}, \mathcal{Q}) \propto softmax(W_r \cdot r) \ \ , s.t. \ \mathcal{A} \in V \tag{11}$$

Figure 2 shows the proposed neural network architecture.

Note that, for zero pronoun resolution task, antecedents of zero pronouns are always noun phrases (NPs), while our model generates only one word (a noun or a pronoun) as the result. To better adapt our model to zero pronoun resolution task, we further process the output result in the following procedure. First, for a given zero pronoun, we extract a set of NPs as its candidates utilizing the same strategy as (Chen and Ng, 2015). Then, we use our model to generate an answer (one word) for the zero pronoun. After that, we go through all the candidates from the nearest to the far-most. For an NP candidate, if the produced answer is its head word, we then regard this NP as the antecedent of the given zero pronoun. By doing so, for a given zero pronoun, we generate an NP as the prediction of its antecedent.

2.4 Unknown Words Processing

Because of the restriction on both memory occupation and training time, it is usually suggested to use a shortlist of vocabulary in neural network training. However, we often replace the out-of-vocabularies to a unique special token, such as $\langle unk \rangle$. But this may place an obstacle in real world test. When the model predicts the answer as $\langle unk \rangle$, we do not know what is the exact word it represents in the document, as there may have many $\langle unk \rangle$s in the document.

In this paper, we propose to use a simple but effective way to handle unknown words issue. The idea is straightforward, which can be illustrated as follows.

- Identify all unknown words inside of each $\langle \mathcal{D}, \mathcal{Q}, \mathcal{A} \rangle$;
- Instead of replacing all these unknown words into one unique token $\langle unk \rangle$, we make a hash table to project these unique unknown words to numbered tokens, such as $\langle unk1 \rangle, \langle unk2 \rangle, ..., \langle unkN \rangle$ in terms of its occurrence order in the document. Note that, the same words are projected to the same unknown word tokens, and all these projections are only valid inside of current sample. For example, $\langle unk1 \rangle$ indicate the first unknown word, say "apple", in the current sample, but in another sample the $\langle unk1 \rangle$ may indicate the unknown word "orange". That is, the unknown word labels are indicating position features rather than the exact word;
- Insert these unknown marks in the vocabulary. These marks may only take up dozens of slots, which is negligible to the size of shortlists (usually 30K $\sim$ 100K).

(a) *The weather today is not as pleasant as the weather of yesterday.*
(b) *The **<unk>** today is not as **<unk>** as the **<unk>** of yesterday.*
(c) *The **<unk1>** today is not as **<unk2>** as the **<unk1>** of yesterday.*

Figure 3: Example of unknown words processing. a) original sentence; b) original unknown words processing method; c) our method

We take one sentence "The weather of today is not as pleasant as the weather of yesterday." as an example to show our unknown word processing method, which is shown in Figure 3.

If we do not discriminate the unknown words and assign different unknown words with the same token $\langle unk \rangle$, it would be impossible for us to know what is the exact word that $\langle unk \rangle$ represents for in the real test. However, when using our proposed unknown word processing method, if the model predicts a $\langle unkX \rangle$ as the answer,

we can simply scan through the original document and identify its position according to its unknown word number X and replace the $\langle unkX \rangle$ with the real word. For example, in Figure 3, if we adopt original unknown words processing method, we could not know whether the $\langle unk \rangle$ is the word "weather" or "pleasant". However, when using our approach, if the model predicts an answer as $\langle unk1 \rangle$, from the original text, we can know that $\langle unk1 \rangle$ represents the word "weather".

3 Experiments

3.1 Data

In our experiments, we choose a selection of public news data to generate large-scale pseudo training data for pre-training our neural network model (pre-training step)[1]. In the adaptation step, we used the official dataset OntoNotes Release 5.0[2] which is provided by CoNLL-2012 shared task, to carry out our experiments. The CoNLL-2012 shared task dataset consists of three parts: a training set, a development set and a test set. The datasets are made up of 6 different domains, namely Broadcast News (BN), Newswires (NW), Broadcast Conversations (BC), Telephone Conversations (TC), Web Blogs (WB), and Magazines (MZ). We closely follow the experimental settings as (Kong and Zhou, 2010; Chen and Ng, 2014, 2015, 2016), where we treat the training set for training and the development set for testing, because only the training and development set are annotated with ZPs. The statistics of training and testing data is shown in Table 1 and 2 respectively.

	Sentences #	Query #
General Train	18.47M	1.81M
Domain Train	122.8K	9.4K
Validation	11,191	2,667

Table 1: Statistics of training data, including pseudo training data and OntoNotes 5.0 training data.

3.2 Neural Network Setups

Training details of our neural network models are listed as follows.

[1]The news data is available at http://www.sogou.com/labs/dl/cs.html

[2]http://catalog.ldc.upenn.edu/LDC2013T19

	Docs	Sentences	Words	AZPs
Test	172	6,083	110K	1,713

Table 2: Statistics of test set (OntoNotes 5.0 development data).

- Embedding: We use randomly initialized embedding matrix with uniformed distribution in the interval [-0.1,0.1], and set units number as 256. No pre-trained word embeddings are used.
- Hidden Layer: We use GRU with 256 units, and initialize the internal matrix by random orthogonal matrices (Saxe et al., 2013). As GRU still suffers from the gradient exploding problem, we set gradient clipping threshold to 10.
- Vocabulary: As the whole vocabulary is very large (over 800K), we set a shortlist of 100K according to the word frequency and unknown words are mapped to 20 $\langle unkX \rangle$ using the proposed method.
- Optimization: We used ADAM update rule (Kingma and Ba, 2014) with an initial learning rate of 0.001, and used negative log-likelihood as the training objective. The batch size is set to 32.

All models are trained on Tesla K40 GPU. Our model is implemented with Theano (Theano Development Team, 2016) and Keras (Chollet, 2015).

3.3 Experimental results

Same to the previous researches that are related to zero pronoun resolution, we evaluate our system performance in terms of F-score (F). We focus on AZP resolution process, where we assume that gold AZPs and gold parse trees are given[3]. The same experimental setting is utilized in (Chen and Ng, 2014, 2015, 2016). The overall results are shown in Table 3, where the performances of each domain are listed in detail and overall performance is also shown in the last column.

- **Overall Performance**

We employ four Chinese ZP resolution baseline systems on OntoNotes 5.0 dataset. As we can

[3]All gold information are provided by the CoNLL-2012 shared task dataset

	NW (84)	MZ (162)	WB (284)	BN (390)	BC (510)	TC (283)	**Overall**
Kong and Zhou (2010)	34.5	32.7	45.4	51.0	43.5	48.4	44.9
Chen and Ng (2014)	38.1	31.0	50.4	45.9	53.8	**54.9**	48.7
Chen and Ng (2015)	46.4	39.0	51.8	53.8	49.4	52.7	50.2
Chen and Ng (2016)	48.8	41.5	56.3	**55.4**	50.8	53.1	52.2
Our Approach†	**59.2**	**51.3**	**60.5**	53.9	**55.5**	52.9	**55.3**

Table 3: Experimental result (F-score) on the OntoNotes 5.0 test data. The best results are marked with bold face. † indicates that our approach is statistical significant over the baselines (using t-test, with $p < 0.05$). The number in the brackets indicate the number of AZPs.

see that our model significantly outperforms the previous state-of-the-art system (Chen and Ng, 2016) by 3.1% in overall F-score, and substantially outperform the other systems by a large margin. When observing the performances of different domains, our approach also gives relatively consistent improvements among various domains, except for BN and TC with a slight drop. All these results approve that our proposed approach is effective and achieves significant improvements in AZP resolution.

In our quantitative analysis, we investigated the reasons of the declines in the BN and TC domain. A primary observation is that the word distributions in these domains are fairly different from others. The average document length of BN and TC are quite longer than other domains, which suggest that there is a bigger chance to have unknown words than other domains, and add difficulties to the model training. Also, we have found that in the BN and TC domains, the texts are often in oral form, which means that there are many irregular expressions in the context. Such expressions add noise to the model, and it is difficult for the model to extract useful information in these contexts. These phenomena indicate that further improvements can be obtained by filtering stop words in contexts, or increasing the size of task-specific data, while we leave this in the future work.

- **Effect of UNK processing**

As we have mentioned in the previous section, traditional unknown word replacing methods are vulnerable to the real word test. To alleviate this issue, we proposed the UNK processing mechanism to recover the UNK tokens to the real words. In Table 4, we compared the performance that with and without the proposed UNK processing, to show whether the proposed UNK processing method is effective. As we can see that, by applying our UNK processing mechanism, the model do learned the positional features in these low-frequency words, and brings over 3% improvements in F-score, which indicated the effectiveness of our UNK processing approach.

	F-score
Without UNK replacement	52.2
With UNK replacement	**55.3**

Table 4: Performance comparison on whether using the proposed unknown words processing.

- **Effect of Domain Adaptation**

We also tested out whether our domain adaptation method is effective. In this experiments, we used three different types of training data: only pseudo training data, only task-specific data, and our adaptation method, i.e. using pseudo training data in the pre-training step and task-specific data for domain adaptation step. The results are given in Table 5. As we can see that, using either pseudo training data or task-specific data alone can not bring inspiring result. By adopting our domain adaptation method, the model could give significant improvements over the other models, which demonstrate the effectiveness of our proposed two-step training approach. An intuition behind this phenomenon is that though pseudo training data is fairly big enough to train a reliable model parameters, there is still a gap to the real zero pronoun resolution tasks. On the contrary, though task-specific training data is exactly the same type as the real test, the quantity is not enough to train a reasonable model (such as word embedding). So it is better to make use of both to

take the full advantage.

However, as the original task-specific data is fairly small compared to pseudo training data, we also wondered if the large-scale pseudo training data is only providing rich word embedding information. So we use the large-scale pseudo training data for embedding training using GloVe toolkit (Pennington et al., 2014), and initialize the word embeddings in the "only task-specific data" system. From the result we can see that the pseudo training data provide more information than word embeddings, because though we used GloVe embeddings in "only task-specific data", it still can not outperform the system that uses domain adaptation which supports our claim.

	F-score
Only Pseudo Training Data	41.1
Only Task-Specific Data	44.2
Only Task-Specific Data + GloVe	50.9
Domain Adaptation	**55.3**

Table 5: Performance comparison of using different training data.

4 Error Analysis

To better evaluate our proposed approach, we performed a qualitative analysis of errors, where two major errors are revealed by our analysis, as discussed below.

4.1 Effect of Unknown Words

Our approach does not do well when there are lots of $\langle unk \rangle$s in the context of ZPs, especially when the $\langle unk \rangle$s appears near the ZP. An example is given below, where words with # are regarded as $\langle unk \rangle$s in our model.

> ϕ 登上# 太平山# 顶，将 香港岛# 和 维多利亚港# 的 美景 尽收眼底 。
> ϕ Successfully climbed# the peak of [Taiping Mountain]#, to have a panoramic view of the beauty of [Hong Kong Island]# and [Victoria Harbour]#.

In this case, the words "登上/climbed" and "太平山/Taiping Mountain" that appears immediately after the ZP "ϕ" are all regarded as $\langle unk \rangle$s in our model. As we model the sequence of words by RNN, the $\langle unk \rangle$s make the model more difficult to capture the semantic information of the sentence, which in turn influence the overall performance. Especially for the words that are near the ZP, which play important roles when modeling context information for the ZP. By looking at the word "顶/peak", it is hard to comprehend the context information, due to the several surrounding $\langle unk \rangle$s. Though our proposed unknown words processing method is effective in empirical evaluation, we think that more advanced method for unknown words processing would be of a great help in improving comprehension of the context.

4.2 Long Distance Antecedents

Also, our model makes incorrect decisions when the correct antecedents of ZPs are in long distance. As our model chooses answer from words in the context, if there are lots of words between the ZP and its antecedent, more noise information are introduced, and adds more difficulty in choosing the right answer. For example:

> 我 帮 不 了 那个 人 ... ... 那 天 结束 后 ϕ 回到 家中 。
> I can't help that guy ... ... After that day, ϕ return home.

In this case, the correct antecedent of ZP "ϕ" is the NP candidate "我/I". By seeing the contexts, we observe that there are over 30 words between the ZP and its antecedent. Although our model does not intend to fill the ZP gap only with the words near the ZP, as most of the antecedents appear just a few words before the ZPs, our model prefers the nearer words as correct antecedents. Hence, once there are lots of words between ZP and its nearest antecedent, our model can sometimes make wrong decisions. To correctly handle such cases, our model should learn how to filter the useless words and enhance the learning of long-term dependency.

5 Related Work

5.1 Zero pronoun resolution

For Chinese zero pronoun (ZP) resolution, early studies employed heuristic rules to Chinese ZP resolution. Converse (2006) proposes a rule-based method to resolve the zero pronouns, by utilizing Hobbs algorithm (Hobbs, 1978) in the CTB documents. Then, supervised approaches to this task have been vastly explored. Zhao and Ng (2007) first present a supervised machine learning approach to the identification and resolution of Chinese ZPs. Kong and Zhou (2010) develop a tree-kernel based approach for Chinese ZP resolution. More recently, unsupervised approaches

have been proposed. Chen and Ng (2014) develop an unsupervised language-independent approach, utilizing the integer linear programming to using ten overt pronouns. Chen and Ng (2015) propose an end-to-end unsupervised probabilistic model for Chinese ZP resolution, using a salience model to capture discourse information. Also, there have been many works on ZP resolution for other languages. These studies can be divided into rule-based and supervised machine learning approaches. Ferrández and Peral (2000) proposed a set of hand-crafted rules for Spanish ZP resolution. Recently, supervised approaches have been exploited for ZP resolution in Korean (Han, 2006) and Japanese (Isozaki and Hirao, 2003; Iida et al., 2006, 2007; Sasano and Kurohashi, 2011). Iida and Poesio (2011) developed a cross-lingual approach for Japanese and Italian ZPs where an ILP-based model was employed to zero anaphora detection and resolution.

In sum, most recent researches on ZP resolution are supervised approaches, which means that their performance highly relies on large-scale annotated data. Even for the unsupervised approach (Chen and Ng, 2014), they also utilize a supervised pronoun resolver to resolve ZPs. Therefore, the advantage of our proposed approach is obvious. We are able to generate large-scale pseudo training data for ZP resolution, and also we can benefit from the task-specific data for fine-tuning via the proposed two-step training approach.

5.2 Cloze-style Reading Comprehension

Our neural network model is mainly motivated by the recent researches on cloze-style reading comprehension tasks, which aims to predict one-word answer given the document and query. These models can be seen as a general model of mining the relations between the document and query, so it is promising to combine these models to the specific domain.

A representative work of cloze-style reading comprehension is done by Hermann et al. (2015). They proposed a methodology for obtaining large quantities of $\langle \mathcal{D}, \mathcal{Q}, \mathcal{A} \rangle$ triples. By using this method, a large number of training data can be obtained without much human intervention, and make it possible to train a reliable neural network. They used attention-based neural networks for this task. Evaluation on CNN/DailyMail datasets showed that their approach is much effective than traditional baseline systems.

While our work is similar to Hermann et al. (2015), there are several differences which can be illustrated as follows. Firstly, though we both utilize the large-scale corpus, they require that the document should accompany with a brief summary of it, while this is not always available in most of the document, and it may place an obstacle in generating limitless training data. In our work, we do not assume any prerequisite of the training data, and directly extract queries from the document, which makes it easy to generate large-scale training data. Secondly, their work mainly focuses on reading comprehension in the general domain. We are able to exploit large-scale training data for solving problems in the specific domain, and we proposed two-step training method which can be easily adapted to other domains as well.

6 Conclusion

In this study, we propose an effective way to generate and exploit large-scale pseudo training data for zero pronoun resolution task. The main idea behind our approach is to automatically generate large-scale pseudo training data and then utilize an attention-based neural network model to resolve zero pronouns. For training purpose, two-step training approach is employed, i.e. a **pre-training** and **adaptation** step, and this can be also easily applied to other tasks as well. The experimental results on OntoNotes 5.0 corpus are encouraging, showing that the proposed model and accompanying approaches significantly outperforms the state-of-the-art systems.

The future work will be carried out on two main aspects: First, as experimental results show that the unknown words processing is a critical part in comprehending context, we will explore more effective way to handle the UNK issue. Second, we will develop other neural network architecture to make it more appropriate for zero pronoun resolution task.

Abstract

Discourse modes play an important role in writing composition and evaluation. This paper presents a study on the manual and automatic identification of *narration*, *exposition*, *description*, *argument* and *emotion expressing* sentences in narrative essays. We annotate a corpus to study the characteristics of discourse modes and describe a neural sequence labeling model for identification. Evaluation results show that discourse modes can be identified automatically with an average F1-score of 0.7. We further demonstrate that discourse modes can be used as features that improve automatic essay scoring (AES). The impacts of discourse modes for AES are also discussed.

1 Introduction

Discourse modes, also known as rhetorical modes, describe the purpose and conventions of the main kinds of language based communication.Most common discourse modes include narration, description, exposition and argument. A typical text would make use of all the modes, although in a given one there will often be a main mode. Despite their importance in writing composition and assessment (Braddock et al., 1963), there is relatively little work on analyzing discourse modes based on computational models. We aim to contribute for automatic discourse mode identification and its application on writing assessment.

The use of discourse modes is important in writing composition, because they relate to several aspects that would influence the quality of a text.

First, discourse modes reflect the organization of a text. Natural language texts consist of sentences which form a unified whole and make up the discourse (Clark et al., 2013). Recognizing the structure of text organization is a key part for discourse analysis. Meurer (2002) points that discourse modes stand for unity as they constitute general patterns of language organization strategically used by the writer. Smith (2003) also proposes to study discourse passages from a linguistic view of point through discourse modes. The organization of a text can be realized by segmenting text into passages according to the set of discourse modes that are used to indicate the functional relationship between the several parts of the text. For example, the writer can present major events through narration, provide details with description and establish ideas with argument. The combination and interaction of various discourse modes make an organized unified text.

Second, discourse modes have rhetorical significance. Discourse modes are closely related to rhetoric (Connors, 1981; Brooks and Warren, 1958), which offers a principle for learning how to express material in the best way. Discourse modes have different preferences on expressive styles. Narration mainly controls story progression by introducing and connecting events; exposition is to instruct or explain so that the language should be precise and informative; argument is used to convince or persuade through logical and inspiring statements; description attempts to bring detailed observations of people and scenery, which is related to the writing of figurative language; the way to express emotions may relate to the use of rhetorical devices and poetic language. Discourse modes reflect the variety of expressive styles. The flexible use of various discourse modes should be important evidence of language proficiency.

According to the above thought, we propose the discourse mode identification task. In particular, we make the following contributions:

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 112–122
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1011

- We build a corpus of narrative essays written by Chinese students in native language. Sentence level discourse modes are annotated with acceptable inter-annotator agreement. Corpus analysis reveals the characteristics of discourse modes in several aspects, including discourse mode distribution, co-occurrence and transition patterns.

- We describe a multi-label neural sequence labeling approach for discourse mode identification so that the co-occurrence and transition preferences can be captured. Experimental results show that discourse modes can be identified with an average F1-score of 0.7, indicating that automatic discourse mode identification is feasible.

- We demonstrate the effectiveness of taking discourse modes into account for automatic essay scoring. A higher ratio of description and emotion expressing can indicate essay quality to a certain extent. Discourse modes can be potentially used as features for other NLP applications.

2 Related Work

2.1 Discourse Analysis

Discourse analysis is an important subfield of natural language processing (Webber et al., 2011). Discourse is expected to be both cohesive and coherent. Many principles are proposed for discourse analysis, such as coherence relations (Hobbs, 1979; Mann and Thompson, 1988), the centering theory for local coherence (Grosz et al., 1995) and topic-based text segmentation (Hearst, 1997). In some domains, discourse can be segmented according to specific discourse elements (Hutchins, 1977; Teufel and Moens, 2002; Burstein et al., 2003; Clerehan and Buchbinder, 2006; Song et al., 2015).

This paper focuses on discourse modes influenced by Smith (2003). From the linguistic view of point, discourse modes are supposed to have different distributions of situation entity types such as event, state and generic (Smith, 2003; Mavridou et al., 2015). Therefore, there is work on automatically labeling clause level situation entity types (Palmer et al., 2007; Friedrich et al., 2016). Actually, situation entity type identification is also a challenging problem. It is even harder for processing Chinese language, since Chinese doesn't have grammatical tense (Xue and Zhang, 2014) and sentence components are often omitted. This increases the difficulties for situation entity type based discourse mode identification. In this paper, we investigate an end-to-end approach to directly model discourse modes without the necessity of identifying situation entity types first.

2.2 Automatic Writing Assessment

Automatic writing assessment is an important application of natural language processing. The task aims to let computers have the ability to appreciate and criticize writing. It would be hugely beneficial for applications like automatic essay scoring (AES) and content recommendation.

AES is the task of building a computer-aided scoring system, in order to reduce the involvement of human raters. Traditional approaches are based on supervised learning with designed feature templates (Larkey, 1998; Burstein, 2003; Attali and Burstein, 2006; Chen and He, 2013; Phandi et al., 2015; Cummins et al., 2016). Recently, automatic feature learning based on neural networks starts to draw attentions (Alikaniotis et al., 2016; Dong and Zhang, 2016; Taghipour and Ng, 2016).

Writing assessment involves highly technical aspects of language and discourse. In addition to give a score, it would be better to provide explainable feedbacks to learners at the same time. Some work has studied several aspects such as spelling errors (Brill and Moore, 2000), grammar errors (Rozovskaya and Roth, 2010), coherence (Barzilay and Lapata, 2008), organization of argumentative essays (Persing et al., 2010) and the use of figurative language (Louis and Nenkova, 2013). This paper extends this line of work by taking discourse modes into account.

2.3 Neural Sequence Modeling

A main challenge of discourse analysis is hard to collect large scale data due to its complexity, which may lead to data sparseness problem. Recently, neural networks become popular for natural language processing (Bengio et al., 2003; Collobert et al., 2011). One of the advantages is the ability of automatic representation learning. Representing words or relations with continuous vectors (Mikolov et al., 2013; Ji and Eisenstein, 2014) embeds semantics in the same space, which benefits alleviating the data sparseness problem

and enables end-to-end and multi-task learning. Recurrent neural networks (RNNs) (Graves, 2012) and the variants like Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) and Gated Recurrent (GRU) (Cho et al., 2014) neural networks show good performance for capturing long distance dependencies on tasks like Named Entity Recognition (NER) (Chiu and Nichols, 2016; Ma and Hovy, 2016), dependency parsing (Dyer et al., 2015) and semantic composition of documents (Tang et al., 2015). This work describes a hierarchical neural architecture with multiple label outputs for modeling the discourse mode sequence of sentences.

3 Discourse Mode Annotation

We are interested in the use of discourse modes in writing composition. This section describes the discourse modes we are going to study, an annotated corpus of student essays and what we learn from corpus analysis.

3.1 Discourse Modes

Discourse modes have several taxonomies in the literature. Four basic discourse modes are *narration*, *description*, *exposition* and *argument* in English composition and rhetoric (Bain, 1890). Smith (2003) proposes five modes for studying discourse passages: *narrative*, *description*, *report*, *information* and *argument*. In Chinese composition, discourse modes are categorized into *narration*, *description*, *exposition*, *argument* and *emotion expressing* (Zhu, 1983).

These taxonomies are similar. Their elements can mostly find corresponding ones in other taxonomies literally or conceptually, e.g., exposition mode has similar functions to information mode. Emotion expressing that is to express the writer's emotions is relatively special. It can be realized by expressing directly or through lyrical writing with beautiful and poetic language. It is also related to appeal to emotion, which is a method for argumentation by the manipulation of the recipient's emotions in classical rhetoric (Aristotle and Kennedy, 2006). Proper emotion expressing can touch the hearts of the readers and improve the expressiveness of writing. Therefore, considering it as an independent mode is also reasonable.

We cope with essays written in Chinese in this work so that we follow the Chinese convention with five discourse modes. Emotion expressing is added on the basis of four recognized discourse modes and Smith's report mode is viewed as a subtype of description mode: *dialogue description*.

In summary, we study the following discourse modes:

- **Narration** introduces an event or series of events into the universe of discourse. The events are temporally related according to narrative time.
  E.g., *Last year, we drove to San Francisco along the State Route 1 (SR 1).*

- **Exposition** has a function to explain or instruct. It provides background information in narrative context. The information presented should be general and (expected to be) well accepted truth.
  E.g., *SR 1 is a major north-south state highway that runs along most of the Pacific coastline of the U.S.*

- **Description** re-creates, invents, or vividly show what things are like according to the five senses so that the reader can picture that which is being described.
  E.g., *Along SR 1 are stunning rugged coastline, coastal forests and cliffs, beautiful little towns and some of the West coast's most amazing nature.*

- **Argument** makes a point of view and proves its validity towards a topic in order to convince or persuade the reader.
  E.g., *Point Arena Lighthouse is a must see along SR 1, in my opinion.*

- **Emotion expressing**[1] presents the writer's emotions, usually in a subjective, personal and lyrical way, to involve the reader to experience the same situations and to be touched.
  E.g., *I really love the ocean, the coastline and all the amazing scenery along the route. When could I come back again?*

The distinction between discourse modes is expected to be clarified conceptually by considering their different communication purposes. However, there would still be specific ambiguous and vague cases. We will describe the data annotation and corpus analysis in the following parts.

[1] In some cases, we use emotion for short.

	INITIAL			FINAL		
	P	R	F	P	R	F
Nar	0.90	0.88	0.89	0.96	0.84	0.90

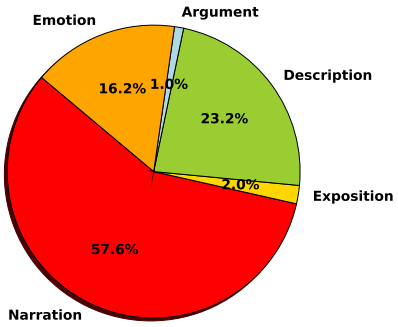

Figure 1: The distribution of dominant modes.

3.2 Data Annotation

Discourse modes are almost never found in a pure form but are embedded one within another to help the writer achieve the purpose, but the emphasis varies in different types of writing. We focus on narrative essays. A good narrative composition must properly manipulate multiple discourse modes to make it vivid and impressive.

The corpus has 415 narrative essays written by high school students in their native Chinese language.The average number of sentences is 32 and the average length is 670 words.

We invited two high school teachers to annotate discourse modes at sentence level, expecting their background help for annotation. A detail manual was discussed before annotation.

We notice that discourse modes can mix in the same sentence. Therefore, the annotation standard allows that one sentence can have multiple modes. But we require that every sentence should have a *dominant mode*. The annotators should try to think in the writer's perspective and guess the writer's main purpose of writing the sentence in order to decide the dominant mode.

Among the discourse modes, description can be applied in various situations. We focus on the following description types: portrait, appearance, action, dialogue, psychological, environment and detail description. If a sentence has any type of description, it would be assigned a description label.

3.3 Corpus Analysis

We conducted corpus analysis on the annotated data to gain observations on several aspects.

Inter-Annotator Agreement: 50 essays were independently annotated by two annotators. We evaluate the inter-annotator agreement on the dominant mode. The two annotators' annotations are used as the golden answer and prediction respectively. We compute the precision, recall and F1-score for each discourse mode separately to measure the inter-annotator agreement. Precision and recall are symmetric for the two annotators.

The result of the first round annotation is shown in the INITIAL columns of Table 1. The agreement on argument mode is low, while the agreement on other modes is acceptable. The average F1-score is 0.69. The Cohen's Kappa (Cohen et al., 1960) is 0.55 over all judgements on the dominant mode.

The main disagreement on argument lies in the confusion with emotion expressing. Consider the following sentence:

> *Father's love is the fire that lights the lamp of hope.*

One annotator thought that it is expressed in an emotional and lyrical way so that the discourse mode should be emotion expressing. The other one thought that it (implicitly) gives a point and should be an argument. Many disagreements happened in cases like this.

Based on the observations of the first round annotation, we discussed and updated the manual and let the annotators rechecked their annotations. The final result is shown in the FINAL columns of Table 1. The agreement on description decreases. Annotators seem to be more conservative on labeling description as the dominant mode. The overall average F1-score increases to 0.78 and the Cohen's Kappa is 0.72. This indicates that humans can reach an acceptable agreement on the dominant discourse mode of sentences after training.

Discourse mode distribution: After the training phase, the annotators labeled the whole corpus. Figure 1 shows the distribution of dominant

Mode	Nar	Exp	Des	Emo	Arg
Nar	5285	11	2552	65	2
Exp	-	148	11	1	1
Des	-	-	2538	105	8
Emo	-	-	-	1947	63
Arg	-	-	-	-	318

Table 2: Co-occurrence of discourse modes in the same sentences. The numbers in diagonal indicate the number of sentences with a single mode.

from \ to	Nar	Exp	Des	Emo	Arg
Nar	72%	-	17%	7%	1%
Exp	59%	8%	8%	16%	6%
Des	42%	-	53%	3%	-
Emo	25%	2%	4%	66%	1%
Arg	27%	-	4%	12%	54%
Begin with	50%	3%	6%	32%	7%
End with	12%	1%	2%	76%	6%

Table 3: Transition between discourse modes of consecutive sentences and the distribution of discourse modes that essays begin with and end with.

discourse modes. The distribution is imbalanced. Narration, description and emotion expressing are the main discourse modes in narrative essays, while exposition and argument are rare.

Co-occurrence: Statistics show that 78% of sentences have only one discourse mode, and 19% have two discourse modes, and 3% have more than two discourse modes.

Table 2 shows the co-occurrence of discourse modes. The numbers that are in the diagonal represent the distribution of discourse modes of sentences with only one mode. The numbers that are not in the diagonal indicate the co-occurrence of modes in the same sentences. We can see that description tends to co-occur with narration and emotion expressing. Description can provide states that happen together with events and emotion-evoking scenes are often described to elicit a strong emotional response, for example:

> *The bright moon hanging on the distant sky reminds me of my hometown miles away.*

Emotion expressing and argument also co-occur in some cases. It is reasonable, since a successful emotional appeal can enhance the effectiveness of an argument.

Generally, these observations are consistent with intuition. Properly combining multiple modes could produce impressive sentences.

Transition: Table 3 shows the transition matrix between the dominant modes of consecutive sentences within the same paragraphs. All modes tend to transit to themselves except exposition, which is rare and usually brief. This means that discourse modes of adjacent sentences have high correlation. We also see that narration and emotion are more often at the beginning and the end of essays. The above observations indicate that discourse modes have local preferred patterns.

To summarize, the implications of corpus analysis include: (1) Manual identification of discourse modes is feasible with an acceptable inter-annotator agreement; (2) The distribution of discourse modes in narrative essays is imbalanced; (3) About 22% sentences have multiple discourse modes; (4) Discourse modes have local transition patterns that consecutive discourse modes have high correlation.

4 Discourse Mode Identification based on Neural Sequence Labeling

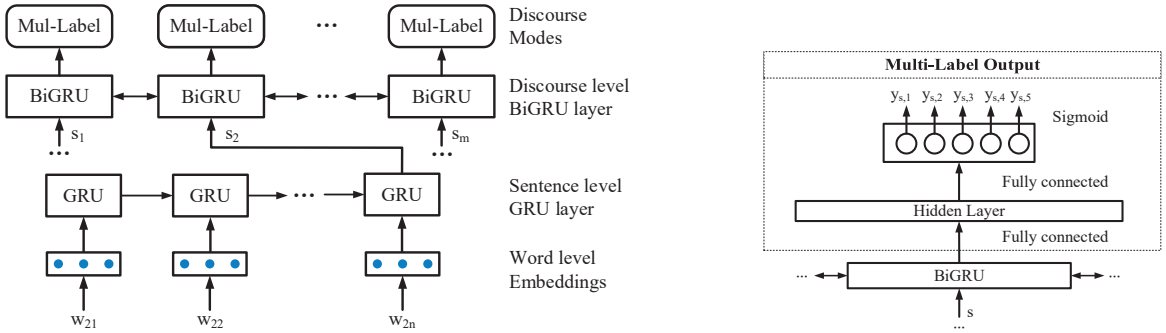
This section describes the proposed method for discourse mode identification. According to the corpus analysis, sentences often have multiple discourse modes and prefer local transition patterns. Therefore, we view this task as a multi-label sequence labeling problem.

4.1 Model

We propose a hierarchical neural sequence labeling model to capture multiple level information. Figure 2(a) shows the basic architecture. We introduce it from the bottom up.

Word level embedding layer: We transform words into continuous vectors, word embeddings. Vector representation of words is useful for capturing semantic relatedness. This should be effective in our case, since large amount of training data is not available. It is unrealistic to learn the embedding parameters on limited data so that we just look up embeddings of words from a pre-trained word embedding table. The pre-trained word embeddings were learned with the Word2Vec toolkit (Mikolov et al., 2013) on a domain corpus which consists of about 490,000 student essays. The embeddings are kept unchanged during learning and prediction.

Sentence level GRU layer: Each sentence is a sequence of words. We feed the word embeddings into a forward recurrent neural networks. Here,



(a) The basic hierarchical architecture.

(b) The detail of the Mul-Label layer

Figure 2: The multi-label neural sequence labeling model for discourse mode identification.

we use the GRU (Cho et al., 2014) as the recurrent unit. The GRU is to make each recurrent unit to adaptively capture dependencies of different time scales. The output of the last time-step is used as the representation of a sentence.

Discourse level bidirectional-GRU layer: An essay consists of a sequence of sentences. Accessing information of past and future sentences provides more contextual information for current prediction. Therefore, we use a bidirectional RNN to connect sentences. We use the GRU as the recurrent unit, which is also shown effective on semantic composition of documents for sentiment classification (Tang et al., 2015). The BiGRU represents the concatenation of the hidden states of the forward GRU and the backward GRU units.

Multi-Label layer: Since one sentence can have more than one discourse mode, our model allows multiple label outputs. Figure 2(b) details the Mul-Label layer in Figure 2(a). The representation of each sentence after the bidirectional-GRU layer is first fully connected to a hidden layer. The hidden layer output is then fully connected to a five-way output layer, corresponding to five discourse modes. The sigmoid activation function is applied to each way to get the probability that whether corresponding discourse mode should be assigned to the sentence.

In the training phase, the probability of any labeled discourse modes is set to 1 and the others are set to 0. In the prediction phase, if the predicted probability of a discourse mode is larger than 0.5, the discourse mode would be assigned.

4.1.1 Considering Paragraph Boundaries

Different from NER that processes a single sentence each time, our task processes sequences of sentences in discourse, which are usually grouped by paragraphs to split the whole discourse into several relatively independent segments. Sentences from different paragraphs should have less effect to each other, even though they are adjacent.

To capture paragraph boundary information, we insert an empty sentence at the end of every paragraph to indicate a paragraph boundary. The empty sentence is represented by a zero vector and its outputs are set to zeros as well. We expect this modification can better capture position related information.

4.2 Implementation Details

We implement the model using the Keras library.[2] The models are trained with the binary cross-entropy objective. The optimizer is Adam (Kingma and Ba, 2014). The word embedding dimension is 50. The dimension of the hidden layer in Mul-Label layer is 100. The length of sentences is fixed as 40. All other parameters are set by default parameter values. We adopt early stopping strategy (Caruana et al., 2000) to decide when the training process stops.

4.3 Evaluation

4.3.1 Data

We use 100 essays as the test data. The remaining ones are used as the training data. 10% of the shuffled training data is used for validation.

4.3.2 Comparisons

We compare the following systems:

- SVM: We use bag of ngram (unigram and bigram) features to train a support vector classifier for sentence classification.

[2] https://github.com/fchollet/keras/

- CNN: We implement a convolutional neural network (CNN) based method (Kim, 2014), as it is the state-of-the-art for sentence classification.

- GRU: We use the sentence level representation in Figure 2(a) for sentence classification.

- GRU-GRU(GG): This method is introduced in this paper in §4.1, but it doesn't consider paragraph information.

- GRU-GRU-SEG (GG-SEG): The model considers paragraph information on the top of GG as introduced in §4.1.1.

The first three classification based methods classify sentences independently. To deal with multiple labels, the classifiers are trained for each discourse mode separately. At prediction time, if the classifier for any discourse mode predicts a sentence as positive, the corresponding discourse mode would be assigned.

4.3.3 Evaluation Results

Table 4 shows the experimental results. We evaluate the systems for each discourse mode with F1-score, which is the harmonic mean of precision and recall. The best performance is in bold.

The SVM performs worst among all systems. The reason is due to the data sparseness and term-mismatch problem, since the size of the annotated dataset is not big enough. In contrast, systems based on neural networks with pre-trained word embeddings achieve much better performance.

The CNN and GRU have comparable performance. The GRU is slightly better. The two methods don't consider the semantic representations of adjacent sentences.

The GG and GG-SEG explore the semantic information of sentences in a sequence by the bidirectional GRU layer. The results demonstrate that considering such information improve the performance on all discourse modes. This proves the advantage of sequential identification compared with isolated sentence classification.

We can see that the GG-SEG further improves the performance on three minority discourse modes compared with GG. This means that the minority modes may have stronger preference to special locations. Exposition benefits most, since many exposition sentences in our dataset are isolated.

Model \ Mode	Nar	Des	Emo	Arg	Exp
SVM	0.672	0.588	0.407	0.152	0.095
CNN	0.793	0.764	0.594	0.333	0.293
GRU	0.800	0.784	0.615	0.402	0.364
GG	**0.822**	**0.797**	0.680	0.423	0.481
GG-SEG	0.815	0.791	**0.717**	**0.483**	**0.667**

Table 4: The F1-scores of systems on each discourse mode.

The performance on argument is not so good. As we discussed in corpus analysis, argument and emotion expressing mode interact frequently. Because the amount of emotion expressing sentences is much more, distinguishing argument from them is hard. Actually, their functions in narrative essays seem to be similar that both are to deepen the author's response or evoke the reader's response to the story.

The overall average F1-score can reach to 0.7 and the performance on identifying three most common discourse modes are consistent, with an average F1-score above 0.76 using the proposed neural sequence labeling models. Automatic discourse mode identification should be feasible.

5 Essay Scoring with Discourse Modes

Discourse mode identification can potentially provide features for downstream NLP applications. This section describes our attempt to explore discourse modes for automatic essay scoring (AES).

5.1 Essay Scoring Framework

We adopt the standard regression framework for essay scoring. We use support vector regression (SVR) and Bayesian linear ridge regression (BLRR), which are used in recent work (Phandi et al., 2015). The key is to design effective features.

5.2 Features

The basic feature sets are based on (Phandi et al., 2015).The original feature sets include:

- Length features
- Part-Of-Speech (POS) features
- Prompt features
- Bag of words features

We re-implement the feature extractors exactly according to the description in (Phandi et al., 2015) except for the POS features, since we don't

Prompt	#Essays	Avg. len	Score	
			Range	Median
1	4000	628	0-60	46
2	4000	660	0-50	41
3	3300	642	0-50	41

Table 5: Details of the three datasets for AES.

have correct POS ngrams for Chinese. We complement two additional features: (1) The number of words occur in Chinese Proficiency Test 6 vocabulary; (2) The number of Chinese idioms used.

We further design discourse mode related features for each essay:

- Mode ratio: For each discourse mode, we compute its mode ratio according to $ratio = \frac{\#\text{sentences with the discourse mode}}{\#\text{sentences in the essay}}$. Such features indicate the distribution of discourse modes.

- Bag of ngrams of discourse modes: We use the number of unigrams and bigrams of the dominant discourse modes of the sequence of sentences in the essay as features.

5.3 Experimental Settings

The experiments were conducted on narrative essays written by Chinese middle school students in native language during regional tests. There are three prompts and students are required to write an essay related to the given prompt with no less than 600 Chinese characters. All these essays were evaluated by professional teachers.

We randomly sampled essays from each prompt for experiments. Table 5 shows the details of the datasets. We ran experiments on each prompt dataset respectively by 5-fold cross-validation.

The GG-SEG model was used to identify discourse modes of sentences. Notice that a sentence can have multiple discourse modes. The mode ratio features are computed for each mode separately. When extracting the bag of ngrams of discourse modes features, the discourse mode with highest prediction probability was chosen as the dominant discourse mode.

We use the Quadratic Weighted Kappa (QWK) as the evaluation metric.

5.4 Evaluation Results

Table 6 shows the evaluation results of AES on three datasets. We can see that the BLRR algorithm performs better than the SVR algorithm. No matter which algorithm is adopted, adding discourse mode features make positive contributions for AES compared with using basic feature sets. The trends are consistent over all three datasets.

Prompt	QWK Score		
	1	2	3
SVR-Basic	0.554	0.468	0.457
+ mode	0.6	0.501	0.481
BLRR-Basic	0.683	0.557	0.513
+ mode	**0.696**	**0.565**	**0.527**

Table 6: Evaluation results of AES on three datasets. Basic: the basic feature sets; mode: discourse mode features.

Prompt	1	2	3	Avg
LEN	0.59	0.52	0.45	0.52
Des	0.23	0.24	0.24	0.24
Emo	0.09	0.15	0.12	0.12
Exp	-0.07	0.01	0.01	-0.03
Arg	-0.08	-0.06	-0.1	-0.08
Nar	-0.11	-0.15	-0.12	-0.13

Table 7: Pearson correlation coefficients of mode ratio to essay score. LEN represents essay length.

Impact of discourse mode ratio on scores: We are interested in which discourse mode correlates to essay scores best. Table 7 shows the Pearson correlation coefficient between the mode ratio and essay score. LEN represents the correlation of essay length and is listed as a reference. We can see that the ratio of narration has a negative correlation, which means just narrating stories without auxiliary discourse modes would lead to poor scores. The description mode ratio has the strongest positive correlation to essay scores. This may indicate that using vivid language to provide detail information is essential in writing narrative essays. Emotion expressing also has a positive correlation. It is reasonable since emotional writing can involve readers into the stories. The ratio of argument shows a negative correlation. The reason may be that: first, the identification of argument is not good enough; second, the existence of an argument doesn't mean the quality of argumentation is good. Exposition has little effect on essay scores.

Generally, the distribution of discourse modes shows correlations to the quality of essays. This may relate to the difficulties of manipulating different discourse modes. It is easy for students to use narration, but it is more difficult to manipulate description and emotion expressing well. As a result, the ability of descriptive and emotional writ-

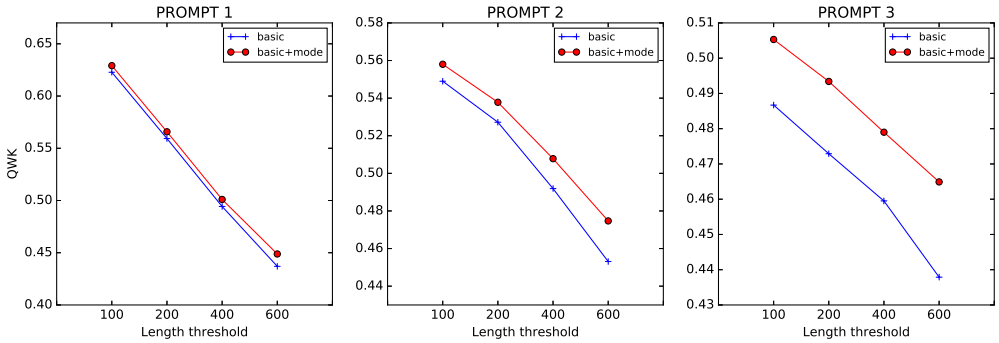


Figure 3: QWK scores on essays satisfying different length thresholds on three prompts. Basic: the basic feature sets; mode: discourse mode features.

ing should be an indicator of language proficiency and can better distinguish the quality of writing.

Impact on scoring essays with various length: It is easy to understand that length is a strong indicator for essay scoring. It is interesting to study that when the effect of length becomes weaker, e.g., the lengths of essays are close, how does the performance of the AES system change?

We conducted experiments on essays with various lengths. Only essays that the length is no less than a given threshold are selected for evaluation. The threshold is set to 100, 200, 400 and 600 Chinese characters respectively. We ran 5-fold cross-validation with BLRR on the datasets after essay selection.

Figure 3 shows the results on three datasets. We can see the following trends: (1) The QWK scores decrease along with shorter essays are removed gradually; (2) Adding discourse mode features always improves the performance; (3) As the threshold becomes larger, the improvements by adding discourse mode features become larger.

The results indicate that the current AES system can achieve a high correlation score when the lengths of essays differ obviously. Even the simple features like length can judge that short essays tend to have low scores. However, when the lengths of essays are close, AES would face greater challenges, because it is required to deeper understand the properties of well written essays. In such situations, features that can model more advanced aspects of writing, such as discourse modes, should play a more important role. It should be also essential for evaluating essays written in the native language of the writer, when spelling and grammar are not big issues any more.

6 Conclusion

This paper has introduced a fundamental but less studied task in NLP—discourse mode identification, which is designed in this work to automatically identify five discourse modes in essays.

A corpus of narrative student essays was manually annotated with discourse modes at sentence level, with acceptable inter-annotator agreement. The corpus analysis revealed several aspects of characteristics of discourse modes including the distribution, co-occurrence and transition patterns.

Considering these characteristics, we proposed a neural sequence labeling approach for identifying discourse modes. The experimental results demonstrate that automatic discourse mode identification is feasible.

We evaluated discourse mode features for automatic essay scoring and draw preliminary observations. Discourse mode features can make positive contributions, especially in challenging situations when simple surface features don't work well. The ratio of description and emotion expressing is shown to be positively correlated to essay scores.

In future, we plan to exploit discourse mode identification for providing novel features for more downstream NLP applications.

A Convolutional Encoder Model for Neural Machine Translation

Jonas Gehring, Michael Auli, David Grangier, Yann N. Dauphin
Facebook AI Research

Abstract

The prevalent approach to neural machine translation relies on bi-directional LSTMs to encode the source sentence. We present a faster and simpler architecture based on a succession of convolutional layers. This allows to encode the source sentence simultaneously compared to recurrent networks for which computation is constrained by temporal dependencies. On WMT'16 English-Romanian translation we achieve competitive accuracy to the state-of-the-art and on WMT'15 English-German we outperform several recently published results. Our models obtain almost the same accuracy as a very deep LSTM setup on WMT'14 English-French translation. We speed up CPU decoding by more than two times at the same or higher accuracy as a strong bi-directional LSTM.[1]

1 Introduction

Neural machine translation (NMT) is an end-to-end approach to machine translation (Sutskever et al., 2014). The most successful approach to date encodes the source sentence with a bi-directional recurrent neural network (RNN) into a variable length representation and then generates the translation left-to-right with another RNN where both components interface via a soft-attention mechanism (Bahdanau et al., 2015; Luong et al., 2015a; Bradbury and Socher, 2016; Sennrich et al., 2016a). Recurrent networks are typically parameterized as long short term memory networks (LSTM; Hochreiter et al. 1997) or gated recurrent units (GRU; Cho et al. 2014), often with residual or skip connections (Wu et al., 2016; Zhou et al., 2016) to enable stacking of several layers (§2).

There have been several attempts to use convolutional encoder models for neural machine translation in the past but they were either only applied to rescoring n-best lists of classical systems (Kalchbrenner and Blunsom, 2013) or were not competitive to recurrent alternatives (Cho et al., 2014a). This is despite several attractive properties of convolutional networks. For example, convolutional networks operate over a fixed-size window of the input sequence which enables the simultaneous computation of all features for a source sentence. This contrasts to RNNs which maintain a hidden state of the entire past that prevents parallel computation within a sequence.

A succession of convolutional layers provides a shorter path to capture relationships between elements of a sequence compared to RNNs.[2] This also eases learning because the resulting tree-structure applies a fixed number of non-linearities compared to a recurrent neural network for which the number of non-linearities vary depending on the time-step. Because processing is bottom-up, all words undergo the same number of transformations, whereas for RNNs the first word is over-processed and the last word is transformed only once.

In this paper we show that an architecture based on convolutional layers is very competitive to recurrent encoders. We investigate simple average pooling as well as parameterized convolutions as an alternative to recurrent encoders and enable very deep convolutional encoders by using residual connections (He et al., 2015; §3).

We experiment on several standard datasets and compare our approach to variants of recurrent encoders such as uni-directional and bi-directional LSTMs. On WMT'16 English-Romanian translation we achieve accuracy that is very competitive to the current state-of-the-art result. We perform competitively on WMT'15 English-German, and nearly match the performance of the best WMT'14 English-French system based on a deep LSTM setup when comparing on a commonly used subset

of the training data (Zhou et al. 2016; §4, §5).

2 Recurrent Neural Machine Translation

The general architecture of the models in this work follows the encoder-decoder approach with soft attention first introduced in (Bahdanau et al., 2015). A source sentence $\mathbf{x} = (x_1, \ldots, x_m)$ of m words is processed by an encoder which outputs a sequence of states $\mathbf{z} = (z_1 \ldots, z_m)$.

The decoder is an RNN network that computes a new hidden state s_{i+1} based on the previous state s_i, an embedding g_i of the previous target language word y_i, as well as a conditional input c_i derived from the encoder output $\mathbf{z}$. We use LSTMs (Hochreiter and Schmidhuber, 1997) for all decoder networks whose state s_i comprises of a cell vector and a hidden vector h_i which is output by the LSTM at each time step. We input c_i into the LSTM by concatenating it to g_i.

The translation model computes a distribution over the V possible target words y_{i+1} by transforming the LSTM output h_i via a linear layer with weights W_o and bias b_o:

$$p(y_{i+1}|y_1, \ldots, y_i, \mathbf{x}) = \text{softmax}(W_o h_{i+1} + b_o)$$

The conditional input c_i at time i is computed via a simple dot-product style attention mechanism (Luong et al., 2015a). Specifically, we transform the decoder hidden state h_i by a linear layer with weights W_d and b_d to match the size of the embedding of the previous target word g_i and then sum the two representations to yield d_i. Conditional input c_i is a weighted sum of attention scores $\mathbf{a_i} \in \mathbb{R}^m$ and encoder outputs $\mathbf{z}$. The attention scores $\mathbf{a_i}$ are determined by a dot product between h_i with each z_j, followed by a softmax over the source sequence:

$$d_i = W_d h_i + b_d + g_i,$$
$$a_{ij} = \frac{\exp\left(d_i^T z_j\right)}{\sum_{t=1}^{m} \exp\left(d_i^T z_t\right)}, \quad c_i = \sum_{j=1}^{m} a_{ij} z_j$$

In preliminary experiments, we did not find the MLP attention of (Bahdanau et al., 2015) to perform significantly better in terms of BLEU nor perplexity. However, we found the dot-product attention to be more favorable in terms of training and evaluation speed.

We use bi-directional LSTMs to implement recurrent encoders similar to (Zhou et al., 2016) which achieved some of the best WMT14 English-French results reported to date. First, each word of the input sequence $\mathbf{x}$ is embedded in distributional space resulting in $\mathbf{e} = (e_1, \ldots, e_m)$. The embeddings are input to two stacks of uni-directional RNNs where the output of each layer is reversed before being fed into the next layer. The first stack takes the original sequence while the second takes the reversed input sequence; the output of the second stack is reversed so that the final outputs of the stacks align. Finally, the top-level hidden states of the two stacks are concatenated and fed into a linear layer to yield $\mathbf{z}$. We denote this encoder architecture as BiLSTM.

3 Non-recurrent Encoders

3.1 Pooling Encoder

A simple baseline for non-recurrent encoders is the pooling model described in (Ranzato et al., 2015) which simply averages the embeddings of k consecutive words. Averaging word embeddings does not convey positional information besides that the words in the input are somewhat close to each other. As a remedy, we add position embeddings to encode the absolute position of each source word within a sentence. Each source embedding e_j therefore contains a position embedding l_j as well as the word embedding w_j. Position embeddings have also been found helpful in memory networks for question-answering and language modeling (Sukhbaatar et al., 2015). Similar to the recurrent encoder (§2), the attention scores a_{ij} are computed from the pooled representations z_j, however, the conditional input c_i is a weighted sum of the embeddings e_j, not z_j, i.e.,

$$e_j = w_j + l_j, \quad z_j = \frac{1}{k} \sum_{t=-\lfloor k/2 \rfloor}^{\lfloor k/2 \rfloor} e_{j+t},$$

$$c_i = \sum_{j=1}^{m} a_{ij} e_j$$

The input sequence is padded prior to pooling such that the encoder output matches the input length $|\mathbf{z}| = |\mathbf{x}|$. We set k to 5 in all experiments as (Ranzato et al., 2015).

3.2 Convolutional Encoder

A straightforward extension of pooling is to learn the kernel in a convolutional neural network (CNN). The encoder output z_j contains information about a fixed-sized context depending on the kernel width k but the desired context width may vary. This can

be addressed by stacking several layers of convolutions followed by non-linearities: additional layers increase the total context size while non-linearities can modulate the effective size of the context as needed. For instance, stacking 5 convolutions with kernel width $k = 3$ results in an input field of 11 words, i.e., each output depends on 11 input words, and the non-linearities allow the encoder to exploit the full input field, or to concentrate on fewer words as needed.

To ease learning for deep encoders, we add residual connections from the input of each convolution to the output and then apply the non-linear activation function to the output (tanh; He et al., 2015); the non-linearities are therefore not 'bypassed'. Multi-layer CNNs are constructed by stacking several blocks on top of each other. The CNNs do not contain pooling layers which are commonly used for down-sampling, i.e., the full source sequence length will be retained after the network has been applied. Similar to the pooling model, the convolutional encoder uses position embeddings.

The final encoder consists of two stacked convolutional networks (Figure 1): CNN-a produces the encoder output z_j to compute the attention scores $\mathbf{a_i}$, while the conditional input c_i to the decoder is computed by summing the outputs of CNN-c,

$$z_j = \text{CNN-a}(\mathbf{e})_j, \quad c_i = \sum_{j=1}^{m} a_{ij} \, \text{CNN-c}(\mathbf{e})_j.$$

In practice, we found that two different CNNs resulted in better perplexity as well as BLEU compared to using a single one (§5.3). We also found this to perform better than directly summing the e_i without transformation as for the pooling model.

3.3 Related Work

There are several past attempts to use convolutional encoders for neural machine translation, however, to our knowledge none of them were able to match the performance of recurrent encoders. (Kalchbrenner and Blunsom, 2013) introduce a convolutional sentence encoder in which a multi-layer CNN generates a fixed sized embedding for a source sentence, or an n-gram representation followed by transposed convolutions for directly generating a per-token decoder input. The latter requires the length of the translation prior to generation and both models were evaluated by rescoring the output of an existing translation system. (Cho et al., 2014a) propose a gated recursive CNN which is repeatedly applied until a fixed-size representation is obtained but the recurrent encoder achieves higher accuracy. In follow-up work, the authors improved the model via a soft-attention mechanism but did not reconsider convolutional encoder models (Bahdanau et al., 2015).

Concurrently to our work, (Kalchbrenner et al., 2016) have introduced convolutional translation models without an explicit attention mechanism but their approach does not yet result in state-of-the-art accuracy. (Lamb and Xie, 2016) also proposed a multi-layer CNN to generate a fixed-size encoder representation but their work lacks quantitative evaluation in terms of BLEU. Meng et al. (2015) and (Tu et al., 2015) applied convolutional models to score phrase-pairs of traditional phrase-based and dependency-based translation models. Convolutional architectures have also been successful in language modeling but so far failed to outperform LSTMs (Pham et al., 2016).

4 Experimental Setup

4.1 Datasets

We evaluate different encoders and ablate architectural choices on a small dataset from the German-English machine translation track of IWSLT 2014 (Cettolo et al., 2014) with a similar setting to (Ranzato et al., 2015). Unless otherwise stated, we restrict training sentences to have no more than 175 words; test sentences are not filtered. This is a higher threshold compared to other publications but ensures proper training of the position embeddings for non-recurrent encoders; the length threshold did not significantly effect recurrent encoders. Length filtering results in 167K sentence pairs and we test on the concatenation of *tst2010, tst2011, tst2012, tst2013* and *dev2010* comprising 6948 sentence pairs.[3] Our final results are on three major WMT tasks:

WMT'16 English-Romanian. We use the same data and pre-processing as (Sennrich et al., 2016a) and train on 2.8M sentence pairs.[4] Our model is word-based instead of relying on byte-pair encoding (Sennrich et al., 2016b). We evaluate on *newstest2016*.

WMT'15 English-German. We use all available parallel training data, namely Europarl v7, Com-

[3] Different to the other datasets, we lowercase the training data and evaluate with case-insensitive BLEU.

[4] We followed the pre-processing of https://github.com/rsennrich/wmt16-scripts/blob/master/sample/preprocess.sh and added the back-translated data from http://data.statmt.org/rsennrich/wmt16_backtranslations/en-ro.

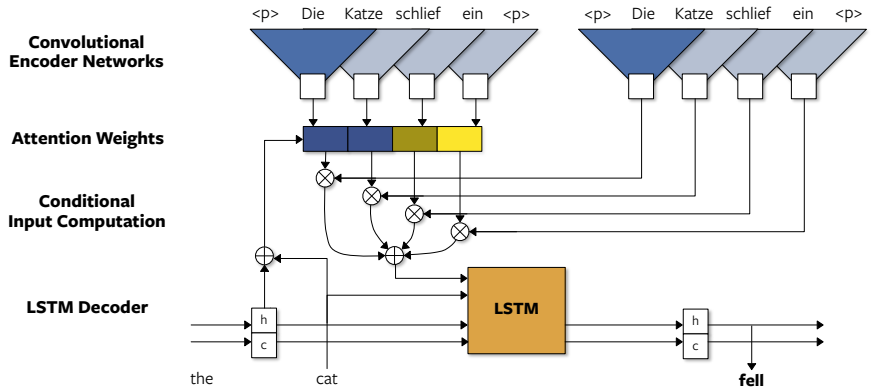

Figure 1: Neural machine translation model with single-layer convolutional encoder networks. CNN-a is on the left and CNN-c is at the right. Embedding layers are not shown.

mon Crawl and News Commentary v10 and apply the standard Moses tokenization to obtain 3.9M sentence pairs (Koehn et al., 2007). We report results on *newstest2015*.

WMT'14 English-French. We use a commonly used subset of 12M sentence pairs (Schwenk, 2014), and remove sentences longer than 150 words. This results in 10.7M sentence-pairs for training. Results are reported on *ntst14*.

A small subset of the training data serves as validation set (5% for IWSLT'14 and 1% for WMT) for early stopping and learning rate annealing (§4.3). For IWSLT'14, we replace words that occur fewer than 3 times with a <unk> symbol, which results in a vocabulary of 24158 English and 35882 German word types. For WMT datasets, we retain 200K source and 80K target words. For English-French only, we set the target vocabulary to 30K types to be comparable with previous work.

4.2 Model parameters

We use 512 hidden units for both recurrent encoders and decoders. We reset the decoder hidden states to zero between sentences. For the convolutional encoder, 512 hidden units are used for each layer in CNN-a, while layers in CNN-c contain 256 units each. All embeddings, including the output produced by the decoder before the final linear layer, are of 256 dimensions. On the WMT corpora, we find that we can improve the performance of the bidirectional LSTM models (BiLSTM) by using 512-dimensional word embeddings.

Model weights are initialized from a uniform distribution within $[-0.05, 0.05]$. For convolutional layers, we use a uniform distribution of $\left[-kd^{-0.5}, kd^{-0.5}\right]$, where k is the kernel width (we use 3 throughout this work) and d is the input size for the first layer and the number of hidden units for subsequent layers (Collobert et al., 2011b). For CNN-c, we transform the input and output with a linear layer each to match the smaller embedding size. The model parameters were tuned on IWSLT'14 and cross-validated on the larger WMT corpora.

4.3 Optimization

Recurrent models are trained with Adam as we found them to benefit from aggressive optimization. We use a step width of $3.125 \cdot 10^{-4}$ and early stopping based on validation perplexity (Kingma and Ba, 2014). For non-recurrent encoders, we obtain best results with stochastic gradient descent (SGD) and annealing: we use a learning rate of 0.1 and once the validation perplexity stops improving, we reduce the learning rate by an order of magnitude each epoch until it falls below 10^{-4}.

For all models, we use mini-batches of 32 sentences for IWSLT'14 and 64 for WMT. We use truncated back-propagation through time to limit the length of target sequences per mini-batch to 25 words. Gradients are normalized by the mini-batch size. We re-normalize the gradients if their norm exceeds 25 (Pascanu et al., 2013). Gradients of convolutional layers are scaled by $\mathrm{sqrt}(\dim(input))^{-1}$ similar to (Collobert et al., 2011b). We use dropout on the embeddings and decoder outputs h_i with a rate of 0.2 for IWSLT'14 and 0.1 for WMT (Srivastava et al., 2014). All models are implemented in Torch (Collobert et al., 2011a) and trained on a single GPU.

4.4 Evaluation

We report accuracy of single systems by training several identical models with different ran-

dom seeds (5 for IWSLT'14, 3 for WMT) and pick the one with the best validation perplexity for final BLEU evaluation. Translations are generated by a beam search and we normalize log-likelihood scores by sentence length. On IWSLT'14 we use a beam width of 10 and for WMT models we tune beam width and word penalty on a separate test set, that is *newsdev2016* for WMT'16 English-Romanian, *newstest2014* for WMT'15 English-German and *ntst1213* for WMT'14 English-French.[5] The word penalty adds a constant factor to log-likelihoods, except for the end-of-sentence token.

Prior to scoring the generated translations against the respective references, we perform unknown word replacement based on attention scores (Jean et al., 2015). Unknown words are replaced by looking up the source word with the maximum attention score in a pre-computed dictionary. If the dictionary contains no translation, then we simply copy the source word. Dictionaries were extracted from the aligned training data that was aligned with `fast_align` (Dyer et al., 2013). Each source word is mapped to the target word it is most frequently aligned to.

For convolutional encoders with stacked CNN-c layers we noticed for some models that the attention maxima were consistently shifted by one word. We determine this per-model offset on the above-mentioned development sets and correct for it. Finally, we compute case-sensitive tokenized BLEU, except for WMT'16 English-Romanian where we use *detokenized* BLEU to be comparable with Sennrich et al. (2016a).[6]

5 Results

5.1 Recurrent vs. Non-recurrent Encoders

We first compare recurrent and non-recurrent encoders in terms of perplexity and BLEU on IWSLT'14 with and without position embeddings (§3.1) and include a phrase-based system (Koehn et al., 2007). Table 1 shows that a single-layer convolutional model with position embeddings (Convolutional) can outperform both a uni-directional LSTM encoder (LSTM) as well as a bi-directional LSTM encoder (BiLSTM). Next, we increase the depth of the convolutional encoder. We choose a good setting by independently varying the number of layers in CNN-a and CNN-c between 1 and 10 and obtained best validation set perplexity with six layers for CNN-a and three layers for CNN-c. This configuration outperforms BiLSTM by 0.7 BLEU (Deep Convolutional 6/3). We investigate depth in the convolutional encoder more in §5.3.

System/Encoder	BLEU wrd+pos	BLEU wrd	PPL wrd+pos
Phrase-based	–	28.4	–
LSTM	27.4	27.3	10.8
BiLSTM	29.7	29.8	9.9
Pooling	26.1	19.7	11.0
Convolutional	29.9	20.1	9.1
Deep Convolutional 6/3	30.4	25.2	8.9

Table 1: Accuracy of encoders with position features (wrd+pos) and without (wrd) in terms of BLEU and perplexity (PPL) on IWSLT'14 German to English translation; results include unknown word replacement. Deep Convolutional 6/3 is the only multi-layer configuration, more layers for the LSTMs did not improve accuracy on this dataset.

Among recurrent encoders, the BiLSTM is 2.3 BLEU better than the uni-directional version. The simple pooling encoder which does not contain any parameters is only 1.3 BLEU lower than a uni-directional LSTM encoder and 3.6 BLEU lower than BiLSTM. The results without position embeddings (words) show that position information is crucial for convolutional encoders. In particular for shallow models (Pooling and Convolutional), whereas deeper models are less effected. Recurrent encoders do not benefit from explicit position information because this information can be naturally extracted through the sequential computation.

When tuning model settings, we generally observe good correlation between perplexity and BLEU. However, for convolutional encoders perplexity gains translate to smaller BLEU improvements compared to recurrent counterparts (Table 1). We observe a similar trend on larger datasets.

5.2 Evaluation on WMT Corpora

Next, we evaluate the BiLSTM encoder and the convolutional encoder architecture on three larger tasks and compare against previously published results. On WMT'16 English-Romanian translation we compare to (Sennrich et al., 2016a), the winning single system entry for this language pair. Their model consists of a bi-directional GRU encoder, a GRU decoder and MLP-based attention.

[5] Specifically, we select a beam from $\{5, 10\}$ and a word penalty from $\{0, -0.5, -1, -1.5\}$

Table 2: Accuracy on three WMT tasks, including results published in previous work. For deep convolutional encoders, we include the number of layers in CNN-a and CNN-c, respectively.

They use byte pair encoding (BPE) to achieve open-vocabulary translation and dropout in all components of the neural network to achieve 28.1 BLEU; we use the same pre-processing but no BPE (§4).

The results (Table 2) show that a deep convolutional encoder can perform competitively to the state of the art on this dataset (Sennrich et al., 2016a). Our bi-directional LSTM encoder baseline is 0.6 BLEU lower than the state of the art but uses only 512 hidden units compared to 1024. A single-layer convolutional encoder with embedding size 256 performs at 27.1 BLEU. Increasing the number of convolutional layers to 8 in CNN-a and 4 in CNN-c achieves 27.8 BLEU which outperforms our baseline and is competitive to the state of the art.

On WMT'15 English to German, we compare to a BiLSTM baseline and prior work: (Jean et al., 2015) introduce a large output vocabulary; the decoder of (Chung et al., 2016) operates on the character-level; (Yang et al., 2016) uses LSTMs instead of GRUs and feeds the conditional input to the output layer as well as to the decoder.

Our single-layer BiLSTM baseline is competitive to prior work and a two-layer BiLSTM encoder performs 0.6 BLEU better at 24.1 BLEU. Previous work also used multi-layer setups, e.g., (Chung et al., 2016) has two layers both in the encoder and the decoder with 1024 hidden units, and (Yang et al., 2016) use 1000 hidden units per LSTM. We use 512 hidden units for both LSTM and convolutional encoders. Our convolutional model with either 8 or 15 layers in CNN-a outperform the BiLSTM encoder with both a single decoder layer or two decoder layers.

Finally, we evaluate on the larger WMT'14 English-French corpus. On this dataset the recurrent architectures benefit from an additional layer both in the encoder and the decoder. For a single-layer decoder, a deep convolutional encoder outperforms the BiLSTM accuracy by 0.3 BLEU and for a two-layer decoder, our very deep convolutional encoder with up to 20 layers outperforms the BiLSTM by 0.4 BLEU. It has 40% fewer parameters than the BiLSTM due to the smaller embedding sizes. We also outperform several previous systems, including the very deep encoder-decoder model proposed by (Luong et al., 2015a). Our best result is just 0.2 BLEU below (Zhou et al., 2016) who use a very deep LSTM setup with a 9-layer encoder, a 7-layer decoder, shortcut connections and extensive regularization with dropout and L2 regularization.

5.3 Convolutional Encoder Architecture Details

We next motivate our design of the convolutional encoder (§3.2). We use the smaller IWSLT'14 German-English setup without unknown word replacement to enable fast experimental turn-around. BLEU results are averaged over three training runs initialized with different seeds.

Figure 2 shows accuracy for a different number of layers of both CNNs with and without residual connections. Our first observation is that computing the conditional input c_i directly over embeddings $\mathbf{e}$ (line "without CNN-c") is already working well at 28.3 BLEU with a single CNN-a layer and at 29.1 BLEU for CNN-a with 7 layers (Figure 2a). Increasing the number of CNN-c layers is beneficial up to three layers and beyond this we did not observe further improvements. Similarly, increasing the number of layers in CNN-a beyond six does not increase accuracy on this relatively small dataset. In general, choosing two to three times as many layers in CNN-a as in CNN-c is a good rule of thumb. Without residual connections, the model fails to utilize the increase in modeling power from additional layers, and performance drops significantly for deeper encoders (Figure 2b).

Our convolutional architecture relies on two sets of networks, CNN-a for attention score computation $\mathbf{a_i}$ and CNN-c for the conditional input c_i to be fed to the decoder. We found that using the same network for both tasks, similar to recurrent encoders, resulted in poor accuracy of 22.9 BLEU. This compares to 28.5 BLEU for separate single-layer networks, or 28.3 BLEU when aggregating embeddings for c_i. Increasing the number of layers in the single network setup did not help. Figure 2(a) suggests that the attention weights (CNN-a) need to integrate information from a wide context which can be done with a deep stack. At the same time, the vectors which are averaged (CNN-c) seem to benefit from a shallower, more local representation closer to the input words. Two stacks are an easy way to achieve these contradicting requirements.

In Appendix A we visualize attention scores and find that alignments for CNN encoders are less sharp compared to BiLSTMs, however, this does not affect the effectiveness of unknown word replacement once we adjust for shifted maxima. In Appendix B we investigate whether deep convolutional encoders are required for translating long sentences and observe that even relatively shallow encoders perform well on long sentences.

5.4 Training and Generation Speed

For training, we use the fast CuDNN LSTM implementation for layers without attention and experiment on IWSLT'14 with batch size 32. The single-layer BiLSTM model trains at 4300 target words/second, while the 6/3 deep convolutional encoder compares at 6400 words/second on an NVidia Tesla M40 GPU. We do not observe shorter overall training time since SGD converges slower than Adam which we use for BiLSTM models.

We measure generation speed on an Intel Haswell CPU clocked at 2.50GHz with a single thread for BLAS operations. We use vocabulary selection which can speed up generation by up to a factor of ten at no cost in accuracy via making the time to compute the final output layer negligible (Mi et al., 2016; L'Hostis et al., 2016). This shifts the focus from the efficiency of the encoder to the efficiency of the decoder. On IWSLT'14 (Table 3a) the convolutional encoder increases the speed of the overall model by a factor of 1.35 compared to the BiLSTM encoder while improving accuracy by 0.7 BLEU. In this setup both encoders models have the same hidden layer and embedding sizes.

On the larger WMT'15 English-German task (Table 3b) the convolutional encoder speeds up generation by 2.1 times compared to a two-layer BiLSTM. This corresponds to 231 source words/second with beam size 5. Our best model on this dataset generates 203 words/second but at slightly lower accuracy compared to the full vocabulary setting in Table 2. The recurrent encoder uses larger embeddings than the convolutional encoder which were required for the models to match in accuracy.

The smaller embedding size is not the only reason for the speed-up. In Table 3a (a), we compare a Conv 6/3 encoder and a BiLSTM with equal embedding sizes. The convolutional encoder is still 1.34x faster (at 0.7 higher BLEU) although it requires roughly 1.6x as many FLOPs. We believe that this is likely due to better cache locality for convolutional layers on CPUs: an LSTM with fused gates[7] requires two big matrix multiplications with different weights as well as additions, multiplications and non-linearities for each source word, while the output of each convolutional layer can be computed as whole with a single matrix multiply.

For comparison, the quantized deep LSTM-

[7] Our bi-directional LSTM implementation is based on torch rnnlib which uses fused LSTM gates (https://github.com/facebookresearch/torch-rnnlib/) and which we consider an efficient implementation.

based model in (Wu et al., 2016) processes 106.4 words/second for English-French on a CPU with 88 cores and 358.8 words/second on a custom TPU chip. The optimized RNNsearch model and C++ decoder described by (Junczys-Dowmunt et al., 2016) translates 265.3 words/s on a CPU with a similar vocabulary selection technique, computing 16 sentences in parallel, i.e., 16.6 words/s on a single core.

6 Conclusion

We introduced a simple encoder model for neural machine translation based on convolutional networks. This approach is more parallelizable than recurrent networks and provides a shorter path to capture long-range dependencies in the source. We find it essential to use source position embeddings as well as different CNNs for attention score computation and conditional input aggregation.

Our experiments show that convolutional encoders perform on par or better than baselines based on bi-directional LSTM encoders. In comparison to other recent work, our deep convolutional encoder is competitive to the best published results to date (WMT'16 English-Romanian) which are obtained with significantly more complex models (WMT'14 English-French) or stem from improvements that are orthogonal to our work (WMT'15 English-German). Our architecture also leads to large generation speed improvements: translation models with our convolutional encoder can translate twice as fast as strong baselines with bi-directional recurrent encoders.

Future work includes better training to enable faster convergence with the convolutional encoder to better leverage the higher processing speed. Our fast architecture is interesting for character level encoders where the input is significantly longer than for words. Also, we plan to investigate the effectiveness of our architecture on other sequence-to-sequence tasks, e.g. summarization, constituency parsing, dialog modeling.

A Alignment Visualization

In Figure 4 and Figure 5, we plot attention scores for a sample WMT'15 English-German and WMT'14 English-French translation with BiLSTM and deep convolutional encoders. The translation is on the x-axis and the source sentence on the y-axis.

The attention scores of the BiLSTM output are sharp but do not necessarily represent a correct alignment. For CNN encoders the scores are less focused but still indicate an approximate source location, e.g., in Figure 4b, when moving the clause "over 1,000 people were taken hostage" to the back of the translation. For some models, attention maxima are consistently shifted by one token as both in Figure 4b and Figure 5b.

Interestingly, convolutional encoders tend to focus on the last token (Figure 4b) or both the first and last tokens (Figure 5b). Motivated by the hypothesis that the this may be due to the decoder depending on the length of the source sentence (which it cannot determine without position embeddings), we explicitly provided a distributed representation of the input length to the decoder and attention module. However, this did not cause a change in attention patterns nor did it improve translation accuracy.

B Performance by Sentence Length

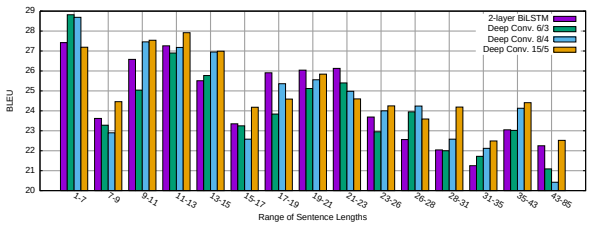

Figure 3: BLEU per sentence length on WMT'15 English-German *newstest2015*. The test set is partitioned into 15 equally-sized buckets according to source sentence length.

One characteristic of our convolutional encoder architecture is that the context over which outputs are computed depends on the number of layers. With bi-directional RNNs, every encoder output depends on the entire source sentence. In Figure 3, we evaluate whether limited context affects the translation quality on longer sentences of WMT'15 English-German which often requires moving verbs over long distances. We sort the *newstest2015* test set by source length, partition it into 15 equally-sized buckets, and compare the BLEU scores of models listed in Table 2 on a per-bucket basis.

There is no clear evidence for sub-par translations on sentences that are longer than the observable context per encoder output. We include a small encoder with a 6-layer CNN-c and a 3-layer CNN-a in the comparison which performs worse than a 2-layer BiLSTM (23.3 BLEU vs. 24.1). With 6 convolutional layers at kernel width 3, each encoder output contains information of 13 adjacent source words. Looking at the accuracy for sentences with 15 words or more, this relatively shallow CNN is either on par or better than the BiLSTM for 5 out of 10 buckets; the BiLSTM has access to the entire source context. Similar observations can be made for the deeper convolutional encoders.

Abstract

Deep Neural Networks (DNNs) have provably enhanced the state-of-the-art Neural Machine Translation (NMT) with their capability in modeling complex functions and capturing complex linguistic structures. However NMT systems with deep architecture in their encoder or decoder RNNs often suffer from severe gradient diffusion due to the non-linear recurrent activations, which often make the optimization much more difficult. To address this problem we propose novel linear associative units (LAU) to reduce the gradient propagation length inside the recurrent unit. Different from conventional approaches (LSTM unit and GRU), LAUs utilizes linear associative connections between input and output of the recurrent unit, which allows unimpeded information flow through both space and time direction. The model is quite simple, but it is surprisingly effective. Our empirical study on Chinese-English translation shows that our model with proper configuration can improve by 11.7 BLEU upon Groundhog and the best reported results in the same setting. On WMT14 English-German task and a larger WMT14 English-French task, our model achieves comparable results with the state-of-the-art.

1 Introduction

Neural Machine Translation (NMT) is an end-to-end learning approach to machine translation which has recently shown promising results on multiple language pairs (Luong et al., 2015; Shen et al., 2015; Wu et al., 2016; Zhang et al., 2016; Tu et al., 2016; Zhang and Zong, 2016; Jean et al., 2015; Meng et al., 2015). Unlike conventional Statistical Machine Translation (SMT) systems (Koehn et al., 2003; Chiang, 2005; Liu et al., 2006; Xiong et al., 2006; Mi et al., 2008) which consist of multiple separately tuned components, NMT aims at building upon a single and large neural network to directly map input text to associated output text. Typical NMT models consists of two recurrent neural networks (RNNs), an encoder to read and encode the input text into a distributed representation and a decoder to generate translated text conditioned on the input representation (Sutskever et al., 2014; Bahdanau et al., 2014).

Driven by the breakthrough achieved in computer vision (He et al., 2015; Srivastava et al., 2015), research in NMT has recently turned towards studying Deep Neural Networks (DNNs). Wu et al. (2016) and Zhou et al. (2016) found that deep architectures in both the encoder and decoder are essential for capturing subtle irregularities in the source and target languages. However, training a deep neural network is not as simple as stacking layers. Optimization often becomes increasingly difficult with more layers. One reasonable explanation is the notorious problem of vanishing/exploding gradients which was first studied in the context of vanilla RNNs (Pascanu et al., 2013b). Most prevalent approaches to solve this problem rely on short-cut connections between adjacent layers such as residual or fast-forward connections (He et al., 2015; Srivastava et al., 2015; Zhou et al., 2016). Differ-

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 136–145
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1013

ent from previous work, we choose to reduce the gradient path inside the recurrent units and propose a novel Linear Associative Unit (LAU) which creates a fusion of both linear and nonlinear transformations of the input. Through this design, information can flow across several steps both in time and in space with little attenuation. The mechanism makes it easy to train deep stack RNNs which can efficiently capture the complex inherent structures of sentences for NMT. Based on LAUs, we also propose a NMT model , called DEEPLAU, with deep architecture in both the encoder and decoder.

Although DEEPLAU is fairly simple, it gives remarkable empirical results. On the NIST Chinese-English task, DEEPLAU with proper settings yields the best reported result and also a 4.9 BLEU improvement over a strong NMT baseline with most known techniques (e.g, dropout) incorporated. On WMT English-German and English-French tasks, it also achieves performance superior or comparable to the state-of-the-art.

2 Neural machine translation

A typical neural machine translation system is a single and large neural network which directly models the conditional probability $p(\mathbf{y}|\mathbf{x})$ of translating a source sentence $\mathbf{x} = \{x_1, x_2, \cdots, x_{T_x}\}$ to a target sentence $\mathbf{y} = \{y_1, y_2, \cdots, y_{T_y}\}$.

Attention-based NMT, with RNNsearch as its most popular representative, generalizes the conventional notion of encoder-decoder in using an array of vectors to represent the source sentence and dynamically addressing the relevant segments of them during decoding. The process can be explicitly split into an encoding part, a decoding part and an attention mechanism. The model first encodes the source sentence $\mathbf{x}$ into a sequence of vectors $\mathbf{c} = \{h_1, h_2, \cdots, h_{T_x}\}$. In general, h_i is the annotation of x_i from a bi-directional RNN which contains information about the whole sentence with a strong focus on the parts of x_i. Then, the RNNsearch model decodes and generates the target translation $\mathbf{y}$ based on the context $\mathbf{c}$ and the partial traslated sequence $\mathbf{y}_{<t}$ by maximizing the probability of $p(y_i|y_{<i}, \mathbf{c})$. In the attention model, $\mathbf{c}$ is dynamically obtained according to the contribution of the source annotation made to the word prediction. This is called automatic alignment (Bahdanau et al., 2014) or attention mechanism (Luong et al., 2015), but it is essentially reading with content-based addressing defined in (Graves et al., 2014). With this addressing strategy the decoder can attend to the source representation that is most relevant to the stage of decoding.

Deep neural models have recently achieved a great success in a wide range of problems. In computer vision, models with more than 100 convolutional layers have outperformed shallow ones by a big margin on a series of image tasks (He et al., 2015; Srivastava et al., 2015). Following similar ideas of building deep CNNs, some promising improvements have also been achieved on building deep NMT systems. Zhou et al. (2016) proposed a new type of linear connections between adjacent layers to simplify the training of deeply stacked RNNs. Similarly, Wu et al. (2016) introduced residual connections to their deep neural machine translation system and achieve great improvements. However the optimization of deep RNNs is still an open problem due to the massive recurrent computation which makes the gradient propagation path extremely tortuous.

3 Model Description

In this section, we discuss Linear Associative Unit (LAU) to ease the training of deep stack of RNNs. Based on this idea, we further propose DEEPLAU, a neural machine translation model with a deep encoder and decoder.

3.1 Recurrent Layers

A recurrent neural network (Williams and Zipser, 1989) is a class of neural network that has recurrent connections and a state (or its more sophisticated memory-like extension). The past information is built up through the recurrent connections. This makes RNN applicable for sequential prediction tasks of arbitrary length. Given a sequence of vectors $\mathbf{x} = \{\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_T\}$ as input, a standard RNN computes the sequence hidden states $\mathbf{h} = \{\mathbf{h}_1, \mathbf{h}_2, \cdots, \mathbf{h}_T\}$ by iterating the following

equation from $t = 1$ to $t = T$:

$$\mathbf{h}_t = \phi(\mathbf{x}_t, \mathbf{h}_{t-1}) \quad (1)$$

ϕ is usually a nonlinear function such as composition of a logistic sigmoid with an affine transformation.

3.2 Gated Recurrent Unit

It is difficult to train RNNs to capture long-term dependencies because the gradients tend to either vanish (most of the time) or explode. The effect of long-term dependencies is dropped exponentially with respect to the gradient propagation length. The problem was explored in depth by (Hochreiter and Schmidhuber, 1997; Pascanu et al., 2013b). A successful approach is to design a more sophisticated activation function than a usual activation function consisting of gating functions to control the information flow and reduce the propagation path. There is a long thread of work aiming to solve this problem, with the long short-term memory units (LSTM) being the most salient examples and gated recurrent unit (GRU) being the most recent one (Hochreiter and Schmidhuber, 1997; Cho et al., 2014). RNNs employing either of these recurrent units have been shown to perform well in tasks that require capturing long-term dependencies.

GRU can be viewed as a slightly more dramatic variation on LSTM with fewer parameters. The activation function is armed with two specifically designed gates called update and reset gates to control the flow of information inside each hidden unit. Each hidden state at time-step t is computed as follows

$$\mathbf{h}_t = (1 - \mathbf{z}_t) \odot \mathbf{h}_{t-1} + \mathbf{z}_t \odot \tilde{\mathbf{h}}_t \quad (2)$$

where $\odot$ is an element-wise product, $\mathbf{z}_t$ is the update gate, and $\tilde{\mathbf{h}}_t$ is the candidate activation.

$$\tilde{\mathbf{h}}_t = \tanh(\mathbf{W}_{xh}\mathbf{x}_t + \mathbf{W}_{hh}(\mathbf{r}_t \odot \mathbf{h}_{t-1})) \quad (3)$$

where $\mathbf{r}_t$ is the reset gate. Both reset and update gates are computed as :

$$\mathbf{r}_t = \sigma(\mathbf{W}_{xr}\mathbf{x}_t + \mathbf{W}_{hr}\mathbf{h}_{t-1}) \quad (4)$$

$$\mathbf{z}_t = \sigma(\mathbf{W}_{xz}\mathbf{x}_t + \mathbf{W}_{hz}\mathbf{h}_{t-1}) \quad (5)$$

This procedure of taking a linear sum between the existing state and the newly computed state is similar to the LSTM unit.

3.3 Linear Associative Unit

GRU can actually be viewed as a non-linear activation function with gating mechanism. Here we propose LAU which extends GRU by having an additional linear transformation of the input in its dynamics. More formally, the state update function becomes

$$\begin{aligned}\mathbf{h}_t =&((1 - \mathbf{z}_t) \odot \mathbf{h}_{t-1} + \mathbf{z}_t \odot \tilde{\mathbf{h}}_t) \odot (1 - \mathbf{g}_t) \\ &+ \mathbf{g}_t \odot \mathbf{H}(\mathbf{x}_t).\end{aligned} \quad (6)$$

Here the updated $\mathbf{h}_t$ has three sources: 1) the direct transfer from previous state $\mathbf{h}_{t-1}$, 2) the candidate update $\tilde{\mathbf{h}}_t$, and 3) a direct contribution from the input $\mathbf{H}(\mathbf{x}_t)$. More specifically, $\tilde{\mathbf{h}}_t$ contains the nonlinear information of the input and the previous hidden state.

$$\tilde{\mathbf{h}}_t = \tanh(\mathbf{f}_t \odot (\mathbf{W}_{xh}\mathbf{x}_t) + \mathbf{r}_t \odot (\mathbf{W}_{hh}\mathbf{h}_{t-1})), \quad (7)$$

where $\mathbf{f}_t$ and $\mathbf{r}_t$ express how much of the nonlinear abstraction are produced by the input $\mathbf{x}_t$ and previous hidden state $\mathbf{h}_t$, respectively. For simplicity, we set $\mathbf{f}_t = 1 - \mathbf{r}_t$ in this paper and find that this works well in our experiments. The term $\mathbf{H}(\mathbf{x}_t)$ is usually an affine linear transformation of the input $\mathbf{x}_t$ to mach the dimensions of $\mathbf{h}_t$, where $\mathbf{H}(\mathbf{x}_t) = \mathbf{W}_x x_t$. The associated term $\mathbf{g}_t$ (the input gate) decides how much of the linear transformation of the input is carried to the hidden state and then the output. The gating function $\mathbf{r}_t$ (reset gate) and $\mathbf{z}_t$ (update gate) are computed following Equation (4) and (5) while $\mathbf{g}_t$ is computed as

$$\mathbf{g}_t = \sigma(\mathbf{W}_{xg}\mathbf{x}_t + \mathbf{W}_{hg}\mathbf{h}_{t-1}). \quad (8)$$

The term $\mathbf{g}_t \odot \mathbf{H}(\mathbf{x}_t)$ therefore offers a direct way for input $\mathbf{x}_t$ to go to later hidden layers, which can eventually lead to a path to the output layer when applied recursively. This mechanism is potentially very useful for translation where the input, no matter whether it is the source word or the attentive reading (context), should sometimes be directly carried to the next stage of processing without any substantial composition or nonlinear transformation. To understand this, imagine we want to translate a English sentence containing a relative rare entity name such as "Bahrain" to Chinese: LAU is potentially able to retain the embedding of this word in its hidden state, which

will otherwise be prone to serious distortion due to the scarcity of training instances for it.

3.4 DEEPLAU

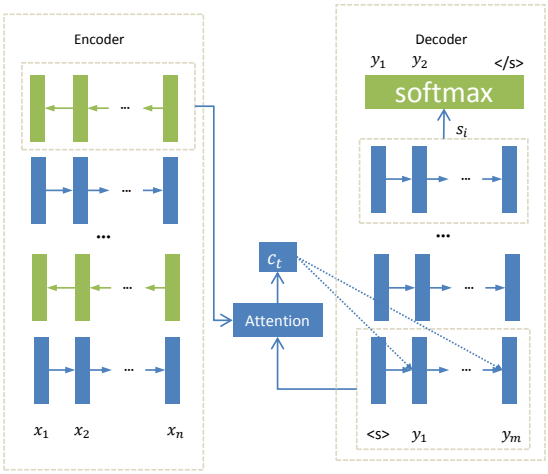

Figure 1: DEEPLAU: a neural machine translation model with deep encoder and decoder.

Graves et al. (2013) explored the advantages of deep RNNs for handwriting recognition and text generation. There are multiple ways of combining one layer of RNN with another. Pascanu et al. (2013a) introduced Deep Transition RNNs with Skip connections (DT(S)-RNNs). Kalchbrenner et al. (2015) proposed to make a full connection of all the RNN hidden layers. In this work we employ vertical stacking where only the output of the previous layer of RNN is fed to the current layer as input. The input at recurrent layer ℓ (denoted as $\mathbf{x}_t^\ell$) is exactly the output of the same time step at layer $\ell - 1$ (denoted as $\mathbf{h}_t^{\ell-1}$). Additionally, in order to learn more temporal dependencies, the sequences can be processed in different directions. More formally, given an input sequence $\mathbf{x} = (\mathbf{x}_1, ..., \mathbf{x}_T)$, the output on layer ℓ is

$$\mathbf{h}_t^{(\ell)} = \begin{cases} \mathbf{x}_t, & \ell = 1 \\ \phi^\ell(\mathbf{h}_{t+d}^{(\ell)}, \mathbf{h}_t^{(\ell-1)}), & \ell > 1 \end{cases} \quad (9)$$

where

- $\mathbf{h}_t^{(\ell)}$ gives the output of layer ℓ at location t.
- ϕ is a recurrent function and we choose LAUs in this work.
- The directions are marked by a direction term $d \in \{-1, 1\}$. If we fixed d to -1, the input will be processed in forward direction, otherwise backward direction.

The deep architecture of DEEPLAU, as shown in Figure 1, consists of three parts: a stacked LAU-based encoder, a stacked LAU-based decoder and an improved attention model.

Encoder One shortcoming of conventional RNNs is that they are only able to make use of previous context. In machine translation, where whole source utterances are transcribed at once, there is no reason not to exploit future context as well. Thus bi-directional RNNs are proposed to integrate information from the past and the future. The typical bidirectional approach processes the raw input in backward and forward direction with two separate layers, and then concatenates them together. Following Zhou et al. (2016), we choose another bidirectional approach to process the sequence in order to learn more temporal dependencies in this work. Specifically, an RNN layer processes the input sequence in forward direction. The output of this layer is taken by an upper RNN layer as input, processed in reverse direction. Formally, following Equation (9), we set $d = (-1)^\ell$. This approach can easily build a deeper network with the same number of parameters compared to the classical approach. The final encoder consists of L_{enc} layers and produces the output $\mathbf{h}^{L_{\text{enc}}}$ to compute the conditional input $\mathbf{c}$ to the decoder.

Attention Model The alignment model $\alpha_{t,j}$ scores how well the output at position t matches the inputs around position j based on $\mathbf{s}_{t-1}^1$ and $\mathbf{h}_j^{L_{\text{enc}}}$ where $\mathbf{h}_j^{L_{\text{enc}}}$ is the top-most layer of the encoder at step j and $\mathbf{s}_{t-1}^1$ is the first layer of decoder at step $t - 1$. It is intuitively beneficial to exploit the information of y_{t-1} when reading from the source sentence representation, which is missing from the implementation of attention-based NMT in (Bahdanau et al., 2014). In this work, we build a more effective alignment path by feeding both the previous hidden state $\mathbf{s}_{t-1}^1$ and the context word y_{t-1} to the attention model, inspired by the recent implementation of attention-based

NMT[1]. The conditional input $\mathbf{c}_j$ is a weighted sum of attention score $\alpha_{t,j}$ and encoder output $\mathbf{h}^{L_{\text{enc}}}$. Formally, the calculation of $\mathbf{c}_j$ is

$$\mathbf{c}_j = \sum_{t=1}^{t=L_x} \alpha_{t,j} \mathbf{h}_t^{L_{\text{enc}}} \tag{10}$$

where

$$\begin{aligned} e_{t,j} &= \mathbf{v}_a^T \sigma(\mathbf{W}_a \mathbf{s}_{t-1}^1 + \mathbf{U}_a \mathbf{h}_j^{L_{\text{enc}}} + \mathbf{W}_y \mathbf{y}_{t-1}) \\ \alpha_{t,j} &= \text{softmax}(e_{t,j}). \end{aligned} \tag{11}$$

σ is a nonlinear function with the information of y_{t-1} (its word embedding being $\mathbf{y}_{t-1}$) added. In our preliminary experiments, we found that GRU works slightly better than tanh function, but we chose the latter for simplicity.

Decoder The decoder follows Equation (9) with fixed direction term $d = -1$. At the first layer, we use the following input:

$$\mathbf{x}_t = [\mathbf{c}_t, \mathbf{y}_{t-1}]$$

where $\mathbf{y}_{t-1}$ is the target word embedding at time step t, $\mathbf{c}_t$ is dynamically obtained follows Equation (10). There are L_{dec} layers of RNNs armed with LAUs in the decoder. At inference stage, we only utilize the top-most hidden states $\mathbf{s}^{L_{\text{dec}}}$ to make the final prediction with a softmax layer:

$$p(y_i | y_{<i}, \mathbf{x}) = \text{softmax}(\mathbf{W}_o \mathbf{s}_i^{L_{\text{dec}}}) \tag{12}$$

.

4 Experiments

4.1 Setup

We mainly evaluated our approaches on the widely used NIST Chinese-English translation task. In order to show the usefulness of our approaches, we also provide results on other two translation tasks: English-French, English-German. The evaluation metric is BLEU[2] (Papineni et al., 2002).

For Chinese-English, our training data consists of 1.25M sentence pairs extracted from LDC corpora[3], with 27.9M Chinese words and 34.5M English words respectively. We choose NIST 2002 (MT02) dataset as our development set, and the NIST 2003 (MT03), 2004 (MT04) 2005 (MT05) and 2006 (MT06) datasets as our test sets.

For English-German, to compare with the results reported by previous work (Luong et al., 2015; Zhou et al., 2016; Jean et al., 2015), we used the same subset of the WMT 2014 training corpus that contains 4.5M sentence pairs with 91M English words and 87M German words. The concatenation of news-test 2012 and news-test 2013 is used as the validation set and news-test 2014 as the test set.

To evaluate at scale, we also report the results of English-French. To compare with the results reported by previous work on end-to-end NMT (Sutskever et al., 2014; Bahdanau et al., 2014; Jean et al., 2015; Luong et al., 2014; Zhou et al., 2016), we used the same subset of the WMT 2014 training corpus that contains 12M sentence pairs with 304M English words and 348M French words. The concatenation of news-test 2012 and news-test 2013 serves as the validation set and news-test 2014 as the test set.

4.2 Training details

Our training procedure and hyper parameter choices are similar to those used by (Bahdanau et al., 2014). In more details, we limit the source and target vocabularies to the most frequent $30K$ words in both Chinese-English and English-French. For English-German, we set the source and target vocabularies size to $120K$ and $80K$, respectively.

For all experiments, the dimensions of word embeddings and recurrent hidden states are both set to 512. The dimension of c_t is also of size 512. Note that our network is more narrow than most previous work where hidden states of dimmention 1024 is used. we initialize parameters by sampling each element from the Gaussian distribution with mean 0 and variance 0.04^2.

Parameter optimization is performed using stochastic gradient descent. Adadelta (Zeiler,

[1] github.com/nyu-dl/dl4mt-tutorial/tree/master/session2

[2] For Chinese-English task, we apply case-insensitive NIST BLEU. For other tasks, we tokenized the reference and evaluated the performance with *multi-bleu.pl*. The metrics are exactly the same as in previous work.

[3] The corpora include LDC2002E18, LDC2003E07, LDC2003E14, Hansards portion of LDC2004T07, LDC2004T08 and LDC2005T06.

2012) is used to automatically adapt the learning rate of each parameter ($\epsilon = 10^{-6}$ and $\rho = 0.95$). To avoid gradient explosion, the gradients of the cost function which had ℓ_2 norm larger than a predefined threshold τ were normalized to the threshold (Pascanu et al., 2013a). We set τ to 1.0 at the beginning and halve the threshold until the BLEU score does not change much on the development set. Each SGD is a mini-batch of 128 examples. We train our NMT model with the sentences of length up to 80 words in the training data, while for the Moses system we use the full training data. Translations are generated by a beam search and log-likelihood scores are normalized by sentence length. We use a beam width of 10 in all the experiments. Dropout was also applied on the output layer to avoid over-fitting. The dropout rate is set to 0.5. Except when otherwise mentioned, NMT systems are have 4 layers encoders and 4 layers decoders.

4.3 Results on Chinese-English Translation

Table 1 shows BLEU scores on Chinese-English datasets. Clearly DEEPLAU leads to a remarkable improvement over their competitors. Compared to DEEPGRU, DEEPLAU is +4.89 BLEU score higher on average four test sets, showing the modeling power gained from the liner associative connections. We suggest it is because LAUs apply adaptive gate function conditioned on the input which make it able to automatically decide how much linear information should be transferred to the next step.

To show the power of DEEPLAU, we also make a comparison with previous work. Our best single model outperforms both a phrased-based MT system (Moses) as well as an open source attention-based NMT system (Groundhog) by +7.3 and +6.8 BLEU points respectively on average. The result is also better than some other state-of-the-art variants of attention-based NMT mode with big margins. After PosUnk and ensemble, DEEPLAU seizes another notable gain of +4.38 BLEU and outperform Moses by +11.68 BLEU.

4.4 Results on English-German Translation

The results on English-German translation are presented in Table 2. We compare our NMT systems with various other systems including the winning system in WMT14 (Buck et al., 2014), a phrase-based system whose language models were trained on a huge monolingual text, the Common Crawl corpus. For end-to-end NMT systems, to the best of our knowledge, Wu et al. (2016) is currently the SOTA system and about 4 BLEU points on top of previously best reported results even though Zhou et al. (2016) used a much deeper neural network[4].

Following Wu et al. (2016), the BLEU score represents the averaged score of 8 models we trained. Our approach achieves comparable results with SOTA system. As can be seen from the Table 2, DeepLAU performs better than the word based model and even not much worse than the best wordpiece models achieved by Wu et al. (2016). Note that DEEPLAU are sim-

[4]It is also worth mentioning that the result reported by Zhou et al. (2016) does not include PosUnk, and this comparison is not fair enough.

SYSTEM	Architecture	Voc.	BLEU
Existing systems			
Buck et al. (2014)	Winning WMT14 system phrase-based + large LM	-	20.7
Jean et al. (2015)	gated RNN with search + LV + PosUnk	$500K$	19.4
Luong et al. (2015)	LSTM with 4 layers + dropout + local att. + PosUnk	$80K$	20.9
Shen et al. (2015)	gated RNN with search + PosUnk + MRT	$80K$	20.5
Zhou et al. (2016)	LSTM with 16 layers + F-F connections	$80K$	20.6
Wu et al. (2016)	LSTM with 8 laysrs + RL-refined Word	$80K$	23.1
Wu et al. (2016)	LSTM with 8 laysrs + RL-refined WPM-32K	-	24.6
Wu et al. (2016)	LSTM with 8 laysrs + RL-refined WPM-32K + Ensemble	-	26.3
Our deep NMT systems			
this work	DEEPLAU	$80K$	$22.1(\pm 0.3)$
this work	DEEPLAU + PosUnk	$80K$	$23.8(\pm 0.3)$
this work	DEEPLAU + PosUnk + Ensemble 8 models	$80K$	26.1

Table 2: Case-sensitive BLEU scores on German-English translation.

ple and easy to implement, as opposed to previous models reported in Wu et al. (2016), which dependends on some external techniques to achieve their best performance, such as their introduction of length normalization, coverage penalty, fine-tuning and the RL-refined model.

4.5 Results on English-French Translation

SYSTEM	BLEU
Enc-Dec (Luong et al., 2014)	30.4
RNNsearch (Bahdanau et al., 2014)	28.5
RNNsearch-LV (Jean et al., 2015)	32.7
Deep-Att (Zhou et al., 2016)	35.9
DEEPLAU	35.1

Table 3: English-to-French task: BLEU scores of single neural models.

To evaluate at scale, we also show the results on an English-French task with $12M$ sentence pairs and $30K$ vocabulary in Table 3. Luong et al. (2014) achieves BLEU score of 30.4 with a six layers deep Encoder-Decoder model. The two attention models, RNNSearch and RNNsearch-LV achieve BLEU scores of 28.5 and 32.7 respectively. The previous best single NMT Deep-Att model with an 18 layers encoder and 7 layers decoder achieves BLEU score of 35.9. For DEEPLAU, we obtain the BLEU score of 35.1 with a 4 layers encoder and 4 layers decoder, which is on par with the SOTA system in terms of BLEU. Note that Zhou et al. (2016) utilize a much larger depth as well as external alignment model and extensive regularization to achieve their best results.

4.6 Analysis

Then we will study the main factors that influence our results on NIST Chinese-English translation task. We also compare our approach with two SOTA topologies which were used in building deep NMT systems.

- Residual Networks (ResNet) are among the pioneering works (Szegedy et al., 2016; He et al., 2016) that utilize extra identity connections to enhance information flow such that very deep neural networks can be effectively optimized. Share the similar idea, Wu et al. (2016) introduced to leverage residual connections to train deep RNNs.

- Fast Forward (F-F) connections were proposed to reduce the propagation path length which is the pioneer work to simplify the training of deep NMT model (Zhou et al., 2016). The work can be viewed as a parametric ResNet with short cut connections between adjacent layers. The procedure takes a linear sum between the input and the newly computed state.

LAU vs. GRU Table 4 shows the effect of the novel LAU. By comparing row 3 to row 7, we see that when L_{Enc} and L_{Dec} are set to 2,

SYSTEM	(L_{enc},L_{Dec})	width	AVE.
1 DEEPGRU	(2,1)	512	33.59
2 DEEPGRU	(2,2)	1024	34.68
3 DEEPGRU	(2,2)	512	34.91
4 DEEPGRU	(4,4)	512	34.08
5 4+ResNet	(4,4)	512	36.40
6 4+F-F	(4,4)	512	37.62
7 DEEPLAU	(2,2)	512	37.65
8 DEEPLAU	(4,4)	512	38.97
9 DEEPLAU	(8,6)	512	39.01
10 DEEPLAU	(8,6)	256	38.91

Table 4: BLEU scores of DEEPLAU and DEEPGRU with different model sizes.

the average BLEU scores achieved by DEEPGRU and DEEPLAU are 34.68 and 37.65, respectively. LAU can bring an improvement of 2.97 in terms of BLEU. After increasing the model depth to 4 (row 4 and row 6), the improvement is enlarged to 4.91. When DEEPGRU is trained with larger depth (say, 4), the training becomes more difficult and the performance falls behind its shallow partner. While for DEEPLAU, as can be see in row 9, with increasing the depth even to $L_{\text{Enc}} = 8$ and $L_{\text{Dec}} = 6$ we can still obtain growth by 0.04 BLEU score. Compared to previous shortcut connection methods (row 5 and row 6), The LAU still achieve meaningful improvements over F-F connections and Residual connections by $+1.35$ and $+2.57$ BLEU points respectively.

DEEPLAU introduces more parameters than DEEPGRU. In order to figure out the effect of DEEPLAU comparing models with the same parameter size, we increase the hidden size of DEEPGRU model. Row 3 shows that, after using a twice larger GRU layer, the BLEU score is 34.68, which is still worse than the corresponding DEEPLAU model with fewer parameters.

Depth vs. Width Next we will study the model size. In Table 4, starting from $L_{\text{Enc}} = 2$ and $L_{\text{Dec}} = 2$ and gradually increasing the model depth, we can achieve substantial improvements in terms of BLEU. With $L_{\text{Enc}} = 8$ and $L_{\text{Dec}} = 6$, our DEEPLAU model yields the best BLEU score. We tried to increase the model depth with the same hidden size but failed to see further improvements.

We then tried to increase the hidden size. By comparing row 2 and row 3, we find the improvements is relative small with a wider hidden size. It is also worth mentioning that a deep and thin network with fewer parameters can still achieve comparable results with its shallow partner. This suggests that depth plays a more important role in increasing the complexity of neural networks than width and our deliberately designed LAU benefit from the optimizing of such a deep model.

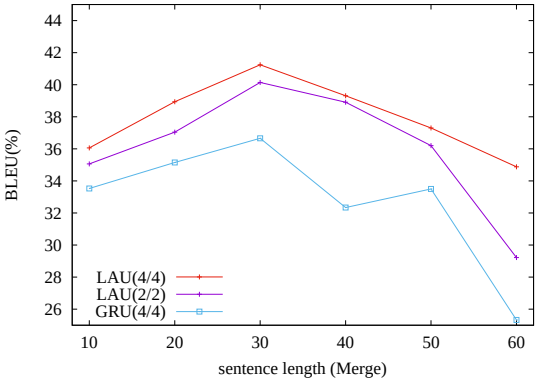

Figure 2: The BLEU scores of generated translations on the merged four test sets with respect to the lengths of source sentences.

About Length A more detailed comparison between DEEPLAU (4 layers encoder and 4 layers decoder), DEEPLAU(2 layer encoder and 2 layer decoder) and DEEPGRU (4 layers encoder and 4 layers decoder), suggest that with deep architectures are essential to the superior performance of our system. In particular, we test the BLEU scores on sentences longer than $\{10, 20, 30, 40, 50, 60\}$ on the merged test set. Clearly, in all curves, performance degrades with increased sentence length. However, DEEPLAU models yield consistently higher BLEU scores than the DEEPGRU model on longer sentences. These observations are consistent with our intuition that very deep RNN model is especially good at modeling the nested latent structures on relatively complicated sentences and LAU plays an important role on optimizing such a complex deep model.

5 Conclusion

We propose a Linear Associative Unit (LAU) which makes a fusion of both linear and non-linear transformation inside the recurrent unit. On this way, gradients decay much slower compared to the standard deep networks which enable us to build a deep neural network for machine translation. Our empirical study shows that it can significantly improve the performance of NMT.

Abstract

Sequence-to-sequence models have shown strong performance across a broad range of applications. However, their application to parsing and generating text using Abstract Meaning Representation (AMR) has been limited, due to the relatively limited amount of labeled data and the non-sequential nature of the AMR graphs. We present a novel training procedure that can lift this limitation using millions of unlabeled sentences and careful preprocessing of the AMR graphs. For AMR parsing, our model achieves competitive results of 62.1 SMATCH, the current best score reported without significant use of external semantic resources. For AMR generation, our model establishes a new state-of-the-art performance of BLEU 33.8. We present extensive ablative and qualitative analysis including strong evidence that sequence-based AMR models are robust against ordering variations of graph-to-sequence conversions.

1 Introduction

Abstract Meaning Representation (AMR) is a semantic formalism to encode the meaning of natural language text. As shown in Figure 1, AMR represents the meaning using a directed graph while abstracting away the surface forms in text. AMR has been used as an intermediate meaning representation for several applications including machine translation (MT) (Jones et al., 2012), summarization (Liu et al., 2015), sentence compression (Takase et al., 2016), and event extraction (Huang et al., 2016). While AMR allows for rich semantic representation, annotating training data in AMR is expensive, which in turn limits the use

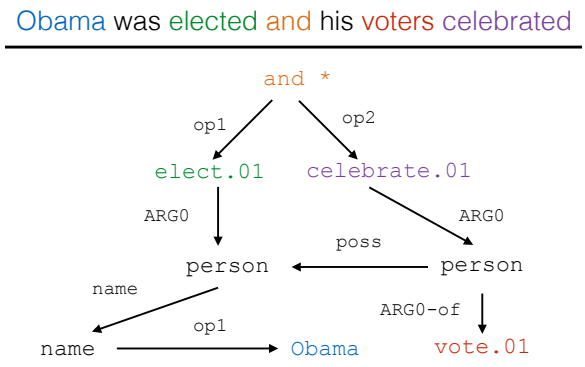

Figure 1: An example sentence and its corresponding Abstract Meaning Representation (AMR). AMR encodes semantic dependencies between entities mentioned in the sentence, such as "Obama" being the "arg0" of the verb "elected".

of neural network models (Misra and Artzi, 2016; Peng et al., 2017; Barzdins and Gosko, 2016).

In this work, we present the first successful sequence-to-sequence (seq2seq) models that achieve strong results for both text-to-AMR parsing and AMR-to-text generation. Seq2seq models have been broadly successful in many other applications (Wu et al., 2016; Bahdanau et al., 2015; Luong et al., 2015; Vinyals et al., 2015). However, their application to AMR has been limited, in part because effective *linearization* (encoding graphs as linear sequences) and data sparsity were thought to pose significant challenges. We show that these challenges can be easily overcome, by demonstrating that seq2seq models can be trained using *any* graph-isomorphic linearization and that unlabeled text can be used to significantly reduce sparsity.

Our approach is two-fold. First, we introduce a novel paired training procedure that enhances both the text-to-AMR parser and AMR-to-text generator. More concretely, first we use self-training to

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 146–157
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1014

bootstrap a high quality AMR parser from millions of unlabeled Gigaword sentences (Napoles et al., 2012) and then use the automatically parsed AMR graphs to pre-train an AMR generator. This paired training allows both the parser and generator to learn high quality representations of fluent English text from millions of weakly labeled examples, that are then fine-tuned using human annotated AMR data.

Second, we propose a preprocessing procedure for the AMR graphs, which includes anonymizing entities and dates, grouping entity categories, and encoding nesting information in concise ways, as illustrated in Figure 2(d). This preprocessing procedure helps overcoming the data sparsity while also substantially reducing the complexity of the AMR graphs. Under such a representation, we show that any depth first traversal of the AMR is an effective linearization, and it is even possible to use a different random order for each example.

Experiments on the LDC2015E86 AMR corpus (SemEval-2016 Task 8) demonstrate the effectiveness of the overall approach. For parsing, we are able to obtain competitive performance of 62.1 SMATCH without using any external annotated examples other than the output of a NER system, an improvement of over 10 points relative to neural models with a comparable setup. For generation, we substantially outperform previous best results, establishing a new state of the art of 33.8 BLEU. We also provide extensive ablative and qualitative analysis, quantifying the contributions that come from preprocessing and the paired training procedure.

2 Related Work

Alignment-based Parsing Flanigan et al. (2014) (JAMR) pipeline concept and relation identification with a graph-based algorithm. Zhou et al. (2016) extend JAMR by performing the concept and relation identification tasks jointly with an incremental model. Both systems rely on features based on a set of alignments produced using bi-lexical cues and hand-written rules. In contrast, our models train directly on parallel corpora, and make only minimal use of alignments to anonymize named entities.

Grammar-based Parsing Wang et al. (2016) (CAMR) perform a series of shift-reduce transformations on the output of an externally-trained dependency parser, similar to Damonte et al. (2017), Brandt et al. (2016), Puzikov et al. (2016), and Goodman et al. (2016). Artzi et al. (2015) use a grammar induction approach with Combinatory Categorical Grammar (CCG), which relies on pretrained CCGBank categories, like Bjerva et al. (2016). Pust et al. (2015) recast parsing as a string-to-tree Machine Translation problem, using unsupervised alignments (Pourdamghani et al., 2014), and employing several external semantic resources. Our neural approach is engineering lean, relying only on a large unannotated corpus of English and algorithms to find and canonicalize named entities.

Neural Parsing Recently there have been a few seq2seq systems for AMR parsing (Barzdins and Gosko, 2016; Peng et al., 2017). Similar to our approach, Peng et al. (2017) deal with sparsity by anonymizing named entities and typing low frequency words, resulting in a very compact vocabulary (2k tokens). However, we avoid reducing our vocabulary by introducing a large set of unlabeled sentences from an external corpus, therefore drastically lowering the out-of-vocabulary rate (see Section 6).

AMR Generation Flanigan et al. (2016) specify a number of tree-to-string transduction rules based on alignments and POS-based features that are used to drive a tree-based SMT system. Pourdamghani et al. (2016) also use an MT decoder; they learn a classifier that linearizes the input AMR graph in an order that follows the output sentence, effectively reducing the number of alignment crossings of the phrase-based decoder. Song et al. (2016) recast generation as a traveling salesman problem, after partitioning the graph into fragments and finding the best linearization order. Our models do not need to rely on a particular linearization of the input, attaining comparable performance even with a per example random traversal of the graph. Finally, all three systems intersect with a large language model trained on Gigaword. We show that our seq2seq model has the capacity to learn the same information as a language model, especially after pretraining on the external corpus.

Data Augmentation Our paired training procedure is largely inspired by Sennrich et al. (2016). They improve neural MT performance for low resource language pairs by using a back-translation MT system for a large monolingual corpus of the target language in order to create synthetic output,

and mixing it with the human translations. We instead pre-train on the external corpus first, and then fine-tune on the original dataset.

3 Methods

In this section, we first provide the formal definition of AMR parsing and generation (section 3.1). Then we describe the sequence-to-sequence models we use (section 3.2), graph-to-sequence conversion (section 3.3), and our paired training procedure (section 3.4).

3.1 Tasks

We assume access to a training dataset D where each example pairs a natural language sentence s with an AMR a. The AMR is a rooted directed acylical graph. It contains nodes whose names correspond to sense-identified verbs, nouns, or AMR specific concepts, for example `elect.01`, `Obama`, and `person` in Figure 1. One of these nodes is a distinguished root, for example, the node `and` in Figure 1. Furthermore, the graph contains labeled edges, which correspond to PropBank-style (Palmer et al., 2005) semantic roles for verbs or other relations introduced for AMR, for example, `arg0` or `op1` in Figure 1. The set of node and edge names in an AMR graph is drawn from a set of tokens C, and every word in a sentence is drawn from a vocabulary W.

We study the task of training an **AMR parser**, i.e., finding a set of parameters θ_P for model f, that predicts an AMR graph $\hat{a}$, given a sentence s:

$$\hat{a} = \underset{a}{\operatorname{argmax}} f\big(a|s;\theta_P\big) \quad (1)$$

We also consider the reverse task, training an **AMR generator** by finding a set of parameters θ_G, for a model f that predicts a sentence $\hat{s}$, given an AMR graph a:

$$\hat{s} = \underset{s}{\operatorname{argmax}} f\big(s|a;\theta_G\big) \quad (2)$$

In both cases, we use the same family of predictors f, sequence-to-sequence models that use global attention, but the models have independent parameters, θ_P and θ_G.

3.2 Sequence-to-sequence Model

For both tasks, we use a stacked-LSTM sequence-to-sequence neural architecture employed in neural machine translation (Bahdanau et al., 2015; Wu et al., 2016).[1] Our model uses a global attention decoder and unknown word replacement with small modifications (Luong et al., 2015).

The model uses a stacked bidirectional-LSTM encoder to encode an input sequence and a stacked LSTM to decode from the hidden states produced by the encoder. We make two modifications to the encoder: (1) we concatenate the forward and backward hidden states at every level of the stack instead of at the top of the stack, and (2) introduce dropout in the first layer of the encoder. The decoder predicts an attention vector over the encoder hidden states using previous decoder states. The attention is used to weigh the hidden states of the encoder and then predict a token in the output sequence. The weighted hidden states, the decoded token, and an attention signal from the previous time step (input feeding) are then fed together as input to the next decoder state. The decoder can optionally choose to output an unknown word symbol, in which case the predicted attention is used to copy a token directly from the input sequence into the output sequence.

3.3 Linearization

Our seq2seq models require that both the input and target be presented as a linear sequence of tokens. We define a linearization order for an AMR graph as any sequence of its nodes and edges. A linearization is defined as (1) a linearization order and (2) a rendering function that generates any number of tokens when applied to an element in the linearization order (see Section 4.2 for implementation details). Furthermore, for parsing, a valid AMR graph must be recoverable from the linearization.

3.4 Paired Training

Obtaining a corpus of jointly annotated pairs of sentences and AMR graphs is expensive and current datasets only extend to thousands of examples. Neural sequence-to-sequence models suffer from sparsity with so few training pairs. To reduce the effect of sparsity, we use an external unannotated corpus of sentences S_e, and a procedure which pairs the training of the parser and generator.

Our procedure is described in Algorithm 1, and first trains a parser on the dataset D of pairs of sentences and AMR graphs. Then it uses self-training

[1] We extended the Harvard NLP seq2seq framework from `http://nlp.seas.harvard.edu/code`.

Algorithm 1 Paired Training Procedure

Input: Training set of sentences and AMR graphs $(s, a) \in \mathcal{D}$, an unannotated external corpus of sentences S_e, a number of self training iterations, N, and an initial sample size k.
Output: Model parameters for AMR parser θ_P and AMR generator θ_G.

$\theta_P \leftarrow$ Train parser on D
▷ Self-train AMR parser.
$S_e^1 \leftarrow$ sample k sentences from S_e
for $i = 1$ to N **do**
    $A_e^i \leftarrow$ Parse S_e^i using parameters θ_P
    ▷ Pre-train AMR parser.
    $\theta_P \leftarrow$ Train parser on (A_e^i, S_e^i)
    ▷ Fine tune AMR parser.
    $\theta_P \leftarrow$ Train parser on D with initial parameters θ_P
    $S_e^{i+1} \leftarrow$ sample $k \cdot 10^i$ new sentences from S_e
end for
$S_e^N \leftarrow$ sample $k \cdot 10^N$ new sentences from S_e
▷ Pre-train AMR generator.
$A_e \leftarrow$ Parse S_e^N using parameters θ_P
$\theta_G \leftarrow$ Train generator on (A_e^N, S_e^N)
▷ Fine tune AMR generator.
$\theta_G \leftarrow$ Train generator on D using initial parameters θ_G
return θ_P, θ_G

to improve the initial parser. Every iteration of self-training has three phases: (1) parsing samples from a large, unlabeled corpus S_e, (2) creating a new set of parameters by training on S_e, and (3) fine-tuning those parameters on the original paired data. After each iteration, we increase the size of the sample from S_e by an order of magnitude. After we have the best parser from self-training, we use it to label AMRs for S_e and pre-train the generator. The final step of the procedure fine-tunes the generator on the original dataset D.

4 AMR Preprocessing

We use a series of preprocessing steps, including AMR linerization, anonymization, and other modifications we make to sentence-graph pairs. Our methods have two goals: (1) reduce the complexity of the linearized sequences to make learning easier while maintaining enough original information, and (2) address sparsity from certain open class vocabulary entries, such as named entities (NEs) and quantities. Figure 2(d) contains example inputs and outputs with all of our preprocessing techniques.

Graph Simplification In order to reduce the overall length of the linearized graph, we first remove variable names and the `instance-of` relation (/) before every concept. In case of re-entrant nodes we replace the variable mention with its co-referring concept. Even though this replacement incurs loss of information, often the surrounding context helps recover the correct realization, e.g., the possessive role `:poss` in the example of Figure 1 is strongly correlated with the surface form *his*. Following Pourdamghani et al. (2016) we also remove senses from all concepts for AMR generation only. Figure 2(a) contains an example output after this stage.

4.1 Anonymization of Named Entities

Open-class types including NEs, dates, and numbers account for 9.6% of tokens in the sentences of the training corpus, and 31.2% of vocabulary W. 83.4% of them occur fewer than 5 times in the dataset. In order to reduce sparsity and be able to account for new unseen entities, we perform extensive anonymization.

First, we anonymize sub-graphs headed by one of AMR's over 140 fine-grained entity types that contain a `:name` role. This captures structures referring to entities such as `person`, `country`, miscellaneous entities marked with `⋆-enitity`, and typed numerical values, `⋆-quantity`. We exclude `date` entities (see the next section). We then replace these sub-graphs with a token indicating fine-grained type and an index, i, indicating it is the ith occurrence of that type.[2] For example, in Figure 2 the sub-graph headed by `country` gets replaced with `country_0`.

On the training set, we use alignments obtained using the JAMR aligner (Flanigan et al., 2014) and the unsupervised aligner of Pourdamghani et al. (2014) in order to find mappings of anonymized subgraphs to spans of text and replace mapped text with the anonymized token that we inserted into the AMR graph. We record this mapping for use during testing of generation models. If a generation model predicts an anonymization token, we find the corresponding token in the AMR graph and replace the model's output with the most frequent mapping observed during training for the entity name. If the entity was never observed, we copy its name directly from the AMR graph.

Anonymizing Dates For dates in AMR graphs, we use separate anonymization tokens for year, month-number, month-name, day-number and day-name, indicating whether the date is mentioned by word or by number.[3] In AMR gener-

[2] In practice we only used three groups of ids: a different one for NEs, dates and constants/numbers.

[3] We also use three date format markers that appear in the text as: *YYYYMMDD*, *YYMMDD*, and *YYYY-MM-DD*.

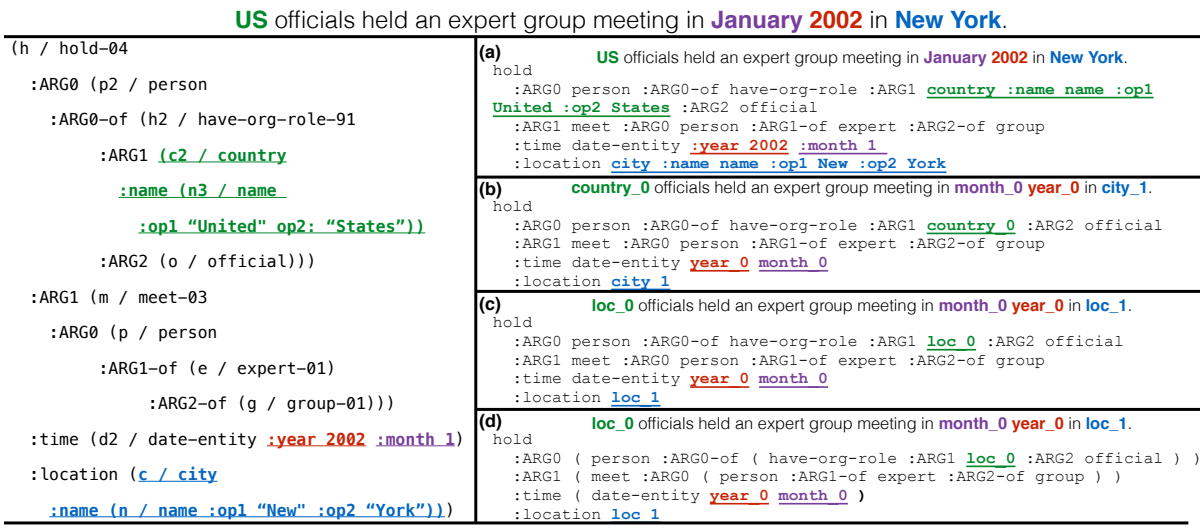

Figure 2: Preprocessing methods applied to sentence (top row) - AMR graph (left column) pairs. Sentence-graph pairs after (a) graph simplification, (b) named entity anonymization, (c) named entity clustering, and (d) insertion of scope markers.

ation, we render the corresponding format when predicted. Figure 2(b) contains an example of all preprocessing up to this stage.

Named Entity Clusters When performing AMR generation, each of the AMR fine-grained entity types is manually mapped to one of the four coarse entity types used in the Stanford NER system (Finkel et al., 2005): person, location, organization and misc. This reduces the sparsity associated with many rarely occurring entity types. Figure 2 (c) contains an example with named entity clusters.

NER for Parsing When parsing, we must normalize test sentences to match our anonymized training data. To produce fine-grained named entities, we run the Stanford NER system and first try to replace any identified span with a fine-grained category based on alignments observed during training. If this fails, we anonymize the sentence using the coarse categories predicted by the NER system, which are also categories in AMR. After parsing, we deterministically generate AMR for anonymizations using the corresponding text span.

4.2 Linearization

Linearization Order Our linearization order is defined by the order of nodes visited by depth first search, including backward traversing steps. For example, in Figure 2, starting at `meet` the order contains `meet`, `:ARG0`, `person`, `:ARG1-of`, `expert`, `:ARG2-of`, `group`, `:ARG2-of`, `:ARG1-of`, `:ARG0`.[4] The order traverses children in the sequence they are presented in the AMR. We consider alternative orderings of children in Section 7 but always follow the pattern demonstrated above.

Rendering Function Our rendering function marks scope, and generates tokens following the pre-order traversal of the graph: (1) if the element is a node, it emits the type of the node. (2) if the element is an edge, it emits the type of the edge and then recursively emits a bracketed string for the (concept) node immediately after it. In case the node has only one child we omit the scope markers (denoted with left "(", and right ")" parentheses), thus significantly reducing the number of generated tokens. Figure 2(d) contains an example showing all of the preprocessing techniques and scope markers that we use in our full model.

5 Experimental Setup

We conduct all experiments on the AMR corpus used in SemEval-2016 Task 8 (LDC2015E86), which contains 16,833/1,368/1,371 train/dev/test examples. For the paired training procedure of Algorithm 1, we use Gigaword as our external corpus and sample sentences that only contain words from the AMR corpus vocabulary W. We subsampled the original sentence to ensure there is no overlap with the AMR training or test sets. Table 2

[4] Sense, `instance-of` and variable information has been removed at the point of linearization.

summarizes statistics about the original dataset and the extracted portions of Gigaword. We evaluate AMR parsing with SMATCH (Cai and Knight, 2013), and AMR generation using BLEU (Papineni et al., 2002)[5].

We validated word embedding sizes and RNN hidden representation sizes by maximizing AMR development set performance (Algorithm 1 – line 1). We searched over the set $\{128, 256, 500, 1024\}$ for the best combinations of sizes and set both to 500. Models were trained by optimizing cross-entropy loss with stochastic gradient descent, using a batch size of 100 and dropout rate of 0.5. Across all models when performance does not improve on the AMR dev set, we decay the learning rate by 0.8.

For the initial parser trained on the AMR corpus, (Algorithm 1 – line 1), we use a single stack version of our model, set initial learning rate to 0.5 and train for 60 epochs, taking the best performing model on the development set. All subsequent models benefited from increased depth and we used 2-layer stacked versions, maintaining the same embedding sizes. We set the initial Gigaword sample size to $k = 200,000$ and executed a maximum of 3 iterations of self-training. For pre-training the parser and generator, (Algorithm 1 – lines 4 and 9), we used an initial learning rate of 1.0, and ran for 20 epochs. We attempt to fine-tune the parser and generator, respectively, after every epoch of pre-training, setting the initial learning rate to 0.1. We select the best performing model on the development set among all of these fine-tuning attempts. During prediction we perform decoding using beam search and set the beam size to 5 both for parsing and generation.

[5]We use the multi-BLEU script from the MOSES decoder suite (Koehn et al., 2007).

6 Results

Parsing Results Table 1 summarizes our development results for different rounds of self-training and test results for our final system, self-trained on 200k, 2M and 20M unlabeled Gigaword sentences. Through every round of self-training, our

parser improves. Our final parser outperforms comparable seq2seq and character LSTM models by over 10 points. While much of this improvement comes from self-training, our model without Gigaword data outperforms these approaches by 3.5 points on F1. We attribute this increase in performance to different handling of preprocessing and more careful hyper-parameter tuning. All other models that we compare against use semantic resources, such as WordNet, dependency parsers or CCG parsers (models marked with * were trained with less data, but only evaluate on newswire text; the rest evaluate on the full test set, containing text from blogs). Our full models outperform JAMR, a graph-based model but still lags behind other parser-dependent systems (CAMR[6]), and resource heavy approaches (SBMT).

Generation Results Table 3 summarizes our AMR generation results on the development and test set. We outperform all previous state-of-the-art systems by the first round of self-training and further improve with the next rounds. Our final model trained on GIGA-20M outperforms TSP and TREETOSTR trained on LDC2015E86, by over 9 BLEU points.[7] Overall, our model incorporates less data than previous approaches as all reported methods train language models on the whole Gigaword corpus. We leave scaling our models to all of Gigaword for future work.

Sparsity Reduction Even after anonymization of open class vocabulary entries, we still encounter a great deal of sparsity in vocabulary given the small size of the AMR corpus, as shown in Table 2. By incorporating sentences from Gigaword we are able to reduce vocabulary sparsity dramatically, as we increase the size of sampled sentences: the out-of-vocabulary rate with a threshold of 5 reduces almost 5 times for GIGA-20M.

Preprocessing Ablation Study We consider the contribution of each main component of our preprocessing stages while keeping our linearization order identical. Figure 2 contains examples for each setting of the ablations we evaluate on. First we evaluate using linearized graphs without parentheses for indicating scope, Figure 2(c), then without named entity clusters, Figure 2(b), and additionally without any anonymization, Figure 2(a).

[6]Since we are currently not using any Wikipedia resources for the prediction of named entities, we compare against the no-wikification version of the CAMR system.

[7]We also trained our generator on GIGA-2M and fine-tuned on LDC2014T12 in order to have a direct comparison with PBMT, and achieved a BLEU score of 29.7, i.e., 2.8 points of improvement.

FULL - ANON	22.7	54.2	32.0

Table 5: SMATCH scores for AMR parsing ablations on preprocessing (DEV set).

Tables 4 summarizes our evaluation on the AMR generation. Each components is required, and scope markers and anonymization contribute the most to overall performance. We suspect without scope markers our seq2seq models are not as effective at capturing long range semantic relationships between elements of the AMR graph. We also evaluated the contribution of anonymization to AMR parsing (Table 5). Following previous work, we find that seq2seq-based AMR parsing is largely ineffective without anonymization (Peng et al., 2017).

7 Linearization Evaluation

In this section we evaluate three strategies for converting AMR graphs into sequences in the context of AMR generation and show that our models are largely agnostic to linearization orders. Our results argue, unlike SMT-based AMR generation methods (Pourdamghani et al., 2016), that seq2seq models can learn to ignore artifacts of the conversion of graphs to linear sequences.

7.1 Linearization Orders

All linearizations we consider use the pattern described in Section 4.2, but differ on the order in which children are visited. Each linearization generates anonymized, scope-marked output (see Section 4), of the form shown in Figure 2(d).

Human The proposal traverses children in the order presented by human authored AMR annotations exactly as shown in Figure 2(d).

Linearization Order	BLEU
HUMAN	21.7
GLOBAL-RANDOM	20.8
RANDOM	20.3

Table 6: BLEU scores for AMR generation for different linearization orders (DEV set).

Global-Random We construct a random global ordering of all edge types appearing in AMR graphs and re-use it for every example in the dataset. We traverse children based on the position in the global ordering of the edge leading to a child.

Random For each example in the dataset we traverse children following a different random order of edge types.

7.2 Results

We present AMR generation results for the three proposed linearization orders in Table 6. Random linearization order performs somewhat worse than traversing the graph according to Human linearization order. Surprisingly, a per example random linearization order performs nearly identically to a global random order, arguing seq2seq models can learn to ignore artifacts of the conversion of graphs to linear sequences.

Human-authored AMR leaks information The small difference between random and global-random linearizations argues that our models are largely agnostic to variation in linearization order. On the other hand, the model that follows the human order performs better, which leads us to suspect it carries extra information not apparent in the graphical structure of the AMR.

To further investigate, we compared the relative ordering of edge pairs under the same parent to the relative position of children nodes derived from those edges in a sentence, as reported by JAMR alignments. We found that the majority of pairs of AMR edges (57.6%) always occurred in the same relative order, therefore revealing no extra generation order information.[8] Of the examples corresponding to edge pairs that showed variation, 70.3% appeared in an order consistent with the order they were realized in the sentence. The relative ordering of some pairs of AMR edges was particularly indicative of generation order. For example, the relative ordering of edges with types `location` and `time`, was 17% more indicative of the generation order than the majority of generated locations before `time`.[9]

To compare to previous work we still report results using human orderings. However, we note that any practical application requiring a system to generate an AMR representation with the intention to realize it later on, e.g., a dialog agent, will need to be trained either using consistent, or random-derived linearization orders. Arguably, our models are agnostic to this choice.

Error Type	%
Coverage	29
Disfluency	23
Anonymization	14
Sparsity	13
Attachment	12
Other	10

Table 7: Error analysis for AMR generation on a sample of 50 examples from the development set.

8 Qualitative Results

Figure 3 shows example outputs of our full system. The generated text for the first graph is nearly perfect with only a small grammatical error due to anonymization. The second example is more challenging, with a deep right-branching structure, and a coordination of the verbs `stabilize` and `push` in the subordinate clause headed by `state`. The model omits some information from the graph, namely the concepts `terrorist` and `virus`. In the third example there are greater parts of the graph that are missing, such as the whole sub-graph headed by `expert`. Also the model makes wrong attachment decisions in the last two sub-graphs (it is the `evidence` that is *unimpeachable* and *irrefutable*, and not the `equipment`), mostly due to insufficient annotation (`thing`) thus making their generation harder.

Finally, Table 7 summarizes the proportions of error types we identified on 50 randomly selected examples from the development set. We found that the generator mostly suffers from coverage issues,

[8] This is consistent with constraints encoded in the annotation tool used to collect AMR. For example, `:ARG0` edges are always ordered before `:ARG1` edges.

[9] Consider the sentences *"She went to school in New York two years ago"*, and *"Two years ago, she went to school in New York"*, where *"two year ago"* is the time modifying constituent for the verb *went* and *"New York"* is the location modifying constituent of *went*.

an inability to mention all tokens in the input, followed by fluency mistakes, as illustrated above. Attachment errors are less frequent, which supports our claim that the model is robust to graph linearization, and can successfully encode long range dependency information between concepts.

9 Conclusions

We applied sequence-to-sequence models to the tasks of AMR parsing and AMR generation, by carefully preprocessing the graph representation and scaling our models via pretraining on millions of unlabeled sentences sourced from Gigaword corpus. Crucially, we avoid relying on resources such as knowledge bases and externally trained parsers. We achieve competitive results for the parsing task (SMATCH 62.1) and state-of-the-art performance for generation (BLEU 33.8).

For future work, we would like to extend our work to different meaning representations such as the Minimal Recursion Semantics (MRS; Copestake et al. (2005)). This formalism tackles certain linguistic phenomena differently from AMR (e.g., negation, and co-reference), contains explicit annotation on concepts for number, tense and case, and finally handles multiple languages[10] (Bender, 2014). Taking a step further, we would like to apply our models on Semantics-Based Machine Translation using MRS as an intermediate representation between pairs of languages, and investigate the added benefit compared to directly translating the surface strings, especially in the case of distant language pairs such as English and Japanese (Siegel, 2000).

Program Induction by Rationale Generation: Learning to Solve and Explain Algebraic Word Problems

Abstract

Solving algebraic word problems requires executing a series of arithmetic operations—a program—to obtain a final answer. However, since programs can be arbitrarily complicated, inducing them directly from question-answer pairs is a formidable challenge. To make this task more feasible, we solve these problems by generating *answer rationales*, sequences of natural language and human-readable mathematical expressions that derive the final answer through a series of small steps. Although rationales do not explicitly specify programs, they provide a scaffolding for their structure via intermediate milestones. To evaluate our approach, we have created a new 100,000-sample dataset of questions, answers and rationales. Experimental results show that indirect supervision of program learning via answer rationales is a promising strategy for inducing arithmetic programs.

1 Introduction

Behaving intelligently often requires mathematical reasoning. Shopkeepers calculate change, tax, and sale prices; agriculturists calculate the proper amounts of fertilizers, pesticides, and water for their crops; and managers analyze productivity. Even determining whether you have enough money to pay for a list of items requires applying addition, multiplication, and comparison. Solving these tasks is challenging as it involves recognizing how goals, entities, and quantities in the real-world map onto a mathematical formalization, computing the solution, and mapping the solution back onto the world. As a proxy for the richness of the real world, a series of papers have used natural language specifications of algebraic word problems, and solved these by either learning to fill in templates that can be solved with equation solvers (Hosseini et al., 2014; Kushman et al., 2014) or inferring and modeling operation sequences (programs) that lead to the final answer (Roy and Roth, 2015).

In this paper, we learn to solve algebraic word problems by inducing and modeling programs that generate not only the answer, but an **answer rationale**, a natural language explanation interspersed with algebraic expressions justifying the overall solution. Such rationales are what examiners require from students in order to demonstrate understanding of the problem solution; they play the very same role in our task. Not only do natural language rationales enhance model interpretability, but they provide a coarse guide to the structure of the arithmetic programs that must be executed. In fact the learner we propose (which relies on a heuristic search; §4) fails to solve this task without modeling the rationales—the search space is too unconstrained.

This work is thus related to models that can explain or rationalize their decisions (Hendricks et al., 2016; Harrison et al., 2017). However, the use of rationales in this work is quite different from the role they play in most prior work, where interpretation models are trained to generate plausible sounding (but not necessarily accurate) post-hoc descriptions of the decision making process they used. In this work, the rationale is generated as a latent variable that gives rise to the answer—it is thus a more faithful representation of the steps used in computing the answer.

This paper makes three contributions. First, we have created a new dataset with more than 100,000 algebraic word problems that includes both answers and natural language answer rationales (§2). Figure 1 illustrates three representative instances

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 158–167
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1015

Problem 1:
Question: Two trains running in opposite directions cross a man standing on the platform in 27 seconds and 17 seconds respectively and they cross each other in 23 seconds. The ratio of their speeds is:
Options: A) 3/7 B) 3/2 C) 3/88 D) 3/8 E) 2/2
Rationale: Let the speeds of the two trains be x m/sec and y m/sec respectively. Then, length of the first train = 27x meters, and length of the second train = 17 y meters. (27x + 17y) / (x + y) = 23 → 27x + 17y = 23x + 23y → 4x = 6y → x/y = 3/2.
Correct Option: B

Problem 2:
Question: From a pack of 52 cards, two cards are drawn together at random. What is the probability of both the cards being kings?
Options: A) 2/1223 B) 1/122 C) 1/221 D) 3/1253 E) 2/153
Rationale: Let s be the sample space.
Then n(s) = 52C2 = 1326
E = event of getting 2 kings out of 4
n(E) = 4C2 = 6
P(E) = 6/1326 = 1/221
Answer is C
Correct Option: C

Problem 3:
Question: For which of the following does $p(a)-p(b) = p(ab)$ for all values of a and b?
Options:A) $p(x) = x^2$, B) $p(x) = x/2$, C) $p(x) = x + 5$, D) $p(x) = 2x1$, E) $p(x) = |x|$
Rationale: To solve this easiest way is just put the value and see that if it equals or not.
with option A. $p(a) = a^2$ and $p(b) = b^2$
so L.H.S = $a^2 - b^2$
and R.H.S = $(a - b)^2 \rightarrow a^2 + b^2 - 2ab$.
so L.H.S not equal to R.H.S
with option B. $p(a) = a/2$ and $p(b) = b/2$
L.H.S = $a/2 - b/2 \rightarrow 1/2(a - b)$
R.H.S = $(a - b)/2$
so L.H.S = R.H.S which is the correct answer.
answer:B
Correct Option: B

Figure 1: Examples of solved math problems.

from the dataset. Second, we propose a sequence to sequence model that generates a sequence of instructions that, when executed, generates the rationale; only after this is the answer chosen (§3). Since the target program is not given in the training data (most obviously, its specific form will depend on the operations that are supported by the program interpreter); the third contribution is thus a technique for inferring programs that generate a rationale and, ultimately, the answer. Even constrained by a text rationale, the search space of possible programs is quite large, and we employ a heuristic search to find plausible next steps to guide the search for programs (§4). Empirically, we are able to show that state-of-the-art sequence to sequence models are unable to perform above chance on this task, but that our model doubles the accuracy of the baseline (§6).

2 Dataset

We built a dataset with 100,000 problems with the annotations shown in Figure 1. Each question is decomposed in four parts, two inputs and two outputs: the description of the problem, which we will denote as the **question**, and the possible (multiple choice) answer options, denoted as **options**. Our goal is to generate the description of the rationale used to reach the correct answer, denoted as **rationale** and the **correct option** label. Problem 1 illustrates an example of an algebra problem, which must be translated into an expression (i.e., $(27x + 17y)/(x + y) = 23$) and then the desired quantity (x/y) solved for. Problem 2 is an example that could be solved by multi-step arithmetic operations proposed in (Roy and Roth, 2015). Finally, Problem 3 describes a problem that is solved by testing each of the options, which has not been addressed in the past.

2.1 Construction

We first collect a set of 34,202 seed problems that consist of multiple option math questions covering a broad range of topics and difficulty levels. Examples of exams with such problems include the GMAT (Graduate Management Admission Test) and GRE (General Test). Many websites contain example math questions in such exams, where the answer is supported by a rationale.

Next, we turned to crowdsourcing to generate new questions. We create a task where users are presented with a set of 5 questions from our seed dataset. Then, we ask the Turker to choose one of the questions and write a similar question. We also force the answers and rationale to differ from the original question in order to avoid paraphrases of the original question. Once again, we manually check a subset of the jobs for each Turker for quality control. The type of questions generated using this method vary. Some turkers propose small changes in the values of the questions (e.g., changing the equality $p(a)p(b) = p(ab)$ in Problem 3 to a different equality is a valid question, as long as the rationale and options are rewritten to reflect the change). We designate these as replica problems as the natural language used in the question and rationales tend to be only minimally unaltered. Others propose new problems in the same topic where the generated questions tend to differ more radically from existing ones. Some Turkers also copy math problems available on the web, and we

		Question	Rationale

Test Examples		250	
Numeric	Average Length	9.6	16.6
	Vocab Size	21,009	14,745
Non-Numeric	Average Length	67.8	89.1
	Vocab Size	17,849	25,034
All	Average Length	77.4	105.7
	Vocab Size	38,858	39,779

Table 1: Descriptive statistics of our dataset.

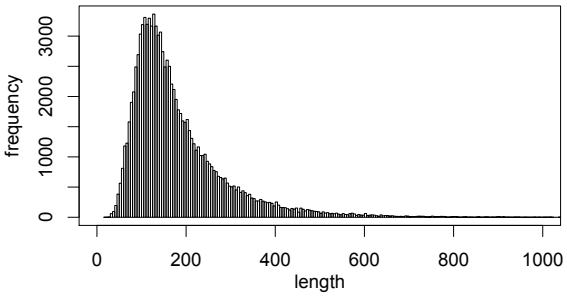

Figure 2: Distribution of examples per length.

define in the instructions that this is not allowed, as it will generate multiple copies of the same problem in the dataset if two or more Turkers copy from the same resource. These Turkers can be detected by checking the nearest neighbours within the collected datasets as problems obtained from online resources are frequently submitted by more than one Turker. Using this method, we obtained 70,318 additional questions.

2.2 Statistics

Descriptive statistics of the dataset is shown in Figure 1. In total, we collected 104,519 problems (34,202 seed problems and 70,318 crowdsourced problems). We removed 500 problems as heldout set (250 for development and 250 for testing). As replicas of the heldout problems may be present in the training set, these were removed manually by listing for each heldout instance the closest problems in the training set in terms of character-based Levenstein distance. After filtering, 100,949 problems remained in the training set.

We also show the average number of tokens (total number of tokens in the question, options and rationale) and the vocabulary size of the questions and rationales. Finally, we provide the same statistics exclusively for tokens that are numeric values and tokens that are not.

Figure 2 shows the distribution of examples based on the total number of tokens. We can see that most examples consist of 30 to 500 tokens, but there are also extremely long examples with more than 1000 tokens in our dataset.

3 Model

Generating rationales for math problems is challenging as it requires models that learn to perform math operations at a finer granularity as each step within the solution must be explained. For instance, in Problem 1, the equation $(27x + 17y)/(x + y) = 23$ must be solved to obtain the answer. In previous work (Kushman et al., 2014), this could be done by feeding the equation into an expression solver to obtain $x/y = 3/2$. However, this would skip the intermediate steps $27x + 17y = 23x + 23y$ and $4x = 6y$, which must also be generated in our problem. We propose a model that jointly learns to generate the text in the rationale, and to perform the math operations required to solve the problem. This is done by generating a program, containing both instructions that generate output and instructions that simply generate intermediate values used by following instructions.

3.1 Problem Definition

In traditional sequence to sequence models (Sutskever et al., 2014; Bahdanau et al., 2014), the goal is to predict the output sequence $\boldsymbol{y} = y_1, \ldots, y_{|\boldsymbol{y}|}$ from the input sequence $\boldsymbol{x} = x_1, \ldots, x_{|\boldsymbol{x}|}$, with lengths $|\boldsymbol{y}|$ and $|\boldsymbol{x}|$.

In our particular problem, we are given the problem and the set of options, and wish to predict the rationale and the correct option. We set $\boldsymbol{x}$ as the sequence of words in the problem, concatenated with words in each of the options separated by a special tag. Note that knowledge about the possible options is required as some problems are solved by the process of elimination or by testing each of the options (e.g. Problem 3). We wish to generate $\boldsymbol{y}$, which is the sequence of words in the rationale. We also append the correct option as the last word in $\boldsymbol{y}$, which is interpreted as the chosen option. For example, $\boldsymbol{y}$ in Problem 1 is "Let the ... = 3/2 . ⟨EOR⟩ B ⟨EOS⟩", whereas in Problem 2 it is "Let s be ... Answer is C ⟨EOR⟩ C ⟨EOS⟩", where "⟨EOS⟩" is the end of sentence symbol and "⟨EOR⟩" is the end of rationale symbol.

Table 2: Example of a program $\boldsymbol{z}$ that would generate the output $\boldsymbol{y}$. In $\boldsymbol{v}$, *italics* indicates string types; ***bold*** indicates float types. Refer to §3.3 for description of variable names.

3.2 Generating Programs to Generate Rationales

We wish to generate a latent sequence of **program instructions**, $\boldsymbol{z} = z_1, \ldots, z_{|\boldsymbol{z}|}$, with length $|\boldsymbol{z}|$, that will generate $\boldsymbol{y}$ when executed.

We express $\boldsymbol{z}$ as a program that can access $\boldsymbol{x}$, $\boldsymbol{y}$, and the memory buffer $\boldsymbol{m}$. Upon finishing execution we expect that the sequence of output tokens to be placed in the output vector $\boldsymbol{y}$.

Table 2 illustrates an example of a sequence of instructions that would generate an excerpt from Problem 2, where columns $\boldsymbol{x}$, $\boldsymbol{z}$, $\boldsymbol{v}$, and $\boldsymbol{r}$ denote the input sequence, the instruction sequence (program), the values of executing the instruction, and where each value v_i is written (i.e., either to the output or to the memory). In this example, instructions from indexes 1 to 14 simply fill each position with the observed output $y_1, \ldots, y_{14}$ with a string, where the `Id` operation simply returns its parameter without applying any operation. As such, running this operation is analogous to generating a word by sampling from a softmax over a vocabulary. However, instruction z_{15} reads the input word x_5, 52, and applies the operation `Str_to_Float`, which converts the word 52 into a floating point number, and the same is done for instruction z_{20}, which reads a previously generated output word y_{17}. Unlike, instructions $z_1, \ldots, z_{14}$, these operations write to the external memory $\boldsymbol{m}$, which stores intermediate values. A more sophisticated instruction—which shows some of the power of our model—is $z_{21} = \texttt{Choose}(m_1, m_2) \rightarrow m_3$ which evaluates $\binom{m_1}{m_2}$ and stores the result in m_3. This process repeats until the model generates the end-of-sentence symbol. The last token of the program as said previously must generate the correct option value, from "A" to "E".

By training a model to generate instructions that can manipulate existing tokens, the model benefits from the additional expressiveness needed to solve math problems within the generation process. In total we define 22 different operations, 13 of which are frequently used operations when solving math problems. These are: `Id`, `Add`, `Subtract`, `Multiply`, `Divide`, `Power`, `Log`, `Sqrt`, `Sine`, `Cosine`, `Tangent`, `Factorial`, and `Choose` (number of combinations). We also provide 2 operations to convert between `Radians` and `Degrees`, as these are needed for the sine, cosine and tangent operations. There are 6 operations that convert floating point numbers into strings and vice-versa. These include the `Str_to_Float` and `Float_to_Str` operations described previously, as well as operations which convert between floating point numbers and fractions, since in many math problems the answers are in the form "3/4". For the same reason, an operation to convert between a floating point number and number grouped in thousands is also used (e.g. 1000000 to "1,000,000" or "1.000.000"). Finally, we define an operation (`Check`) that given the input string, searches through the list of options and returns a string with the option index in {"A", "B", "C", "D", "E"}. If the input value does not match any of the options, or more than one option contains that value, it cannot be applied. For instance, in Problem 2, once the correct probability "1/221" is generated, by applying the check operation to this number we can obtain correct option "C".

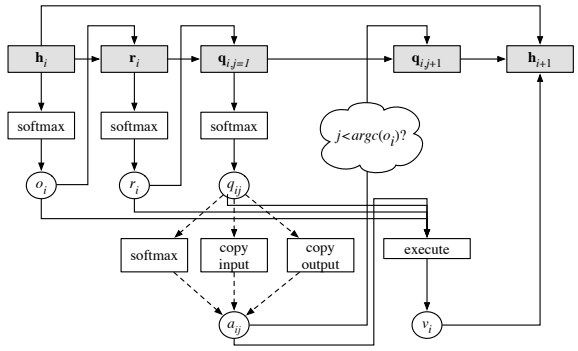

Figure 3: Illustration of the generation process of a single instruction tuple at timestamp i.

3.3 Generating and Executing Instructions

In our model, programs consist of sequences of instructions, $\boldsymbol{z}$. We turn now to how we model each z_i, conditional on the text program specification, and the program's history. The instruction z_i is a tuple consisting of an operation (o_i), an ordered sequence of its arguments ($\boldsymbol{a}_i$), and a decision about where its results will be placed (r_i) (is it appended in the output $\boldsymbol{y}$ or in a memory buffer $\boldsymbol{m}$?), and the result of applying the operation to its arguments (v_i). That is, $z_i = (o_i, r_i, \boldsymbol{a}_i, v_i)$.

Formally, o_i is an element of the pre-specified set of operations $\mathcal{O}$, which contains, for example `add`, `div`, `Str_to_Float`, etc. The number of arguments required by o_i is given by $argc(o_i)$, e.g., $argc(\texttt{add}) = 2$ and $argc(\texttt{log}) = 1$. The arguments are $\boldsymbol{a}_i = a_{i,1}, \ldots, a_{i,argc(o_i)}$. An instruction will generate a return value v_i upon execution, which will either be placed in the output $\boldsymbol{y}$ or hidden. This decision is controlled by r_i. We define the instruction probability as:

$$
\begin{aligned}
p(o_i, \boldsymbol{a}_i, r_i, v_i \mid \boldsymbol{z}_{<i}, \boldsymbol{x}, \boldsymbol{y}, \boldsymbol{m}) = \\
p(o_i \mid \boldsymbol{z}_{<i}, \boldsymbol{x}) \times p(r_i \mid \boldsymbol{z}_{<i}, \boldsymbol{x}, o_i) \times \\
\prod_{j=1}^{argc(o_i)} p(a_{i,j} \mid \boldsymbol{z}_{<i}, \boldsymbol{x}, o_i, \boldsymbol{m}, \boldsymbol{y}) \times \\
[v_i = \text{apply}(o_i, \boldsymbol{a})],
\end{aligned}
$$

where $[p]$ evaluates to 1 if p is true and 0 otherwise, and $\text{apply}(f, \boldsymbol{x})$ evaluates the operation f with arguments $\boldsymbol{x}$. Note that the apply function is not learned, but pre-defined.

The network used to generate an instruction at a given timestamp i is illustrated in Figure 3. We first use the recurrent state $\mathbf{h}_i$ to generate $p(o_i \mid \boldsymbol{z}_{<i}, \boldsymbol{x}) = \underset{o_i \in \mathcal{O}}{\text{softmax}}(\mathbf{h}_i)$, using a softmax over the set of available operations $\mathcal{O}$.

In order to predict r_i, we generate a new hidden state $\mathbf{r}_i$, which is a function of the current program context $\mathbf{h}_i$, and an embedding of the current predicted operation, o_i. As the output can either be placed in the memory $\boldsymbol{m}$ or the output $\boldsymbol{y}$, we compute the probability $p(r_i = \text{OUTPUT} \mid \boldsymbol{z}_{<i}, \boldsymbol{x}, o_i) = \sigma(\mathbf{r}_i \cdot \mathbf{w}_r + b_r)$, where σ is the logistic sigmoid function. If $r_i = \text{OUTPUT}$, v_i is appended to the output $\boldsymbol{y}$; otherwise it is appended to the memory $\boldsymbol{m}$.

Once we generate r_i, we must predict $\boldsymbol{a}_i$, the $argc(o_i)$-length sequence of arguments that operation o_i requires. The jth argument $a_{i,j}$ can be either generated from a softmax over the vocabulary, copied from the input vector $\boldsymbol{x}$, or copied from previously generated values in the output $\boldsymbol{y}$ or memory $\boldsymbol{m}$. This decision is modeled using a latent predictor network (Ling et al., 2016), where the control over which method used to generate $a_{i,j}$ is governed by a latent variable $q_{i,j} \in \{\text{SOFTMAX}, \text{COPY-INPUT}, \text{COPY-OUTPUT}\}$. Similar to when predicting r_i, in order to make this choice, we also generate a new hidden state for each argument slot j, denoted by $\mathbf{q}_{i,j}$ with an LSTM, feeding the previous argument in at each time step, and initializing it with $\mathbf{r}_i$ and by reading the predicted value of the output r_i.

- If $q_{i,j} = \text{SOFTMAX}$, $a_{i,j}$ is generated by sampling from a softmax over the vocabulary $\mathcal{Y}$,

  $$p(a_{i,j} \mid q_{i,j} = \text{SOFTMAX}) = \underset{a_{i,j} \in \mathcal{Y}}{\text{softmax}}(\mathbf{q}_{i,j}).$$

  This corresponds to a case where a string is used as argument (e.g. y_1="Let").

- If $q_{i,j} = \text{COPY-INPUT}$, $a_{i,j}$ is obtained by copying an element from the input vector with a pointer network (Vinyals et al., 2015) over input words $x_1, \ldots, x_{|\boldsymbol{x}|}$, represented by their encoder LSTM state $\mathbf{u}_1, \ldots, \mathbf{u}_{|\boldsymbol{x}|}$. As such, we compute the probability distribution over input words as:

  $$p(a_{i,j} \mid q_{i,j} = \text{COPY-INPUT}) = \underset{a_{i,j} \in x_1, \ldots, x_{|\boldsymbol{x}|}}{\text{softmax}} \left(f(\mathbf{u}_{a_{i,j}}, \mathbf{q}_{i,j})\right) \quad (1)$$

  Function f computes the affinity of each token $x_{a_{i,j}}$ and the current output context $\mathbf{q}_{i,j}$. A common implementation of f, which we follow, is to apply a linear projection from $[\mathbf{u}_{a_{i,j}}; \mathbf{q}_{i,j}]$ into a fixed size vector (where $[\mathbf{u}; \mathbf{v}]$ is vector concatenation), followed by a $\tanh$ and a linear projection into a single value.

- If $q_{i,j} =$ COPY-OUTPUT, the model copies from either the output $\boldsymbol{y}$ or the memory $\boldsymbol{m}$. This is equivalent to finding the instruction z_i, where the value was generated. Once again, we define a pointer network that points to the output instructions and define the distribution over previously generated instructions as:

$$p(a_{i,j} \mid q_{i,j} = \text{COPY-OUTPUT}) = \underset{a_{i,j} \in z_1, \ldots, z_{i-1}}{\text{softmax}} \left(f(\mathbf{h}_{a_{i,j}}, \mathbf{q}_{i,j}) \right)$$

  Here, the affinity is computed using the decoder state $\mathbf{h}_{a_{i,j}}$ and the current state $\mathbf{q}_{i,j}$.

Finally, we embed the argument $a_{i,j}$[1] and the state $\mathbf{q}_{i,j}$ to generate the next state $\mathbf{q}_{i,j+1}$. Once all arguments for o_i are generated, the operation is executed to obtain v_i. Then, the embedding of v_i, the final state of the instruction $\mathbf{q}_{i,|\boldsymbol{a}_i|}$ and the previous state $\mathbf{h}_i$ are used to generate the state at the next timestamp $\mathbf{h}_{i+1}$.

4 Inducing Programs while Learning

The set of instructions $\boldsymbol{z}$ that will generate $\boldsymbol{y}$ is unobserved. Thus, given $\boldsymbol{x}$ we optimize the marginal probability function:

$$p(\boldsymbol{y} \mid \boldsymbol{x}) = \sum_{\boldsymbol{z} \in \mathcal{Z}} p(\boldsymbol{y} \mid \boldsymbol{z}) p(\boldsymbol{z} \mid \boldsymbol{x}) = \sum_{\boldsymbol{z} \in \mathcal{Z}(y)} p(\boldsymbol{z} \mid \boldsymbol{x}),$$

where $p(\boldsymbol{y} \mid \boldsymbol{z})$ is the Kronecker delta function $\delta_{e(\boldsymbol{z}),\boldsymbol{y}}$, which is 1 if the execution of $\boldsymbol{z}$, denoted as $e(\boldsymbol{z})$, generates y and 0 otherwise. Thus, we can redefine $p(\boldsymbol{y}|\boldsymbol{x})$, the marginal over all programs $\mathcal{Z}$, as a marginal over programs that would generate $\boldsymbol{y}$, defined as $\mathcal{Z}(\boldsymbol{y})$. As marginalizing over $\boldsymbol{z} \in \mathcal{Z}(\boldsymbol{y})$ is intractable, we approximate the marginal by generating samples from our model. Denote the set of samples that are generated by $\hat{\mathcal{Z}}(\boldsymbol{y})$. We maximize $\sum \boldsymbol{z} \in \hat{\mathcal{Z}}(\boldsymbol{y}) p(\boldsymbol{z}|\boldsymbol{x})$.

However, generating programs that generate $\boldsymbol{y}$ is not trivial, as randomly sampling from the RNN distribution over instructions at each timestamp is unlikely to generate a sequence $\boldsymbol{z} \in \mathcal{Z}(\boldsymbol{y})$.

This is analogous to the question answering work in Liang et al. (2016), where the query that generates the correct answer must be found during inference, and training proved to be difficult without supervision. In Roy and Roth (2015) this problem is also addressed by adding prior knowledge to constrain the exponential space.

In our work, we leverage the fact that we are generating rationales, where there is a sense of progression within the rationale. That is, we assume that the rationale solves the problem step by step. For instance, in Problem 2, the rationale first describes the number of combinations of two cards in a deck of 52 cards, then describes the number of combinations of two kings, and finally computes the probability of drawing two kings. Thus, while generating the final answer without the rationale requires a long sequence of latent instructions, generating each of the tokens of the rationale requires far less operations.

More formally, given the sequence $z_1, \ldots, z_{i-1}$ generated so far, and the possible values for z_i given by the network, denoted $\mathcal{Z}_i$, we wish to filter $\mathcal{Z}_i$ to $\mathcal{Z}_i(y_k)$, which denotes a set of possible options that contain at least one path capable of generating the next token at index k. Finding the set $\mathcal{Z}_i(y_k)$ is achieved by testing all combinations of instructions that are possible with at most one level of indirection, and keeping those that can generate y_k. This means that the model can only generate one intermediate value in memory (not including the operations that convert strings into floating point values and vice-versa).

Decoding. During decoding we find the most likely sequence of instructions $\boldsymbol{z}$ given $\boldsymbol{x}$, which can be performed with a stack-based decoder. However, it is important to refer that each generated instruction $z_i = (o_i, r_i, a_{i,1}, \ldots, a_{i,|a_i|}, v_i)$ must be executed to obtain v_i. To avoid generating unexecutable code—e.g., log(0)—each hypothesis instruction is executed and removed if an error occurs. Finally, once the "⟨EOR⟩" tag is generated, we only allow instructions that would generate one of the option "A" to "E" to be generated, which guarantees that one of the options is chosen.

5 Staged Back-propagation

As it is shown in Figure 2, math rationales with more than 200 tokens are not uncommon, and with additional intermediate instructions, the size $\boldsymbol{z}$ can easily exceed 400. This poses a practical challenge for training the model.

For both the attention and copy mechanisms,

[1] The embeddings of a given argument $a_{i,j}$ and the return value v_i are obtained with a lookup table embedding and two flags indicating whether it is a string and whether it is a float. Furthermore, if the the value is a float we also add its numeric value as a feature.

for each instruction z_i, the model needs to compute the probability distribution between all the attendable units $\boldsymbol{c}$ conditioned on the previous state $\mathbf{h}_{i-1}$. For the attention model and input copy mechanisms, $\boldsymbol{c} = \boldsymbol{x_{0,i-1}}$ and for the output copy mechanism $\boldsymbol{c} = \boldsymbol{z}$. These operations generally involve an exponential number of matrix multiplications as the size of $\boldsymbol{c}$ and $\boldsymbol{z}$ grows. For instance, during the computation of the probabilities for the input copy mechanism in Equation 1, the affinity function f between the current context $\boldsymbol{q}$ and a given input $\boldsymbol{u}_k$ is generally implemented by projecting $\boldsymbol{u}$ and $\boldsymbol{q}$ into a single vector followed by a non-linearity, which is projected into a single affinity value. Thus, for each possible input $\boldsymbol{u}$, 3 matrix multiplications must be performed. Furthermore, for RNN unrolling, parameters and intermediate outputs for these operations must be replicated for each timestamp. Thus, as $\boldsymbol{z}$ becomes larger the attention and copy mechanisms quickly become a memory bottleneck as the computation graph becomes too large to fit on the GPU. In contrast, the sequence-to-sequence model proposed in (Sutskever et al., 2014), does not suffer from these issues as each timestamp is dependent only on the previous state $\mathbf{h}_{i-1}$.

To deal with this, we use a training method we call **staged back-propagation** which saves memory by considering slices of K tokens in $\boldsymbol{z}$, rather than the full sequence. That is, to train on a mini-batch where $|z| = 300$ with $K = 100$, we would actually train on 3 mini-batches, where the first batch would optimize for the first $\boldsymbol{z}_{1:100}$, the second for $\boldsymbol{z}_{101:200}$ and the third for $\boldsymbol{z}_{201:300}$. The advantage of this method is that memory intensive operations, such as attention and the copy mechanism, only need to be unrolled for K steps, and K can be adjusted so that the computation graph fits in memory.

However, unlike truncated back-propagation for language modeling, where context outside the scope of K is ignored, sequence-to-sequence models require global context. Thus, the sequence of states $\boldsymbol{h}$ is still built for the whole sequence $\boldsymbol{z}$. Afterwards, we obtain a slice $\boldsymbol{h}_{j:j+K}$, and compute the attention vector.[2] Finally, the prediction of the instruction is conditioned on the LSTM state and the attention vector.

[2]This modeling strategy is sometimes known as late fusion, as the attention vector is not used for state propagation, it is incorporated "later".

6 Experiments

We apply our model to the task of generating rationales for solutions to math problems, evaluating it on both the quality of the rationale and the ability of the model to obtain correct answers.

6.1 Baselines

As the baseline we use the attention-based sequence to sequence model proposed by Bahdanau et al. (2014), and proposed augmentations, allowing it to copy from the input (Ling et al., 2016) and from the output (Merity et al., 2016).

6.2 Hyperparameters

We used a two-layer LSTM with a hidden size of $H = 200$, and word embeddings with size 200. The number of levels that the graph $\mathcal{G}$ is expanded during sampling D is set to 5. Decoding is performed with a beam of 200. As for the vocabulary of the softmax and embeddings, we keep the most frequent 20,000 word types, and replace the rest of the words with an unknown token. During training, the model only learns to predict a word as an unknown token, when there is no other alternative to generate the word.

6.3 Evaluation Metrics

The evaluation of the rationales is performed with average sentence level perplexity and BLEU-4 (Papineni et al., 2002). When a model cannot generate a token for perplexity computation, we predict unknown token. This benefits the baselines as they are less expressive. As the perplexity of our model is dependent on the latent program that is generated, we force decode our model to generate the rationale, while maximizing the probability of the program. This is analogous to the method used to obtain sample programs described in Section 4, but we choose the most likely instructions at each timestamp instead of sampling. Finally, the correctness of the answer is evaluated by computing the percentage of the questions, where the chosen option matches the correct one.

6.4 Results

The test set results, evaluated on perplexity, BLEU, and accuracy, are presented in Table 3.

Perplexity. In terms of perplexity, we observe that the regular sequence to sequence model fares poorly on this dataset, as the model requires the generation of many values that tend to be

Model	Perplexity	BLEU	Accuracy
Seq2Seq	524.7	8.57	20.8
+Copy Input	46.8	21.3	20.4
+Copy Output	45.9	20.6	20.2
Our Model	**28.5**	**27.2**	**36.4**

Table 3: Results over the test set measured in Perplexity, BLEU and Accuracy.

sparse. Adding an input copy mechanism greatly improves the perplexity as it allows the generation process to use values that were mentioned in the question. The output copying mechanism improves perplexity slightly over the input copy mechanism, as many values are repeated after their first occurrence. For instance, in Problem 2, the value "1326" is used twice, so even though the model cannot generate it easily in the first occurrence, the second one can simply be generated by copying the first one. We can observe that our model yields significant improvements over the baselines, demonstrating that the ability to generate new values by algebraic manipulation is essential in this task. An example of a program that is inferred is shown in Figure 4. The graph was generated by finding the most likely program $\boldsymbol{z}$ that generates $\boldsymbol{y}$. Each node isolates a value in $\boldsymbol{x}$, $\boldsymbol{m}$, or $\boldsymbol{y}$, where arrows indicate an operation executed with the outgoing nodes as arguments and incoming node as the return of the operation. For simplicity, operations that copy or convert values (e.g. from string to float) were not included, but nodes that were copied/converted share the same color. Examples of tokens where our model can obtain the perplexity reduction are the values "0.025", "0.023", "0.002" and finally the answer "E" , as these cannot be copied from the input or output.

BLEU. We observe that the regular sequence to sequence model achieves a low BLEU score. In fact, due to the high perplexities the model generates very short rationales, which frequently consist of segments similar to "Answer should be D", as most rationales end with similar statements. By applying the copy mechanism the BLEU score improves substantially, as the model can define the variables that are used in the rationale. Interestingly, the output copy mechanism adds no further improvement in the perplexity evaluation. This is because during decoding all values that can be copied from the output are values that could have been generated by the model either from the softmax or the input copy mechanism. As such, adding an output copying mechanism adds little to the expressiveness of the model during decoding.

Finally, our model can achieve the highest BLEU score as it has the mechanism to generate the intermediate and final values in the rationale.

Accuracy. In terms of accuracy, we see that all baseline models obtain values close to chance (20%), indicating that they are completely unable to solve the problem. In contrast, we see that our model can solve problems at a rate that is significantly higher than chance, demonstrating the value of our program-driven approach, and its ability to learn to generate programs.

In general, the problems we solve correctly correspond to simple problems that can be solved in one or two operations. Examples include questions such as "Billy cut up each cake into 10 slices, and ended up with 120 slices altogether. How many cakes did she cut up? A) 9 B) 7 C) 12 D) 14 E) 16", which can be solved in a single step. In this case, our model predicts "120 / 10 = 12 cakes. Answer is C" as the rationale, which is reasonable.

6.5 Discussion.

While we show that our model can outperform the models built up to date, generating complex rationales as those shown in Figure 1 correctly is still an unsolved problem, as each additional step adds complexity to the problem both during inference and decoding. Yet, this is the first result showing that it is possible to solve math problems in such a manner, and we believe this modeling approach and dataset will drive work on this problem.

7 Related Work

Extensive efforts have been made in the domain of math problem solving (Hosseini et al., 2014; Kushman et al., 2014; Roy and Roth, 2015), which aim at obtaining the correct answer to a given math problem. Other work has focused on learning to map math expressions into formal languages (Roy et al., 2016). We aim to generate natural language rationales, where the bindings between variables and the problem solving approach are mixed into a single generative model that attempts to solve the problem while explaining the approach taken.

Our approach is strongly tied with the work on sequence to sequence transduction using the encoder-decoder paradigm (Sutskever et al., 2014;

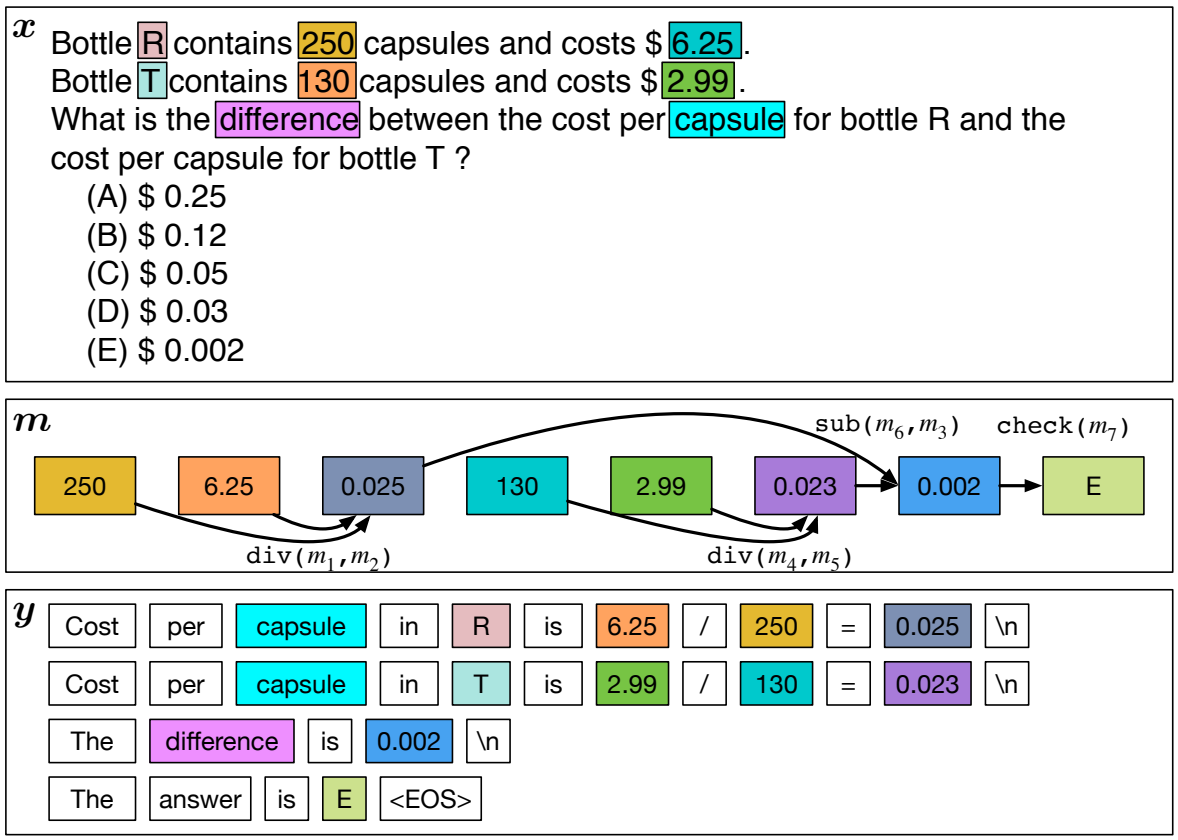

Figure 4: Illustration of the most likely latent program inferred by our algorithm to explain a held-out question-rationale pair.

Bahdanau et al., 2014; Kalchbrenner and Blunsom, 2013), and inherits ideas from the extensive literature on semantic parsing (Jones et al., 2012; Berant et al., 2013; Andreas et al., 2013; Quirk et al., 2015; Liang et al., 2016; Neelakantan et al., 2016) and program generation (Reed and de Freitas, 2016; Graves et al., 2016), namely, the usage of an external memory, the application of different operators over values in the memory and the copying of stored values into the output sequence.

Providing textual explanations for classification decisions has begun to receive attention, as part of increased interest in creating models whose decisions can be interpreted. Lei et al. (2016), jointly modeled both a classification decision, and the selection of the most relevant subsection of a document for making the classification decision. Hendricks et al. (2016) generate textual explanations for visual classification problems, but in contrast to our model, they first generate an answer, and then, conditional on the answer, generate an explanation. This effectively creates a post-hoc justification for a classification decision rather than a program for deducing an answer. These papers, like ours, have jointly modeled rationales and answer predictions; however, we are the first to use rationales to guide program induction.

8 Conclusion

In this work, we addressed the problem of generating rationales for math problems, where the task is to not only obtain the correct answer of the problem, but also generate a description of the method used to solve the problem. To this end, we collect 100,000 question and rationale pairs, and propose a model that can generate natural language and perform arithmetic operations in the same decoding process. Experiments show that our method outperforms existing neural models, in both the fluency of the rationales that are generated and the ability to solve the problem.

Abstract

We propose two novel methodologies for the automatic generation of rhythmic poetry in a variety of forms. The first approach uses a neural language model trained on a phonetic encoding to learn an implicit representation of both the *form* and *content* of English poetry. This model can effectively learn common poetic devices such as rhyme, rhythm and alliteration. The second approach considers poetry generation as a constraint satisfaction problem where a generative neural language model is tasked with learning a representation of content, and a discriminative weighted finite state machine constrains it on the basis of form. By manipulating the constraints of the latter model, we can generate coherent poetry with arbitrary forms and themes. A large-scale extrinsic evaluation demonstrated that participants consider machine-generated poems to be written by humans 54% of the time. In addition, participants rated a machine-generated poem to be the most human-like amongst all evaluated.

1 Introduction

Poetry is an advanced form of linguistic communication, in which a message is conveyed that satisfies both aesthetic and semantic constraints. As poetry is one of the most expressive forms of language, the *automatic* creation of texts recognisable as poetry is difficult. In addition to requiring an understanding of many aspects of language including phonetic patterns such as rhyme, rhythm and alliteration, poetry composition also requires a deep understanding of the meaning of language.

Poetry generation can be divided into two subtasks, namely the problem of *content*, which is concerned with a poem's semantics, and the problem of *form*, which is concerned with the aesthetic rules that a poem follows. These rules may describe aspects of the literary devices used, and are usually highly prescriptive. Examples of different forms of poetry are limericks, ballads and sonnets. Limericks, for example, are characterised by their strict rhyme scheme (AABBA), their rhythm (two unstressed syllables followed by one stressed syllable) and their shorter third and fourth lines. Creating such poetry requires not only an understanding of the language itself, but also of how it sounds when spoken aloud.

Statistical text generation usually requires the construction of a generative language model that explicitly learns the probability of any given word given previous context. Neural language models (Schwenk and Gauvain, 2005; Bengio et al., 2006) have garnered signficant research interest for their ability to learn complex syntactic and semantic representations of natural language (Mikolov et al., 2010; Sutskever et al., 2014; Cho et al., 2014; Kim et al., 2015). Poetry generation is an interesting application, since performing this task automatically requires the creation of models that not only focus on *what* is being written (content), but also on *how* it is being written (form).

We experiment with two novel methodologies for solving this task. The first involves training a model to learn an implicit representation of content and form through the use of a phonological encoding. The second involves training a generative language model to represent content, which is then constrained by a discriminative pronunciation model, representing form. This second model is of particular interest because poetry with arbitrary rhyme, rhythm, repetition and themes can be generated by tuning the pronunciation model.

2 Related Work

Automatic poetry generation is an important task due to the significant challenges involved. Most systems that have been proposed can loosely be categorised as rule-based expert systems, or statistical approaches.

Rule-based poetry generation attempts include case-based reasoning (Gervás, 2000), template-based generation (Colton et al., 2012), constraint satisfaction (Toivanen et al., 2013; Barbieri et al., 2012) and text mining (Netzer et al., 2009). These approaches are often inspired by how humans might generate poetry.

Statistical approaches, conversely, make no assumptions about the creative process. Instead, they attempt to extract statistical patterns from existing poetry corpora in order to construct a language model, which can then be used to generate new poetic variants (Yi et al., 2016; Greene et al., 2010). Neural language models have been increasingly applied to the task of poetry generation. The work of Zhang and Lapata (2014) is one such example, where they were able to outperform all other classical Chinese poetry generation systems with both manual and automatic evaluation. Ghazvininejad et al. (2016) and Goyal et al. (2016) apply neural language models with regularising finite state machines. However, in the former case the rhythm of the output cannot be defined at sample time, and in the latter case the finite state machine is not trained on rhythm at all, as it is trained on dialogue acts. McGregor et al. (2016) construct a phonological model for generating prosodic texts, however there is no attempt to embed semantics into this model.

3 Phonetic-level Model

Our first model is a pure neural language model, trained on a phonetic encoding of poetry in order to represent both form and content. Phonetic encodings of language represent information as sequences of around 40 basic acoustic symbols. Training on phonetic symbols allows the model to learn effective representations of pronunciation, including rhyme and rhythm.

However, just training on a large corpus of poetry data is not enough. Specifically, two problems need to be overcome. 1) Phonetic encoding results in information loss: words that have the same pronunciation (homophones) cannot be perfectly reconstructed from the corresponding phonemes. This means that we require an additional probabilistic model in order to determine the most likely word given a sequence of phonemes. 2) The variety of poetry and poetic devices one can use—e.g., rhyme, rhythm, repetition—means that poems sampled from a model trained on *all* poetry would be unlikely to maintain internal consistency of meter and rhyme. It is therefore important to train the model on poetry which has its own internal consistency.

Thus, the model comprises three steps: transliterating an orthographic sequence to its phonetic representation, training a neural language model on the phonetic encoding, and decoding the generated sequence back from phonemes to orthographic symbols.

Phonetic encoding To solve the first step, we apply a combination of word lookups from the CMU pronunciation dictionary (Weide, 2005) with letter-to-sound rules for handling out-of-vocabulary words. These rules are based on the CART techniques described by Black et al. (1998), and are represented with a simple Finite State Transducer[1]. The number of letters and number of phones in a word are rarely a one-to-one match: letters may match with up to three phones. In addition, virtually all letters can, in some contexts, map to zero phones, which is known as 'wild' or epsilon. Expectation Maximisation is used to compute the probability of a single letter matching a single phone, which is maximised through the application of Dynamic Time Warping (Myers et al., 1980) to determine the most likely position of epsilon characters.

Although this approach offers full coverage over the training corpus—even for abbreviated words like *ask'd* and archaic words like *renewest*—it has several limitations. Irregularities in the English language result in difficulty determining general letter-to-sound rules that can manage words with unusual pronunciations such as "colonel" and "receipt" [2].

In addition to transliterating words into phoneme sequences, we also represent word break characters as a specific symbol. This makes

[1] Implemented using FreeTTS (Walker et al., 2010)

[2] An evaluation of models in American English, British English, German and French was undertaken by Black et al. (1998), who reported an externally validated per token accuracy on British English as low as 67%. Although no experiments were carried out on corpora of early-modern English, it is likely that this accuracy would be significantly lower.

decipherment, when converting back into an orthographic representation, much easier. Phonetic transliteration allows us to construct a phonetic poetry corpus comprising 1,046,536 phonemes.

Neural language model We train a Long-Short Term Memory network (Hochreiter and Schmidhuber, 1997) on the phonetic representation of our poetry corpus. The model is trained using stochastic gradient descent to predict the next phoneme given a sequence of phonemes. Specifically, we maximize a multinomial logistic regression objective over the final softmax prediction. Each phoneme is represented as a 256-dimensional embedding, and the model consists of two hidden layers of size 256. We apply backpropagation-through-time (Werbos, 1990) for 150 timesteps, which roughly equates to four lines of poetry in sonnet form. This allows the network to learn features like rhyme even when spread over multiple lines. Training is preemptively stopped at 25 epochs to prevent overfitting.

Orthographic decoding When decoding from phonemes back to orthographic symbols, the goal is to compute the most likely word corresponding to a sequence of phonemes. That is, we compute the most probable hypothesis word W given a phoneme sequence ρ:

$$arg\,max_i\ P\ (\ W_i \mid \rho\ ) \qquad (1)$$

We can consider the phonetic encoding of plaintext to be a *homophonic cipher*; that is, a cipher in which each symbol can correspond to one or more possible decodings. The problem of homophonic decipherment has received significant research attention in the past; with approaches utilising Expectation Maximisation (Knight et al., 2006), Integer Programming (Ravi and Knight, 2009) and A* search (Corlett and Penn, 2010).

Transliteration from phonetic to an orthographic representation is done by constructing a Hidden Markov Model using the CMU pronunciation dictionary (Weide, 2005) and an n-gram language model. We calculate the transition probabilities (using the n-gram model) and the emission matrix (using the CMU pronunciation dictionary) to determine pronunciations that correspond to a single word. All pronunciations are naively considered equiprobable. We perform Viterbi decoding to find the most likely sequence of words. This means finding the most likely word w_{t+1} given a previous word sequence $(w_{t-n}, ..., w_t)$.

$$arg\,max_{w_{t+1}}\ P\ (\ w_{t+1} \mid w_1,\ \ldots\ ,\ w_t\ ) \qquad (2)$$

If a phonetic sequence does not map to any word, we apply the heuristic of artificially breaking the sequence up into two subsequences at index *n*, such that *n* maximises the n-gram frequency of the subsequences.

And humble and their fit *flees* are wits size
but that one made and made thy step me lies

Cool light the golden dark in any way
the birds a *shade* a laughter turn away

Then adding wastes retreating white as thine
She watched what eyes are breathing awe what shine

But sometimes shines so covered how the beak
Alone in pleasant skies no more to seek

Figure 1: Example output of the phonetic-level model trained on Iambic Pentameter poetry (grammatical errors are emphasised).

Output A popular form of poetry with strict internal structure is the sonnet. Popularised in English by Shakespeare, the sonnet is characterised by a strict rhyme scheme and exactly fourteen lines of Iambic Pentameter (Greene et al., 2010). Since the 17,134 word tokens in Shakespeare's 153 sonnets are insufficient to train an effective model, we augment this corpus with poetry taken from the website *sonnets.org*, yielding a training set of 288,326 words and 1,563,457 characters.

An example of the output when training on this sonnets corpus is provided in Figure 1. Not only is it mostly in strict Iambic Pentameter, but the grammar of the output is mostly correct and the poetry contains rhyme.

4 Constrained Character-level Model

As the example shows, phonetic-level language models are effective at learning poetic form, despite small training sets and relatively few parameters. However, the fact that they require training data with internal poetic consistency implies that they do not generalise to other forms of poetry. That is, in order to generate poetry in Dactylic Hexameter (for example), a phonetic model must be trained on a corpus of Dactylic poetry. Not only is this impractical, but in many cases no corpus of

adequate size even exists. Even when such poetic corpora are available, a new model must be trained for each type of poetry. This precludes tweaking the form of the output, which is important when generating poetry automatically.

We now explore an alternative approach. Instead of attempting to represent both form and content in a single model, we construct a pipeline containing a generative language model representing *content*, and a discriminative model representing *form*. This allows us to represent the problem of creating poetry as a constraint satisfaction problem, where we can modify constraints to restrict the types of poetry we generate.

Character Language Model Rather than train a model on data representing features of *both* content and form, we now use a simple character-level model (Sutskever et al., 2011) focused solely on content. This approach offers several benefits over the word-level models that are prevalent in the literature. Namely, their more compact vocabulary allows for more efficient training; they can learn common prefixes and suffixes to allow us to sample words that are not present in the training corpus and can learn effective language representations from relatively small corpora; and they can handle archaic and incorrect spellings of words.

As we no longer need the model to explicitly represent the form of generated poetry, we can loosen our constraints when choosing a training corpus. Instead of relying on poetry only in sonnet form, we can instead construct a generic corpus of poetry taken from online sources. This corpus is composed of 7.56 million words and 34.34 million characters, taken largely from 20^{th} Century poetry books found online. The increase in corpus size facilitates a corresponding increase in the number of permissible model parameters. This allows us to train a 3-layer LSTM model with 2048-dimensional hidden layers, with embeddings in 128 dimensions. The model was trained to predict the next character given a sequence of characters, using stochastic gradient descent. We attenuate the learning rate over time, and by 20 epochs the model converges.

Rhythm Modeling Although a character-level language model trained on a corpus of generic poetry allows us to generate interesting text, internal irregularities and noise in the training data prevent the model from learning important features such as rhythm. Hence, we require an additional classifier to constrain our model by either accepting or rejecting sampled lines based on the presence or absence of these features. As the presence of *meter* (rhythm) is the most characteristic feature of poetry, it therefore must be our primary focus.

Pronunciation dictionaries have often been used to determine the syllabic stresses of words (Colton et al., 2012; Manurung et al., 2000; Misztal and Indurkhya, 2014), but suffer from some limitations for constructing a classifier. All word pronunciations are considered equiprobable, including archaic and uncommon pronunciations, and pronunciations are provided context free, despite the importance of context for pronunciation[3]. Furthermore, they are constructed from American English, meaning that British English may be misclassified.

These issues are circumvented by applying lightly supervised learning to determine the contextual stress pattern of any word. That is, we exploit the latent structure in our corpus of sonnet poetry, namely, the fact that sonnets are composed of lines in rigid Iambic Pentameter, and are therefore exactly ten syllables long with alternating syllabic stress. This allows us to derive a *syllable-stress distribution*. Although we use the sonnets corpus for this, it is important to note that any corpus with such a latent structure could be used.

We represent each line of poetry as a cascade of Weighted Finite State Transducers (WFST). A WFST is a finite-state automaton that maps between two sets of symbols. It is defined as an eight-tuple where $\langle Q, \Sigma, \rho, I, F, \Delta, \lambda, p \rangle$:

Q : A set of states

Σ : An input alphabet of symbols

ρ : An output alphabet of symbols

I : A set of initial states

F : A set of final states, or sinks

Δ : A transition function mapping pairs of states and symbols to sets of states

λ : A set of weights for initial states

P : A set of weights for final states

[3]For example, the independent probability of stressing the single syllable word *at* is 40%, but this increases to 91% when the following word is *the* (Greene et al., 2010)

A WFST assigns a probability (or weight, in the general case) to each path through it, going from an initial state to an end state. Every path corresponds to an input and output label sequence, and there can be many such paths for each sequence.

WFSTs are often used in a cascade, where a number of machines are executed in series, such that the output tape of one machine is the input tape for the next. Formally, a cascade is represented by the functional composition of several machines.

$$W(x, z) = A(x|y) \circ B(y|z) \circ C(z) \quad (3)$$

Where $W(x, z)$ is defined as the $\oplus$ sum of the path probabilities through the cascade, and x and z are an input sequence and output sequence respectively. In the real semiring (where the product of probabilities are taken in series, and the sum of the probabilities are taken in parallel), we can rewrite the definition of weighted composition to produce the following:

$$W(x, z) = \bigoplus_y A(x \mid y) \otimes B(y \mid z) \otimes C(z) \quad (4)$$

As we are dealing with probabilities, this can be rewritten as:

$$P(x, z) = \sum_y P(x \mid y)P(y \mid z)P(z) \quad (5)$$

We can perform Expectation Maximisation over the poetry corpus to obtain a probabilistic classifier which enables us to determine the most likely stress patterns for each word. Every word is represented by a single transducer.

In each cascade, a sequence of input words is mapped onto a sequence of stress patterns $\langle \times, / \rangle$ where each pattern is between 1 and 5 syllables in length[4]. We initially set all transition probabilities equally, as we make no assumptions about the stress distributions in our training set. We then iterate over each line of the sonnet corpus, using Expectation Maximisation to train the cascades. In practice, there are several de facto variations of Iambic meter which are permissible, as shown in Figure 2. We train the rhythm classifier by converging the cascades to whatever output is the most likely given the line.

[4]Words of more than 5 syllables comprise less than 0.1% of the lexicon (Aoyama and Constable, 1998).

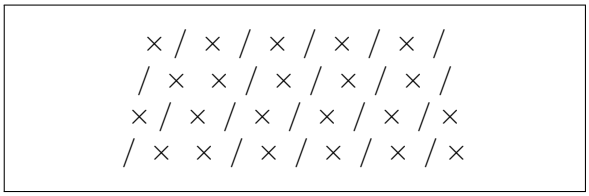

Figure 2: Permissible variations of Iambic Pentameter in Shakespeare's sonnets.

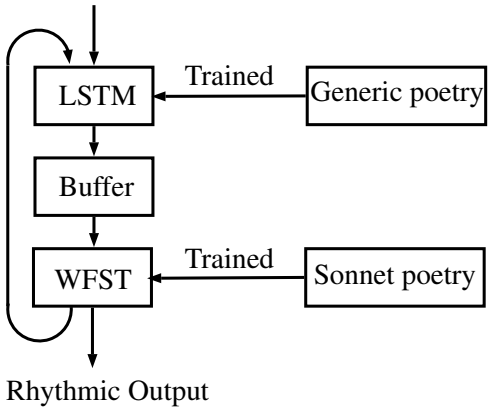

Constraining the model To generate poetry using this model, we sample sequences of characters from the character-level language model. To impose rhythm constrains on the language model, we first represent these sampled characters at the word level and pool sampled characters into word tokens in an intermediary buffer. We then apply the separately trained word-level WFSTs to construct a cascade of this buffer and perform Viterbi decoding over the cascade. This defines the distribution of stress-patterns over our word tokens.

We can represent this cascade as a probabilistic classifier, and accept or reject the buffered output based on how closely it conforms to the desired meter. While sampling sequences of words from this model, the entire generated sequence is passed to the classifier each time a new word is sampled. The pronunciation model then returns the probability that the entire line is within the specified meter. If a new word is rejected by the classifier, the state of the network is rolled back to the last formulaically acceptable state of the line, removing the rejected word from memory. The constraint on rhythm can be controlled by adjusting the acceptability threshold of the classifier. By increasing the threshold, output focuses on form over content. Conversely, decreasing the criterion puts greater emphasis on content.

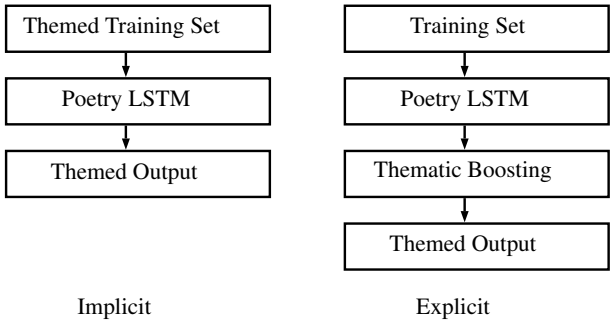

Figure 3: Two approaches for generating themed poetry.

Errors per line	1	2	3	4	Total
Phonetic Model	11	2	3	1	28
Character Model + WFST	6	5	1	1	23
Character Model	3	8	7	7	68

Table 1: Number of lines with n errors from a set of 50 lines generated by each of the three models.

4.1 Themes and Poetic devices

It is important for any generative poetry model to include themes and poetic devices. One way to achieve this would be by constructing a corpus that exhibits the desired themes and devices. To create a themed corpus about 'love', for instance, we would aggregate love poetry to train the model, which would thus learn an implicit representation of love. However, this forces us to generate poetry according to discrete themes and styles from pre-trained models, requiring a new training corpus for each model. In other words, we would suffer from similar limitations as with the phonetic-level model, in that we require a dedicated corpus. Alternatively, we can manipulate the language model by boosting character probabilities at sample time to increase the probability of sampling thematic words like 'love'. This approach is more robust, and provides us with more control over the final output, including the capacity to vary the inclusion of poetic devices in the output.

Themes In order to introduce thematic content, we heuristically boost the probability of sampling words that are semantically related to a theme word from the language model. First, we compile a list of similar words to a *key* theme word by retrieving its semantic neighbours from a distributional semantic model (Mikolov et al., 2013). For example, the theme *winter* might include thematic words *frozen*, *cold*, *snow* and *frosty*. We represent these semantic neighbours at the character level, and heuristically boost their probability by multiplying the sampling probability of these character strings by their cosine similarity to the key word, plus a constant. Thus, the likelihood of sampling a thematically related word is artificially increased, while still constraining the model rhythmically.

Poetic devices A similar method may be used for poetic devices such as assonance, consonance and alliteration. Since these devices can be orthographically described by the repetition of identical sequences of characters, we can apply the same heuristic to boost the probability of sampling character strings that have previously been sampled. That is, to sample a line with many instances of alliteration (multiple words with the same initial sound) we record the historical frequencies of characters sampled at the beginning of each previous word. After a word break character, we boost the probability that those characters will be sampled again in the softmax. We only keep track of frequencies for a fixed number of time steps. By increasing or decreasing the size of this window, we can manipulate the prevalence of alliteration. Variations of this approach are applied to invoke consonance (by boosting intra-word consonants) and assonance (by boosting intra-word vowels). An example of two sampled lines with high degrees of alliteration, assonance and consonance is given in Figure 4c.

5 Evaluation

In order to examine how effective our methodologies for generating poetry are, we evaluate the proposed models in two ways. First, we perform an intrinsic evaluation where we examine the quality of the models and the generated poetry. Second, we perform an extrinsic evaluation where we evaluate the generated output using human annotators, and compare it to human-generated poetry.

5.1 Intrinsic evaluation

To evaluate the ability of both models to generate formulaic poetry that adheres to rhythmic rules, we compared sets of fifty sampled lines from each model. The first set was sampled from the phonetic-level model trained on Iambic poetry. The second set was sampled from the character-level model, constrained to Iambic form. For com-

	Word	Line	Coverage
Wikipedia	64.84%	83.35%	97.53%
Sonnets	85.95%	80.32%	99.36%

Table 2: Error when transliterating text into phonemes and reconstructing back into text.

parison, and to act as a baseline, we also sampled from the *unconstrained* character model.

We created gold-standard syllabic classifications by recording each line spoken-aloud, and marking each syllable as either stressed or unstressed. We then compared these observations to loose Iambic Pentameter (containing all four variants), to determine how many syllabic misclassifications existed on each line. This was done by speaking each line aloud, and noting where the speaker put stresses.

As Table 1 shows, the constrained character level model generated the most formulaic poetry. Results from this model show that 70% of lines had zero mistakes, with frequency obeying an inverse power-law relationship with the number of errors. We can see that the phonetic model performed similarly, but produced more subtle mistakes than the constrained character model: many of the errors were single mistakes in an otherwise correct line of poetry.

In order to investigate this further, we examined to what extent these errors are due to transliteration (i.e., the phonetic encoding and orthographic decoding steps). Table 2 shows the reconstruction accuracy per word and per line when transliterating either Wikipedia or Sonnets to phonemes using the CMU pronunciation dictionary and subsequently reconstructing English text using the n-gram model[5]. Word accuracy reflects the frequency of *perfect* reconstruction, whereas per line tri-gram similarity (Kondrak, 2005) reflects the *overall* reconstruction. Coverage captures the percentage of in-vocabulary items. The relatively low per-word accuracy achieved on the Wikipedia corpus is likely due to the high frequency of out-of-vocabulary words. The results show that a significant number of errors in the phonetic-level model are likely to be caused by transliteration mistakes.

[5]Obviously, calculating this value for the character-level model makes no sense, since no transliteration occurs in that case.

5.2 Extrinsic evaluation

We conducted an indistinguishability study with a selection of automatically generated poetry and human poetry. As extrinsic evaluations are expensive and the phonetic model was unlikely to do well (as illustrated in Figure 4e: the model generates good Iambic form, but not very good English), we only evaluate on the constrained character-level model. Poetry was generated with a variety of themes and poetic devices (see supplementary material).

The aim of the study was to determine whether participants could distinguish between human and machine-generated poetry, and if so to what extent. A set of 70 participants (of whom 61 were English native speakers) were each shown a selection of randomly chosen poetry segments, and were invited to classify them as either human or generated. Participants were recruited from friends and people within poetry communities within the University of Cambridge, with an age range of 17 to 80, and a mean age of 29. Our participants were not financially incentivised, perceiving the evaluation as an intellectual challenge.

In addition to the classification task, each participant was also invited to rate each poem on a 1-5 scale with respect to three criteria, namely readability, form and evocation (how much emotion did a poem elicit). We naively consider the overall quality of a poem to be the mean of these three measures. We used a custom web-based environment, built specifically for this evaluation[6], which is illustrated in Figure 5. Based on human judgments, we can determine whether the models presented in this work can produce poetry of a similar quality to humans.

To select appropriate human poetry that could be meaningfully compared with the machine-generated poetry, we performed a comprehension test on all poems used in the evaluation, using the Dale-Chall readability formula (Dale and Chall, 1948). This formula represents readability as a function of the complexity of the input words. We selected nine machine-generated poems with a high readability score. The generated poems produced an average score of 7.11, indicating that readers over 15 years of age should easily be able to comprehend them.

For our human poems, we focused explicitly on poetry where greater consideration is placed on

prosodic elements like rhythm and rhyme than semantic content (known as "nonsense verse"). We randomly selected 30 poems belonging to that category from the website *poetrysoup.com*, of which eight were selected for the final comparison based on their comparable readability score. The selected poems were segmented into passages of between four and six lines, to match the length of the generated poetry segments. An example of such a segment is shown in Figure 4d. The human poems had an average score of 7.52, requiring a similar level of English aptitude to the generated texts.

The performance of each human poem, alongside the aggregated scores of the generated poems, is illustrated in Table 3. For the *human* poems, our group of participants guessed correctly that they were human 51.4% of the time. For the *generated* poems, our participants guessed correctly 46.2% of the time that they were machine generated. To determine whether our results were statistically significant, we performed a Chi^2 test. This resulted in a p-value of 0.718. This indicates that our participants were unable to tell the difference between human and generated poetry in any significant way. Although our participants generally considered the human poems to be of marginally higher quality than our generated poetry, they were unable to effectively distinguish between them. Interestingly, our results seem to suggest that our participants consider the generated poems to be more 'human-like' than those actually written by humans. In addition, the poem with the highest overall quality rating is a machine generated one. This shows that our approach was effective at generating high-quality rhythmic verse.

It should be noted that the poems that were most 'human-like' and most aesthetic respectively were generated by the neural character model. Generally the set of poetry produced by the neural character model was slightly less readable and emotive than the human poetry, but had above average form. All generated poems included in this evaluation can be found in the supplementary material, and our code is made available online[7].

6 Conclusions

Our contributions are twofold. First, we developed a neural language model trained on a phonetic transliteration of poetic form and content. Although example output looked promising, this model was limited by its inability to generalise to novel forms of verse. We then proposed a more robust model trained on unformed poetic text, whose output form is constrained at sample time. This approach offers greater control over the style of the generated poetry than the earlier method, and facilitates themes and poetic devices.

An indistinguishability test, where participants were asked to classify a randomly selected set of human "nonsense verse" and machine-generated poetry, showed generated poetry to be indistinguishable from that written by humans. In addition, the poems that were deemed most 'humanlike' and most aesthetic were both machine-generated.

In future work, it would be useful to investigate models based on morphemes, rather than characters, which offers potentially superior performance for complex and rare words (Luong et al., 2013), which are common in poetry.

Abstract

In this paper, we present a novel framework for semi-automatically creating linguistically challenging micro-planning data-to-text corpora from existing Knowledge Bases. Because our method pairs data of varying size and shape with texts ranging from simple clauses to short texts, a dataset created using this framework provides a challenging benchmark for microplanning. Another feature of this framework is that it can be applied to any large scale knowledge base and can therefore be used to train and learn KB verbalisers. We apply our framework to DBpedia data and compare the resulting dataset with Wen et al. (2016)'s. We show that while Wen et al.'s dataset is more than twice larger than ours, it is less diverse both in terms of input and in terms of text. We thus propose our corpus generation framework as a novel method for creating challenging data sets from which NLG models can be learned which are capable of handling the complex interactions occurring during in micro-planning between lexicalisation, aggregation, surface realisation, referring expression generation and sentence segmentation. To encourage researchers to take up this challenge, we recently made available a dataset created using this framework in the context of the WEBNLG shared task.

1 Introduction

To train Natural Language Generation (NLG) systems, various input-text corpora have been developed which associate (numerical, formal, linguistic) input with text. As discussed in detail in Section 2, these corpora can be classified into three main types namely, (i) domain specific corpora, (ii) benchmarks constructed from "Expert" Linguistic Annotations and (iii) crowdsourced benchmarks.[1]

In this paper, we focus on how to create data-to-text corpora which can support the learning of micro-planners i.e., data-to-text generation systems that can handle the complex interactions occurring between lexicalisation (mapping data to words), aggregation (exploiting linguistic constructs such as ellipsis and coordination to avoid repetition), surface realisation (using the appropriate syntactic constructs to build sentences), sentence segmentation and referring expression generation.

We start by reviewing the main existing types of NLG benchmarks and we argue for a crowdsourcing approach in which (i) data units are automatically built from an existing Knowledge Base (KB) and (ii) text is crowdsourced from the data (Section 2). We then propose a generic framework for semi-automatically creating training corpora for NLG (Section 3) from existing knowledge bases. In Section 4, we apply this framework to DBpedia data and we compare the resulting dataset with the dataset of Wen et al. (2016) using various metrics to evaluate the linguistic and computational adequacy of both datasets. By applying these metrics, we show that while Wen et al.'s dataset is more than twice larger than ours, it is less diverse both in terms of input and in terms of text. We also com-

[1] We ignore here (Lebret et al., 2016)'s dataset which was created fully automatically from Wikipedia by associating infoboxes with text because this dataset fails to ensure an adequate match between data and text. We manually examined 50 input/output pairs randomly extracted from this dataset and did not find a single example where data and text matched. As such, this dataset is ill-suited for training micro-planners. Moreover, since its texts contain both missing and additional information, it cannot be used to train joint models for content selection and micro-planning either.

https://doi.org/10.18653/v1/P17-1017

pare the performance of a sequence-to-sequence model (Vinyals et al., 2015) on both datasets to estimate the complexity of the learning task induced by each dataset. We show that the performance of this neural model is much lower on the new data set than on the existing ones. We thus propose our corpus generation framework as a novel method for creating challenging data sets from which NLG models can be learned which are capable of generating complex texts from KB data.

2 NLG Benchmarks

Domain specific benchmarks. Several domain specific data-text corpora have been built by researchers to train and evaluate NLG systems. In the sports domain, Chen and Mooney (2008) constructed a dataset mapping soccer games events to text which consists of 1,539 data-text pairs and a vocabulary of 214 words. For weather forecast generation, the dataset of Liang et al. (2009) includes 29,528 data-text pairs with a vocabulary of 345 words. For the air travel domain, Ratnaparkhi (2000) created a dataset consisting of 5,426 data-text pairs with a richer vocabulary (927 words) and in the biology domain, the KBGen shared task (Banik et al., 2013) made available 284 data-text pairs where the data was extracted from an existing knowledge base and the text was authored by biology experts.

An important limitation of these datasets is that, because they are domain specific, systems learned from them are restricted to generating domain specific, often strongly stereotyped text (e.g., weather forecast or soccer game commentator reports). Arguably, training corpora for NLG should support the learning of more generic systems capable of handling a much wider range of linguistic interactions than is present in stereotyped texts. By nature however, domain specific corpora restrict the lexical and often the syntactic coverage of the texts to be produced and thereby indirectly limit the expressivity of the generators trained on them.

Benchmarks constructed from "expert" linguistic annotations. NLG benchmarks have also been proposed where the input data is either derived from dependency parse trees (SR'11 task, Belz et al. 2011) or constructed through manual annotation (AMR Corpus, Banarescu et al. 2012). Contrary to the domain-specific data sets just mentioned, these corpora have a wider coverage and are large enough for training systems that can generate linguistically sophisticated text.

One main drawback of these benchmarks however is that their construction required massive manual annotation of text with complex linguistic structures (parse trees for the SR task and Abstract Meaning Representation for the AMR corpus). Moreover because these structures are complex, the annotation must be done by experts. It cannot be delegated to the crowd. In short, the creation of such benchmark is costly both in terms of time and in terms of expertise.

Another drawback is that, because the input representation derived from a text is relatively close to its surface form[2], the NLG task is mostly restricted to surface realisation (mapping input to sentences). That is, these benchmarks give very limited support for learning models that can handle the interactions between micro-planning subtasks.

Crowdsourced benchmarks. More recently, data-to-text benchmarks have also been created by associating data units with text using crowdsourcing.

Wen et al. (2016) first created data by enumerating all possible combinations of 14 dialog act types (e.g., *request, inform*) and attribute-value pairs present in four small-size, hand-written ontologies about TVs, laptops, restaurants and hotels. They then use crowdsourcing to associate each data unit with a text. The resulting dataset is both large and varied (4 domains) and was successfully exploited to train neural and imitation learning data-to-text generator (Wen et al., 2016; Lampouras and Vlachos, 2016). Similarly, Novikova and Rieser (2016) described a framework for collecting data-text pairs using automatic quality control measures and evaluating how the type of the input representations (text vs pictures) impacts the quality of crowdsourced text.

The crowdsourcing approach to creating input-text corpora has several advantages.

First, it is low cost in that the data is produced automatically and the text is authored by a crowdworker. This is in stark contrast with the previous approach where expert linguists are required to align text with data.

[2]For instance, the input structures made available by the shallow track of the SR task contain all the lemmas present in the corresponding text. In this case, the generation task is limited to determining (i) the linear ordering and (ii) the full form of the word in the input.

Second, because the text is crowd-sourced from the data (rather than the other way round), there is an adequate match between text and data both semantically (the text expresses the information contained in the data) and computationally (the data is sufficiently different from the text to require the learning of complex generation operations such as sentence segmentation, aggregation and referring expression generation).

Third, by exploiting small hand-written ontologies to quickly construct meaningful artificial data, the crowdsourcing approach allows for the easy creation of a large dataset with data units of various size and bearing on different domains. This, in turn, allows for better linguistic coverage and for NLG tasks of various complexity since typically, inputs of larger size increases the need for complex microplanning operations.

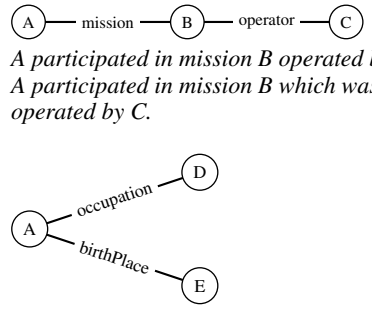
3 The WebNLG Framework for Creating Data-to-Text, Micro-Planning Benchmarks

While as just noted, the crowdsourcing approach presented by Wen et al. (2016) has several advantages, it also has a number of shortcomings.

One important drawback is that it builds on artificial rather than "real" data i.e., data that would be extracted from an existing knowledge base. As a result, the training corpora built using this method cannot be used to train KB verbalisers i.e., generation systems that can verbalise KB fragments.

Another limitation concerns the shape of the input data. Wen et al.'s data can be viewed as trees of depth one (a set of attributes-value pairs describing a single entity e.g., a restaurant or a laptop). As illustrated in Figure 1 however, there is a strong correlation between the shape of the input and the syntactic structure of the corresponding sentence. The path structure T_1 where B is shared by two predicates (*mission* and *operator*) will favour the use of a participial or a passive subject relative clause. In contrast, the branching structure T_2 will favour the use of a new clause with a pronominal subject or a coordinated VP. More generally, allowing for trees of deeper depth is necessary to indirectly promote the introduction in the benchmark of a more varied set of syntactic constructs to be learned by generators.

To address these issues, we introduce a novel method for creating data-to-text corpora from large knowledge bases such as DBPedia. Our



T_1
$S_{1.1}$ *A participated in mission B operated by C.*
$S_{1.2}$ *A participated in mission B which was operated by C.*

T_2
$S_{2.1}$ *A was born in E. She worked as an engineer.*
$S_{2.2}$ *A was born in E and worked as an engineer.*

Figure 1: Input shape and linguistic structures (A = Susan Helms, B = STS 78, C = NASA, D = engineer, E = Charlotte, North Carolina).

method combines (i) a content selection module designed to extract varied, relevant and coherent data units from DBPedia with (ii) a crowdsourcing process for associating data units with human authored texts that correctly capture their meaning. Example 1 shows a data/text unit created by our method using DBPedia as input KB.

(1) a. *(John_E_Blaha birthDate 1942_08_26)*
(John_E_Blaha birthPlace San_Antonio)
(John_E_Blaha occupation Fighter_pilot)

b. *John E Blaha, born in San Antonio on 1942-08-26, worked as a fighter pilot*

Our method has the following features.

First, it can be used to create a data-to-text corpus from any knowledge base where entities are categorised and there is a large number of entities belonging to the same category. As noted above, this means that the resulting corpus can be used to train KB verbalisers i.e., generators that are able to verbalise fragments of existing knowledge bases. It could be used for instance, to verbalise fragments of e.g., MusicBrainz[3], FOAF[4] or LinkedGeoData.[5]

Second, as crowdworkers are required to enter text that matches the data and a majority vote validation process is used to eliminate mis-matched pairs, there is a direct match between text and data. This allows for a clear focus on the non content selection part of generation known as microplanning.

Third, because data of increasing size is matched with texts ranging from simple clauses to

[3] https://musicbrainz.org/
[4] http://www.foaf-project.org/
[5] http://linkedgeodata.org/

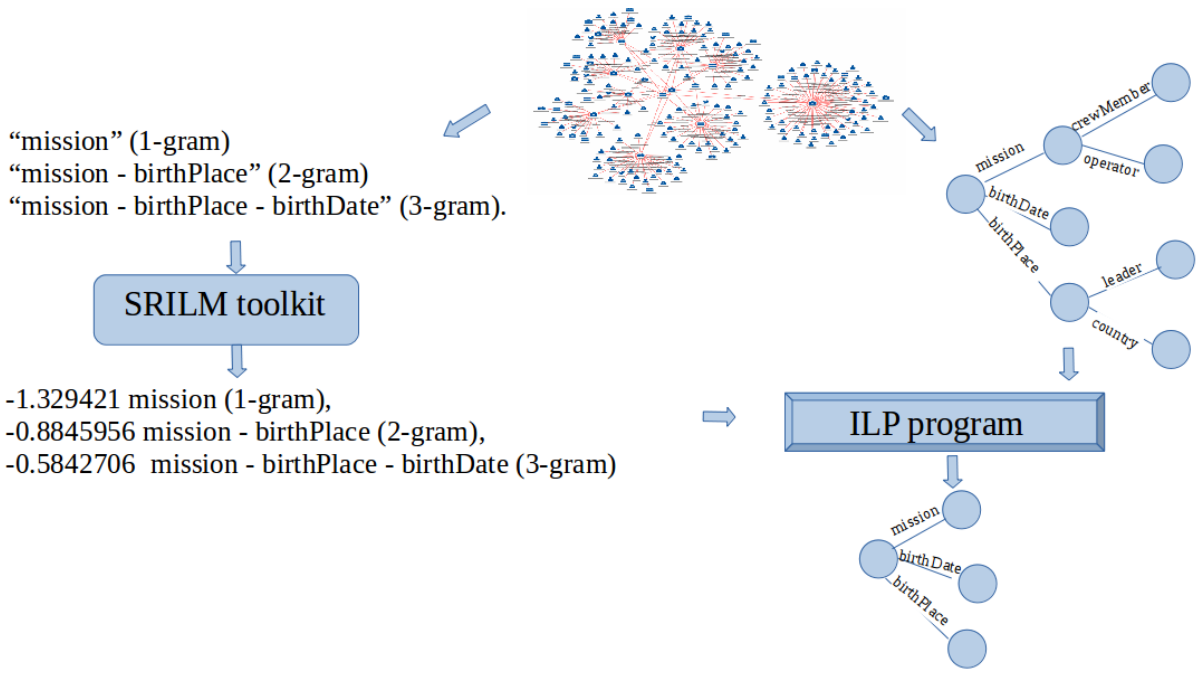


Figure 2: Extracting data units from DBPedia.

short texts consisting of several sentences, the resulting benchmark is appropriate for exercising the main subtasks of microplanning. For instance, in Example (1) above, given the input shown in (1a), generating (1b) involves lexicalising the *occupation* property as the phrase *worked as* (lexicalisation); using PP coordination (*born in San Antonio on 1942-08-26*) to avoid repeating the word *born* (aggregation); and verbalising the three triples using a single complex sentence including an apposition, a PP coordination and a transitive verb construction (sentence segmentation and surface realisation).

3.1 DBPedia

To illustrate the functioning of our benchmark creation framework, we apply it to DBPedia. DBPedia is a multilingual knowledge base that was built from various kinds of structured information contained in Wikipedia (Mendes et al., 2012). This data is stored as RDF (Resource Description Format) triples of the form *(subject, property, object)* where the subject is a URI (Uniform Resource Identifier), the property is a binary relation and the object is either a URI or a literal value such as a string, a date or a number. We use an English version of the DBPedia knowledge base which encompasses 6.2M entities, 739 classes, 1,099 properties with reference values and 1,596 properties with typed literal values.[6]

3.2 Selecting Content

To create data units, we adapted the procedure outlined by Perez-Beltrachini et al. (2016) and sketched in Figure 2. This method can be summarised as follows.

First, DBPedia *category graphs* are extracted from DBPedia by retrieving up to 500 *entity graphs* for entities of the same category.[7] For example, we build a category graph for the Astronaut category by collecting, graphs of depth five for 500 entities of types astronaut.

Next, category graphs are used to learn bi-gram models of DBPedia properties which specify the probability of two properties co-occuring together. Three types of bi-gram models are extracted from category graphs using the SRILM toolkit (Stolcke, 2002): one model (*S*-Model) for bigrams occurring in sibling triples (triples with a shared subject); one model (*C*-Model) for bigrams occurring in chained triples (the object of one triple is the subject of the other); and one model (*M*-Model) which is a linear interpolation of the sibling and the chain model. The intuition is that these sib-

[6] http://wiki.dbpedia.org/dbpedia-dataset-version-2015-10

[7] An entity graph for some entity e is a graph obtained by traversing the DBPedia graph starting in e and stopping at depth five.

ling and chain models capture different types of coherence, namely, topic-based coherence for the *S*-Model and discourse-based coherence for the *C*-Model.

Finally, the content selection task is formulated as an Integer Linear Programming (ILP) problem to select, for a given entity of category C and its entity graph G_e, subtrees of G_e with maximal bi-gram probability and varying size (between 1 and 7 RDF triples).

Category	A	B	M	U	S	W
#Inputs	663	1220	333	508	1137	1207
#I. Patterns	546	369	300	432	184	277
#Properties	38	46	30	41	32	50
#Entities	74	278	47	75	264	224

Table 1: Data statistics from content selection (A:Astronaut, B:Building, M:Monument, U:University, W:Written work, S:Sports team).

We applied this content selection procedure to the DBPedia categories Astronaut (A), Building (B), Monument (M), University (U), Sports team (S) and Written work (W), using the three bi-gram models (*S*-Model, *C*-Model, *M*-Model) and making the number of triples required by the ILP constraint to occur in the output solutions vary between 1 and 7. The results are shown in Table 1. An input is a set of triples produced by the content selection module. The number of input (#Inputs) is thus the number of distinct sets of triples produced by this module. In contrast, input patterns are inputs where subject and object have been abstracted over. That is, the number of input patterns (#I. Patterns) is the number of distinct sets of properties present in the set of inputs. The number of properties (#Properties) is the number of distinct RDF properties occurring in the dataset. Similarly, the number of entities (#Entities) is the number of distinct RDF subjects and objects occurring in each given dataset.

3.3 Associating Content with Text

We associate data with text using the Crowdflower platform.[8] We do this in four main steps as follows.

1. Clarifying properties. One difficulty when collecting texts verbalising sets of DBPedia triples is that the meaning of DBPedia properties may be unclear. We therefore first manually clarified for each category being worked on, those properties which have no obvious lexicalisations (e.g., *crew1up* was replaced by *commander*).

2. Getting verbalisations for single triples. Next, we collected three verbalisations for data units of size one, i.e. single triples consisting of a subject, a property and an object. For each such input, crowdworkers were asked to produce a sentence verbalising its content. We used both *a priori* automatic checks to prevent spamming and *a posteriori* manual checks to remove incorrect verbalisations. We also monitored crowdworkers as they entered their input and banned those who tried to circumvent our instructions and validators. The automatic checks comprise 12 custom javascript validators implemented in the CrowdFlower platform to block contributor answers which fail to meet requirements such as the minimal time a contributor should stay on page, the minimal length of the text produced, the minimal match of tokens between a triple and its verbalisation and various format restrictions used to detect invalid input. The exact match between a triple and its verbalisation was also prohibited. In addition, after data collection was completed, we manually checked each data-text pair and eliminated from the data set any pair where the text either did not match the information conveyed by the triple or was not a well-formed English sentence.

3. Getting verbalisations for input containing more than one triple. The verbalisations collected for single triples were used to construct input with bigger size. Thus, for input with a number of triples more than one, the crowd was asked to merge the sentences corresponding to each triple (obtained in step 2) into a natural sounding text. In such a way, we diminish the risk of having misinterpretations of the original semantics of a data unit. Contributors were also encouraged to change the order, and the wording of sentences, while writing their texts. For each data unit, we collected three verbalisations.

4. Verifying the quality of the collected texts. The verbalisations obtained in Step 3 were verified through crowdsourcing. Each verbalisation collected in Step 3 was displayed to CrowdFlower contributors together with the corresponding set of triples. Then the crowd was asked to assess its fluency, semantic adequacy, and grammaticality. Those criteria were checked by asking the follow-

[8] http://www.crowdflower.com

# Triples	1	2	3	4	5	6	7
# Tokens	4/30/10.48	11/45/22.97	7/37/16.96	17/60/36.38	14/53/29.61	29/80/49.14	24/73/42.95
# Sentences	1/2/1.00	1/4/1.23	1/3/1.02	1/5/2.05	1/4/1.64	1/6/2.85	1/5/2.42

Table 2: Text statistics from crowdsourcing for triple sets of varying sizes (min/max/avg).

ing three questions:

Does the text sound fluent and natural?
Does the text contain all and only the information from the data?
Is the text good English (no spelling or grammatical mistakes)?

We collected five answers per verbalisation. A verbalisation was considered bad, if it received three negative answers in at least one criterion. After the verification step, the total corpus loss was of 8.7%. An example of rejected verbalisation can be found in Example (2). The verbalisation was dropped due to the lack of fluency (awkward lexicalisation of the property *club*).

(2) *(AEK_Athens_F.C. manager Gus_Poyet)*
(Gus_Poyet club Chelsea_F.C.)
AEK Athens F.C. are managed by Gus Poyet, who is in Chelsea_F.C.

Table 2 shows some statistics about the texts obtained using our crowdsourcing procedure for triple sets of size one to seven.

4 Comparing Benchmarks

We now compare a dataset created using our dataset creation framework (henceforth WEBNLG) with the dataset of Wen et al. (2016)[9] (henceforth, RNNLG). Example 3 shows a sample data-text pair taken from the RNNLG dataset.

(3) Dialog Moves
recommend(name=caerus 33;type=television;
screensizerange=medium;family=t5;hasusbport=true)
The caerus 33 is a medium television in the T5 family that's USB-enabled.

As should be clear from the discussion in Section 2 and 3, both datasets are similar in that, in both cases, data is built from ontological information and text is crowdsourced from the data. An important difference between the two datasets is that, while the RNNLG data was constructed by enumerating possible combinations of dialog act types and attribute-value pairs, the WEBNLG data is created using a sophisticated content selection procedure geared at producing sets of data units that are relevant for a given ontological category and that are varied in terms of size, shape and content. We now investigate the impact of this difference on the two datasets (WEBNLG and RNNLG). To assess the degree to which both datasets support the generation of linguistically varied text requiring complex micro-planning operations, we examine a number of data and text related metrics. We also compare the results of an out-of-the-box sequence-to-sequence model as a way to estimate the complexity of the learning task induced by each dataset.

	WEBNLG	RNNLG
Nb. Input	5068	22225
Nb. Data-Text Pairs	13339	30842
Nb. Domains	6	4
Nb. Attributes	172	108
Nb. Input Patterns	2108	2155
Nb. Input / Nb Input Pattern	2.40	10.31
Nb. Input Shapes	58	6

Table 3: Comparing WEBNLG and RNNLG datasets. Attributes are properties in RDF triples or slots in dialog acts.

4.1 Data Comparison

Terminology. The attributes in the RNNLG dataset can be viewed as binary relations between the object talked about (a restaurant, a laptop, a TV or a hotel) and a value. Similarly, in the WEBNLGdataset, DBpedia RDF properties relate a subject entity to an object which can be either an entity or a datatype value. In what follows, we refer to both as *attributes*.

Table 3 shows several statistics which indicate that, while the RNNLG dataset is larger than WEBNLG, WEBNLG is much more diverse in terms of attributes, input patterns and input shapes.

Number of attributes. As illustrated in Example (4) below, different attributes can be lexicalised using different parts of speech. A dataset with a larger number of attributes is therefore more likely to induce texts with greater syntactic variety.

(4) Verb: *X title Y* / *X served as Y*
Relational noun: *X nationality Y* / *X's nationality is Y*
Preposition: *X country Y* / *X is in Y*
Adjective: *X nationality USA* / *X is American*

[9] https://github.com/shawnwun/RNNLG

As shown in Table 3, WEBNLG has a more diverse attribute set than RNNLG both in absolute (172 attributes in WEBNLG against 108 in RNNLG) and in relative terms (RNNLG is a little more than twice as large as WEBNLG).

Number of input patterns. Since attributes may give rise to lexicalisation with different parts of speech, the sets of attributes present in an input (input pattern)[10] indirectly determine the syntactic realisation of the corresponding text. Hence a higher number of input patterns will favour a higher number of syntactic realisations. This is exemplified in Example (5) where two inputs with the same number of attributes give rise to texts with different syntactic forms. While in Example (5a), the attribute set {*country, location, startDate*} is realised by a passive (*is located*), an apposition (*Australia*) and a deverbal nominal (*its construction*), in Example (5b), the attribute set {*almaMater, birthPlace, selection*} induced a passive (*was born*) and two VP coordinations (*graduated and joined*).

(5) a. *('108_St_Georges_Terrace location Perth', 'Perth country Australia', '108_St_Georges_Terrace startDate 1981')*
country, location, startDate
108 St. Georges Terrace is located in Perth, Australia. Its construction began in 1981.
passive, apposition, deverbal nominal

b. *('William_Anders selection 1963', 'William_Anders birthPlace British_Hong_Kong', 'William_Anders almaMater "AFIT, M.S. 1962"')*
almaMater, birthPlace, selection
William Anders was born in British Hong Kong, graduated from AFIT in 1962, and joined NASA in 1963.
passive, VP coordination, VP coordination

Again, despite the much larger size of the RNNLG dataset, the number of input patterns in both datasets is almost the same. That is, the relative variety in input patterns is higher in WEBNLG.

Number of input / Number of input patterns. The ratio between number of inputs and the number of input patterns has an important impact both in terms of linguistic diversity and in terms of learning complexity. A large ratio indicates a "repetitive dataset" where the same pattern is instantiated a high number of times. While this facilitates learning, this also reduces linguistic coverage (less combinations of structures can be learned) and may induce over-fitting. Note that because datasets are typically delexicalised when training NLG models (cf. e.g., Wen et al. 2015 and Lampouras and Vlachos 2016), at training time, different instantiations of the same input pattern reduce to identical input.

The two datasets markedly differ on this ratio which is five times lower in WEBNLG. While in WEBNLG, the same pattern is instantiated in average 2.40 times, it is instantiated 10.31 times in average in RNNLG. From a learning perspective, this means that the RNNLG dataset facilitates learning but also makes it harder to assess how well systems trained on it can generalise to handle unseen input.

Input shape. As mentioned in Section 3, in the RNNLG dataset, all inputs can be viewed as trees of depth one while in the WEBNLG dataset, input may have various shapes. As a result, RNNLG texts will be restricted to syntactic forms which permit expressing such multiple predications of the same entity e.g., subject relative clause, VP and sentence coordination etc. In contrast, the trees extracted by the WEBNLG content selection procedure may be of depth five and therefore allow for further syntactic constructs such as object relative clause and passive participles (cf. Figure 1).

We can show this empirically as well that WEBNLG is far more diverse than RNNLG in terms of input shapes. The RNNLG dataset has only 6 distinct shapes and all of them are of depth 1, i.e., all (attribute, value) pairs in an input are siblings to each other. In contrast, the WEBNLG dataset has 58 distinct shapes, out of which only 7 shapes are with depth 1, all others have depth more than 1 and they cover 49.6% of all inputs.

4.2 Text Comparison

Table 4 gives some statistics about the texts contained in each dataset.

(6) *(Alan_Bean birthDate "1932-03-15")*
Alan Bean was born on March 15, 1932.

(7) *('Alan_Bean nationality United_States', 'Alan_Bean birthDate "1932-03-15"', 'Alan_Bean almaMater "UT Austin, B.S. 1955"', 'Alan_Bean birthPlace Wheeler,_Texas', 'Alan_Bean selection 1963')*
Alan Bean was an American astronaut, born on March 15, 1932 in Wheeler, Texas. He received a Bachelor of Science degree at the University of Texas at Austin in 1955 and was chosen by NASA in 1963.

[10] Recall from section 3 that input patterns are inputs where subjects and objects have been remove thus, in essence, an input pattern is the set of all the attributes occurring in a given input.

As illustrated by the contrast between Examples (6) and (7) above, text length (number of tokens per text) and the number of sentences per text are strong indicators of the complexity of the generation task. We use the Stanford Part-Of-Speech Tagger and Parser version 3.5.2 (dated 2015-04-20, Manning et al. 2014) to tokenize and to perform sentence segmentation on text. As shown in Table 4, WEBNLG's texts are longer both in terms of tokens and in terms of number of sentences per text. Another difference between the two datasets is that WEBNLG contains a higher number of text per input thereby providing a better basis for learning paraphrases.

	WEBNLG	RNNLG
Nb. Text / Input	2.63	1.38
Text Length (avg/median/min/max)	24.36/23/4/80	18.37/19/1/76
Nb. Sentence / Text (avg/median/min/max)	1.45/1/1/6	1.25/1/1/6
Nb. Tokens	290479	531871
Nb. Types	2992	3524
Lexical Sophistication	0.69	0.54
CTTR	3.93	3.42

Table 4: Text statistics from WEBNLG and RNNLG.

The size and the content of the vocabulary is another important factor in ensuring the learning of wide coverage generators. While a large vocabulary makes the learning problem harder, it also allows for larger coverage. WEBNLG exhibits a higher corrected type-token ratio (CTTR), which indicates greater lexical variety, and higher lexical sophistication (LS). Lexical sophistication measures the proportion of relatively unusual or advanced word types in the text. In practice, LS is the proportion of lexical word types (lemma) which are not in the list of 2,000 most frequent words generated from the British National Corpus[11]. Type-token ratio (TTR) is a measure of diversity defined as the ratio of the number of word types to the number of words in a text. To address the fact that this ratio tends to decrease with the size of the corpus, corrected TTR can be used to control for corpus size. It is defined as $T/\sqrt{2N}$, where T is the number of types and N the number of tokens.

Overall, the results shown in Table 4 indicate that WEBNLG texts are both lexically more diverse (higher corrected type/token ratio) and more sophisticated (higher proportion of unfrequent words) than RNNLG's. They also show a proportionately larger vocabulary for WEBNLG (2,992 types for 290,479 tokens in WEBNLG against 3,524 types for 531,871 tokens in RNNLG).

4.3 Neural Generation

Richer and more varied datasets are harder to learn from. As a proof-of-concept study of the comparative difficulty of the two datasets with respect to machine learning, we compare the performance of a sequence-to-sequence model for generation on both datasets.

We use the multi-layered sequence-to-sequence model with attention mechanism described in (Vinyals et al., 2015).[12] The model was trained with 3-layer LSTMs with 512 units each with a batch size of 64 and a learning rate of 0.5.

To allow for a fair comparison, we use a similar amount of data (13K data-text pairs) for both datasets. As RNNLG is bigger in size than WEBNLG, we constructed a balanced sample of RNNLG which included equal number of instances per category (*tv, laptop*, etc). We use a 3:1:1 ratio for training, developement and testing. The training was done in two delexicalisation modes: *fully* and *name only*. In case of fully delexicalisation, all entities were replaced by their generic terms, whereas in *name only* mode only subjects were modified in that way. For instance, the triple (*FC Köln manager Peter Stöger*) was delexicalised as (*SportsTeam manager Manager*) in the first mode, and as (*SportsTeam manager Peter Stöger*) in the second mode. The delexicalisation in sentences was done using the exact match between entities and tokens. For training, we use all the available vocabulary. Input and output vocabulary sizes are reported in Table 5.

Table 5 shows the perplexity results. In both modes, RNNLG yielded lower scores than WEBNLG. This is inline with the observations made above concerning the higher data diversity, larger vocabulary and more complex texts of

[11] We compute LS and CTTR using the Lexical Complexity Analyzer developed by Lu (2012).

[12] We used the TensorFlow code available at https://github.com/tensorflow/models/tree/master/tutorials/rnn/translate. Alternatively, we could have used the implementation of Wen et al. (2016) which is optimised for generation. However the code is geared toward dialog acts and modifying it to handle RDF triples is non trivial. Since the comparison aims at examining the relative performance of the same neural network on the two datasets, we used the tensor flow implementation instead.

WEBNLG. Similary, the BLEU score of the generated sentences (Papineni et al., 2002) is lower for WEBNLG suggesting again a dataset that is more complex and therefore more difficult to learn from.

	Delexicalisation Mode	WEBNLG	RNNLG
Vocab size	Fully	520, 2430	140, 1530
	Name only	1130, 2940	570, 1680
Perplexity	Fully	27.41	17.42
	Name only	25.39	23.93
BLEU	Fully	0.19	0.26
	Name only	0.10	0.27

Table 5: Vocabulary sizes of input, output (number of tokens). Perplexity and BLEU scores.

5 Conclusion

We presented a framework for building NLG data-to-text training corpora from existing knowledge bases.

One feature of our framework is that datasets created using this framework can be used for training and testing KB verbalisers an in particular, verbalisers for RDF knowledge bases. Following the development of the semantic web, many large scale datasets are encoded in the RDF language (e.g., MusicBrainz, FOAF, LinkedGeoData) and official institutions[13] increasingly publish their data in this format. In this context, our framework is useful both for creating training data from RDF KB verbalisers and to increase the number of datasets available for training and testing NLG.

Another important feature of our framework is that it permits creating semantically and linguistically diverse datasets which should support the learning of lexically and syntactically, wide coverage micro-planners. We applied our framework to DBpedia data and showed that although twice smaller than the largest corpora currently available for training data-to-text microplanners, the resulting dataset is more semantically and linguistically diverse. Despite the disparity in size, the number of attributes is comparable in the two datasets. The ratio between input and input patterns is five times lower in our dataset thereby making learning harder but also diminishing the risk of overfitting and providing for wider linguistic coverage. Conversely, the ratio of text per input is twice higher thereby providing better support for learning paraphrases.

[13]See http://museum-api.pbworks.com for examples.

We have recently released a first version of the WebNLG dataset in the context of a shared task on micro-planning[14]. This new dataset consists of 21,855 data/text pairs with a total of 8,372 distinct data input. The input describes entities belonging to 9 distinct DBpedia categories namely, Astronaut, University, Monument, Building, ComicsCharacter, Food, Airport, SportsTeam and WrittenWork. The WebNLG data is licensed under the following license: CC Attribution-Noncommercial-Share Alike 4.0 International and can be downloaded at http://talc1.loria.fr/webnlg/stories/challenge.html.

Recently, several sequence-to-sequence models have been proposed for generation. Our experiments suggest that these are not optimal when it comes to generate linguistically complex texts from rich data. More generally, they indicate that the data-to-text corpora built by our framework are challenging for such models. We hope that the WEBNLG dataset which we have made available for the WEBNLG shared task will drive the deep learning community to take up this new challenge and work on the development of neural generators that can handle the generation of KB verbalisers and of linguistically rich texts.

Abstract

In this paper, we present the gated self-matching networks for reading comprehension style question answering, which aims to answer questions from a given passage. We first match the question and passage with gated attention-based recurrent networks to obtain the question-aware passage representation. Then we propose a self-matching attention mechanism to refine the representation by matching the passage against itself, which effectively encodes information from the whole passage. We finally employ the pointer networks to locate the positions of answers from the passages. We conduct extensive experiments on the SQuAD dataset. The single model achieves 71.3% on the evaluation metrics of exact match on the hidden test set, while the ensemble model further boosts the results to 75.9%. At the time of submission of the paper, our model holds the first place on the SQuAD leaderboard for both single and ensemble model.

1 Introduction

In this paper, we focus on reading comprehension style question answering which aims to answer questions given a passage or document. We specifically focus on the Stanford Question Answering Dataset (SQuAD) (Rajpurkar et al., 2016), a large-scale dataset for reading comprehension and question answering which is manually created through crowdsourcing. SQuAD constrains answers to the space of all possible spans within the reference passage, which is different from cloze-style reading comprehension datasets (Hermann et al., 2015; Hill et al., 2016) in which answers are single words or entities. Moreover, SQuAD requires different forms of logical reasoning to infer the answer (Rajpurkar et al., 2016).

Rapid progress has been made since the release of the SQuAD dataset. Wang and Jiang (2016b) build question-aware passage representation with match-LSTM (Wang and Jiang, 2016a), and predict answer boundaries in the passage with pointer networks (Vinyals et al., 2015). Seo et al. (2016) introduce bi-directional attention flow networks to model question-passage pairs at multiple levels of granularity. Xiong et al. (2016) propose dynamic co-attention networks which attend the question and passage simultaneously and iteratively refine answer predictions. Lee et al. (2016) and Yu et al. (2016) predict answers by ranking continuous text spans within passages.

Inspired by Wang and Jiang (2016b), we introduce a gated self-matching network, illustrated in Figure 1, an end-to-end neural network model for reading comprehension and question answering. Our model consists of four parts: 1) the recurrent network encoder to build representation for questions and passages separately, 2) the gated matching layer to match the question and passage, 3) the self-matching layer to aggregate information from the whole passage, and 4) the pointer-network based answer boundary prediction layer. The key contributions of this work are three-fold.

First, we propose a gated attention-based recurrent network, which adds an additional gate to the attention-based recurrent networks (Bahdanau et al., 2014; Rocktäschel et al., 2015; Wang and Jiang, 2016a), to account for the fact that words in the passage are of different importance to answer a particular question for reading comprehension and question answering. In Wang and Jiang (2016a), words in a passage with their corresponding attention-weighted question context are en-

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 189–198
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1018

coded together to produce question-aware passage representation. By introducing a gating mechanism, our gated attention-based recurrent network assigns different levels of importance to passage parts depending on their relevance to the question, masking out irrelevant passage parts and emphasizing the important ones.

Second, we introduce a self-matching mechanism, which can effectively aggregate evidence from the whole passage to infer the answer. Through a gated matching layer, the resulting question-aware passage representation effectively encodes question information for each passage word. However, recurrent networks can only memorize limited passage context in practice despite its theoretical capability. One answer candidate is often unaware of the clues in other parts of the passage. To address this problem, we propose a self-matching layer to dynamically refine passage representation with information from the whole passage. Based on question-aware passage representation, we employ gated attention-based recurrent networks on passage against passage itself, aggregating evidence relevant to the current passage word from every word in the passage. A gated attention-based recurrent network layer and self-matching layer dynamically enrich each passage representation with information aggregated from both question and passage, enabling subsequent network to better predict answers.

Lastly, the proposed method yields state-of-the-art results against strong baselines. Our single model achieves 71.3% exact match accuracy on the hidden SQuAD test set, while the ensemble model further boosts the result to 75.9%. At the time[1] of submission of this paper, our model holds the first place on the SQuAD leader board.

2 Task Description

For reading comprehension style question answering, a passage **P** and question **Q** are given, our task is to predict an answer **A** to question **Q** based on information found in **P**. The SQuAD dataset further constrains answer **A** to be a continuous subspan of passage **P**. Answer **A** often includes non-entities and can be much longer phrases. This setup challenges us to understand and reason about both the question and passage in order to infer the answer. Table 1 shows a simple example from the SQuAD dataset.

[1] On Feb. 6, 2017

Passage: Tesla later approached Morgan to ask for more funds to build a more powerful transmitter. **When asked where all the money had gone, Tesla responded by saying that he was affected by the Panic of 1901**, which he (Morgan) had caused. Morgan was shocked by the reminder of his part in the stock market crash and by Tesla's breach of contract by asking for more funds. Tesla wrote another plea to Morgan, but it was also fruitless. Morgan still owed Tesla money on the original agreement, and Tesla had been facing foreclosure even before construction of the tower began.
Question: On what did Tesla blame for the loss of the initial money?
Answer: Panic of 1901

Table 1: An example from the SQuAD dataset.

3 Gated Self-Matching Networks

Figure 1 gives an overview of the gated self-matching networks. First, the question and passage are processed by a bi-directional recurrent network (Mikolov et al., 2010) separately. We then match the question and passage with gated attention-based recurrent networks, obtaining question-aware representation for the passage. On top of that, we apply self-matching attention to aggregate evidence from the whole passage and refine the passage representation, which is then fed into the output layer to predict the boundary of the answer span.

3.1 Question and Passage Encoder

Consider a question Q = $\{w_t^Q\}_{t=1}^m$ and a passage P = $\{w_t^P\}_{t=1}^n$. We first convert the words to their respective word-level embeddings ($\{e_t^Q\}_{t=1}^m$ and $\{e_t^P\}_{t=1}^n$) and character-level embeddings ($\{c_t^Q\}_{t=1}^m$ and $\{c_t^P\}_{t=1}^n$). The character-level embeddings are generated by taking the final hidden states of a bi-directional recurrent neural network (RNN) applied to embeddings of characters in the token. Such character-level embeddings have been shown to be helpful to deal with out-of-vocab (OOV) tokens. We then use a bi-directional RNN to produce new representation $u_1^Q, \ldots, u_m^Q$ and $u_1^P, \ldots, u_n^P$ of all words in the question and passage respectively:

$$u_t^Q = \text{BiRNN}_Q(u_{t-1}^Q, [e_t^Q, c_t^Q]) \quad (1)$$

$$u_t^P = \text{BiRNN}_P(u_{t-1}^P, [e_t^P, c_t^P]) \quad (2)$$

We choose to use Gated Recurrent Unit (GRU) (Cho et al., 2014) in our experiment since it performs similarly to LSTM (Hochreiter and Schmidhuber, 1997) but is computationally cheaper.

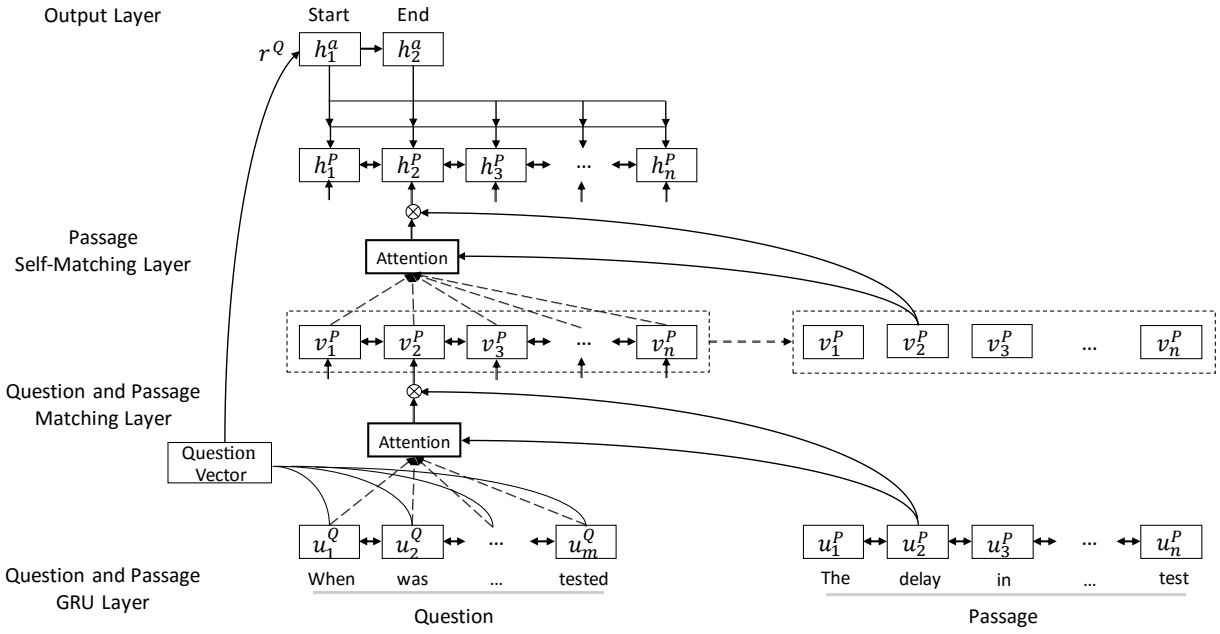

Figure 1: Gated Self-Matching Networks structure overview.

3.2 Gated Attention-based Recurrent Networks

We propose a gated attention-based recurrent network to incorporate question information into passage representation. It is a variant of attention-based recurrent networks, with an additional gate to determine the importance of information in the passage regarding a question. Given question and passage representation $\{u_t^Q\}_{t=1}^m$ and $\{u_t^P\}_{t=1}^n$, Rocktäschel et al. (2015) propose generating sentence-pair representation $\{v_t^P\}_{t=1}^n$ via soft-alignment of words in the question and passage as follows:

$$v_t^P = \text{RNN}(v_{t-1}^P, c_t) \tag{3}$$

where $c_t = att(u^Q, [u_t^P, v_{t-1}^P])$ is an attention-pooling vector of the whole question (u^Q):

$$\begin{aligned} s_j^t &= \text{v}^{\text{T}}\tanh(W_u^Q u_j^Q + W_u^P u_t^P + W_v^P v_{t-1}^P) \\ a_i^t &= \exp(s_i^t)/\Sigma_{j=1}^m \exp(s_j^t) \\ c_t &= \Sigma_{i=1}^m a_i^t u_i^Q \end{aligned} \tag{4}$$

Each passage representation v_t^P dynamically incorporates aggregated matching information from the whole question.

Wang and Jiang (2016a) introduce match-LSTM, which takes u_t^P as an additional input into the recurrent network:

$$v_t^P = \text{RNN}(v_{t-1}^P, [u_t^P, c_t]) \tag{5}$$

To determine the importance of passage parts and attend to the ones relevant to the question, we add another gate to the input ($[u_t^P, c_t]$) of RNN:

$$\begin{aligned} g_t &= \text{sigmoid}(W_g[u_t^P, c_t]) \\ [u_t^P, c_t]^* &= g_t \odot [u_t^P, c_t] \end{aligned} \tag{6}$$

Different from the gates in LSTM or GRU, the additional gate is based on the current passage word and its attention-pooling vector of the question, which focuses on the relation between the question and current passage word. The gate effectively model the phenomenon that only parts of the passage are relevant to the question in reading comprehension and question answering. $[u_t^P, c_t]^*$ is utilized in subsequent calculations instead of $[u_t^P, c_t]$. We call this gated attention-based recurrent networks. It can be applied to variants of RNN, such as GRU and LSTM. We also conduct experiments to show the effectiveness of the additional gate on both GRU and LSTM.

3.3 Self-Matching Attention

Through gated attention-based recurrent networks, question-aware passage representation $\{v_t^P\}_{t=1}^n$ is generated to pinpoint important parts in the passage. One problem with such representation is that it has very limited knowledge of context. One answer candidate is often oblivious to important

cues in the passage outside its surrounding window. Moreover, there exists some sort of lexical or syntactic divergence between the question and passage in the majority of SQuAD dataset (Rajpurkar et al., 2016). Passage context is necessary to infer the answer. To address this problem, we propose directly matching the question-aware passage representation against itself. It dynamically collects evidence from the whole passage for words in passage and encodes the evidence relevant to the current passage word and its matching question information into the passage representation h_t^P:

$$h_t^P = \text{BiRNN}(h_{t-1}^P, [v_t^P, c_t]) \tag{7}$$

where $c_t = att(v^P, v_t^P)$ is an attention-pooling vector of the whole passage (v^P):

$$\begin{aligned} s_j^t &= \text{v}^{\text{T}} \tanh(W_v^P v_j^P + W_v^{\tilde{P}} v_t^P) \\ a_i^t &= \exp(s_i^t) / \Sigma_{j=1}^n \exp(s_j^t) \\ c_t &= \Sigma_{i=1}^n a_i^t v_i^P \end{aligned} \tag{8}$$

An additional gate as in gated attention-based recurrent networks is applied to $[v_t^P, c_t]$ to adaptively control the input of RNN.

Self-matching extracts evidence from the whole passage according to the current passage word and question information.

3.4 Output Layer

We follow Wang and Jiang (2016b) and use pointer networks (Vinyals et al., 2015) to predict the start and end position of the answer. In addition, we use an attention-pooling over the question representation to generate the initial hidden vector for the pointer network. Given the passage representation $\{h_t^P\}_{t=1}^n$, the attention mechanism is utilized as a pointer to select the start position (p^1) and end position (p^2) from the passage, which can be formulated as follows:

$$\begin{aligned} s_j^t &= \text{v}^{\text{T}} \tanh(W_h^P h_j^P + W_{\text{h}}^a h_{t-1}^a) \\ a_i^t &= \exp(s_i^t) / \Sigma_{j=1}^n \exp(s_j^t) \\ p^t &= \arg\max(a_1^t, \ldots, a_n^t) \end{aligned} \tag{9}$$

Here h_{t-1}^a represents the last hidden state of the answer recurrent network (pointer network). The input of the answer recurrent network is the attention-pooling vector based on current predicted probability a^t:

$$\begin{aligned} c_t &= \Sigma_{i=1}^n a_i^t h_i^P \\ h_t^a &= \text{RNN}(h_{t-1}^a, c_t) \end{aligned} \tag{10}$$

When predicting the start position, h_{t-1}^a represents the initial hidden state of the answer recurrent network. We utilize the question vector r^Q as the initial state of the answer recurrent network. $r^Q = att(u^Q, V_r^Q)$ is an attention-pooling vector of the question based on the parameter V_r^Q:

$$\begin{aligned} s_j &= \text{v}^{\text{T}} \tanh(W_u^Q u_j^Q + W_{\text{v}}^Q V_r^Q) \\ a_i &= \exp(s_i) / \Sigma_{j=1}^m \exp(s_j) \\ r^Q &= \Sigma_{i=1}^m a_i u_i^Q \end{aligned} \tag{11}$$

To train the network, we minimize the sum of the negative log probabilities of the ground truth start and end position by the predicted distributions.

4 Experiment

4.1 Implementation Details

We specially focus on the SQuAD dataset to train and evaluate our model, which has garnered a huge attention over the past few months. SQuAD is composed of 100,000+ questions posed by crowd workers on 536 Wikipedia articles. The dataset is randomly partitioned into a training set (80%), a development set (10%), and a test set (10%). The answer to every question is a segment of the corresponding passage.

We use the tokenizer from Stanford CoreNLP (Manning et al., 2014) to preprocess each passage and question. The Gated Recurrent Unit (Cho et al., 2014) variant of LSTM is used throughout our model. For word embedding, we use pre-trained case-sensitive GloVe embeddings[2] (Pennington et al., 2014) for both questions and passages, and it is fixed during training; We use zero vectors to represent all out-of-vocab words. We utilize 1 layer of bi-directional GRU to compute character-level embeddings and 3 layers of bi-directional GRU to encode questions and passages, the gated attention-based recurrent network for question and passage matching is also encoded bidirectionally in our experiment. The hidden vector length is set to 75 for all layers. The hidden size used to compute attention scores is also 75. We also apply dropout (Srivastava et al., 2014) between layers with a dropout rate of 0.2. The model is optimized with AdaDelta (Zeiler, 2012) with an initial learning rate of 1. The ρ and ϵ used in AdaDelta are 0.95 and $1e^{-6}$ respectively.

4.2 Main Results

Two metrics are utilized to evaluate model performance: Exact Match (EM) and F1 score. EM measures the percentage of the prediction that matches one of the ground truth answers exactly. F1 measures the overlap between the prediction and ground truth answers which takes the maximum F1 over all of the ground truth answers. The scores on dev set are evaluated by the official script[3]. Since the test set is hidden, we are required to submit the model to Stanford NLP group to obtain the test scores.

Table 2 shows exact match and F1 scores on the dev and test set of our model and competing approaches[4]. The ensemble model consists of 20 training runs with the identical architecture and hyper-parameters. At test time, we choose the answer with the highest sum of confidence scores amongst the 20 runs for each question. As we can see, our method clearly outperforms the baseline and several strong state-of-the-art systems for both single model and ensembles.

4.3 Ablation Study

We do ablation tests on the dev set to analyze the contribution of components of gated self-matching networks. As illustrated in Table 3, the gated

[3]Downloaded from http://stanford-qa.com

[4]Extracted from SQuAD leaderboard http://stanford-qa.com on Feb. 6, 2017.

Figure 2: Part of the attention matrices for self-matching. Each row is the attention weights of the whole passage for the current passage word. The darker the color is the higher the weight is. Some key evidence relevant to the question-passage tuple is more encoded into answer candidates.

attention-based recurrent network (GARNN) and self-matching attention mechanism positively contribute to the final results of gated self-matching networks. Removing self-matching results in 3.5 point EM drop, which reveals that information in the passage plays an important role. Character-level embeddings contribute towards the model's performance since it can better handle out-of-vocab or rare words. To show the effectiveness of GARNN for variant RNNs, we conduct experiments on the base model (Wang and Jiang, 2016b) of different variant RNNs. The base model match the question and passage via a variant of attention-based recurrent network (Wang and Jiang, 2016a), and employ pointer networks to predict the answer. Character-level embeddings are not utilized. As shown in Table 4, the gate introduced in question and passage matching layer is helpful for both GRU and LSTM on the SQuAD dataset.

5 Discussion

5.1 Encoding Evidence from Passage

To show the ability of the model for encoding evidence from the passage, we draw the alignment of the passage against itself in self-matching. The attention weights are shown in Figure 2, in which the darker the color is the higher the weight is. We can see that key evidence aggregated from the whole passage is more encoded into the answer candidates. For example, the answer "Egg of Columbus" pays more attention to the key information "Tesla", "device" and the lexical variation word "known" that are relevant to the question-passage tuple. The answer "world classic of epoch-making oratory" mainly focuses on the evidence "Michael Mullet", "speech" and lexical variation word "considers". For other words, the attention weights are more evenly distributed between evidence and some irrelevant parts. Self-matching do adaptively aggregate evidence for words in passage.

5.2 Result Analysis

To further analyse the model's performance, we analyse the F1 score for different question types (Figure 3(a)), different answer lengths (Figure 3(b)), different passage lengths (Figure 3(c)) and different question lengths (Figure 3(d)) of our

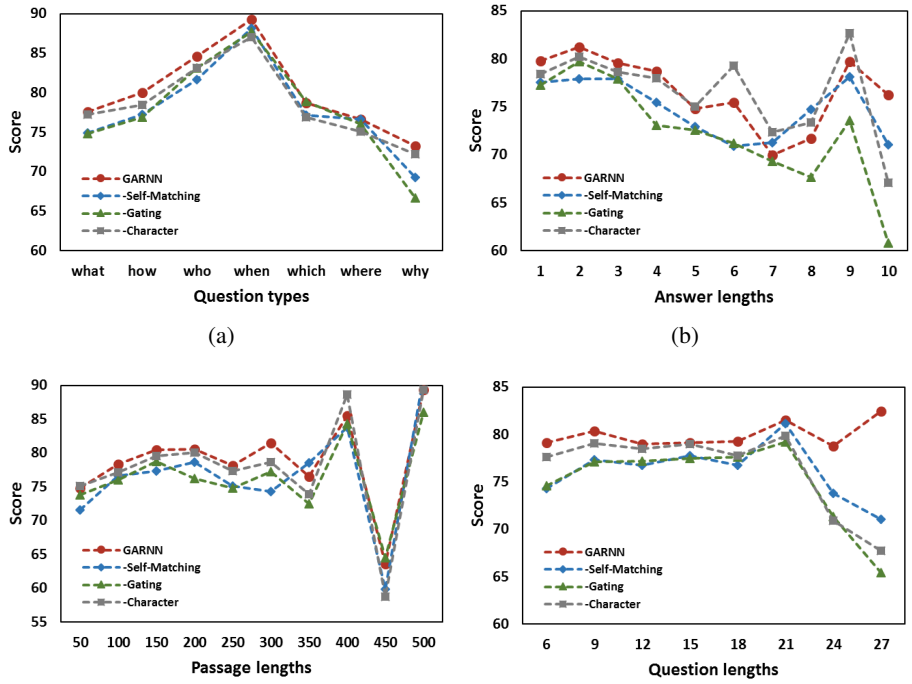

Figure 3: Model performance on different question types (a), different answer lengths (b), different passage lengths (c), different question lengths (d). The point on the x-axis of figure (c) and (d) represent the datas whose passages length or questions length are between the value of current point and last point.

model and its ablation models. As we can see, both four models show the same trend. The questions are split into different groups based on a set of question words we have defined, including "what", "how", "who", "when", "which", "where", and "why". As we can see, our model is better at "when" and "who" questions, but poorly on "why" questions. This is mainly because the answers to why questions can be very diverse, and they are not restricted to any certain type of phrases. From the Graph 3(b), the performance of our model obviously drops with the increase of answer length. Longer answers are harder to predict. From Graph 3(c) and 3(d), we discover that the performance remains stable with the increase in length, the obvious fluctuation in longer passages and questions is mainly because the proportion is too small. Our model is largely agnostic to long passages and focuses on important part of the passage.

6 Related Work

Reading Comprehension and Question Answering Dataset Benchmark datasets play an important role in recent progress in reading comprehension and question answering research. Existing datasets can be classified into two categories according to whether they are manually labeled. Those that are labeled by humans are always in high quality (Richardson et al., 2013; Berant et al., 2014; Yang et al., 2015), but are too small for training modern data-intensive models. Those that are automatically generated from natural occurring data can be very large (Hill et al., 2016; Hermann et al., 2015), which allow the training of more expressive models. However, they are in cloze style, in which the goal is to predict the missing word (often a named entity) in a passage. Moreover, Chen et al. (2016) have shown that the CNN / Daily News dataset (Hermann et al., 2015) requires less reasoning than previously thought, and conclude that performance is almost saturated.

Different from above datasets, the SQuAD provides a large and high-quality dataset. The answers in SQuAD often include non-entities and can be much longer phrase, which is more challenging than cloze-style datasets. Moreover, Rajpurkar et al. (2016) show that the dataset retains a diverse set of answers and requires different forms of logical reasoning, including multi-sentence reasoning. MS MARCO (Nguyen et al., 2016) is also a large-scale dataset. The questions in the dataset

are real anonymized queries issued through Bing or Cortana and the passages are related web pages. For each question in the dataset, several related passages are provided. However, the answers are human generated, which is different from SQuAD where answers must be a span of the passage.

End-to-end Neural Networks for Reading Comprehension Along with cloze-style datasets, several powerful deep learning models (Hermann et al., 2015; Hill et al., 2016; Chen et al., 2016; Kadlec et al., 2016; Sordoni et al., 2016; Cui et al., 2016; Trischler et al., 2016; Dhingra et al., 2016; Shen et al., 2016) have been introduced to solve this problem. Hermann et al. (2015) first introduce attention mechanism into reading comprehension. Hill et al. (2016) propose a window-based memory network for CBT dataset. Kadlec et al. (2016) introduce pointer networks with one attention step to predict the blanking out entities. Sordoni et al. (2016) propose an iterative alternating attention mechanism to better model the links between question and passage. Trischler et al. (2016) solve cloze-style question answering task by combining an attentive model with a reranking model. Dhingra et al. (2016) propose iteratively selecting important parts of the passage by a multiplying gating function with the question representation. Cui et al. (2016) propose a two-way attention mechanism to encode the passage and question mutually. Shen et al. (2016) propose iteratively inferring the answer with a dynamic number of reasoning steps and is trained with reinforcement learning.

Neural network-based models demonstrate the effectiveness on the SQuAD dataset. Wang and Jiang (2016b) combine match-LSTM and pointer networks to produce the boundary of the answer. Xiong et al. (2016) and Seo et al. (2016) employ variant coattention mechanism to match the question and passage mutually. Xiong et al. (2016) propose a dynamic pointer network to iteratively infer the answer. Yu et al. (2016) and Lee et al. (2016) solve SQuAD by ranking continuous text spans within passage. Yang et al. (2016) present a fine-grained gating mechanism to dynamically combine word-level and character-level representation and model the interaction between questions and passages. Wang et al. (2016) propose matching the context of passage with the question from multiple perspectives.

Different from the above models, we introduce self-matching attention in our model. It dynamically refines the passage representation by looking over the whole passage and aggregating evidence relevant to the current passage word and question, allowing our model make full use of passage information. Weightedly attending to word context has been proposed in several works. Ling et al. (2015) propose considering window-based contextual words differently depending on the word and its relative position. Cheng et al. (2016) propose a novel LSTM network to encode words in a sentence which considers the relation between the current token being processed and its past tokens in the memory. Parikh et al. (2016) apply this method to encode words in a sentence according to word form and its distance. Since passage information relevant to question is more helpful to infer the answer in reading comprehension, we apply self-matching based on question-aware representation and gated attention-based recurrent networks. It helps our model mainly focus on question-relevant evidence in the passage and dynamically look over the whole passage to aggregate evidence.

Another key component of our model is the attention-based recurrent network, which has demonstrated success in a wide range of tasks. Bahdanau et al. (2014) first propose attention-based recurrent networks to infer word-level alignment when generating the target word. Hermann et al. (2015) introduce word-level attention into reading comprehension to model the interaction between questions and passages. Rocktäschel et al. (2015) and Wang and Jiang (2016a) propose determining entailment via word-by-word matching. The gated attention-based recurrent network is a variant of attention-based recurrent network with an additional gate to model the fact that passage parts are of different importance to the particular question for reading comprehension and question answering.

7 Conclusion

In this paper, we present gated self-matching networks for reading comprehension and question answering. We introduce the gated attention-based recurrent networks and self-matching attention mechanism to obtain representation for the question and passage, and then use the pointer-networks to locate answer boundaries. Our model achieves state-of-the-art results on the SQuAD

dataset, outperforming several strong competing systems. As for future work, we are applying the gated self-matching networks to other reading comprehension and question answering datasets, such as the MS MARCO dataset (Nguyen et al., 2016).

Abstract

Generating answer with natural language sentence is very important in real-world question answering systems, which needs to obtain a right answer as well as a coherent natural response. In this paper, we propose an end-to-end question answering system called COREQA in sequence-to-sequence learning, which incorporates copying and retrieving mechanisms to generate natural answers within an encoder-decoder framework. Specifically, in COREQA, the semantic units (words, phrases and entities) in a natural answer are dynamically predicted from the vocabulary, copied from the given question and/or retrieved from the corresponding knowledge base jointly. Our empirical study on both synthetic and real-world datasets demonstrates the efficiency of COREQA, which is able to generate correct, coherent and natural answers for knowledge inquired questions.

1 Introduction

Question answering (QA) systems devote to providing exact answers, often in the form of phrases and entities for natural language questions (Woods, 1977; Ferrucci et al., 2010; Lopez et al., 2011; Yih et al., 2015), which mainly focus on analyzing questions, retrieving related facts from text snippets or knowledge bases (KBs), and finally predicting the answering semantic units-**SU** (words, phrases and entities) through ranking (Yao and Van Durme, 2014) and reasoning (Kwok et al., 2001).

However, in real-world environments, most people prefer the correct answer replied with a more natural way. For example, most existing commercial products such as Siri[1] will reply a natural answer "*Jet Li is 1.64m in height.*" for the question "*How tall is Jet Li?*", rather than only answering one entity "*1.64m*". Basic on this observation, we define the "natural answer" as the natural response in our daily communication for replying factual questions, which is usually expressed in a complete/partial natural language sentence rather than a single entity/phrase. In this case, the system needs to not only parse question, retrieve relevant facts from KB but also generate a proper reply. To this end, most previous approaches employed message-response patterns. Figure 1 schematically illustrates the major steps and features in this process. The system first needs to recognize the topic entity "*Jet Li*" in the question and then extract multiple related facts *<Jet Li, gender, Male>*, *<Jet Li, birthplace, Beijing>* and *<Jet Li, nationality, Singapore>* from KB. Based on the chosen facts and the commonly used message-response patterns "*where was %entity from?*" - "*%entity was born in %birthplace, %pronoun is %nationality citizen.*"[2], the system could finally generate the natural answer (McTear et al., 2016).

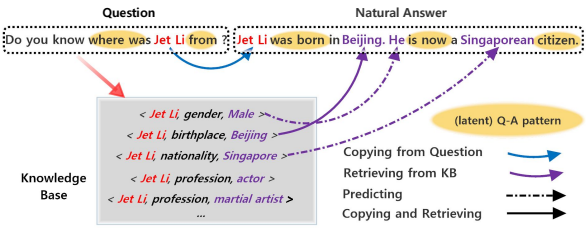

Figure 1: Incorporating copying and retrieving mechanisms in generating a natural answer.

In order to generate natural answers, typical

[2] In this pattern, *%entity* indicates the placeholder of the topic entity, *%property* indicates the property value of the topic entity.

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 199–208
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1019

products need lots of Natural Language Processing (NLP) tools and pattern engineering (McTear et al., 2016), which not only suffers from high costs of manual annotations for training data and patterns, but also have low coverage that cannot flexibly deal with variable linguistic phenomena in different domains. Therefore, this paper devotes to develop an end-to-end paradigm that generates natural answers without any NLP tools (e.g. POS tagging, parsing, etc.) and pattern engineering. This paradigm tries to consider question answering in an end-to-end framework. In this way, the complicated QA process, including analyzing question, retrieving relevant facts from KB, and generating correct, coherent, natural answers, could be resolved jointly.

Nevertheless, generating natural answers in an end-to-end manner is not an easy task. The key challenge is that the words in a natural answer may be generated by different ways, including: *1)* the common words usually are predicted using a (conditional) language model (e.g. "*born*" in Figure 1); *2)* the major entities/phrases are selected from the source question (e.g. "*Jet Li*"); *3)* the answering entities/phrases are retrieved from the corresponding KB (e.g. "*Beijing*"). In addition, some words or phrases even need to be inferred from related knowledge (e.g. "*He*" should be inferred from the value of "*gender*"). And we even need to deal with some morphological variants (e.g. "*Singapore*" in KB but "*Singaporean*" in answer). Although existing end-to-end models for KB-based question answering, such as GenQA (Yin et al., 2016), were able to retrieve facts from KBs with neural models. Unfortunately, they cannot copy SUs from the question in generating answers. Moreover, they could not deal with complex questions which need to utilize multiple facts. In addition, existing approaches for conversational (Dialogue) systems are able to generate natural utterances (Serban et al., 2016; Li et al., 2016) in sequence-to-sequence learning (Seq2Seq). But they cannot interact with KB and answer information-inquired questions. For example, CopyNet (Gu et al., 2016) is able to copy words from the original source in generating the target through incorporating copying mechanism in conventional Seq2Seq learning, but they cannot retrieve SUs from external memory (e.g. KBs, Texts, etc.).

Therefore, facing the above challenges, this paper proposes a neural generative model called COREQA with Seq2Seq learning, which is able to reply an answer in a natural way for a given question. Specifically, we incorporate **CO**pying and **RE**trieving mechanisms within Seq2Seq learning. COREQA is able to analyze the question, retrieve relevant facts and generate a sequence of SUs using a hybrid method with a completely end-to-end learning framework. We conduct experiments on both synthetic data sets and real-world datasets, and the experimental results demonstrate the efficiency of COREQA compared with existing end-to-end QA/Dialogue methods.

In brief, our main contributions are as follows:

- We propose a new and practical question answering task which devotes to generating natural answers for information inquired questions. It can be regarded as a fusion task of QA and Dialogue.
- We propose a neural network based model, named as COREQA, by incorporating copying and retrieving mechanism in Seq2Seq learning. In our knowledge, it is the first end-to-end model that could answer complex questions in a natural way.
- We implement experiments on both synthetic and real-world datasets. The experimental results demonstrate that the proposed model could be more effective for generating correct, coherent and natural answers for knowledge inquired questions compared with existing approaches.

2 Background: Neural Models for Sequence-to-Sequence Learning

2.1 RNN Encoder-Decoder

Recurrent Neural Network (RNN) based Encoder-Decoder is the backbone of Seq2Seq learning (Cho et al., 2014). In the Encoder-Decoder framework, an encoding RNN first transform a source sequential object $X = [x_1, ..., x_{L_X}]$ into an encoded representation $\mathbf{c}$. For example, we can utilize the basic model: $\mathbf{h}_t = f(x_t, \mathbf{h}_{t-1}); \mathbf{c} = \phi(\mathbf{h}_1, ..., \mathbf{h}_{L_X})$, where $\{\mathbf{h}_t\}$ are the RNN hidden states, $\mathbf{c}$ is the context vector which could be assumed as an abstract representation of X. In practice, gated RNN variants such as LSTM (Hochreiter and Schmidhuber, 1997) and GRU (Chung et al., 2014) are commonly used for learning long-term dependencies. And the another encoding

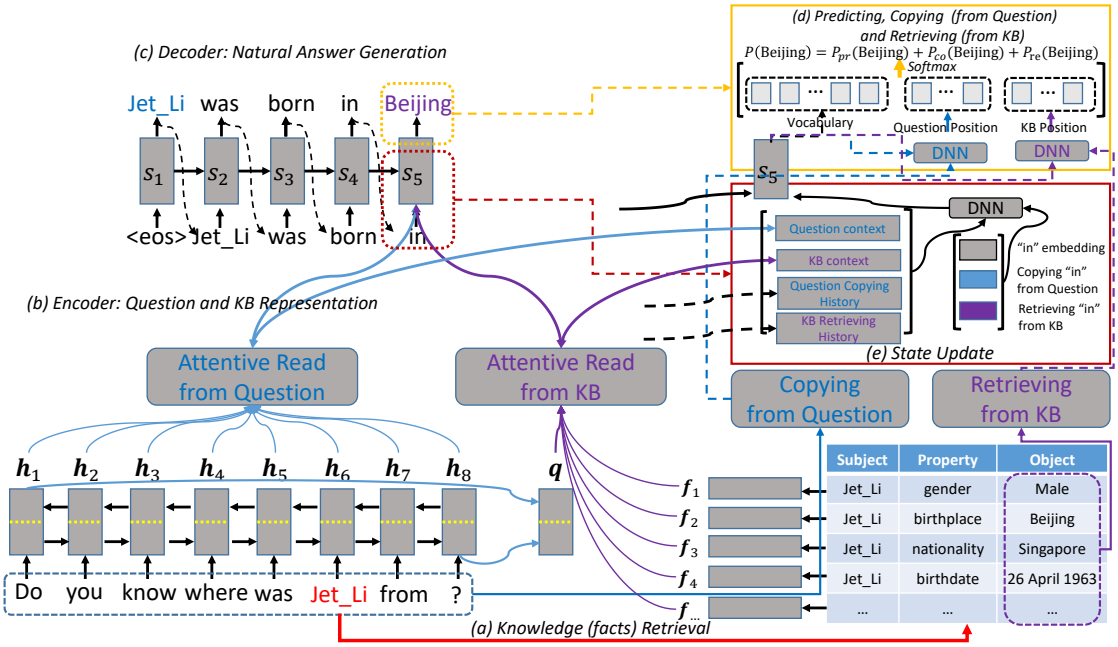

Figure 2: The overall diagram of COREQA.

tricks is Bi-directional RNN, which connect two hidden states of positive time direction and negative time direction. Once the source sequence is encoded, another decoding RNN model is to generate a target sequence $Y = [y_1, ..., y_{L_Y}]$, through the following prediction model: $\mathbf{s}_t = f(y_{t-1}, \mathbf{s}_{t-1}, \mathbf{c})$; $p(y_t|y_{<t}, X) = g(y_{t-1}, \mathbf{s}_t, \mathbf{c})$, where $\mathbf{s}_t$ is the RNN hidden state at time t, the predicted target word y_t at time t is typically performed by a $softmax$ classifier over a settled vocabulary (e.g. 30,000 words) through function g.

2.2 The Attention Mechanism

The prediction model of classical decoders for each target word y_i share the same context vector $\mathbf{c}$. However, a fixed vector is not enough to obtain a better result on generating a long targets.The attention mechanism in the decoding can dynamically choose context $\mathbf{c}_t$ at each time step (Bahdanau et al., 2014), for example, representing $\mathbf{c}_t$ as the weighted sum of the source states $\{\mathbf{h}_t\}$,

$$\mathbf{c}_t = \sum_{i=1}^{L_X} \alpha_{ti}\mathbf{h}_i; \quad \alpha_{ti} = \frac{e^{\rho(\mathbf{s}_{t-1}, \mathbf{h}_i)}}{\sum_{i'} e^{\rho(\mathbf{s}_{t-1}, \mathbf{h}'_i)}} \quad (1)$$

where the function ρ use to compute the attentive strength with each source state, which usually adopts a neural network such as multi-layer perceptron (MLP).

2.3 The Copying Mechanism

Seq2Seq learning heavily rely on the "meaning" for each word in source and target sequences, however, some words in sequences are "no-meaning" symbols and it is improper to encode them in encoding and decoding processes. For example, generating the response *"Of course, read"* for replying the message *"Can you read the word 'read'?"* should not consider the meaning of the second *"read"*. By incorporating the copying mechanism, the decoder could directly copy the sub-sequences of source into the target (Vinyals et al., 2015). The basic approach is to jointly predict the indexes of the target word in the fixed vocabulary and/or matched positions in the source sequences (Gu et al., 2016; Gulcehre et al., 2016).

3 COREQA

To generate natural answers for information inquired questions, we should first recognize key topics in the question, then extract related facts from KB, and finally fusion those instance-level knowledge with some global-level "smooth" and "glue" words to generate a coherent reply. In this section, we present COREQA, a differentiable Seq2Seq model to generate natural answers, which is able to analyze the question, retrieve relevant facts and predict SUs in an end-to-end fashion, and the predicted SUs may be predicted from the vo-

cabulary, copied from the given question, and/or retrieved from the corresponding KB.

3.1 Model Overview

As illustrated in Figure 2, COREQA is an encoder-decoder framework plugged with a KB engineer. A knowledge retrieval module is firstly employed to retrieve related facts from KB by question analysis (see Section 3.2). And then the input question and the retrieved facts are transformed into the corresponding representations by **Encoders** (see Section 3.3). Finally, the encoded representations are feed to **Decoder** for generating the target natural answer (see Section 3.4).

3.2 Knowledge (facts) Retrieval

We mainly focus on answering the information inquired questions (factual questions, and each question usually contains one or more topic entities). This paper utilizes the gold topic entities for simplifying our design. Given the topic entities, we retrieve the related facts from the corresponding KB. KB consists of many relational data, which usually are sets of inter-linked subject-property-object (*SPO*) triple statements. Usually, question contains the information used to match the *subject* and *property* parts in a fact triple, and answer incorporates the *object* part information.

3.3 Encoder

The encoder transforms all discrete input symbols (including words, entities, properties and properties' values) and their structures into numerical representations which are able to feed into neural models (Weston et al., 2014).

3.3.1 Question Encoding

Following (Gu et al., 2016), a bi-directional RNN (Schuster and Paliwal, 1997) is used to transform the question sequence into a sequence of concatenated hidden states with two independent RNNs. The forward and backward RNN respectively obtain $\{\overrightarrow{\mathbf{h}}_1, ..., \overrightarrow{\mathbf{h}}_{L_X}\}$ and $\{\overleftarrow{\mathbf{h}}_{L_X}, ..., \overleftarrow{\mathbf{h}}_1\}$. The concatenated representation is considered to be the short-term memory of question ($\mathbf{M}_Q = \{\mathbf{h}_t\}, \mathbf{h}_t = [\overrightarrow{\mathbf{h}}_t, \overleftarrow{\mathbf{h}}_{L_X-t+1}]$). $\mathbf{q} = [\overrightarrow{\mathbf{h}}_{L_X}, \overleftarrow{\mathbf{h}}_1]$ is used to represent the entire question, which could be used to compute the similarity between the question and the retrieved facts.

3.3.2 Knowledge Base Encoding

We use s, p and o denote the subject, property and object (value) of one fact f, and $\mathbf{e}_s$, $\mathbf{e}_p$ and $\mathbf{e}_o$ to denote its corresponding embeddings. The fact representation $\mathbf{f}$ is then defined as the concatenation of $\mathbf{e}_s$, $\mathbf{e}_p$ and $\mathbf{e}_o$. The list of all related facts' representations, $\{\mathbf{f}\} = \{\mathbf{f}_1, ..., \mathbf{f}_{L_F}\}$ (refer to $\mathbf{M}_{KB}$, L_F denotes the maximum of candidate facts), is considered to be a short-term memory of KB while answering questions about the topic entities.

In addition, given the distributed representation of question and candidate facts, we define the matching scores function between question and facts as $S(q, f_j) = DNN_1(\mathbf{q}, \mathbf{f}_j) = tanh(\mathbf{W}_2 \cdot tanh(\mathbf{W}_1 \cdot [\mathbf{q}, \mathbf{f}_j] + \mathbf{b}_1) + \mathbf{b}_2)$, , where DNN_1 is the matching function defined by a two-layer perceptron, $[\cdot, \cdot]$ denotes vector concatenation, and $\mathbf{W}_1$, $\mathbf{W}_2$, $\mathbf{b}_1$ and $\mathbf{b}_2$ are the learning parameters. In fact, we will make a slight change of the matching function because it will also depend on the state of decoding process at different times. The modified function is $S(q, s_t, f_j) = DNN_1(\mathbf{q}, \mathbf{s}_t, \mathbf{f}_j)$ where s_t is the hidden state of decoder at time t.

3.4 Decoder

The decoder uses an RNN to generate a natural answer based on the short-term memory of question and retrieved facts which represented as $\mathbf{M}_Q$ and $\mathbf{M}_{KB}$, respectively. The decoding process of COREQA have the following differences compared with the conventional decoder:

Answer words prediction: COREQA predicts SUs based on a mixed probabilistic model of three modes, namely the ***predict-mode***, the ***copy-mode*** and the ***retrieve-mode***, where the first mode predicts words with the vocabulary, and the two latter modes pick SUs from the questions and matched facts, respectively;

State update: the predicted word at step $t-1$ is used to update $\mathbf{s}_t$, but COREQA uses not only its word embedding but also its corresponding positional attention informations in $\mathbf{M}_Q$ and $\mathbf{M}_{KB}$;

Reading short-Memory $\mathbf{M}_Q$ and $\mathbf{M}_{KB}$: $\mathbf{M}_Q$ and $\mathbf{M}_{KB}$ are fed into COREQA with two ways, the first one is the "meaning" with embeddings and the second one is the positions of different words (properties' values).

3.4.1 Answer Words Prediction

The generated words (entities) may come from vocabulary, source question and matched KB. Accordingly, our model use three correlative output

layer: *shortlist* prediction layer, *question location* copying layer and *candidate-facts location* retrieving layer, respectively. And we use the $softmax$ classifier of the above three cascaded output layers to pick SUs. We assume a vocabulary $\mathcal{V} = \{v_1, ..., v_N\} \cup \{\text{UNK}\}$, where UNK indicates any out-of-vocabulary (OOV) words. Therefore, we have adopted another two set of SUs $\mathcal{X}_Q$ and $\mathcal{X}_{KB}$ which cover words/entities in the source question and the partial KB. That is, we have adopted the instance-specific vocabulary $\mathcal{V} \cup \mathcal{X}_Q \cup \mathcal{X}_{KB}$ for each question. It's important to note that these three vocabularies $\mathcal{V}$, $\mathcal{X}_Q$ and $\mathcal{X}_{KB}$ may overlap.

At each time step t in the decoding process, given the RNN state $\mathbf{s}_t$ together with $\mathbf{M}_Q$ and $\mathbf{M}_{KB}$, the probabilistic function for generating any target SU y_t is a "mixture" model as follow

$$\begin{aligned} &p(y_t|\mathbf{s}_t, y_{t-1}, \mathbf{M}_Q, \mathbf{M}_{KB}) = \\ &p_{pr}(y_t|\mathbf{s}_t, y_{t-1}, \mathbf{c}_t) \cdot p_m(pr|\mathbf{s}_t, y_{t-1}) + \\ &p_{co}(y_t|\mathbf{s}_t, y_{t-1}, \mathbf{M}_Q) \cdot p_m(co|\mathbf{s}_t, y_{t-1}) + \\ &p_{re}(y_t|\mathbf{s}_t, y_{t-1}, \mathbf{M}_{KB}) \cdot p_m(re|\mathbf{s}_t, y_{t-1}) \end{aligned} \tag{2}$$

where pr, co and re stand for the predict-mode, the copy-mode and the retrieve-mode, respectively, $p_m(\cdot|\cdot)$ indicates the probability model for choosing different modes (we use a $softmax$ classifier with two-layer MLP). The probability of the three modes are given by

$$\begin{aligned} p_{pr}(y_t|\cdot) &= \frac{1}{Z} e^{\psi_{pr}(y_t)} \\ p_{co}(y_t|\cdot) &= \frac{1}{Z} \sum\nolimits_{j:Q_j=y_t} e^{\psi_{co}(y_t)} \\ p_{re}(y_t|\cdot) &= \frac{1}{Z} \sum\nolimits_{j:KB_j=y_t} e^{\psi_{re}(y_t)} \end{aligned} \tag{3}$$

where $\psi_{pr}(\cdot)$, $\psi_{co}(\cdot)$ and $\psi_{re}(\cdot)$ are score functions for choosing SUs in predict-mode (from $\mathcal{V}$), copy-mode (from $\mathcal{X}_Q$) and retrieve-mode (from $\mathcal{X}_{KB}$), respectively. And Z is the normalization term shared by the three modes, $Z = e^{\psi_{pr}(v)} + \sum_{j:Q_j=v} e^{\psi_{co}(v)} + \sum_{j:KB_j=v} e^{\psi_{re}(v)}$. And the three modes could compete with each other through a $softmax$ function in generating target SUs with the shared normalization term (as shown in Figure 2. Specifically, the scoring functions of each mode are defined as follows:

Predict-mode: Some generated words need reasoning (e.g. "He" in Figure 1) and morphological transformation (e.g. "Singaporean" in Figure 1). Therefore, we modify the function as $\psi_{pr}(y_t = v_i) = \mathbf{v}_i^T \mathbf{W}_{pr}[\mathbf{s}_t, \mathbf{c}_{q_t}, \mathbf{c}_{kb_t}]$, where $\mathbf{v}_i \in \mathcal{R}^{d_o}$ is the word vector at the output layer (not the input word embedding), $\mathbf{W}_{pr} \in \mathcal{R}^{(d_h+d_i+d_f)\times d_o}$ (d_i, d_h and d_f indicate the size of input word vector, RNN decoder hidden state and fact representation respectively), and $\mathbf{c}_{q_t}$ and $\mathbf{c}_{kb_t}$ are the temporary memory of reading $\mathbf{M}_Q$ and $\mathbf{M}_{KB}$ at time t (see Section 3.4.3).

***Co*py-mode**: The score for "copying" the word x_j from question Q is calculated as $\psi_{co}(y_t = x_j) = DNN_2(\mathbf{h}_j, \mathbf{s}_t, \mathbf{hist}_Q)$, where DNN_2 is a neural network function with a two-layer MLP and $\mathbf{hist}_Q \in \mathcal{R}^{L_X}$ is an accumulated vector which record the attentive history for each word in question (similar with the coverage vector in (Tu et al., 2016)).

***Re*trieve-mode**: The score for "retrieving" the entity word v_j from retrieval facts ("Object" part) is calculated as $\psi_{re}(y_t = v_j) = DNN_3(\mathbf{f}_j, \mathbf{s}_t, \mathbf{hist}_{KB})$, where DNN_3 is also a neural network function and $\mathbf{hist}_{KB} \in \mathcal{R}^{L_F}$ is an accumulated vector which record the attentive history for each fact in candidate facts.

3.4.2 State Update

In the generic decoding process, each RNN hidden state $\mathbf{s}_t$ is updated with the previous state $\mathbf{s}_{t-1}$, the word embedding of previous predicted symbol y_{t-1}, and an optional context vector $\mathbf{c}_t$ (with attention mechanism). However, y_{t-1} may not come from vocabulary $\mathcal{V}$ and not owns a word vector. Therefore, we modify the state update process in COREQA. More specifically, y_{t-1} will be represented as concatenated vector of $[\mathbf{e}(y_{t-1}), \mathbf{r}_{q_{t-1}}, \mathbf{r}_{kb_{t-1}}]$, where $\mathbf{e}(y_{t-1})$ is the word embedding associated with y_{t-1}, $\mathbf{r}_{q_{t-1}}$ and $\mathbf{r}_{kb_{t-1}}$ are the weighted sum of hidden states in $\mathbf{M}_Q$ and $\mathbf{M}_{KB}$ corresponding to y_{t-1} respectively.

$$\begin{aligned} \mathbf{r}_{q_t} &= \sum\nolimits_{j=1}^{L_X} \rho_{tj} \mathbf{h}_j, \mathbf{r}_{kb_t} = \sum\nolimits_{j=1}^{L_F} \delta_{tj} \mathbf{f}_j \\ \rho_{tj} &= \begin{cases} \frac{1}{K_1} p_{co}(x_j|\cdot), & x_j = y_t \\ \mathbf{0} & otherwise \end{cases} \\ \delta_{tj} &= \begin{cases} \frac{1}{K_2} p_{re}(f_j|\cdot), & object(f_j) = y_t \\ \mathbf{0} & otherwise \end{cases} \end{aligned} \tag{4}$$

where $object(f)$ indicate the "object" part of fact f (see Figure 2), and K_1 and K_2 are the normalization terms which equal $\sum_{j':x'_j=y_t} p_{co}(x'_j|\cdot)$ and $\sum_{j':object(f'_j)=y_t} p_{re}(f'_j|\cdot)$, respectively, and it

could consider the multiple positions matching y_t in source question and KB.

3.4.3 Reading short-Memory $\mathbf{M}_Q$ and $\mathbf{M}_{KB}$

COREQA employ the attention mechanism at decoding process. At each decoder time t, we selective read the context vector $\mathbf{c}_{q_t}$ and $\mathbf{c}_{kb_t}$ from the short-term memory of question $\mathbf{M}_Q$ and retrieval facts $\mathbf{M}_{KB}$ (alike to Formula 1). In addition, the accumulated attentive vectors $\mathbf{hist}_Q$ and $\mathbf{hist}_{KB}$ are able to record the positional information of SUs in the source question and retrieved facts.

3.5 Training

Although some target SUs in answer are copied and retrieved from the source question and the external KB respectively, COREQA is fully differential and can be optimized in an end-to-end manner using back-propagation. Given the batches of the source questions $\{X\}_M$ and target answers $\{Y\}_M$ both expressed with natural language (symbolic sequences), the objective function is to minimize the negative log-likelihood:

$$\mathcal{L} = -\frac{1}{N}\sum_{k=1}^{M}\sum_{t=1}^{L_Y} log[p(y_t^{(k)}|y_{<t}^{(k)}, X^{(k)}] \quad (5)$$

where the superscript (k) indicates the index of one question-answer (Q-A) pair. The network is no need for any additional labels for training models, because the three modes sharing the same $softmax$ classifier for predicting target words, they can learn to coordinate with each other by maximizing the likelihood of observed Q-A pairs.

4 Experiments

In this section, we present our main experimental results in two datasets. The first one is a small synthetic dataset in a restricted domain (only involving four properties of persons) (Section 4.1). The second one is a big dataset in open domain, where the Q-A pairs are extracted from community QA website and grounded against a KB with an Integer Linear Programming (ILP) method (Section 4.2). COREQA and all baseline models are trained on a NVIDIA TITAN X GPU using TensorFlow[3] tools, where we used the Adam (Kingma and Ba, 2014) learning rule to update gradients in all experimental configures. The sources codes and data will be released at the personal homepage of the first author[4].

4.1 Natural QA in Restricted Domain

Task: The QA systems need to answer questions involving 4 concrete properties of birthdate (including `year`, `month` and `day`) and `gender`). Through merely involving 4 properties, there are plenty of QA patterns which focus on different aspects of birthdate, for example, "*What year were you born?*" touches on "`year`", but "*When is your birthday?*" touches on "`month` and `day`".

Dataset: Firstly, 108 different Q-A patterns have been constructed by two annotators, one in charge of raising question patterns and another one is responsible for generating corresponding suitable answer patterns, e.g. `When is` $\%e$ `birthday?` $\rightarrow$ `She was born in` $\%m$ $\%d$`th.` where the variables $\%e$, $\%y$, $\%m$, $\%d$ and $\%g$ (deciding *she* or *he*) indicates the person's name, birth year, birth month, birth day and gender, respectively. Then we randomly generate a KB which contains 80,000 person entities, and each entity including four facts. Given KB facts, we can finally obtain specific Q-A pairs. And the sampling KB, patterns, and the generated Q-A pairs are shown in Table 1. In order to maintain the diversity, we randomly select 6 patterns for each person. Finally, we totally obtain 239,934 sequences pairs (half patterns may be unmatched because of "gender" property).

Q-A Patterns	**Examples** (e.g. KB facts (e2,year,1987);(e2,month,6); (e2,day,20);(e2,gender,male))
When is $\%e$ birthday? He was born in $\%m$ $\%d$th.	When is e2 birthday? He was born in June 20th.
What year were $\%e$ born? $\%e$ is born in $\%y$ year.	What year were e2 born? e2 is born in 1987 year.

Table 1: Sample KB facts, patterns and their generated Q-A pairs.

Experimental Setting: The total 239,934 Q-A pairs are split into training (90%) and testing set (10%). The baseline includes 1) generic RNN Encoder-Decoder (marked as *RNN*), 2) Seq2Seq with attention (marked as *RNN+atten*), 3) *CopyNet*, and 4) *GenQA*. For a fair comparison, we use bi-directional LSTM for encoder and another LSTM for decoder for all Seq2Seq models, with hidden layer size = 600 and word embedding dimen-

[3]https://www.tensorflow.org/

[4]http://www.nlpr.ia.ac.cn/cip/shizhuhe/publications.html

sion = 200. We set L_F as 5.

Metrics: We adopt (**automatic evaluation (AE)** to test the effects of different models. **AE** considers the precisions of the entire predicted answers and four specific properties, and the answer is complete correct only when all predicted properties' values is right. To measure the performance of the proposed method, we select following metrics, including P_g[5], P_y, P_m and P_d which denote the precisions for 'gender', 'year', 'month' and 'day' properties, respectively. And P_A, R_A and $F1_A$ indicate the precision, recall and F1 in the complete way.

Experimental Results: The **AE** experimental results are shown in Table 2. It is very clear from Table 2 that COREQA significantly outperforms all other compared methods. The reason of the GenQA's poor performance is that all synthetic questions need multiple facts, and GenQA will "safely" choose the most frequent property ("gender") for all questions. We also found the performances on "year" and "day" have a little worse than other properties such as "gender", it may because there have more ways to answer questions about "year" and "day".

Models	P_g	P_y	P_m	P_d	P_A	R_A	$F1_A$
RNN	72.2	0	1.1	0.2	0	27.5	0
RNN+atten	55.8	1.1	11.3	9.5	1.7	34	3.2
CopyNet	75.2	8.7	28.3	5.8	3.7	32.5	6.7
GenQA	73.4	0	0	0	0	27.1	0
COREQA	**100**	**84.8**	**93.4**	**81**	**87.4**	**94**	**90.6**

Table 2: The AE results (%) on synthetic test data.

Discussion: Because of the feature of directly "hard" copy and retrieve SUs from question and KB, COREQA could answer questions about unseen entities.To evaluate the effects of answering questions about unseen entities, we re-construct 2,000 new person entities and their corresponding facts about four known properties, and obtain 6,081 Q-A pairs through matching the sampling patterns mentioned above. The experimental results are shown in Table 3, it can be seen that the performance did not fall too much.

Entities	P_g	P_y	P_m	P_d	P_A	R_A	$F1_A$
Seen	100	84.8	93.4	81	87.4	94	90.6
Unseen	75.1	84.5	93.5	81.2	63.8	85.1	73.1

Table 3: The AE (%) for seen and unseen entities.

[5]The "gender" is right when the entity name (e.g. 'e2') or the personal pronoun (e.g. 'She') in answer is correct.

4.2 Natural QA in Open Domain

Task: To test the performance of the proposed approach in open domains, we modify the task of GenQA (Yin et al., 2016) for supporting multi-facts (a typical example is shown in Figure 1). That is, a natural QA system should generate a sequence of SUs as the natural answer for a given natural language question through interacting with a KB.

Dataset: GenQA have released a corpus[6], which contains a crawling KB and a set of ground Q-A pairs. However, the original Q-A pairs only matched with just one single fact. In fact, we found that a lot of questions need more than one fact (about 20% based on sampling inspection). Therefore, we crawl more Q-A pairs from Chinese community QA website (Baidu Zhidao[7]). Combined with the originally published corpus, we create a lager and better-quality data for natural question answering. Specifically, an Integral Linear Programming (ILP) based method is employed to automatically construct "grounding" Q-A pairs with the facts in KB (inspired by the work of adopting ILP to parse questions (Yahya et al., 2012)). In ILP, the main constraints and considered factors are listed below: 1) the "`subject`" entity and "`object`" entity of a triple have to match with question words/phrases (marked as *subject mention*) and answer words/phrases (marked as *object mention*) respectively; 2) any two *subject mentions* or *object mentions* should not overlap; 3) a *mention* can match at most one `entity`; 4) the edit distance between the Q-A pair and the matched candidate fact (use a space to joint three parts) is smaller, they are more relevant. Finally, we totally obtain 619,199 instances (an instance contains a question, an answer, and multiple facts), and the number of instances that can match one and multiple facts in KB are 499,809 and 119,390, respectively. Through the evaluation of 200 sampling instances, we estimate that approximate 81% matched facts are helpful for the generating answers. However, strictly speaking, only 44% instances are truly correct grounding. In fact, grounding the Q-A pairs from community QA website is a very challenge problem, we will leave it in the future work.

Experimental Setting: The dataset is split into training (90%) and testing set (10%). The sen-

[6]https://github.com/jxfeb/Generative_QA

[7]https://zhidao.baidu.com/

tences in Chinese are segmented into word sequences with Jieba[8] tool. And we use the words with the frequency larger than 3, which covering 98.4% of the word in the corpus. For a fair comparison, we use bi-directional LSTM for the encoder and another LSTM for decoder for all Seq2Seq models, with hidden layer size = 1024 and word embedding dimension = 300. We select CopyNet (more advanced Seq2Seq model) and GenQA for comparison. We set L_F as 10.

Metrics: Besides adopting the **AE** as a metric (same as GenQA (Yin et al., 2016)), we additionally use **manual evaluation (ME)** as another metric. **ME** considers three aspects about the quality of the generated answer (refer to (Asghar et al., 2016)): 1) **correctness**; 2) syntactical **fluency**; 3) **coherence** with the question. We employ two annotators to rate such three aspects of CopyNet, GenQA and COREQA. Specifically, we sample 100 questions, and conduct $C_3^2 = 3$ pair-wise comparisons for each question and count the winning times of each model (comparisons may both win or both lose).

Experimental Results: The **AE** and **ME** results are shown in Table 4 and Table 5, respectively. Meanwhile, we separately present the results according to the number of the facts which a question needs in KB, including just one single fact (marked as **Single**), multiple facts (marked as **Multi**) and all (marked as **Mixed**). In fact, we train two separate models for **Single** and **Multi** questions for the unbalanced data . From Table 4 and Table 5, we can clearly observe that COREQA significantly outperforms all other baseline models. And COREQA could generate a better natural answer in three aspects: correctness, fluency and coherence. CopyNet cannot interact with KB which is important to generate correct answers. For example, for "Who is the director of The_Little_Chinese_Seamstress?", if without the fact (The_Little_Chinese_Seamstress, director, Dai_Siji), QA systems cannot generate a correct answer.

Models	Single	Multi	Mixed
CopyNet	9.7	0.8	8.7
GenQA	47.2	28.9	45.1
COREQA	**58.4**	**42.7**	**56.6**

Table 4: The AE accuracies (%) on real world test data.

[8]https://github.com/fxsjy/jieba

Models	Correctness	Fluency	Coherence
CopyNet	0	13.3	3.3
GenQA	26.7	33.3	20
COREQA	**46.7**	**50**	**60**

Table 5: The ME results (%) on sampled mixed test data.

Case Study and Error Analysis: Table 6 gives some examples of generated by COREQA and the gold answers to the questions in test set. It is very clearly seen that the parts of generating SUs are predicted from the vocabulary, and other SUs are copied from the given question (marked as **bold**) and retrieved from the KB (marked as underline). And we analyze sampled examples and believe that there are several major causes of errors: **1)** did not match the right facts (ID 6); **2)** the generated answers contain some repetition of meaningless words (ID 7); **3)** the generated answers are not coherence natural language sentences (ID 8).

5 Related Work

Seq2Seq learning is to maximize the likelihood of predicting the target sequence Y conditioned on the observed source sequence X (Sutskever et al., 2014), which has been applied successfully to a large number of NLP tasks such as Machine Translation (Wu et al., 2016) and Dialogue (Vinyals and Le, 2015). Our work is partially inspired by the recent work of QA and Dialogue which have adopted Seq2Seq learning. CopyNet (Gu et al., 2016) and Pointer Networks (Vinyals et al., 2015; Gulcehre et al., 2016) which could incorporate copying mechanism in conventional Seq2Seq learning. Different from our application which deals with knowledge inquired questions and generates natural answers, CopyNet (Gu et al., 2016) and Pointer Networks (Gulcehre et al., 2016) can only copy words from the original input sequence. In contrast, COREQA is able to retrieve SUs from external memory. And GenQA (Yin et al., 2016) can only deal with the simple questions which could be answered by one fact, and it also did not incorporate the copying mechanism in Seq2Seq learning.

Moreover, our work is also inspired by Neural Abstract Machine (Graves et al., 2016; Yin et al., 2015; Liang et al., 2016) which could retrieve facts from KBs with neural models. Unlike natural answer, Neural Abstract Machine (Mou et al., 2016) is concentrating on obtaining concrete answer en-

6 Conclusion and Future Work

In this paper, we propose an end-to-end system to generate natural answers through incorporating copying and retrieving mechanisms in sequence-to-sequence learning. Specifically, the sequences of SUs in the generated answer may be predicted from the vocabulary, copied from the given question and retrieved from the corresponding KB. And the future work includes: a) lots of questions cannot be answered directly by facts in a KB (e.g. "*Who is Jet Li's father-in-law?*"), we plan to learn QA system with latent knowledge (e.g. KB embedding (Bordes et al., 2013)); b) we plan to adopt memory networks (Sukhbaatar et al., 2015) to encode the temporary KB for each question.

Abstract

We present a framework for question answering that can efficiently scale to longer documents while maintaining or even improving performance of state-of-the-art models. While most successful approaches for reading comprehension rely on recurrent neural networks (RNNs), running them over long documents is prohibitively slow because it is difficult to parallelize over sequences. Inspired by how people first skim the document, identify relevant parts, and carefully read these parts to produce an answer, we combine a coarse, fast model for selecting relevant sentences and a more expensive RNN for producing the answer from those sentences. We treat sentence selection as a latent variable trained jointly from the answer only using reinforcement learning. Experiments demonstrate the state of the art performance on a challenging subset of the WIKIREADING dataset (Hewlett et al., 2016) and on a new dataset, while speeding up the model by 3.5x-6.7x.

1 Introduction

Reading a document and answering questions about its content are among the hallmarks of natural language understanding. Recently, interest in question answering (QA) from unstructured documents has increased along with the availability of large scale datasets for reading comprehension (Hermann et al., 2015; Hill et al., 2015; Rajpurkar et al., 2016; Onishi et al., 2016; Nguyen et al., 2016; Trischler et al., 2016a).

Current state-of-the-art approaches for QA over documents are based on recurrent neural networks (RNNs) that encode the document and the question to determine the answer (Hermann et al., 2015; Chen et al., 2016; Kumar et al., 2016; Kadlec et al., 2016; Xiong et al., 2016). While such models have access to all the relevant information, they are slow because the model needs to be run sequentially over possibly thousands of tokens, and the computation is not parallelizable. In fact, such models usually truncate the documents and consider only a limited number of tokens (Miller et al., 2016; Hewlett et al., 2016). Inspired by studies on how people answer questions by first skimming the document, identifying relevant parts, and carefully reading these parts to produce an answer (Masson, 1983), we propose a coarse-to-fine model for question answering.

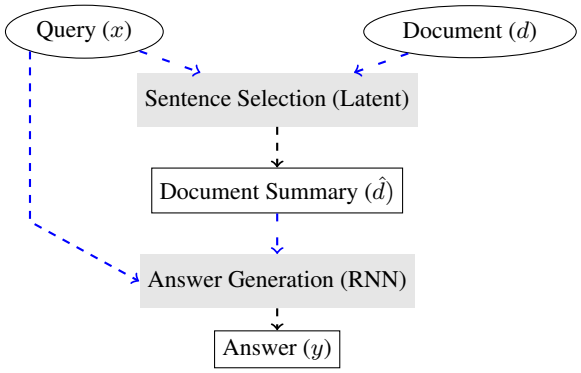

Figure 1: Hierarchical question answering: the model first selects relevant sentences that produce a document summary ($\hat{d}$) for the given query (x), and then generates an answer (y) based on the summary ($\hat{d}$) and the query x.

Our model takes a hierarchical approach (see Figure 1), where first a fast model is used to select a few sentences from the document that are relevant for answering the question (Yu et al., 2014; Yang et al., 2016a). Then, a slow RNN is employed to produce the final answer from the selected sentences. The RNN is run over a fixed number of tokens, regardless of the length of the document. Empirically, our model encodes the

y: 158 people

Figure 2: A training example containing a document d, a question x and an answer y in the WIKISUGGEST dataset. In this example, the sentence s_5 is necessary to answer the question.

text up to 6.7 times faster than the base model, which reads the first few paragraphs, while having access to four times more tokens.

A defining characteristic of our setup is that an answer does not necessarily appear verbatim in the input (the genre of a movie can be determined even if not mentioned explicitly). Furthermore, the answer often appears multiple times in the document in spurious contexts (the year '2012' can appear many times while only once in relation to the question). Thus, we treat sentence selection as a latent variable that is trained jointly with the answer generation model from the answer only using reinforcement learning. Treating sentence selection as a latent variable has been explored in classification (Yessenalina et al., 2010; Lei et al., 2016), however, to our knowledge, has not been applied for question answering.

We find that jointly training sentence selection and answer generation is especially helpful when locating the sentence containing the answer is hard. We evaluate our model on the WIKIREADING dataset (Hewlett et al., 2016), focusing on examples where the document is long and sentence selection is challenging, and on a new dataset called WIKISUGGEST that contains more natural questions gathered from a search engine.

To conclude, we present a modular framework and learning procedure for QA over long text. It captures a limited form of document structure such as sentence boundaries and deals with long documents or potentially multiple documents. Experiments show improved performance compared to the state of the art on the subset of WIKIREADING, comparable performance on other datasets, and a 3.5x-6.7x speed up in document encoding, while allowing access to much longer documents.

	% answer string exists	avg # of ans. match	% match first sent
WIKIREADING	47.1	1.22	75.1
WR-LONG	50.4	2.18	31.3
WIKISUGGEST	100	13.95	33.6

Table 1: Statistics on string matches of the answer y^* in the document. The third column only considers examples with answer match. Often the answer string is missing or appears many times while it is relevant to query only once.

2 Problem Setting

Given a training set of question-document-answer triples $\{x^{(i)}, d^{(i)}, y^{(i)}\}_{i=1}^{N}$, our goal is to learn a model that produces an answer y for a question-document pair (x, d). A document d is a list of sentences $s_1, s_2, \ldots, s_{|d|}$, and we assume that the answer can be produced from a small latent subset of the sentences. Figure 2 illustrates a training example in which sentence s_5 is in this subset.

3 Data

We evaluate on WIKIREADING, WIKIREADING LONG, and a new dataset, WIKISUGGEST.

WIKIREADING (Hewlett et al., 2016) is a QA dataset automatically generated from Wikipedia and Wikidata: given a Wikipedia page about an entity and a Wikidata property, such as PROFESSION, or GENDER, the goal is to infer the target value based on the document. Unlike other recently released large-scale datasets (Rajpurkar et al., 2016; Trischler et al., 2016a), WIKIREADING does not annotate answer spans, making sentence selection more challenging.

Due to the structure and short length of most Wikipedia documents (median number of sentences: 9), the answer can usually be inferred from the first few sentences. Thus, the data is not ideal for testing a sentence selection model compared to a model that uses the first few sentences. Table 1 quantifies this intuition: We consider sentences containing the answer y^* as a proxy for sentences that should be selected, and report how often y^* appears in the document. Additionally, we report how frequently this proxy oracle sentence is the first sentence. We observe that in WIKIREADING, the answer appears verbatim in 47.1% of the examples, and in 75% of them the match is in the first sentence. Thus, the importance of modeling sentence selection is limited.

To remedy that, we filter WIKIREADING and ensure a more even distribution of answers throughout the document. We prune short docu-

	# of uniq. queries	# of examples	# of words / query	# of tokens / doc.
WIKIREADING	867	18.58M	2.35	489.2

WIKISUGGEST	3.47M	3.47M	5.03	5962.2

Table 2: Data statistics.

ments with less than 10 sentences, and only consider Wikidata properties for which Hewlett et al. (2016)'s best model obtains an accuracy of less than 60%. This prunes out properties such as GENDER, GIVEN NAME, and INSTANCE OF.[1] The resulting WIKIREADING LONG dataset contains 1.97M examples, where the answer appears in 50.4% of the examples, and appears in the first sentence only 31% of the time. On average, the documents in WIKIREADING LONG contain 1.2k tokens, more tokens than those of SQuAD (average 122 tokens) or CNN (average 763 tokens) datasets (see Table 2). Table 1 shows that the exact answer string is often missing from the document in WIKIREADING. This is since Wikidata statements include properties such as NATIONALITY, which are not explicitly mentioned, but can still be inferred. A drawback of this dataset is that the queries, Wikidata properties, are not natural language questions and are limited to 858 properties.

To model more realistic language queries, we collect the WIKISUGGEST dataset as follows. We use the Google Suggest API to harvest natural language questions and submit them to Google Search. Whenever Google Search returns a box with a short answer from Wikipedia (Figure 3), we create an example from the question, answer, and the Wikipedia document. If the answer string is missing from the document this often implies a spurious question-answer pair, such as ('what time is half time in rugby', '80 minutes, 40 minutes'). Thus, we pruned question-answer pairs without the exact answer string. We examined fifty examples after filtering and found that 54% were well-formed question-answer pairs where we can ground answers in the document, 20% contained answers without textual evidence in the document (the answer string exists in an irreleveant context), and 26% contain incorrect QA pairs such as the last two examples in Figure 3. The data collection was performed in May 2016.

[1]These three relations alone account for 33% of the data.

4 Model

Our model has two parts (Figure 1): a fast sentence selection model (Section 4.1) that defines a distribution $p(s \mid x, d)$ over sentences given the input question (x) and the document (d), and a more costly answer generation model (Section 4.3) that generates an answer y given the question and a document summary, $\hat{d}$ (Section 4.2), that focuses on the relevant parts of the document.

4.1 Sentence Selection Model

Following recent work on sentence selection (Yu et al., 2014; Yang et al., 2016b), we build a feed-forward network to define a distribution over the sentences $s_1, s_2, \ldots, s_{|d|}$. We consider three simple sentence representations: a bag-of-words (BoW) model, a chunking model, and a (parallelizable) convolutional model. These models are efficient at dealing with long documents, but do not fully capture the sequential nature of text.

BoW Model Given a sentence s, we denote by $\text{BoW}(s)$ the bag-of-words representation that averages the embeddings of the tokens in s. To define a distribution over the document sentences, we employ a standard attention model (e.g., (Hermann et al., 2015)), where the BoW representation of the query is concatenated to the BoW representation of each sentence s_l, and then passed through a single layer feed-forward network:

$$h_l = [\text{BoW}(x); \text{BoW}(s_l)]$$
$$v_l = v^\top \text{ReLU}(W h_l),$$
$$p(s = s_l \mid x, d) = \text{softmax}(v_l),$$

where $[;]$ indicates row-wise concatenation, and the matrix W, the vector v, and the word embeddings are learned parameters.

Chunked BoW Model To get more fine-grained granularity, we split sentences into fixed-size smaller chunks (seven tokens per chunk) and score each chunk separately (Miller et al., 2016). This is beneficial if questions are answered with sub-sentential units, by allowing to learn attention over different chunks. We split a sentence s_l into a fixed number of chunks $(c_{l,1}, c_{l,2} \ldots, c_{l,J})$, generate a BoW representation for each chunk, and score it exactly as in the BoW model. We obtain a distribution over chunks, and compute sentence probabilities by marginalizing over chunks from the same sentence. Let $p(c = c_{l,j} \mid x, d)$ be the distribution over chunks from all sentences, then:

$$p(s = s_l \mid x, d) = \sum_{j=1}^{J} p(c = c_{l,j} \mid x, d),$$

with the same parameters as in the BoW model.

Convolutional Neural Network Model While our sentence selection model is designed to be fast, we explore a convolutional neural network (CNN) that can compose the meaning of nearby words. A CNN is still efficient, since all filters can be computed in parallel. Following previous work (Kim, 2014; Kalchbrenner et al., 2014), we concatenate the embeddings of tokens in the query x and the sentence s_l, and run a convolutional layer with F filters and width w over the concatenated embeddings. This results in F features for every span of length w, and we employ max-over-time-pooling (Collobert et al., 2011) to get a final representation $h_l \in \mathbb{R}^F$. We then compute $p(s = s_l \mid x, d)$ by passing h_l through a single layer feed-forward network as in the BoW model.

4.2 Document Summary

After computing attention over sentences, we create a summary that focuses on the document parts related to the question using deterministic soft attention or stochastic hard attention. Hard attention is more flexible, as it can focus on multiple sentences, while soft attention is easier to optimize and retains information from multiple sentences.

Hard Attention We sample a sentence $\hat{s} \sim p(s \mid x, d)$ and fix the document summary $\hat{d} = \hat{s}$ to be that sentence during training. At test time, we choose the most probable sentence. To extend the document summary to contain more information, we can sample without replacement K sentences from the document and define the summary to be the concatenation of the sampled sentences $\hat{d} = [\hat{s}_1; \hat{s}_2; \ldots; \hat{s}_K]$.

Soft Attention In the soft attention model (Bahdanau et al., 2015) we compute a weighted average of the tokens in the sentences according to $p(s \mid x, d)$. More explicitly, let $\hat{d}_m$ be the mth token of the document summary. Then, by fixing the length of every sentence to M tokens,[2] the *blended* tokens are computed as follows:

$$\hat{d}_m = \sum_{l=1}^{|d|} p(s = s_l \mid x, d) \cdot s_{l,m},$$

where $s_{l,m}$ is the mth word in the lth sentence ($m \in \{1, \ldots, M\}$).

As the answer generation models (Section 4.3) take a sequence of vectors as input, we average the tokens at the word level. This gives the hard attention an advantage since it samples a "real" sentence without mixing words from different sentences. Conversely, soft attention is trained more easily, and has the capacity to learn a low-entropy distribution that is similar to hard attention.

4.3 Answer Generation Model

State-of-the-art question answering models use RNN models to encode the document and question and selects the answer. We focus on a hierarchical model with fast sentence selection, and do not subscribe to a particular answer generation architecture.

Here we implemented the state-of-the-art word-level sequence-to-sequence model with placeholders, described by Hewlett et al. (2016). This models can produce answers that does not appear in the sentence verbatim. This model takes the query tokens, and the document (or document summary) tokens as input and encodes them with a Gated Recurrent Unit (GRU; Cho et al. (2014)). Then, the answer is decoded with another GRU model, defining a distribution over answers $p(y \mid x, \hat{d})$. In this work, we modified the original RNN: the word embeddings for the RNN decoder input, output and original word embeddings are shared.

[2] Long sentences are truncated and short ones are padded.

5 Learning

We consider three approaches for learning the model parameters (denoted by θ): (1) We present a pipeline model, where we use distant supervision to train a sentence selection model independently from an answer generation model. (2) The hard attention model is optimized with REINFORCE (Williams, 1992) algorithm. (3) The soft attention model is fully differentiable and is optimized end-to-end with backpropagation.

Distant Supervision While we do not have an explicit supervision for sentence selection, we can define a simple heuristic for labeling sentences. We define the gold sentence to be the first sentence that has a full match of the answer string, or the first sentence in the document if no full match exists. By labeling gold sentences, we can train sentence selection and answer generation independently with standard supervised learning, maximizing the log-likelihood of the gold sentence and answer, given the document and query. Let y^* and s^* be the target answer and sentence , where s^* also serves as the document summary. The objective is to maximize:

$$\begin{aligned} J(\theta) &= \log p_\theta(y^*, s^* \mid x, d) \\ &= \log p_\theta(s^* \mid x, d) + \log p_\theta(y^* \mid s^*, x). \end{aligned}$$

Since at test time we do not have access to the target sentence s^* needed for answer generation, we replace it by the model prediction $\arg\max_{s_l \in d} p_\theta(s = s_l \mid d, x)$.

Reinforcement Learning Because the target sentence is missing, we use reinforcement learning where our action is sentence selection, and our goal is to select sentences that lead to a high reward. We define the reward for selecting a sentence as the log probability of the correct answer given that sentence, that is, $R_\theta(s_l) = \log p_\theta(y = y^* \mid s_l, x)$. Then the learning objective is to maximize the expected reward:

$$\begin{aligned} J(\theta) &= \sum_{s_l \in d} p_\theta(s = s_l \mid x, d) \cdot R_\theta(s_l) \\ &= \sum_{s_l \in d} p_\theta(s = s_l \mid x, d) \cdot \log p_\theta(y = y^* \mid s_l, x). \end{aligned}$$

Following REINFORCE (Williams, 1992), we approximate the gradient of the objective with a sample, $\hat{s} \sim p_\theta(s \mid x, d)$:

$$\begin{aligned} \nabla J(\theta) \approx \nabla \log p_\theta(y \mid \hat{s}, x) \\ + \log p_\theta(y \mid \hat{s}, x) \cdot \nabla \log p_\theta(\hat{s} \mid x, d). \end{aligned}$$

Sampling K sentences is similar and omitted for brevity.

Training with REINFORCE is known to be unstable due to the high variance induced by sampling. To reduce variance, we use curriculum learning, start training with distant supervision and gently transition to reinforcement learning, similar to DAGGER (Ross et al., 2011). Given an example, we define the probability of using the distant supervision objective at each step as r^e, where r is the decay rate and e is the index of the current training epoch.[3]

Soft Attention We train the soft attention model by maximizing the log likelihood of the correct answer y^* given the input question and document $\log p_\theta(y^* \mid d, x)$. Recall that the answer generation model takes as input the query x and document summary $\hat{d}$, and since $\hat{d}$ is an average of sentences weighted by sentence selection, the objective is differentiable and is trained end-to-end.

6 Experiments

Experimental Setup We used 70% of the data for training, 10% for development, and 20% for testing in all datasets. We used the first 35 sentences in each document as input to the hierarchical models, where each sentence has a maximum length of 35 tokens. Similar to Miller et al. (2016), we add the first five words in the document (typically the title) at the end of each sentence sequence for WIKISUGGEST. We add the sentence index as a one hot vector to the sentence representation.

We coarsely tuned and fixed most hyperparameters for all models. The word embedding dimension is set to 256 for both sentence selection and answer generation models. We used the decay rate of 0.8 for curriculum learning. Hidden dimension is fixed at 128, batch size at 128, GRU state cell at 512, and vocabulary size at 100K. For CNN sentence selection model, we used 100 filters and set filter width as five. The initial learning rate and gradient clipping coefficients for each model are tuned on the development set. The ranges for learning rates were 0.00025, 0.0005, 0.001, 0.002, 0.004 and 0.5, 1.0 for gradient clipping coefficient.

[3] We tuned $r \in [0.3, 1]$ on the development set.

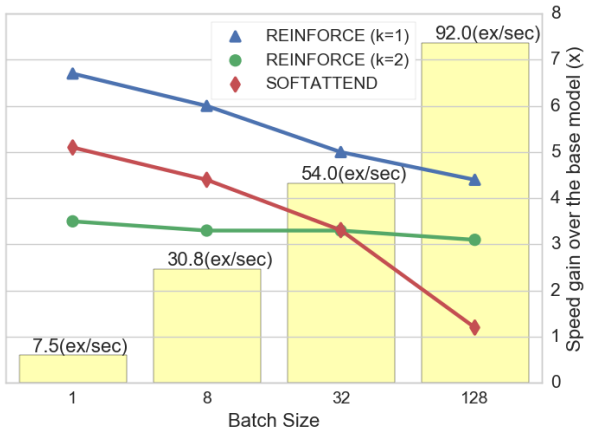

Figure 4: Runtime for document encoding on an Intel Xeon CPU E5-1650 @3.20GHz on WIKIREADING at test time. The boxplot represents the throughput of BASE and each line plot shows the proposed models' speed gain over BASE. Exact numbers are reported in the supplementary material.

We halved the learning rate every 25k steps. We use the Adam (Kingma and Ba, 2015) optimizer and TensorFlow framework (Abadi et al., 2015).

Evaluation Metrics Our main evaluation metric is answer accuracy, the proportion of questions answered correctly. For sentence selection, since we do not know which sentence contains the answer, we report approximate accuracy by matching sentences that contain the answer string (y^*). For the soft attention model, we treat the sentence with the highest probability as the predicted sentence.

Models and Baselines The models PIPELINE, REINFORCE, and SOFTATTEND correspond to the learning objectives in Section 5. We compare these models against the following baselines:

> **FIRST** always selects the first sentence of the document. The answer appears in the first sentence in 33% and 15% of documents in WIKISUGGEST and WIKIREADING LONG.
> **BASE** is the re-implementation of the best model by Hewlett et al. (2016), consuming the first 300 tokens. We experimented with providing additional tokens to match the length of document available to hierarchical models, but this performed poorly.[4]
> **ORACLE** selects the first sentence with the answer string if it exists, or otherwise the first sentence in the document.

[4]Our numbers on WIKIREADING outperform previously reported numbers due to modifications in implementation and better optimization.

Dataset	Learning	Accuracy
WIKIREADING LONG	FIRST	26.7
	BASE	40.1
	ORACLE	43.9
	PIPELINE	36.8
	SOFTATTEND	38.3

	REINFORCE (K=2)	73.9

Table 3: Answer prediction accuracy on the test set. K is the number of sentences in the document summary.

Answer Accuracy Results Table 3 summarizes answer accuracy on all datasets. We use BOW encoder for sentence selection as it is the fastest. The proposed hierarchical models match or exceed the performance of BASE, while reducing the number of RNN steps significantly, from 300 to 35 (or 70 for K=2), and allowing access to later parts of the document. Figure 4 reports the speed gain of our system. While throughput at training time can be improved by increasing the batch size, at test time real-life QA systems use batch size 1, where REINFORCE obtains a 3.5x-6.7x speedup (for K=2 or K=1). In all settings, REINFORCE was at least three times faster than the BASE model.

All models outperform the FIRST baseline, and utilizing the proxy oracle sentence (ORACLE) improves performance on WIKISUGGEST and WIKIREADNG LONG. In WIKIREADING, where the proxy oracle sentence is often missing and documents are short, BASE outperforms ORACLE.

Jointly learning answer generation and sentence selection, REINFORCE outperforms PIPELINE, which relies on a noisy supervision signal for sentence selection. The improvement is larger in WIKIREADING LONG, where the approximate supervision for sentence selection is missing for 51% of examples compared to 22% of examples in WIKISUGGEST.[5]

On WIKIREADING LONG, REINFORCE outper-

[5]The number is lower than in Table 1 because we cropped sentences and documents, as mentioned above.

	SOFTATTEND (BOW)		49.9

Table 4: Approximate sentence selection accuracy on the development set for all models. We use ORACLE to find a proxy gold sentence and report the proportion of times each model selects the proxy sentence.

forms all other models (excluding ORACLE, which has access to gold labels at test time). In other datasets, BASE performs slightly better than the proposed models, at the cost of speed. In these datasets, the answers are concentrated in the first few sentences. BASE is advantageous in categorical questions (such as GENDER), gathering bits of evidence from the whole document, at the cost of speed. Encouragingly, our system almost reaches the performance of ORACLE in WIKIREADING, showing strong results in a limited token setting.

Sampling an additional sentence into the document summary increased performance in all datasets, illustrating the flexibility of hard attention compared to soft attention. Additional sampling allows recovery from mistakes in WIKIREADING LONG, where sentence selection is challenging.[6] Comparing hard attention to soft attention, we observe that REINFORCE performed better than SOFTATTEND. The attention distribution learned by the soft attention model was often less peaked, generating noisier summaries.

Sentence Selection Results Table 4 reports sentence selection accuracy by showing the proportion of times models selects the proxy gold sentence when it is found by ORACLE. In WIKIREADING LONG, REINFORCE finds the approximate gold sentence in 74.4% of the examples where the the answer is in the document. In WIKISUGGEST performance is at 67.5%, mostly due to noise in the data. PIPELINE performs slightly better as it is directly trained towards our noisy evaluation. However, not all sentences that contain the answer are useful to answer the question (first example in Table 6). REINFORCE learned to choose sentences that are likely to generate a correct answer rather than proxy gold sentences, improving the final answer accuracy. On WIKIREADING LONG, complex models (CNN and CHUNKBOW) outperform the simple BOW, while on WIKISUGGEST BOW performed best.

[6] Sampling more help pipeline methods less.

	WR LONG	WIKI SUGGEST
No evidence in doc.	29	8
Error in answer generation	13	15
Noisy query & answer	0	24
Error in sentence selection	8	3

Table 5: Manual error analysis on 50 errors from the development set for REINFORCE (K=1).

Qualitative Analysis We categorized the primary reasons for the errors in Table 5 and present an example for each error type in Table 6. All examples are from REINFORCE with BOW sentence selection. The most frequent source of error for WIKIREADING LONG was lack of evidence in the document. While the dataset does not contain false answers, the document does not always provide supporting evidence (examples of properties without clues are ELEVATION ABOVE SEA LEVEL and SISTER). Interestingly, the answer string can still appear in the document as in the first example in Table 6: 'Saint Petersburg' appears in the document (4th sentence). Answer generation at times failed to generate the answer even when the correct sentence was selected. This was pronounced especially in long answers. For the automatically collected WIKISUGGEST dataset, noisy question-answer pairs were problematic, as discussed in Section 3. However, the models frequently guessed the spurious answer. We attribute higher proxy performance in sentence selection for WIKISUGGEST to noise. In manual analysis, sentence selection was harder in WIKIREADING LONG, explaining why sampling two sentences improved performance.

In the first correct prediction (Table 6), the model generates the answer, even when it is not in the document. The second example shows when our model spots the relevant sentence without obvious clues. In the last example the model spots a sentence far from the head of the document.

tion distribution over sentences, $p(s_l \mid d, x)$, for different learning procedures. The increased frequency of the answer string in WIKISUGGEST vs. WIKIREADING LONG is evident in the leftmost plot. SOFTATTEND and CHUNKBOW clearly distribute attention more evenly across the sentences compared to BOW and CNN.

7 Related Work

There has been substantial interest in datasets for reading comprehension. MCTest (Richardson et al., 2013) is a smaller-scale datasets focusing on common sense reasoning; bAbi (Weston et al., 2015) is a synthetic dataset that captures various aspects of reasoning; and SQuAD (Rajpurkar et al., 2016; Wang et al., 2016; Xiong et al., 2016) and NewsQA (Trischler et al., 2016a) are QA datasets where the answer is a span in the document. Compared to Wikireading, some datasets covers shorter passages (average 122 words for SQuAD). Cloze-style question answering datasets (Hermann et al., 2015; Onishi et al., 2016; Hill et al., 2015) assess machine comprehension but do not form questions. The recently released MS MARCO dataset (Nguyen et al., 2016) consists of query logs, web documents and crowd-sourced answers.

Answer sentence selection is studied with the TREC QA (Voorhees and Tice, 2000), WikiQA (Yang et al., 2016b) and SelQA (Jurczyk et al., 2016) datasets. Recently, neural networks models (Wang and Nyberg, 2015; Severyn and

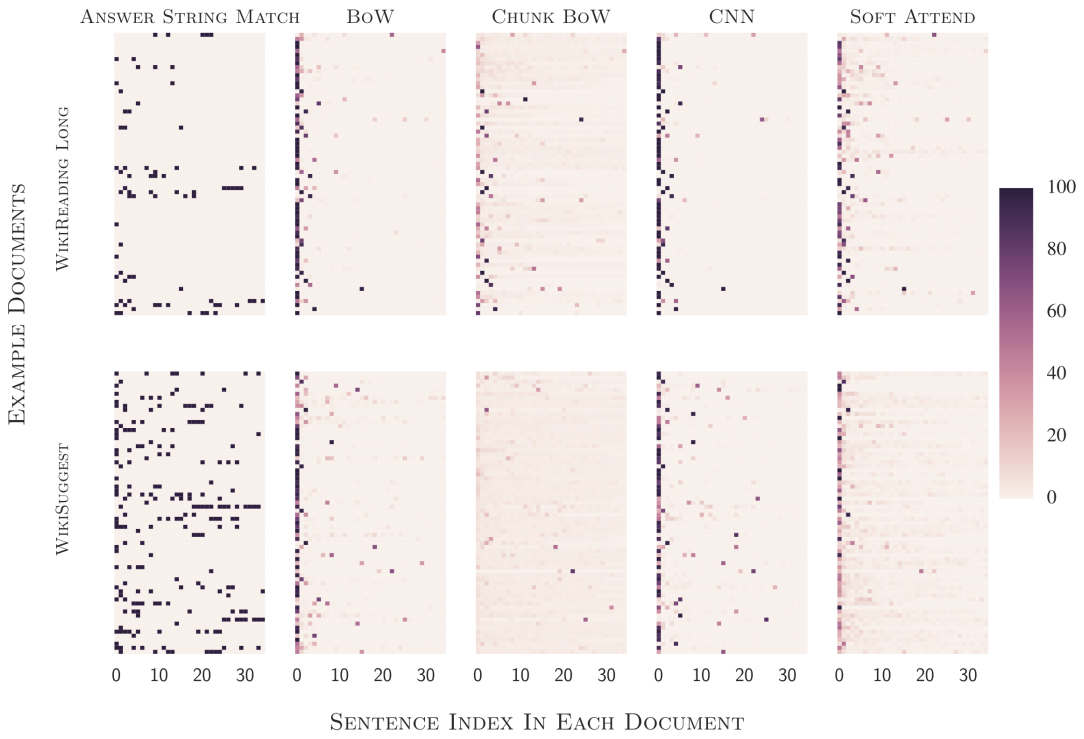

Figure 5: For a random subset of documents in the development set, we visualized the learned attention over the sentences ($p(s_l|d, x)$).

Moschitti, 2015; dos Santos et al., 2016) achieved improvements on TREC datsaet. Sultan et al. (2016) optimized the answer sentence extraction and the answer extraction jointly, but with gold labels for both parts. Trischler et al. (2016b) proposed a model that shares the intuition of observing inputs at multiple granularities (sentence, word), but deals with multiple choice questions. Our model considers answer sentence selection as latent and generates answer strings instead of selecting text spans, and we found that WIKIREADING dataset suits our purposes best with some pruning, which still provided 1.97 million examples compared to 2K questions for TREC dataset.

Hierarchical models which treats sentence selection as a latent variable have been applied text categorization (Yang et al., 2016b), extractive summarization (Cheng and Lapata, 2016), machine translation (Ba et al., 2014) and sentiment analysis (Yessenalina et al., 2010; Lei et al., 2016). To the best of our knowledge, we are the first to use the hierarchical nature of a document for QA.

Finally, our work is related to the reinforcement learning literature. Hard and soft attention were examined in the context of caption generation (Xu et al., 2015). Curriculum learning was investigated in Sachan and Xing (2016), but they focused on the ordering of training examples while we combine supervision signals. Reinforcement learning recently gained popularity in tasks such as coreference resolution (Clark and Manning, 2016), information extraction (Narasimhan et al., 2016), semantic parsing (Andreas et al., 2016) and textual games (Narasimhan et al., 2015; He et al., 2016).

8 Conclusion

We presented a coarse-to-fine framework for QA over long documents that quickly focuses on the relevant portions of a document. In future work we would like to deepen the use of structural clues and answer questions over multiple documents, using paragraph structure, titles, sections and more. Incorporating coreference resolution would be another important direction for future work. We argue that this is necessary for developing systems that can efficiently answer the information needs of users over large quantities of text.

Abstract

With the rapid growth of knowledge bases (KBs) on the web, how to take full advantage of them becomes increasingly important. Question answering over knowledge base (KB-QA) is one of the promising approaches to access the substantial knowledge. Meanwhile, as the neural network-based (NN-based) methods develop, NN-based KB-QA has already achieved impressive results. However, previous work did not put more emphasis on question representation, and the question is converted into a fixed vector regardless of its candidate answers. This simple representation strategy is not easy to express the proper information in the question. Hence, we present an end-to-end neural network model to represent the questions and their corresponding scores dynamically according to the various candidate answer aspects via cross-attention mechanism. In addition, we leverage the global knowledge inside the underlying KB, aiming at integrating the rich KB information into the representation of the answers. As a result, it could alleviates the out-of-vocabulary (OOV) problem, which helps the cross-attention model to represent the question more precisely. The experimental results on WebQuestions demonstrate the effectiveness of the proposed approach.

1 Introduction

As the amount of the knowledge bases (KBs) grows, people are paying more attention to seeking effective methods for accessing these precious intellectual resources. There are several tailor-made languages designed for querying KBs, such as SPARQL (Prudhommeaux and Seaborne, 2008). However, to handle such query languages, users are required to not only be familiar with the particular language grammars, but also be aware of the architectures of the KBs. By contrast, knowledge base-based question answering (KB-QA) (Unger et al., 2014), which takes natural language as query language, is a more user-friendly solution, and has become a research focus in recent years.

Given natural language questions, the goal of KB-QA is to automatically return answers from the KB. There are two mainstream research directions for this task: semantic parsing-based (SP-based) (Zettlemoyer and Collins, 2009, 2012; Kwiatkowski et al., 2013; Cai and Yates, 2013; Berant et al., 2013; Yih et al., 2015, 2016; Reddy et al., 2016) and information retrieval-based (IR-based) (Yao and Van Durme, 2014; Bordes et al., 2014a,b, 2015; Dong et al., 2015; Xu et al., 2016a,b) methods. SP-based methods usually focus on constructing a semantic parser that could convert natural language questions into structured expressions like logical forms. IR-based methods usually search answers from the KB based on the information conveyed in questions, where ranking techniques are often adopted to make correct selections from candidate answers.

Recently, with the progress of deep learning, neural network-based (NN-based) methods have been introduced to the KB-QA task (Bordes et al., 2014b). Different from previous methods, NN-based methods represent both of the questions and the answers as semantic vectors. Then the complex process of KB-QA could be converted into a similarity matching process between an input question and its candidate answers in a semantic space. The candidates with the highest similarity score will be selected as the final answers. Because they are more adaptive, NN-based methods have attracted more and more attention, and this

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 221–231
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1021

paper also focuses on using end-to-end neural networks to answer questions over knowledge base.

In NN-based methods, the crucial step is to compute the similarity score between a question and a candidate answer, where the key is to learn their representations. Previous methods put more emphasis on learning representation of the answer end. For example, Bordes et al. (2014a) consider the importance of the subgraph of the candidate answer. Dong et al. (2015) make use of the context and the type of the answer. However, the representation of the question end is oligotrophic. Existing approaches often represent a question into a single vector using simple bag-of-words (BOW) model (Bordes et al., 2014a,b), whereas the relatedness to the answer end is neglected. We argue that a question should be represented differently according to the different focuses of various answer aspects[1].

Take the question "Who is the president of France?" and one of its candidate answers "Francois Hollande" as an example. When dealing with the answer entity `Francois Holland`, "president" and "France" in the question is more focused, and the question representation should bias towards the two words. While facing the answer type `/business/board_member`, "Who" should be the most prominent word. Meanwhile, some questions may value answer type more than other answer aspects. While in some other questions, answer relation may be the most important information we should consider, which is dynamic and flexible corresponding to different questions and answers. Obviously, this is an attention mechanism, which reveals the mutual influences between the representation of questions and the corresponding answer aspects.

We believe that such kind of representation is more expressive. Dong et al. (2015) represents questions using three CNNs with different parameters when dealing with different answer aspects including answer path, answer context and answer type. The method is very enlightening and achieves the best performance on WebQeustions at that time among the end-to-end approaches. However, we argue that simply selecting three independent CNNs is mechanical and inflexible. Thus, we go one step further, and propose a cross-attention based neural network to perform KB-QA. The cross-attention model, which stands for the mutual attention between the question and the answer aspects, contains two parts: the answer-towards-question attention part and the question-towards-answer attention part. The former help learn flexible and adequate question representation, and the latter help adjust the question-answer weight, getting the final score. We illustrate in section 3.2 for more details. In this way, we formulate the cross-attention mechanism to model the question answering procedure. Note that our proposed model is an entire end-to-end approach which only depends on training data. Some integrated systems which use extra patterns and resources are not directly comparable to ours. Our target is to explore a better solution following the end-to-end KB-QA technical path.

Moreover, we notice that the representations of the KB resources (entities and relations) are also limited in previous work. specifically, they are often learned barely on the QA training data, which results in two limitations. 1) The global information of the KB is deficient. For example, if question-answer pair (q, a) appears in the training data, and the global KB information implies us that a' is similar to a[2], denoted by (a $\sim a'$), then (q, a') is more probable to be right. However, current QA training mechanism cannot guarantee (a $\sim a'$) could be learned. 2) The problem of out-of-vocabulary (OOV) stands out. Due to the limited coverage of the training data, the OOV problem is common while testing, and many answer entities in testing candidate set have never been seen before. The attention of these resources become the same because they shared the same OOV embedding, and this will do harm to the proposed attention model. To tackle these two problems, we additionally incorporates KB itself as training data for training embeddings besides original question-answer pairs. In this way, the global structure of the whole knowledge could be captured, and the OOV problem could be alleviated naturally.

In summary, the contributions are as follows.
1) We present a novel cross-attention based NN model tailored to KB-QA task, which considers the mutual influence between the representation of questions and the corresponding answer aspects.
2) We leverage the global KB information, aiming at represent the answers more precisely. It also al-

[1] An answer aspect could be the answer entity itself, the answer type, the answer context, etc.

[2] The complete KB is able to offer this kind of information, e.g., a and a' share massive context.

leviates the OOV problem, which is very helpful to the cross-attention model.
3) The experimental results on the open dataset WebQuestions demonstrate the effectiveness of the proposed approach.

2 Overview

The goal of KB-QA task could be formulated as follows. Given a natural language question q, the system returns an entity set A as answers. The architecture of our proposed KB-QA system is shown in Figure 1, which illustrates the basic flow of our approach. First, we identify the topic entity of the question, and generate candidate answers from Freebase. Then, a cross-attention based neural network is employed to represent the question under the influence of the candidate answer aspects. Finally, the similarity score between the question and each corresponding candidate answer is calculated, and the candidates with highest score will be selected as the final answers[3].

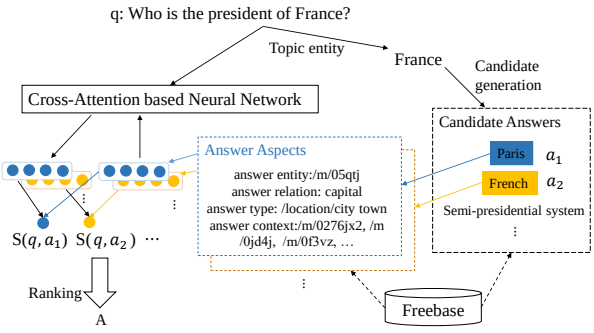

Figure 1: The overview of the proposed KB-QA system.

We utilize Freebase (Bollacker et al., 2008) as our knowledge base. It has more than 3 billion facts, and is used as the supporting KB for many QA tasks. In Freebase, the facts are represented by subject-predicate-object triples (s, p, o). For clarity, we call each basic element a resource, which could be either an entity or a relation. For example, `(/m/0f8l9c, location.country.capital, /m/05qtj)`[4] describes the fact that the capital of France is Paris, where `/m/0f8l9c` and `/m/05qtj` are entities denoting `France` and `Paris` respectively, and `location.country.capital` is a relation.

3 Our Approach

3.1 Candidate Generation

All the entities in Freebase should be candidate answers ideally, but in practice, this is time consuming and not really necessary. For each question q, we use Freebase API (Bollacker et al., 2008) to identify a topic entity, which could be simply understood as the main entity of the question. For example, France is the topic entity of question "Who is the president of France?". Freebase API method is able to resolve as many as 86% questions if we use the top1 result (Yao and Van Durme, 2014). After getting the topic entity, we collect all the entities directly connected to it and the ones connected with 2-hop[5]. These entities constitute a candidate set C_q .

3.2 The Neural Cross-Attention Model

We present a cross-attention based neural network, which represents the question dynamically according to different answer aspects, also considering their connections. Concretely, each aspect of the answer focuses on different words of the question and thus decides how the question is represented. Then the question pays different attention to each answer aspect to decide their weights. Figure 2 is the architecture of our model. We will illustrate how the system works as follows.

3.2.1 Question Representation

First of all, we have to obtain the representation of each word in the question. These representations retain all the information of the question, and could serve the following steps. Suppose question q is expressed as $q = (x_1, x_2, ..., x_n)$, where x_i denotes the ith word. As shown in Figure 2, we first look up a word embedding matrix $E_w \in \mathbb{R}^{d \times v_w}$ to get the word embeddings, which is randomly initialized, and updated during the training process. Here, d means the dimension of the embeddings and v_w denotes the vocabulary size of natural language words.

Then, the embeddings are fed into a long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) networks. LSTM has been proven to

[3]We also adopt a margin strategy to obtain multiple answers for a question and this will be explained in the next section.

[4]Note that the Freebase prefixes are omitted for neatness.

[5]For example, (/m/0f8l9c, governing_officials, government.position_held.office_holder, /m/02qg4z) is a 2-top connection.

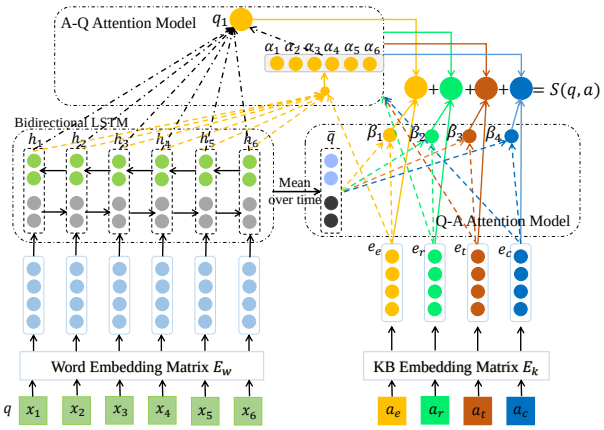

Figure 2: The architecture of the proposed cross-attention based neural network. Note that only one aspect(in orange color) is depicted for clarity. The other three aspects follow the same way.

be effective in many natural language processing (NLP) tasks such as machine translation (Sutskever et al., 2014) and dependency parsing (Dyer et al., 2015), and it is adept in harnessing long sentences. Note that if we use unidirectional LSTM, the outcome of a specific word contains only the information of the words before it, whereas the words after it are not taken into account. To avoid this, we employ bidirectional LSTM as Bahdanau (2015) does, which consists of both forward and backward networks. The forward LSTM handles the question from left to right, and the backward LSTM processes in the reverse order. Thus, we could acquire two hidden state sequences, one from the forward one $(\overrightarrow{h_1}, \overrightarrow{h_2}, ..., \overrightarrow{h_n})$ and the other from the backward one $(\overleftarrow{h_1}, \overleftarrow{h_2}, ..., \overleftarrow{h_n})$. We concatenate the forward hidden state and the backward hidden state of each word, resulting in $h_j = [\overrightarrow{h_j}; \overleftarrow{h_j}]$. The hidden unit of forward and backward LSTM is $\frac{d}{2}$, so the concatenated vector is of dimension d. In this way, we obtain the representation of each word in the question.

3.2.2 Answer aspect representation

We directly use the embedding for each answer aspect through the KB embedding matrix $E_k \in \mathbb{R}^{d \times v_k}$. Here, v_k means the vocabulary size of the KB resources. The embedding matrix is randomly initialized and learned during training, and could be further enhanced with the help of global information as described in Section 3.3. Concretely, we employ four kinds of answer aspects: answer entity a_e, answer relation a_r, answer type a_t and answer context a_c[6]. Their embeddings are denoted as e_e, e_r, e_t and e_c, respectively. It is worth noting that the answer context consists of multiple KB resources, and we denote it as $(c_1, c_2, ..., c_m)$. We first acquire their KB embeddings $(e_{c_1}, e_{c_2}, ..., e_{c_m})$ through E_k, then calculate an average embedding by $e_c = \frac{1}{m}\sum_{i=1}^{m} e_{c_i}$.

3.2.3 Cross-Attention model

The most crucial part of the proposed approach is the cross-attention mechanism. The cross-attention mechanism is composed of two parts: the answer-towards-question attention part and the question-towards-answer attention part.

The proposed cross-attention model could also be intuitively interpreted as a re-reading mechanism (Hermann et al., 2015). Our aim is to select correct answers from a candidate set. When we judge a candidate answer, suppose we first look at its type, and we will reread the question to find out which part of the question should be more focused (handling attention). Then we go to next aspect and reread the question again, until the all the aspects are utilized. After we read all the answer aspects and get all the scores, the final similarity score between question and answer should be a weighted sum of all the scores. We believe that this mechanism is beneficial for the system to better understand the question with the help of the answer aspects, and it may lead to a performance promotion.

• Answer-towards-question(A-Q) attention

Based on our assumption, each answer aspect should focus on different words of the same question. The extent of attention can be measured by the relatedness between each word representation h_j and an answer aspect embedding e_i. We propose the following formulas to calculate the weights.

$$\alpha_{ij} = \frac{\exp(\omega_{ij})}{\sum_{k=1}^{n} \exp(\omega_{ik})} \quad (1)$$

$$\omega_{ij} = f(W^T[h_j; e_i] + b) \quad (2)$$

Here, α_{ij} denotes the weight of attention from answer aspect e_i to the jth word in the question, where $e_i \in \{e_e, e_r, e_t, e_c\}$. $f(\cdot)$ is a non-linear activation function, such as hyperbolic tangent transformation here. Let n be the length of the question. $W \in \mathbb{R}^{2d \times d}$ is an intermediate matrix and b

[6]Answer context is the 1-hop entities and predicates which connect to the answer entity along the answer path.

is the offset. Both of them are randomly initialized and updated during training. Subsequently, according to the specific answer aspect e_i, the attention weights are employed to calculate a weighted sum of the hidden representations, resulting in a semantic vector that represent the question.

$$q_i = \sum_{j=1}^{n} \alpha_{ij} h_j \tag{3}$$

The similarity score of the question q and this particular candidate answer aspect e_i ($e_i \in \{e_e, e_r, e_t, e_c\}$) could be defined as follows.

$$S(q, e_i) = h(q_i, e_i) \tag{4}$$

The scoring function $h(\cdot)$ is computed as the inner product between the sentence representation q_i, which has already carried the attention from the answer aspect part, and the corresponding answer aspect e_i, and is parametrized into the network and updated during the training process.

• **Question-towards-answer(Q-A) attention**

Intuitively, different question should value the four answer aspect differently. Since we have already calculated the scores of (q, e_i), we define the final similarity score of the question q and each candidate answer a as follows.

$$S(q, a) = \sum_{e_i \in \{e_e, e_r, e_t, e_c\}} \beta_{e_i} S(q, e_i) \tag{5}$$

$$\beta_{e_i} = \frac{\exp(\omega_{e_i})}{\sum_{e_k \in \{e_e, e_r, e_t, e_c\}} \exp(\omega_{e_k})} \tag{6}$$

$$\omega_{e_i} = f\left(W^T [\overline{q}; e_i] + b\right) \tag{7}$$

$$\overline{q} = \frac{1}{n} \sum\nolimits_{j}^{n} h_j \tag{8}$$

Here β_{e_i} denotes the attention of question towards answer aspects, indicating which answer aspect should be more focused in one (q, a) pair. $W \in \mathbb{R}^{2d \times d}$ is also a intermediate matrix as in the answer-towards-question attention part, and b is an offset value.[7] $\overline{q}$ is calculated by averagely pooling all the bi-directional LSTM hidden state sequences, resulting a vector which represents the question to determine which answer aspect should be more focused.

[7]Note that the W and b in the two attention part is different and independent.

3.2.4 Training

We first construct the training data. Since we have (q, a) pairs as supervision data, candidate set C_q can be divided into two subsets, namely, correct answer set P_q and wrong answer set N_q. For each correct answer $a \in P_q$, we randomly select k wrong answers $a' \in N_q$ as negative examples. For some topic entities, there may be not enough wrong answers to acquire k wrong answers. Under this circumstance, we extend N_q from other randomly selected candidate set C'_q. With the generated training data, we are able to make use of pairwise training. The training loss is given as follows, which is a hinge loss.

$$L_{q,a,a'} = [\gamma + S(q, a') - S(q, a)]_+ \tag{9}$$

where γ is a positive real number that ensures a margin between positive and negative examples. And $[z]_+$ means $max(0, z)$. The intuition of this training strategy is to guarantee the score of positive question-answer pairs to be higher than negative ones with a margin. The objective function is as follows.

$$\min \sum_{q} \frac{1}{|P_q|} \sum_{a \in P_q} \sum_{a' \in N_q} L_{q,a,a'} \tag{10}$$

We adopt stochastic gradient descent (SGD) to minimize the learning process, shuffled mini-batches are utilized.

3.2.5 Inference

In testing stage, given the candidate answer set C_q, we have to calculate $S(q, a)$ for each $a \in C_q$, and find out the maximum value S_{max}.

$$S_{\max} = \arg\max_{a \in C_q} \{S(q, a)\} \tag{11}$$

It is worth noting that many questions have more than one answer, so it is improper to set the candidate answer which have the maximum value as the final answer. Instead, we take advantage of the margin γ. If the score of a candidate answer is within the margin compared with S_{max}, we put it in the final answer set.

$$A = \{\hat{a} | S_{\max} - S(q, \hat{a}) < \gamma\} \tag{12}$$

3.3 Combining Global Knowledge

In this section, we elaborate how the global information of a KB could be leveraged. As stated before, we try to take into account the complete knowledge information of the KB. To this

end, we adopt TransE model (Bordes et al., 2013) and integrate its outcome into our training process. In TransE, relations are considered as translations in the embedding space. For consistency, we denote each fact as (s, p, o). TransE utilizes pairwise training strategy as well. Randomly sampled corrupted facts (s', p, o') are the negative examples. The distance measure $d(s + p, o)$ is defined as $\|s + p - o\|_2^2$. And the training loss is given as follows.

$$L_k = \sum_{(s,p,o)\in S} \sum_{(s',p,o')\in S'} [\gamma_k + d(s + p, o) - d(s' + p, o')]_+ \tag{13}$$

Where S is the set of KB facts and S' is the corrupted facts. In our QA task, we filter out the completely unrelated facts to save time. Specifically, we first collect all the topic entities of all the questions as initial set. Then, we expand the set by adding directly connected and 2-hop entities. Finally, all the facts containing these entities form the positive set, and the negative facts are randomly corrupted. This is a compromising solution due to the large scale of Freebase. To employ the global information in our training process, we adopt a multi-task training strategy. Specifically, we perform KB-QA training and TransE training in turn. The proposed training process ensures that the global KB information acts as additional supervision, and the interconnections among the resources are fully considered. In addition, as more KB resources are involved, the OOV problem is relieved. Since all the OOV resources have exactly the same attention towards a question, it will weaken the effectiveness of the attention model. So the alleviation of OOV is able to bring additional benefits to the attention model.

4 Experiments

To evaluate the proposed method, we conduct experiments on WebQuestions (Berant et al., 2013) dataset that includes 3,778 question-answer pairs for training and 2,032 for testing. The questions are collected from Google Suggest API, and the answers are labeled manually by Amazon MTurk. All the answers are from Freebase. We use three-quarter of the training data as training set, and the left as validate set. We use F_1 score as evaluation matric, and the average result is computed by the script provided by Berant et al. (2013).

Note that our proposed approach is an entire end-to-end method, which totally depends on training data. It is worth noting that Yih et al. (2015; 2016) achieve much higher F_1 scores than other methods. Their staged system is able to address more questions with constraints and aggregations. However, their approach applies numbers of manually designed rules and features, which come from the observations on the training set questions. These particular manual efforts reduce the adaptability of their approach. Moreover, there are some integrated systems such as Xu et al. (2016a; 2016b) achieve higher F_1 scores which leverage Wikipedia free text as external knowledge, so their systems are not directly comparable to ours.

4.1 Settings

For KB-QA training, we use mini-batch stochastic gradient descent to minimize the pairwise training loss. The minibatch size is set to 100. The learning rate is set to 0.01. Both the word embedding matrix E_w and KB embedding matrix E_v are normalized after each epoch. The embedding size d = 512, then the hidden unit size is 256. Margin γ is set to 0.6. Negative example number k = 2000. We set the embedding dimension to 512 in TransE training process, and the minibatch size is also 100. γ_k is set to 1. All these hyperparameters of the proposed network is determined according to the performance on the validate set.

4.2 Results

The effectiveness of the proposed approach

To demonstrate the effectiveness of the proposed approach, we compare our method with state-of-the-art end-to-end NN-based methods.

Methods	Avg F_1
Bordes et al., 2014b	29.7
Bordes et al., 2014a	39.2
Yang et al., 2014	41.3
Dong et al., 2015	40.8
Bordes et al., 2015	42.2
our approach	**42.9**

Table 1: The evaluation results on WebQuestions.

Table 1 shows the results on WebQuestions dataset. Bordes et al. (2014b) apply BOW method to obtain a single vector for both questions and answers. Bordes et al. (2014a) further improve their work by proposing the concept of subgraph embeddings. Besides the answer path, the sub-

graph contains all the entities and relations connected to the answer entity. The final vector is also obtained by bag-of-words strategy. Yang et al. (2014) follow the SP-based manner, but uses embeddings to map entities and relations into KB resources, then the question can be converted into logical forms. They jointly consider the two mapping processes. Dong et al. (2015) use three columns of Convolutional Neural Networks (CNNs) to represent questions corresponding to three aspects of the answers, namely the answer context, the answer path and the answer type. Bordes et al. (2015) put KB-QA into the memory networks framework (Sukhbaatar et al., 2015), and achieves the state-of-the-art performance of end-to-end methods. Our approach employs bidirectional LSTM, cross-attention model and global KB information.

From the results, we observe that our approach achieves the best performance of all the end-to-end methods on WebQuestions. Bordes et al. (2014b; 2014a; 2015) all utilize BOW model to represent the questions, while ours takes advantage of the attention of answer aspects to dynamically represent the questions. Also note that Bordes et al. (2015) uses additional training data such as Reverb (Fader et al., 2011) and their original dataset SimpleQuestions. Dong et al. (2015) employs three fixed CNNs to represent questions, while ours is able to express the focus of each unique answer aspect to the words in the question. Besides, our approach employs the global KB information. So, we believe that the results faithfully show that the proposed approach is more effective than the other competitive methods.

Model Analysis

In this part, we further discuss the impacts of the components of our model. Table 2 indicates the effectiveness of different parts in the model.

Methods	Avg F_1
LSTM	38.2
Bi_LSTM	39.1
Bi_LSTM+A-Q-ATT	41.6
Bi_LSTM+C-ATT	41.8
Bi_LSTM+GKI	40.4
Bi_LSTM+A-Q-ATT+GKI	42.6
Bi_LSTM+C-ATT+GKI	42.9

Table 2: The ablation results of our models.

LSTM employs unidirectional LSTM, and uses the last hidden state as the question representation. *Bi_LSTM* adopts a bidirectional LSTM. *A-Q-ATT* denotes the answer-towards-question attention part, and C-ATT stands for our cross-attention. *GKI* means global knowledge information. *Bi_LSTMS+C-ATT+GKI* is our full proposed approach. From the results, we could observe the following.

1) *Bi_LSTM+C-ATT* dramatically improves the F_1 score by 2.7 points compared with *Bi_LSTM*, 0.2 points higher than *Bi_LSTM+A-Q-ATT*. Similarly, *Bi_LSTM+C-ATT+GKI* significantly outperforms *Bi_LSTM+GKI* by 2.5 points, improving *Bi_LSTM+A-Q-ATT+GKI* by 0.3 points. The results prove that the proposed cross-attention model is effective.

2) *Bi_LSTM+GKI* performs better than *Bi_LSTM*, and achieves an improvement of 1.3 points. Similarly, *Bi_LSTM+C-ATT+GKI* improves *Bi_LSTM+C-ATT* by 1.1 points, which indicates that the proposed training strategy successfully leverages the global information of the underlying KB.

3) *Bi_LSTM+C-ATT+GKI* achieves the best performance as we expected, and improves the original *Bi_LSTM* dramatically by 3.8 points. This directly shows the power of the attention model and the global KB information.

To illustrate the effectiveness of the attention mechanism clearly, we present the attention weights of a question in the form of heat map as shown in Figure 3.

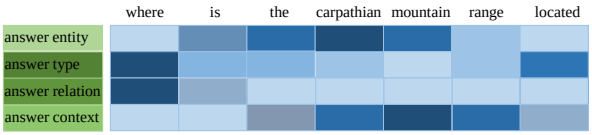

Figure 3: The visualized attention heat map. Answer entity: `/m/06npd(Slovakia)`, answer relation: `partially_containedby`, answer type: `/location/country`, answer context: `(/m/04dq9kf, /m/01mp, ...)`

From this example we observe that our methods is able to capture the attention properly. It is instructive to figure out the attention part of the question when dealing with different answer aspects. The heat map will help us understand which parts are most useful for selecting correct answers. For instance, from Figure 3, we can see that `location.country` is paying great attention

to "Where", indicating that "Where" is much more important than the other parts in the question when dealing with this type. In other words, the other parts are not that crucial since "Where" is strongly implying that the question is asking about a location. As for Q-A attention part, we see that answer type and answer relation are more important than other answer aspects in this example.

4.3 Error Analysis

We randomly sample 100 imperfectly answered questions and categorize the errors into two main classes as follows.

Wrong attention

In some occasions (18 in 100 questions, 18%), we find the generated attention weights unreasonable. For instance, for question "What are the songs that Justin Bieber wrote?", answer type `/music/composition` pays the most attention on "What" rather than "songs". We think this is due to the bias of the training data, and we believe these errors could be solved by introducing more instructive training data.

Complex questions and label errors

Another challenging problem is the complex questions (35%). For example, "When was the last time Knicks won the championship?" is actually to ask the last championship, but the predicted answers give all the championships. This is due to that the model cannot learn what "last" mean in the training process. In addition, the label mistakes also influence the evaluation (3%), such as, "What college did John Nash teach at?", where the labeled answer is `Princeton University`, but `Massachusetts Institute of Technology` should also be an answer, and the proposed method is able to answer it correctly. Other errors include topic entity generation error and the multiple answers error (giving more answers than expected). We guess these errors are caused by the simple implementations of the related steps in our method, and we will not explain them in detail.

5 Related Work

The past years have seen a growing amount of research on KB-QA, shaping an interaction paradigm that allows end users to profit from the expressive power of Semantic Web data while at the same time hiding their complexity behind an intuitive and easy-to-use interface. At the same time the growing amount of data has led to a heterogeneous data landscape where QA systems struggle to keep up with the volume, variety and veracity of the underlying knowledge.

5.1 Neural Network-based KB-QA

In recent years, deep neural networks have been applied to many NLP tasks, showing promising results. Bordes et al. (2014b) was the first to introduce NN-based method to solve KB-QA problem. The questions and KB triples were represented by vectors in a low dimensional space. Thus the cosine similarity could be used to find the most possible answer. BOW method was employed to obtain a single vector for both the questions and the answers. Pairwise training was utilized, and the negative examples were randomly selected from the KB facts. Bordes et al. (2014a) further improved their work by proposing the concept of subgraph embeddings. The key idea was to involve as much information as possible in the answer end. Besides the answer triple, the subgraph contained all the entities and relations connected to the answer entity. The final vector was also obtained by bag-of-words strategy.

Yih et al. (2014) focused on single-relation questions. The KB-QA task was divided into two steps. Firstly, they found the topic entity of the question. Then, the rest of the question was represented by CNNs and used to match relations. Yang et al. (2014) tackled entity and relation mapping as joint procedures. Actually, these two methods followed the SP-based manner, but they took advantage of neural networks to obtain intermediate mapping results.

The most similar work to ours is Dong et al. (2015). They considered the different aspects of answers, using three columns of CNNs to represent questions respectively. The difference is that our approach uses cross-attention mechanism for each unique answer aspect, so the question representation is not fixed to only three types. Moreover, we utilize the global KB information.

Xu et al. (2016a; 2016b) proposed integrated systems to address KB-QA problems incorporating Wikipedia free text, in which they used multi-channel CNNs to extract relations.

5.2 Attention-based Model

The attention mechanism has been widely used in different areas. Bahdanau et al. (2015) first applied attention model in NLP. They improved

the encoder-decoder Neural Machine Translation (NMT) framework by jointly learning align and translation. They argued that representing source sentence by a fixed vector is unreasonable, and proposed a soft-align method, which could be understood as attention mechanism. Rush et al. (2015) implemented sentence-level summarization task. They utilized local attention-based model that generated each word of the summary conditioned on the input sentence. Wang et al. (2016) proposed an inner attention mechanism that the attention was imposed directly to the input. And their experiment on answer selection showed the advantage of inner attention compared with traditional attention methods.

Yin et al. (2016) tackled simple question answering by an attentive convolutional neural network. They stacked an attentive max-pooling above convolution layer to model the relationship between predicates and question patterns. Our approach differs from previous work in that we use attentions to help represent questions dynamically, not generating current word from vocabulary as before.

6 Conclusion

In this paper, we focus on KB-QA task. Firstly, we consider the impacts of the different answer aspects when representing the question, and propose a novel cross-attention model for KB-QA. Specifically, we employ the focus of the answer aspects to each question word and the attention weights of the question towards the answer aspects. This kind of dynamic representation is more precise and flexible. Secondly, we leverage the global KB information, which could take full advantage of the complete KB, and also alleviate the OOV problem for the attention model. The extensive experiments demonstrate that the proposed approach could achieve better performance compared with state-of-the-art end-to-end methods.

Translating Neuralese

Jacob Andreas **Anca Dragan** **Dan Klein**
Computer Science Division
University of California, Berkeley
{jda,anca,klein}@cs.berkeley.edu

Abstract

Several approaches have recently been proposed for learning decentralized deep multiagent policies that coordinate via a differentiable communication channel. While these policies are effective for many tasks, interpretation of their induced communication strategies has remained a challenge. Here we propose to interpret agents' messages by translating them. Unlike in typical machine translation problems, we have no parallel data to learn from. Instead we develop a translation model based on the insight that agent messages and natural language strings mean the same thing *if they induce the same belief about the world in a listener*. We present theoretical guarantees and empirical evidence that our approach preserves both the semantics and pragmatics of messages by ensuring that players communicating through a translation layer do not suffer a substantial loss in reward relative to players with a common language.[1]

1 Introduction

Several recent papers have described approaches for learning *deep communicating policies* (DCPs): decentralized representations of behavior that enable multiple agents to communicate via a differentiable channel that can be formulated as a recurrent neural network. DCPs have been shown to solve a variety of coordination problems, including reference games (Lazaridou et al., 2016b), logic puzzles (Foerster et al., 2016), and simple control (Sukhbaatar et al., 2016). Appealingly, the agents' communication protocol can be learned via direct backpropagation through the communication channel, avoiding many of the challenging inference problems associated with learning in classical decentralized decision processes (Roth et al., 2005).

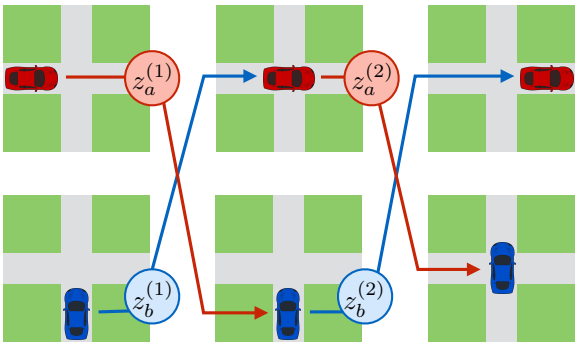

Figure 1: Example interaction between a pair of agents in a deep communicating policy. Both cars are attempting to cross the intersection, but cannot see each other. By exchanging message vectors $z^{(t)}$, the agents are able to coordinate and avoid a collision. This paper presents an approach for *understanding* the contents of these message vectors by translating them into natural language.

But analysis of the strategies induced by DCPs has remained a challenge. As an example, Figure 1 depicts a driving game in which two cars, which are unable to see each other, must both cross an intersection without colliding. In order to ensure success, it is clear that the cars must communicate with each other. But a number of successful communication strategies are possible—for example, they might report their exact (x, y) coordinates at every timestep, or they might simply announce whenever they are entering and leaving the intersection. If these messages were communicated in natural language, it would be straightforward to determine which strategy was being employed. However, DCP agents instead communicate with an automatically induced protocol of unstructured, real-valued recurrent state vectors—an artificial language we might call "neuralese," which superficially bears little resemblance to natural language, and thus frustrates attempts at direct interpretation.

[1] We have released code and data at http://github.com/jacobandreas/neuralese.

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 232–242
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1022

We propose to understand neuralese messages by *translating* them. In this work, we present a simple technique for inducing a dictionary that maps between neuralese message vectors and short natural language strings, given only examples of DCP agents interacting with other agents, and humans interacting with other humans. Natural language already provides a rich set of tools for describing beliefs, observations, and plans—our thesis is that these tools provide a useful complement to the visualization and ablation techniques used in previous work on understanding complex models (Strobelt et al., 2016; Ribeiro et al., 2016).

While structurally quite similar to the task of machine translation between pairs of human languages, interpretation of neuralese poses a number of novel challenges. First, there is no natural source of parallel data: there are no bilingual "speakers" of both neuralese and natural language. Second, there may not be a direct correspondence between the strategy employed by humans and DCP agents: even if it were constrained to communicate using natural language, an automated agent might choose to produce a different message from humans in a given state. We tackle both of these challenges by appealing to the grounding of messages in gameplay. Our approach is based on one of the core insights in natural language semantics: messages (whether in neuralese or natural language) have similar meanings *when they induce similar beliefs about the state of the world*.

Based on this intuition, we introduce a translation criterion that matches neuralese messages with natural language strings by minimizing statistical distance in a common representation space of distributions over speaker states. We explore several related questions:

- What makes a good translation, and under what conditions is translation possible at all? (Section 4)
- How can we build a model to translate between neuralese and natural language? (Section 5)
- What kinds of theoretical guarantees can we provide about the behavior of agents communicating via this translation model? (Section 6)

Our translation model and analysis are general, and in fact apply equally to human–computer and human–human translation problems grounded in gameplay. In this paper, we focus our experiments specifically on the problem of interpreting communication in deep policies, and apply our approach to the driving game in Figure 1 and two reference games of the kind shown in Figure 2. We find that this approach outperforms a more conventional machine translation criterion both when attempting to interoperate with neuralese speakers and when predicting their state.

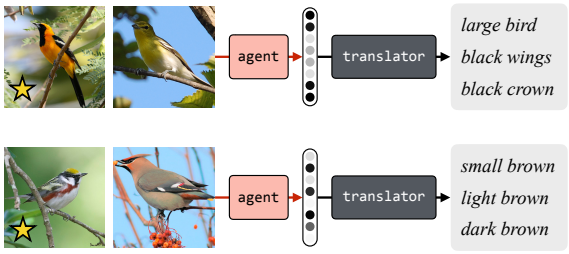

Figure 2: Overview of our approach—best-scoring translations generated for a reference game involving images of birds. The speaking agent's goal is to send a message that uniquely identifies the bird on the left. From these translations it can be seen that the learned model appears to discriminate based on coarse attributes like size and color.

2 Related work

A variety of approaches for learning deep policies with communication were proposed essentially simultaneously in the past year. We have broadly labeled these as "deep communicating policies"; concrete examples include Lazaridou et al. (2016b), Foerster et al. (2016), and Sukhbaatar et al. (2016). The policy representation we employ in this paper is similar to the latter two of these, although the general framework is agnostic to low-level modeling details and could be straightforwardly applied to other architectures. Analysis of communication strategies in all these papers has been largely ad-hoc, obtained by clustering states from which similar messages are emitted and attempting to manually assign semantics to these clusters. The present work aims at developing tools for performing this analysis automatically.

Most closely related to our approach is that of Lazaridou et al. (2016a), who also develop a model for assigning natural language interpretations to learned messages; however, this approach relies on supervised cluster labels and is targeted specifically towards referring expression games. Here we attempt to develop an approach that can handle general multiagent interactions without assuming a prior discrete structure in space of observations.

The literature on learning decentralized multiagent policies in general is considerably larger (Bernstein et al., 2002; Dibangoye et al., 2016). This includes work focused on communication in multiagent settings (Roth et al., 2005) and even communication using natural language messages (Vogel et al., 2013b). All of these approaches employ structured communication schemes with manually engineered messaging protocols; these are, in some sense, automatically interpretable, but at the cost of introducing considerable complexity into both training and inference.

Our evaluation in this paper investigates communication strategies that arise in a number of different games, including reference games and an extended-horizon driving game. Communication strategies for reference games were previously explored by Vogel et al. (2013a), Andreas and Klein (2016) and Kazemzadeh et al. (2014), and reference games specifically featuring end-to-end communication protocols by Yu et al. (2016). On the control side, a long line of work considers nonverbal communication strategies in multiagent policies (Dragan and Srinivasa, 2013).

Another group of related approaches focuses on the development of more general machinery for interpreting deep models in which messages have no explicit semantics. This includes both visualization techniques (Zeiler and Fergus, 2014; Strobelt et al., 2016), and approaches focused on generating explanations in the form of natural language (Hendricks et al., 2016; Vedantam et al., 2017).

3 Problem formulation

Games Consider a cooperative game with two players a and b of the form given in Figure 3. At every step t of this game, player a makes an observation $x_a^{(t)}$ and receives a message $z_b^{(t-1)}$ from b. It then takes an action $u_a^{(t)}$ and sends a message $z_a^{(t)}$ to b. (The process is symmetric for b.) The distributions $p(u_a|x_a, z_b)$ and $p(z_a|x_a)$ together define a policy π which we assume is shared by both players, i.e. $p(u_a|x_a, z_b) = p(u_b|x_b, z_a)$ and $p(z_a|x_a) = p(z_b|x_b)$. As in a standard Markov decision process, the actions $(u_a^{(t)}, u_b^{(t)})$ alter the world state, generating new observations for both players and a reward shared by both.

The distributions $p(z|x)$ and $p(u|x, z)$ may also be viewed as defining a *language*: they specify how a speaker will generate messages based on world states, and how a listener will respond to these messages. Our goal in this work is to learn to translate between pairs of languages generated by different policies. Specifically, we assume that we have access to two policies for the same game: a "robot policy" π_r and a "human policy" π_h. We would like to use the representation of π_h, the behavior of which is transparent to human users, in order to *understand* the behavior of π_r (which is in general an uninterpretable learned model); we will do this by inducing bilingual dictionaries that map message vectors z_r of π_r to natural language strings z_h of π_h and vice-versa.

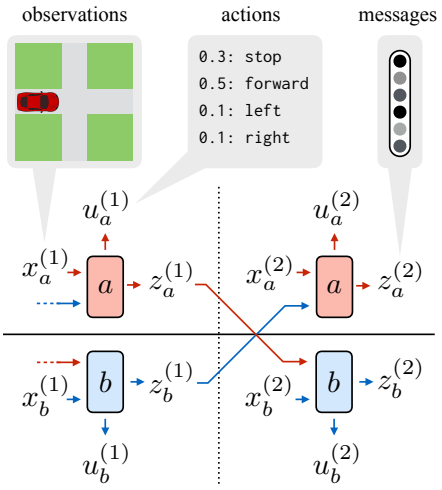

Figure 3: Schematic representation of communication games. At every timestep t, players a and b make an observation $x^{(t)}$ and receive a message $z^{(t-1)}$, then produce an action $u^{(t)}$ and a new message $z^{(t)}$.

Learned agents π_r Our goal is to present tools for interpretation of learned messages that are agnostic to the details of the underlying algorithm for acquiring them. We use a generic DCP model as a basis for the techniques developed in this paper. Here each agent policy is represented as a deep recurrent Q network (Hausknecht and Stone, 2015). This network is built from communicating cells of the kind depicted in Figure 4. At every timestep, this agent receives three pieces of information: an

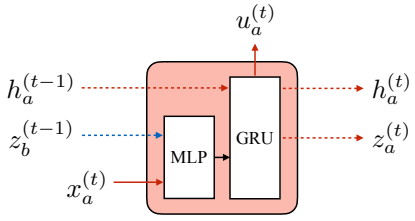

Figure 4: Cell implementing a single step of agent communication (compare with Sukhbaatar et al. (2016) and Foerster et al. (2016)). *MLP* denotes a multilayer perceptron; *GRU* denotes a gated recurrent unit (Cho et al., 2014). Dashed lines represent recurrent connections.

observation of the current state of the world, the agent's memory vector from the previous timestep, and a message from the other player. It then produces three outputs: a predicted Q value for every possible action, a new memory vector for the next timestep, and a message to send to the other agent.

Sukhbaatar et al. (2016) observe that models of this form may be viewed as specifying a single RNN in which weight matrices have a particular block structure. Such models may thus be trained using the standard recurrent Q-learning objective, with communication protocol learned end-to-end.

Human agents π_h The translation model we develop requires a representation of the distribution over messages $p(z_a|x_a)$ employed by human speakers (without assuming that humans and agents produce equivalent messages in equivalent contexts). We model the human message generation process as categorical, and fit a simple multilayer perceptron model to map from observations to words and phrases used during human gameplay.

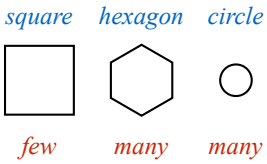
4 What's in a translation?

What does it mean for a message z_h to be a "translation" of a message z_r? In standard machine translation problems, the answer is that z_h is likely to co-occur in parallel data with z_r; that is, $p(z_h|z_r)$ is large. Here we have no parallel data: even if we could observe natural language and neuralese messages produced by agents in the same state, we would have no guarantee that these messages actually served the same function. Our answer must instead appeal to the fact that both natural language and neuralese messages are grounded in a common environment. For a given neuralese message z_r, we will first compute a grounded representation of that message's meaning; to translate, we find a natural-language message whose meaning is most similar. The key question is then what form this grounded meaning representation should take. The existing literature suggests two broad approaches:

Semantic representation The meaning of a message z_a is given by its denotations: that is, by the set of world states of which z_a may be felicitously predicated, given the existing context available to a listener. In probabilistic terms, this says that the meaning of a message z_a is represented by the distribution $p(x_a|z_a, x_b)$ it induces over speaker states. Examples of this approach include Guerin and Pitt (2001) and Pasupat and Liang (2016).

Pragmatic representation The meaning of a message z_a is given by the behavior it induces in a listener. In probabilistic terms, this says that the meaning of a message z_a is represented by the distribution $p(u_b|z_a, x_b)$ it induces over actions given the listener's observation x_b. Examples of this approach include Vogel et al. (2013a) and Gauthier and Mordatch (2016).

These two approaches can give rise to rather different behaviors. Consider the following example:



The top language (in blue) has a unique name for every kind of shape, while the bottom language (in red) only distinguishes between shapes with few sides and shapes with many sides. Now imagine a simple reference game with the following form: player a is covertly assigned one of these three shapes as a reference target, and communicates that reference to b; b must then pull a lever labeled `large` or `small` depending on the size of the target shape. Blue language speakers can achieve perfect success at this game, while red language speakers can succeed at best two out of three times.

How should we translate the blue word *hexagon* into the red language? The semantic approach suggests that we should translate *hexagon* as *many*: while *many* does not uniquely identify the hexagon, it produces a distribution over shapes that is closest to the truth. The pragmatic approach instead suggests that we should translate *hexagon* as *few*, as this is the only message that guarantees that the listener will pull the correct lever `large`. So in order to produce a correct listener action, the translator might have to "lie" and produce a maximally inaccurate listener belief.

If we were exclusively concerned with building a translation layer that allowed humans and DCP agents to interoperate as effectively as possible, it would be natural to adopt a pragmatic representation strategy. But our goals here are broader: we also want to facilitate *understanding*, and specifically to help users of learned systems form true beliefs about the systems' computational processes and representational abstractions. The example above demonstrates that "pragmatically" optimizing directly for task performance can sometimes lead to translations that produce inaccurate beliefs.

We instead build our approach around semantic representations of meaning. By preserving semantics, we allow listeners to reason accurately about the content and interpretation of messages. We might worry that by adopting a semantics-first view, we have given up all guarantees of effective interoperation between humans and agents using a translation layer. Fortunately, this is not so: as we will see in Section 6, it is possible to show that players communicating via a semantic translator perform only boundedly worse (and sometimes better!) than pairs of players with a common language.

5 Translation models

In this section, we build on the intuition that messages should be translated via their semantics to define a concrete translation model—a procedure for constructing a natural language $\leftrightarrow$ neuralese dictionary given agent and human interactions.

We understand the meaning of a message z_a to be represented by the distribution $p(x_a|z_a, x_b)$ it induces over speaker states given listener context. We can formalize this by defining the belief distribution β for a message z and context x_b as:

$$\beta(z_a, x_b) = p(x_a|z_a, x_b) = \frac{p(z_a|x_a)p(x_b|x_a)}{\sum_{x'_a} p(z_a|x'_a)p(x_b|x'_a)}$$

Here we have modeled the listener as performing a single step of Bayesian inference, using the listener state and the message generation model (by assumption shared between players) to compute the posterior over speaker states. While in general neither humans nor DCP agents compute explicit representations of this posterior, past work has found that both humans and suitably-trained neural networks can be modeled as Bayesian reasoners (Frank et al., 2009; Paige and Wood, 2016).

This provides a context-specific representation of belief, but for messages z and z' to have the same semantics, they must induce the same belief over *all* contexts in which they occur. In our probabilistic formulation, this introduces an outer expectation over contexts, providing a final measure q of the quality of a translation from z to z':

$$\begin{aligned} q(z, z') &= \mathbb{E}\big[\mathcal{D}_{\text{KL}}(\beta(z, X_b) \,||\, \beta(z', X_b)) \mid z, z'\big] \\ &= \sum_{x_a, x_b} p(x_a, x_b|z, z')\mathcal{D}_{\text{KL}}(\beta(z, x_b) \,||\, \beta(z', x_b)) \\ &\propto \sum_{x_a, x_b} p(x_a, x_b) \cdot p(z|x_a) \cdot p(z'|x_a) \\ &\qquad \cdot \mathcal{D}_{\text{KL}}(\beta(z, x_b) \,||\, \beta(z', x_b)); \end{aligned} \tag{1}$$

Algorithm 1 Translating messages

given: a phrase inventory L
function TRANSLATE(z)
  return $\arg\min_{z' \in L} \hat{q}(z, z')$

function $\hat{q}(z, z')$
  // sample contexts and distractors
  $x_{ai}, x_{bi} \sim p(X_a, X_b)$ for $i = 1..n$
  $x'_{ai} \sim p(X_a|x_{bi})$
  // compute context weights
  $\tilde{w}_i \leftarrow p(z|x_{ai}) \cdot p(z'|x_{ai})$
  $w_i \leftarrow \tilde{w}_i / \sum_j \tilde{w}_j$
  // compute divergences
  $k_i \leftarrow \sum_{x \in \{x_a, x'_a\}} p(z|x) \log \frac{p(z|x)}{p(z'|x)}$
  return $\sum_i w_i k_i$

recalling that in this setting

$$\begin{aligned} \mathcal{D}_{\text{KL}}(\beta \,||\, \beta') &= \sum_{x_a} p(x_a|z, x_b) \log \frac{p(x_a|z, x_b)}{p(x_a|z', x_b)} \\ &\propto \sum_{x_a} p(x_a|x_b)p(z|x_a) \log \frac{p(z|x_a)}{p(z'|x_a)} \end{aligned} \tag{2}$$

which is zero when the messages z and z' give rise to identical belief distributions and increases as they grow more dissimilar. To translate, we would like to compute $tr(z_r) = \arg\min_{z_h} q(z_r, z_h)$ and $tr(z_h) = \arg\min_{z_r} q(z_h, z_r)$. Intuitively, Equation 1 says that we will measure the quality of a proposed translation $z \mapsto z'$ by asking the following question: in contexts where z is likely to be used, how frequently does z' induce the same belief about speaker states as z?

While this translation criterion directly encodes the semantic notion of meaning described in Section 4, it is doubly intractable: the KL divergence and outer expectation involve a sum over all observations x_a and x_b respectively; these sums are not in general possible to compute efficiently. To avoid this, we approximate Equation 1 by sampling. We draw a collection of samples (x_a, x_b) from the prior over world states, and then generate for each sample a sequence of distractors (x'_a, x_b) from $p(x'_a|x_b)$ (we assume access to both of these distributions from the problem representation). The KL term in Equation 1 is computed over each true sample and its distractors, which are then normalized and averaged to compute the final score.

Sampling accounts for the outer $p(x_a, x_b)$ in Equation 1 and the inner $p(x_a|x_b)$ in Equation 2.

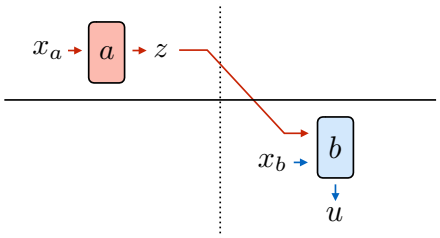


Figure 5: Simplified game representation used for analysis in Section 6. A speaker agent sends a message to a listener agent, which takes a single action and receives a reward.

The only quantities remaining are of the form $p(z|x_a)$. In the case of neuralese, this distribution already is part of the definition of the agent policy π_r and can be reused directly. For natural language, we use transcripts of human interactions to fit a model that maps from world states to a distribution over frequent utterances as discussed in Section 3. Details of these model implementations are provided in Appendix B, and the full translation procedure is given in Algorithm 1.

6 Belief and behavior

The translation criterion in the previous section makes no reference to listener actions at all. The shapes example in Section 4 shows that some model performance might be lost under translation. It is thus reasonable to ask whether this translation model of Section 5 can make any guarantees about the effect of translation on behavior. In this section we explore the relationship between belief-preserving translations and the behaviors they produce, by examining the effect of belief accuracy and strategy mismatch on the reward obtained by cooperating agents.

To facilitate this analysis, we consider a simplified family of communication games with the structure depicted in Figure 5. These games can be viewed as a subset of the family depicted in Figure 3; and consist of two steps: a listener makes an observation x_a and sends a single message z to a speaker, which makes its own observation x_b, takes a single action u, and receives a reward. We emphasize that the results in this section concern the theoretical properties of idealized games, and are presented to provide intuition about high-level properties of our approach. Section 8 investigates empirical behavior of this approach on real-world tasks where these ideal conditions do not hold.

Our first result is that translations that minimize semantic dissimilarity q cause the listener to take near-optimal actions:[2]

[2]Proof is provided in Appendix A.

Proposition 1.
Semantic translations reward rational listeners. Define a *rational listener* as one that chooses the best action in expectation over the speaker's state:

$$U(z, x_b) = \arg\max_u \sum_{x_a} p(x_a|x_b, z) r(x_a, x_b, u)$$

for a reward function $r \in [0, 1]$ that depends only on the two observations and the action.[3] Now let a be a speaker of a language r, b be a listener of the same language r, and b' be a listener of a different language h. Suppose that we wish for a and b' to interact via the translator $tr : z_r \mapsto z_h$ (so that a produces a message z_r, and b' takes an action $U(z_h = tr(z_r), x_{b'})$). If tr respects the semantics of z_r, then the bilingual pair a and b' achieves only boundedly worse reward than the monolingual pair a and b. Specifically, if $q(z_r, z_h) \leq D$, then

$$\mathbb{E}r(X_a, X_b, U(tr(Z))) \geq \mathbb{E}r(X_a, X_b, U(Z)) - \sqrt{2D} \quad (3)$$

So as discussed in Section 4, even by committing to a semantic approach to meaning representation, we have still succeeded in (approximately) capturing the nice properties of the pragmatic approach.

Section 4 examined the consequences of a mismatch between the set of primitives available in two languages. In general we would like some measure of our approach's robustness to the lack of an exact correspondence between two languages. In the case of humans in particular we expect that a variety of different strategies will be employed, many of which will not correspond to the behavior of the learned agent. It is natural to want some assurance that we can identify the DCP's strategy as long as *some* human strategy mirrors it. Our second observation is that it is possible to exactly recover a translation of a DCP strategy from a mixture of humans playing different strategies:

Proposition 2.
Semantic translations find hidden correspondences. Consider a fixed robot policy π_r and a set of human policies $\{\pi_{h1}, \pi_{h2}, \ldots\}$ (recalling from Section 3 that each π is defined by distributions

[3]This notion of rationality is a fairly weak one: it permits many suboptimal communication strategies, and requires only that the listener do as well as possible given a fixed speaker—a first-order optimality criterion likely to be satisfied by any richly-parameterized model trained via gradient descent.

$p(z|x_a)$ and $p(u|z, x_b)$). Suppose further that the messages employed by these human strategies are *disjoint*; that is, if $p_{hi}(z|x_a) > 0$, then $p_{hj}(z|x_a) = 0$ for all $j \neq i$. Now suppose that all $q(z_r, z_h) = 0$ for all messages in the support of some $p_{hi}(z|x_a)$ and > 0 for all $j \neq i$. Then every message z_r is translated into a message produced by π_{hi}, and messages from other strategies are ignored.

This observation follows immediately from the definition of $q(z_r, z_h)$, but demonstrates one of the key distinctions between our approach and a conventional machine translation criterion. Maximizing $p(z_h|z_r)$ will produce the natural language message most often produced in contexts where z_r is observed, regardless of whether that message is useful or informative. By contrast, minimizing $q(z_h, z_r)$ will find the z_h that corresponds most closely to z_r even when z_h is rarely used.

The disjointness condition, while seemingly quite strong, in fact arises naturally in many circumstances—for example, players in the driving game reporting their spatial locations in absolute vs. relative coordinates, or speakers in a color reference game (Figure 6) discriminating based on lightness vs. hue. It is also possible to relax the above condition to require that strategies be only *locally* disjoint (i.e. with the disjointness condition holding for each fixed x_a), in which case overlapping human strategies are allowed, and the recovered robot strategy is a context-weighted mixture of these.

7 Evaluation

7.1 Tasks

In the remainder of the paper, we evaluate the empirical behavior of our approach to translation. Our evaluation considers two kinds of tasks: reference games and navigation games. In a reference game (e.g. Figure 6a), both players observe a pair of candidate referents. A speaker is assigned a target referent; it must communicate this target to a listener, who then performs a choice action corresponding to its belief about the true target. In this paper we consider two variants on the reference game: a simple color-naming task, and a more complex task involving natural images of birds. For examples of human communication strategies for these tasks, we obtain the XKCD color dataset (McMahan and Stone, 2015; Monroe et al., 2016) and the Caltech Birds dataset (Welinder et al., 2010) with accompanying natural language descriptions (Reed et al., 2016). We use standard train / validation / test splits for both of these datasets.

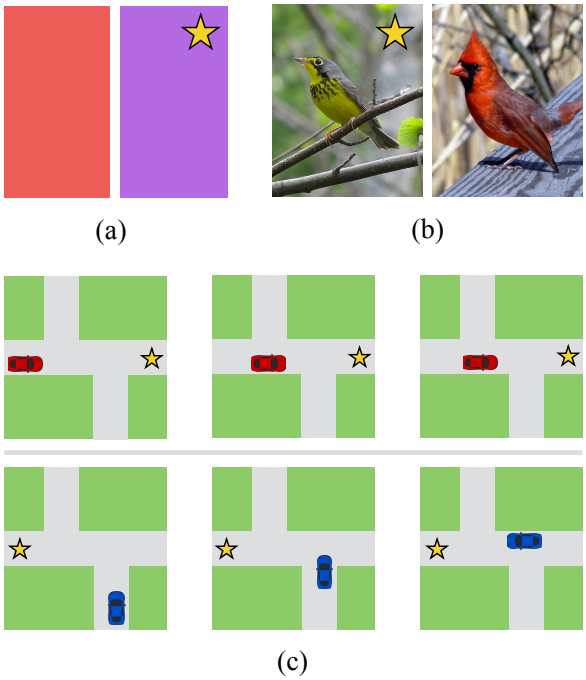

Figure 6: Tasks used to evaluate the translation model. (a–b) Reference games: both players observe a pair of reference candidates (colors or images); Player a is assigned a target (marked with a star), which player b must guess based on a message from a. (c) Driving game: each car attempts to navigate to its goal (marked with a star). The cars cannot see each other, and must communicate to avoid a collision.

The final task we consider is the driving task (Figure 6c) first discussed in the introduction. In this task, two cars, invisible to each other, must each navigate between randomly assigned start and goal positions without colliding. This task takes a number of steps to complete, and potentially involves a much broader range of communication strategies. To obtain human annotations for this task, we recorded both actions and messages generated by pairs of human Amazon Mechanical Turk workers playing the driving game with each other. We collected close to 400 games, with a total of more than 2000 messages exchanged, from which we held out 100 game traces as a test set.

7.2 Metrics

A mechanism for understanding the behavior of a learned model should allow a human user both to correctly infer its beliefs and to successfully interoperate with it; we accordingly report results of both "belief" and "behavior" evaluations.

To support easy reproduction and comparison (and in keeping with standard practice in machine

translation), we focus on developing automatic measures of system performance. We use the available training data to develop simulated models of human decisions; by first showing that these models track well with human judgments, we can be confident that their use in evaluations will correlate with human understanding. We employ the following two metrics:

Belief evaluation This evaluation focuses on the denotational perspective in semantics that motivated the initial development of our model. We have successfully understood the semantics of a message z_r if, after translating $z_r \mapsto z_h$, a human listener can form a correct belief about the state in which z_r was produced. We construct a simple state-guessing game where the listener is presented with a translated message and two state observations, and must guess which state the speaker was in when the message was emitted.

When translating from natural language to neuralese, we use the learned agent model to directly guess the hidden state. For neuralese to natural language we must first construct a "model human listener" to map from strings back to state representations; we do this by using the training data to fit a simple regression model that scores (state, sentence) pairs using a bag-of-words sentence representation. We find that our "model human" matches the judgments of real humans 83% of the time on the colors task, 77% of the time on the birds task, and 77% of the time on the driving task. This gives us confidence that the model human gives a reasonably accurate proxy for human interpretation.

Behavior evaluation This evaluation focuses on the cooperative aspects of interpretability: we measure the extent to which learned models are able to interoperate with each other by way of a translation layer. In the case of reference games, the goal of this semantic evaluation is identical to the goal of the game itself (to identify the hidden state of the speaker), so we perform this additional pragmatic evaluation only for the driving game. We found that the most data-efficient and reliable way to make use of human game traces was to construct a "deaf" model human. The evaluation selects a full game trace from a human player, and replays both the human's actions and messages exactly (disregarding any incoming messages); the evaluation measures the quality of the natural-language-to-neuralese translator, and the extent to which the learned agent model can accommodate a (real) human given translations of the human's messages.

(a)

as listener	as speaker: R	as speaker: H

		0.60	belief (ours)
H*	0.50	0.77	
	0.57		
	0.75		

Table 1: Evaluation results for reference games. (a) The colors task. (b) The birds task. Whether the model human is in a listener or speaker role, translation based on belief matching outperforms both random and machine translation baselines.

Baselines We compare our approach to two baselines: a *random* baseline that chooses a translation of each input uniformly from messages observed during training, and a *direct* baseline that directly maximizes $p(z'|z)$ (by analogy to a conventional machine translation system). This is accomplished by sampling from a DCP speaker in training states labeled with natural language strings.

8 Results

In all below, "R" indicates a DCP agent, "H" indicates a real human, and "H*" indicates a model human player.

Reference games Results for the two reference games are shown in Table 1. The end-to-end trained model achieves nearly perfect accuracy in both

		0.45	direct
		0.61	belief (ours)
H*	0.5	0.77	
	0.45		
	0.57		

Table 2: Belief evaluation results for the driving game. Driving states are challenging to identify based on messages alone (as evidenced by the comparatively low scores obtained by single-language pairs) . Translation based on belief achieves the best overall performance in both directions.

R / R	H / H	R / H	
1.93 / 0.71	— / 0.77	1.35 / 0.64	random
		1.49 / **0.67**	direct
		1.54 / 0.67	belief (ours)

Table 3: Behavior evaluation results for the driving game. Scores are presented in the form "reward / completion rate". While less accurate than either humans or DCPs with a shared language, the models that employ a translation layer obtain higher reward and a greater overall success rate than baselines.

cases, while a model trained to communicate in natural language achieves somewhat lower performance. Regardless of whether the speaker is a DCP and the listener a model human or vice-versa, translation based on the belief-matching criterion in Section 5 achieves the best performance; indeed, when translating neuralese color names to natural language, the listener is able to achieve a slightly higher score than it is natively. This suggests that the automated agent has discovered a more effective strategy than the one demonstrated by humans in the dataset, and that the effectiveness of this strategy is preserved by translation. Example translations from the reference games are depicted in Figure 2 and Figure 7.

Driving game Behavior evaluation of the driving game is shown in Table 3, and belief evaluation is shown in Table 2. Translation of messages in the driving game is considerably more challenging than in the reference games, and scores are uniformly lower; however, a clear benefit from the belief-matching model is still visible. Belief matching leads to higher scores on the belief evaluation in both directions, and allows agents to obtain a higher reward on average (though task completion rates remain roughly the same across all agents). Some example translations of driving game messages are shown in Figure 8.

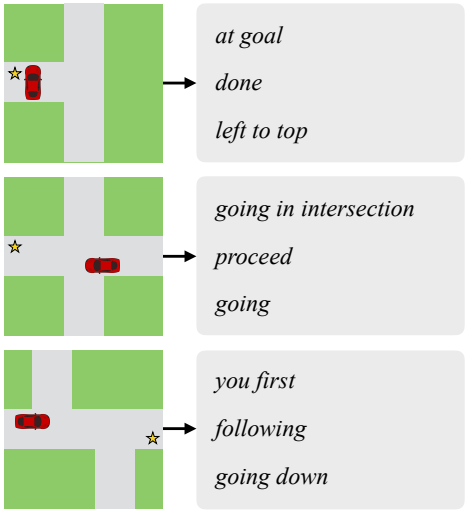

Figure 8: Best-scoring translations generated for driving task generated from the given speaker state.

9 Conclusion

We have investigated the problem of interpreting message vectors from deep networks by translating them. After introducing a translation criterion based on matching listener beliefs about speaker states, we presented both theoretical and empirical evidence that this criterion outperforms a conventional machine translation approach at recovering the content of message vectors and facilitating collaboration between humans and learned agents.

While our evaluation has focused on understanding the behavior of deep communicating policies, the framework proposed in this paper could be much more generally applied. Any encoder–decoder model (Sutskever et al., 2014) can be thought of as a kind of communication game played between the encoder and the decoder, so we can analogously imagine computing and translating "beliefs" induced by the encoding to explain what features of the input are being transmitted. The current work has focused on learning a purely categorical model of the translation process, supported by an unstructured inventory of translation candidates, and future work could explore the *compositional* structure of messages, and attempt to synthesize novel natural language or neuralese messages from scratch. More broadly, the work here shows that the denotational perspective from formal semantics provides a framework for precisely framing the demands of interpretable machine learning (Wilson et al., 2016), and particularly for ensuring that human users without prior exposure to a learned model are able to interoperate with it, predict its behavior, and diagnose its errors.

Obtaining referential word meanings from visual and distributional information: Experiments on object naming

Sina Zarrieß and **David Schlangen**

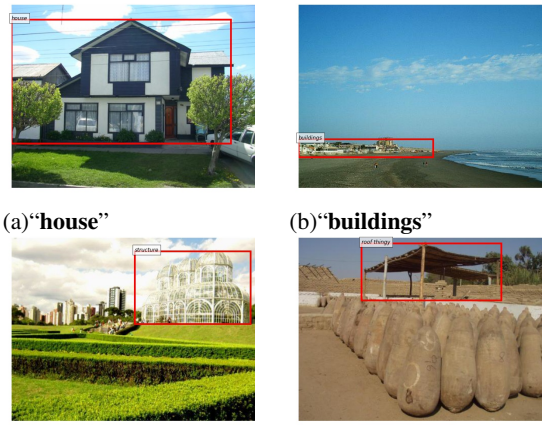
{sina.zarriess,david.schlangen}@uni-bielefeld.de

Abstract

We investigate object naming, which is an important sub-task of referring expression generation on real-world images. As opposed to mutually exclusive labels used in object recognition, object names are more flexible, subject to communicative preferences and semantically related to each other. Therefore, we investigate models of referential word meaning that link visual to lexical information which we assume to be given through distributional word embeddings. We present a model that learns individual predictors for object names that link visual and distributional aspects of word meaning during training. We show that this is particularly beneficial for zero-shot learning, as compared to projecting visual objects directly into the distributional space. In a standard object naming task, we find that different ways of combining lexical and visual information achieve very similar performance, though experiments on model combination suggest that they capture complementary aspects of referential meaning.

1 Introduction

Expressions referring to objects in visual scenes typically include a word naming the type of the object: E.g., *house* in Figure 1 (a), or, as a very general type, *thingy* in Figure 1 (d). Determining such a name is a crucial step for referring expression generation (REG) systems, as many other decisions concerning, e.g., the selection of attributes follow from it (Dale and Reiter, 1995; Krahmer and Van Deemter, 2012). For a long time, however, research on REG mostly assumed the availability of symbolic representations of referent and scene, and sidestepped questions about how speakers actually choose these names, due to the lack of models capable of capturing what a word like *house* refers to in the real world.



(a)"**house**" (b)"**buildings**"

(c)"large **structure**" (d)"roof **thingy**"

Figure 1: Examples of object names in the REFERIT corpus referring to instances of buildings

Recent advances in image processing promise to fill this gap, with state-of-the-art computer vision systems being able to classify images into thousands of different categories (e.g. Szegedy et al. (2015)). However, classification is not naming (Ordonez et al., 2016). Standard object classification schemes are inherently "flat", and treat object labels as mutually exclusive (Deng et al., 2014). A state-of-the-art object recognition system would be trained to classify the object in e.g. Figure 1 (a) as either *house* or *building*, ignoring the lexical similarity between these two names. In contrast, humans seem to be more flexible as to the chosen level of generality. Depending on the prototypicality of the object to name, and possibly other visual properties, a general name might be more or less appropriate. For instance, a robin can be named *bird*, but a penguin is better referred

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 243–254
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1023

to as "*penguin*" (Rosch, 1978); along the same lines, the rather unusual building in Figure 1 (c) that is not easy to otherwise categorise was named "*structure*".

Other work at the intersection of image and language processing has investigated models that learn to directly associate visual objects with a continuous representation of word meaning, i.e. through cross-modal transfer into distributional vector spaces (Frome et al., 2013; Norouzi et al., 2013). Here, the idea is to exploit a powerful model of lexical similarity induced from large amounts text for being able to capture inherent lexical relations between object categories. Thus, under the assumption that such semantic spaces represent, in some form at least, taxonomic knowledge, this makes labels on different levels of specificity available for a given object. Moreover, if the mapping is sufficiently general, it should be able to map objects to an appropriate label, even if during training of the mapping this label has not been seen (*zero-shot learning*).

While cross-modal transfer seems to be a conceptually attractive model for learning object names, it is based on an important assumption that, in our view, has not received sufficient attention in previous works: it assumes that a given distributional vector space constitutes an optimal target representation that visual instances of objects can be mapped to. However, distributional representations of word meaning are known to capture a rather fuzzy notion of lexical similarity, e.g. *car* is similar to *van* and to *street*. A cross-modal transfer model is "forced" to learn to map objects into the same area in the semantic space if their names are distributionally similar, but regardless of their actual visual similarity. Indeed, we have found in a recent study that the contribution of distributional information to learning referential word meanings is restricted to certain types of words and does not generalize across the vocabulary (Zarrieß and Schlangen, 2017).

The goal of this work is to learn a model of referential word meaning that makes accurate object naming predictions and goes beyond treating words as independent, mutually exclusive labels in a flat classification scheme. We extend upon work on learning models of referential word use from corpora of images paired with referring expressions (Schlangen et al., 2016; Zarrieß and Schlangen, 2017) that treats words as individual predictors capturing referential appropriateness. We explore different ways of linking these predictors to distributional knowledge, during application and during training. We find that these different models achieve very similar performance in a standard object naming task, though experiments on model combination suggest that they capture complementary aspects of referential meaning. In a zero-shot setup of an object naming task, we find that combining lexical and visual information during training is most beneficial, outperforming variants of cross-modal transfer.

2 Related Work

Grounding and Reference An early example for work in REG that goes beyond Dale and Reiter (1995)'s dominant symbolic paradigm is Deb Roy's work from the early 2000s (Roy et al., 2002; Roy, 2002, 2005). Roy et al. (2002) use computer vision techniques to process a video feed, and to compute colour, positional and spatial features. These features are then associated in a learning process with certain words, resulting in an association of colour features with colour words, spatial features with prepositions, etc., and based on this, these words can be interpreted with reference to the scene currently presented to the video feed. Whereas Roy's work still looked at relatively simple scenes with graphical objects, research on REG has recently started to investigate set-ups based on real-world images (Kazemzadeh et al., 2014; Gkatzia et al., 2015; Zarrieß and Schlangen, 2016; Mao et al., 2015). Importantly, the low-level visual features that can be extracted from these scenes correspond less directly to particular word classes. Moreover, the visual scenes contain many different types of objects, which poses new challenges for REG. For instance, Zarrieß and Schlangen (2016) find that semantic errors related to mismatches between nouns (e.g. the system generates *tree* vs. *man*) are particularly disturbing for users. Whereas Zarrieß and Schlangen (2016) propose a strategy to avoid object names when the systems confidence is low, we focus on improving the generation of object names, using distributional knowledge as an additional source. Similarly, Ordonez et al. (2016) have studied the problem of deriving appropriate object names, or so-called entry-level categories, from the output of an object recognizer. Their approach focusses on linking abstract object categories in ImageNet

to actual words via various translation procedures. We are interested in learning referential appropriateness and extensional word meanings directly from actual human referring expressions (REs) paired with objects in images, using an existing object recognizer for feature extraction.

Multi-modal distributional semantics Distributional semantic models are a well-known method for capturing lexical word meaning in a variety of tasks (Turney and Pantel, 2010; Mikolov et al., 2013; Erk, 2016). Recent work on multimodal distributional vector spaces (Feng and Lapata, 2010; Silberer and Lapata, 2014; Kiela and Bottou, 2014; Lazaridou et al., 2015b; Kottur et al., 2016) has aimed at capturing semantic similarity even more accurately by integrating distributional and perceptual features associated with words (mostly taken from images) into a single representation.

Cross-modal transfer Rather than fusing different modalities into a single, joint space, other work has looked at cross-modal mapping between spaces. Herbelot and Vecchi (2015) present a model that learns to map vectors in a distributional space to vectors in a set-theoretic space, showing that there is a functional relationship between distributional information and conceptual knowledge representing quantifiers and predicates. More related to our work are cross-modal mapping models,that learn to transfer from a representation of an object or image in the visual space to a vector in a distributional space (Socher et al., 2013; Frome et al., 2013; Norouzi et al., 2013; Lazaridou et al., 2014). Here, the motivation is to exploit the rich lexical knowledge encoded in a distributional space for learning visual classifications. In practice, these models are mostly used for zero-shot learning where the test set contains object categories not observed during training. When tested on standard object recognition tasks, transfer, however, comes at a price. Frome et al. (2013) and Norouzi et al. (2013) both find that it slightly degrades performance as compared to a plain object classification using standard accuracy metrics (called flat "hit @k metric" in their paper). Interestingly though, Frome et al. (2013) report better performance using "hierarchical precision", which essentially means that transfer predicts words that are ontologically closer to the gold label and makes "semantically more reasonable errors". To the best of our knowledge, this pattern has not been systematically investigated any further. Another known problem with cross-modal transfer is that it seems to generalize less well than expected, i.e. tends to reproduce word vectors observed during training (Lazaridou et al., 2015a). In this work, we present a model that exploits distributional knowledge for learning referential word meaning as well, but explore and compare different ways of combining visual and lexical aspects of referential word meaning.

3 Task and Data

We define *object naming* as follows: Given an object x in an image, the task is to predict a word w that could be used as the head noun of a realistic referring expression. (Cf. discussion above: "*bird*" when naming a robin, but "*penguin*" when naming a penguin.) To get at this, we develop our approach using a corpus of referring expressions produced by human users under natural, interactive conditions (Kazemzadeh et al., 2014), and train and test on the corresponding head nouns in these REs. This is similar to picture naming setups used in psycholinguistic research (cf. Levelt et al. (1991)) and based on the simplifying assumption that the name used for referring to an object can be determined successfully without looking at other objects in the image.

We now summarise the details of our setup:

Corpus We train and test on the REFERIT corpus (Kazemzadeh et al., 2014), which is based on the SAIAPR image collection (Grubinger et al., 2006) (99.5k image regions;120K REs). We follow (Schlangen et al., 2016) and select words with a minimum frequency of 40 in these two data sets, which gives us a vocabulary of 793 words.

Names For most of our experiments, we only use a subset of this vocabulary, namely the set of object names. As the REs contain nouns that cannot be considered to be object names (*background, bottom*, etc.), we extract a list of names from the semantically annotated held-out set released with the REFERIT. These correspond to 'entry-level' nouns mentioned in Kazemzadeh et al. (2014). This gives us a list of 159 names. This set corresponds to the majority of object names in the corpus: out of the 99.5K available image regions, we use 80K for training and testing. Thus, our experiments are on a smaller scale as compared

to (Ordonez et al., 2016). Nevertheless, the data is challenging, as the corpus contains references to objects that fall outside of the object labeling scheme that available object recognition systems are typically optimized for, cf. Hu et al. (2015)'s discussion on "stuff" entities such "sky" or "grass" in the REFERIT data. For testing, we remove relational REs (containing a relational preposition such as 'left of X'), because here we cannot be sure that the head noun of the target is fully informative; we also remove REs with more than one head noun from our list (i.e. these are mostly relational expressions as well such as 'girl laughing at boy'). We pair each image region from the test set with its corresponding names from the remaining REs.

Image and Word Embeddings Following Schlangen et al. (2016), we derive representations of our visual inputs with a convolutional neural network, 'GoogleNet' (Szegedy et al., 2015), which was trained on the ImageNet corpus (Deng et al., 2009), and extract the final fully-connected layer before the classification layer, to give us a 1024 dimensional representation of the region. We add 7 features that encode information about the region relative to the image, thus representing each object as a vector of 1031 features. As distributional word vectors, we use the `word2vec` representations provided by Baroni et al. (2014) (trained with CBOW, 5-word context window, 10 negative samples, 400 dimensions).

4 Three Models of Interfacing Visual and Distributional Information

4.1 Direct Cross-Modal Mapping

Following Lazaridou et al. (2014), referential meaning can be represented as a translation function that projects visual representations of objects to linguistic representations of words in a distributional vector space. Thus, in contrast to standard object recognition systems or the other models we will use here, cross-modal mapping does not treat words as individual labels or classifiers, but learns to directly predict continuous representations of words in a vector space, such as the space defined by the `word2vec` embeddings that we use in this work. This model will be called TRANSFER below.

During training, we pair each object with the distributional embedding of its name, and use standard Ridge regression for learning the transformation. Lazaridou et al. (2014) and Lazaridou et al. (2015a) test a range of technical tweaks and different algorithms for cross-modal mapping. For ease of comparison with other models, we stick with simple Ridge Regression in this work.

For decoding, we map an object into the distributional space, and retrieve the nearest neighbors of the predicted vector using cosine similarity. In theory, the model should generalize easily to words that it has not observed in a pair with an object during training as it can map an object anywhere in the distributional space.

4.2 Lexical Mapping Through Individual Word Classifiers

Another approach is to keep visual and distributional information separate, by training a separate visual classifier for each word w in the vocabulary. Predictions can then be mapped into distributional space during application time via the vectors of the predicted words. Here, we use Schlangen et al. (2016)'s WAC model, building the training set for each word w as follows: all visual objects in a corpus that have been referred to as w are used as positive instances, the remaining objects as negative instances. Thus, the classifiers learn to predict referential appropriateness for individual words based on the visual features of the objects they refer to, in isolation of other words.

During decoding, we apply all word classifiers from the model's vocabulary to the given object, and take the argmax over the individual word probabilities. The model predicts names directly, without links into a distributional space.

In order to extend the model's vocabulary for zero-shot learning, we follow Norouzi et al. (2013) and associate the top n words with their corresponding distributional vector and compute the convex combination of these vectors. Then, in parallel to cross-modal mapping, we retrieve the nearest neighbors of the combined embedding from the distributional space. Thus, with this model, we use two different modes of decoding: one that projects into distributional space, one that only applies the available word classifiers.

We did some small-scale experiments to find an optimal value for n, similar to Norouzi et al. (2013). In our case, performance started to decrease systematically with $n > 10$, but did not differ significantly for values below 10. In Section 5, we will report results for n set to 5 and 10.

4.3 Word Prediction via Cross-Modal Similarity Mapping

Finally, we implement an approach that combines ideas from cross-modal mapping with the WAC model: we train individual predictors for each word in the vocabulary, but, during training, we exploit lexical similarity relations encoded in a distributional space. Instead of treating a word as a binary classifier, we annotate its training instances with a fine-grained similarity signal according to their object names. When building the training set for such a word predictor w, instead of simply dividing objects into w and $\neg w$ instances, we label each object with a real-valued similarity obtained from cosine similarity between w and v in a distributional vector space, where v is the word that was used to refer to the object. Thus, we task the model with jointly learning similarities and referential appropriateness, by training it with Ridge regression on a continuous output space. Object instances where $v = w$ (i.e., the positive instances in the binary setup) have maximal similarity; the remaining instances have a lower value which is more or less close to maximal similarity. This is the SIM-WAP model, recently proposed in Zarrieß and Schlangen (2017).

Importantly, and going beyond Zarrieß and Schlangen (2017), this model allows for an innovative treatment of words that only exist in a distributional space (without being paired with visual referents in the image corpus): as the predictors are trained on a continuous output space, no genuine positive instances of a word's referent are needed. When training a predictor for such a word w, we use all available objects from our corpus and annotate them with the expected lexical similarity between w and the actual object names v, which for all objects will be below the maximal value that marks genuine positive instances. During decoding, this model does not need to project its predictions into a distributional space, but it simply applies all available predictors to the object, and takes the argmax over the predicted referential appropriateness scores.

5 Experiment 1: Naming Objects

This Section reports on experiments in a standard setup of the object naming task where all object names are paired with visual instances of their referents during training. In a comparable task, i.e. object recognition with known object categories, cross-modal projection or transfer approaches have been reported to perform worse than standard object classification methods (Frome et al., 2013; Norouzi et al., 2013). This seems to suggest that lexical or at least distributional knowledge is detrimental when learning what a word refers to in the real world and that referential meaning should potentially be learned from visual object representation only.

5.1 Model comparison

Setup We use the train/test split of REFERIT data as in (Schlangen et al., 2016). We consider image regions with non-relational referring expressions that contain at least one of the 159 head nouns from the list of entry-level nouns (see section 3). This amounts to 6208 image regions for testing and 73K instances for training.

Results Table 1 shows accuracies in the object naming task for the TRANSFER, WAC and SIM-WAP models according to their accuracies in the top n, including two variants of WAC where its top 5 and top 10 predictions are projected into the distributional space. Overall, the models achieve very similar performance. However, there is an interesting pattern when comparing accuracies @1 and @2 to accuracies in the top 5 predictions. Thus, looking at accuracies for the top (two) predictions, the various models that link referential meaning to word representations in the distributional space all perform slightly worse than the plain WAC model, i.e. individual word classifiers trained on visual features only. This might suggest that certain aspects of referential word meaning are learned less accurately when mapping from visual to distributional space (which replicates results reported in the literature on standard object recognition benchmarks). On the other hand, the SIM-WAP model is on a par with WAC in terms of the @5 accuracy. This effect suggests that distributional knowledge that SIM-WAP has access to during training sometimes distracts the model from predicting the exact name chosen by a human speaker, but that SIM-WAP is still able to rank it among the most probable names. As a simple accuracy-based evaluation is not suited to fully explain this pattern, we carry out a more detailed analysis in Section 5.3.

	hit @k(%)		
	@1	@2	@5
transfer	48.34	60.49	74.89
wac	**49.34**	**61.86**	**75.35**
wac, project top5	48.73	61.10	74.07

wac + transfer + sim-wap	**52.19**	**64.71**	**78.40**

Table 2: Object naming acc., combined models

5.2 Model combination

In order to get more insight into why the TRANSFER and SIM-WAP models produce slightly worse results than individual visual word classifiers, we now test to what extent the different models are complementary and combine them by aggregating over their naming predictions. If the models are complementary, their combination should lead to more confident and accurate naming decisions.

Setup We combine TRANSFER, SIM-WAP and WAC by aggregating the scores they predict for different object names for a given object. During testing, we apply all models to an image region and consider words ranked among the top 10. We first normalize the referential appropriateness scores in each top-10 list and then compute their sum. This aggregation scheme will give more weight to words that appear in the top 10 list of different models, and less weight to words that only get top-ranked by a single model. We test on the same data as in Section 5.1.

Results Table 2 shows that all model combinations improve over the results of their isolated models in Table 1, suggesting that WAC, TRANSFER and SIM-WAP indeed do capture complementary aspects of referential word meaning. On their own, the distributionally informed models are less tuned to specific word occurrences than the visual word classifiers in the WAC model, but they can add useful information which leads to a clear overall improvement. We take this as a promising finding, supporting our initial hypothesis that knowledge on lexical distributional meaning should and can be exploited when learning how to use words for reference.

	Av. cosine similarity			
	among top k		gold - top k	
	5	10	5	10
transfer	**0.32**	**0.27**	**0.28**	**0.25**
wac	0.18	0.20	0.18	0.16
sim-wap	**0.32**	0.26	**0.28**	**0.25**

Table 3: Cosine similarities between word2vec embeddings of nouns generated in the top k

5.3 Analysis

Figure 2 illustrates objects from our test set where the combination of TRANSFER, SIM-WAP and WAC predicts an accurate name, whereas the models in isolation do not. These examples give some interesting insight into why the models capture different aspects of referential word meaning.

Word Similarities Many of the examples in Figure 2 suggest that the object names ranked among the top 3 by the TRANSFER and SIM-WAP model are semantically similar to each other, whereas WAC generates object names on top that describe very different underlying object categories, such as *seal* / *rock* in Figure 2(a), *animal* / *lamp* in Figure 2(g) or *chair* / *shirt* in Figure 2(c). To quantify this general impression, Table 3 shows cosine similarities among words in the top n generated by our models, using their word2vec embeddings. The average cosine similarity between words in our vocabulary is 0.17. The TRANSFER and SIM-WAP model rank words on top that are clearly more similar to each other than word pairs on average, whereas words ranked top by the WAC model are more dissimilar to each other. Another remarkable finding is that the words generated by TRANSFER and SIM-WAP are not only more similar among the top predictions, but also more similar to the gold name (Table 3 , right columns). This result is noteworthy since the accuracies for the top predictions shown in Table 1 are slightly below WAC. In general, this suggests that there is a trade-off between optimizing a model of referential word meaning to exact naming decisions, or tailoring it to make lexically consistent predictions. This parallels findings by Frome et al. (2013) who found that their transfer-based object recognition made "semantically more reasonable" errors than a standard convolutional network while

not improving accuracies for object recognition, see discussion in Section 2. Additional evaluation metrics, such as success rates in a human evaluation (cf. Zarrieß and Schlangen (2016)), would be an interesting direction for more detailed investigation here.

Word Use But even though the WAC classifiers lack knowledge on lexical similarities, they seem to able to detect relatively specific instances of word use such as *hut* in Figure 2(b), *shirt* in 2(c) or *lamp* in 2(h). Here, the combination with TRANSFER and SIM-WAP is helpful to give more weight to the object name that is taxonomically correct (sometimes pushing up words below the top-3 and hence not shown in Figure 2). In Figure 1(e), SIM-WAP and TRANSFER give more weight to typical names for persons, whereas WAC top-ranks more unusual names, reflecting that the person is difficult to identify visually. Another observation is that the mapping models have difficulties dealing with object names in singular and plural. As these words have very similar representations in the distributional space, they are often predicted as likely variants among the top 10 by SIM-WAP and TRANSFER, whereas the WAC model seems to predict inappropriate plural words less often among the top 3. Such specific phenomena at the intersection of visual and semantic similarity have found very little attention in the literature. We will investigate them further in our Experiments on zero-shot naming in the following Section.

6 Zero-Shot Naming

Zero-shot learning is an attractive prospect for REG from images, as it promises to overcome dependence on pairings of visual instances and natural names being available for all names, if visual/referential data can be generalised from other types of information. Previous work has looked at the feasibility of zero-shot learning as a function of semantic similarity or ontological closeness between unknown and known categories, and confirmed the intuition that the task is harder the less close unknown categories are to known ones (Frome et al., 2013; Norouzi et al., 2013).

Our experiments on object naming in Section 5 suggest that lexical similarities encoded in a distributional space might not always fully carry over to referential meaning. This could constitute an additional challenge for zero-shot learning, as distributional similarities might be misleading when the model has to fully rely on them for learning referential word meanings. Therefore, the following experiments investigate the performance of our models in zero-shot naming as a function of the lexical relation between unknown and known object names, i.e. namely hypernyms and singular/plurals. Both relations are typically captured by distributional models of word meaning in terms of closeness in the vector space, but their visual and referential relation is clearly different.

6.1 Vocabulary Splits and Testsets

Random As in previous work on zero-shot learning, we consider zero-shot naming for words of varying degrees of similarity. We randomly split our 159 names from Experiment 1 into 10 subsets. We train the models on 90% of the nouns (and all their visual instances in the image corpus) and test on the set of image regions that are named with words which the model did not observe during training. Results reported in Table 4 on the random test set correspond to averaged scores from cross-validation over the 10 splits.

Hypernyms We manually split the model's vocabulary into set of hypernyms (see Appendix A) and the remaining nouns. We train the models on those 84K image regions that where not named with a hypernym, and test on 8895 image regions that were named with a hypernym in the corpus. We checked that for each of these hypernyms, the vocabulary contains at least one or two names that can be considered as hyponyms, i.e. the model sees objects during training that are instances of *vehicle* for example, but never encounters actual uses of that name. This test set is particularly interesting from an REG perspective, as objects named with very general terms by human speakers are often difficult to describe with more common, but more specific terms, as is illustrated by the uses of *structure* and *thingy* in Figure 1.

Singulars/Plurals We pick 68 words from our vocabulary that can be grouped into 34 singular-plural noun pairs (see Appendix A). From each pair, we randomly include the singular or plural noun in the set of zero-shot nouns. Thus, we make sure that the model encounters singular and plural names during training, but it never encounters both variants of a name. This results training split of 23K image regions and a test split of 13825 instances.

Table 4: Accuracies in zero-shot object naming on different vocabulary splits

6.2 Evaluation

Some previous work on zero-shot image labeling assumes additional components that first identify whether an image should be labelled by a known or unknown word (Frome et al., 2013). We follow Lazaridou et al. (2014) and let the model decide whether to refer to an object by a known or unknown name. Related to that, distinct evaluation procedures have been used in the literature on zero-shot learning:

Testing on full vocabulary A realistic way to test zero-shot learning performance is to consider all words from a given vocabulary during testing, though the testset only contains instances of objects that have been named with a 'zero-shot word' (for which no visual instances were seen during training). Accuracies in this setup reflect how well the model is able to generalize, i.e. how often it decides to deviate from the words it was trained on, and (implicitly) predicts that the given object requires a "new" name. In case of the (i) hypernym and (ii) singular/plural test set, this accuracy also reflects to what extent the model is able to detect cases where (i) a more general or vague term is needed, where (ii) an unknown singular/plural counterpart of a known object type occurs.

Testing on disjoint vocabulary Alternatively, the model's vocabulary can be restricted during testing to zero-shot words only, such that names encountered during training and testing are disjoint, see e.g. (Lampert et al., 2009, 2013). This setup factors out the generalization problem, and assesses to what extent a model is able to capture the referential meaning of a word that does not have instances in the training data.

6.3 Results

As compared to Experiment 1 where models achieved similar performance, differences are more pronounced in the zero-shot setup, as shown in Table 4. In particular, we find that the SIM-WAP model which induces individual predictors for words that have not been observed in the training data is clearly more successful than TRANSFER or WAC that project predictions into the distributional space. When tested on the full vocabulary, we find that TRANSFER and WAC very rarely generate names whose referents were excluded from training, which is in line with observations made by Lazaridou et al. (2015a). The SIM-WAP predictors generalize much better, in particular on the singular/plural testset.

An interesting exception is the good performance of the TRANSFER model on the hypernym test set, when evaluated with a disjoint vocabulary. This corroborates evidence from Experiment 1, namely that the transfer model captures taxonomic aspects of object names better than the other models. Projection via individual word classifiers, on the other hand, seems to generalize better than TRANSFER, at least when looking at accuracies @2 ... @10. Thus, combining several vectors predicted by a model of referential word meaning can provide additional information, as compared to mapping an object to a single vector in distributional space. More work is needed to establish how these approaches can be integrated more effectively.

7 Discussion and Conclusion

In this paper, we have investigated models of referential word meaning, using different ways of combining visual information about a word's referent and distributional knowledge about its lexical similarities. Previous cross-modal mapping models essentially force semantically similar objects to be mapped into the same area in the semantic space regardless of their actual visual similarity. We found that cross-modal mapping produces semantically appropriate and mutually highly similar object names in its top-n list, but does not preserve differences in referential word use (e.g. appropriatness of *person* vs. *woman*) especially within the same semantic field. We have shown that it is beneficial for performance in standard and zero-shot object naming to treat words as individual predictors that capture referential appropriateness and are only indirectly linked to a distributional space, either through lexical mapping during application or through cross-modal similarity mapping during training. As we have tested these approaches on a rather small vocabulary, which may limit generality of conclusions, future work will be devoted to scaling up these findings to larger test sets, as e.g. recently collected through conversational agents (Das et al., 2016) that circumvent the need for human-human interaction data. Also from an REG perspective, various extensions of this approach are possible, such as the inclusion of contextual information during object naming and its combination with attribute selection.

Abstract

In this paper, we aim to understand whether current language and vision (LaVi) models truly grasp the interaction between the two modalities. To this end, we propose an extension of the MS-COCO dataset, FOIL-COCO, which associates images with both correct and 'foil' captions, that is, descriptions of the image that are highly similar to the original ones, but contain one single mistake ('foil word'). We show that current LaVi models fall into the traps of this data and perform badly on three tasks: a) caption classification (correct vs. foil); b) foil word detection; c) foil word correction. Humans, in contrast, have near-perfect performance on those tasks. We demonstrate that merely utilising language cues is not enough to model FOIL-COCO and that it challenges the state-of-the-art by requiring a fine-grained understanding of the relation between text and image.

1 Introduction

Most human language understanding is grounded in perception. There is thus growing interest in combining information from language and vision in the NLP and AI communities.

So far, the primary testbeds of Language and Vision (LaVi) models have been 'Visual Question Answering' (VQA) (e.g. Antol et al. (2015); Malinowski and Fritz (2014); Malinowski et al. (2015); Gao et al. (2015); Ren et al. (2015)) and 'Image Captioning' (IC) (e.g. Hodosh et al. (2013); Fang et al. (2015); Chen and Lawrence Zitnick (2015); Donahue et al. (2015); Karpathy and Fei-Fei (2015); Vinyals et al. (2015)). Whilst some models have seemed extremely successful on those tasks, it remains unclear how the reported results should be interpreted and what those models are actually learning. There is an emerging feeling in the community that the VQA task should be revisited, especially as many current dataset can be handled by 'blind' models which use language input only, or by simple concatenation of language and vision features (Agrawal et al., 2016; Jabri et al., 2016; Zhang et al., 2016; Goyal et al., 2016a). In IC too, Hodosh and Hockenmaier (2016) showed that, contrarily to what prior research had suggested, the task is far from been solved, since IC models are not able to distinguish between a correct and incorrect caption.

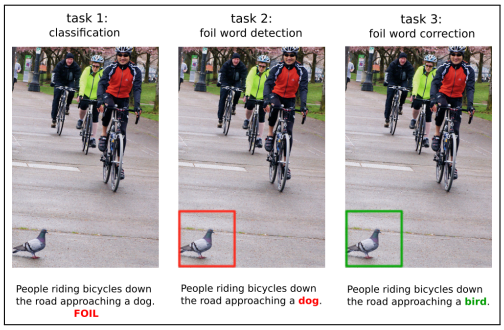

Figure 1: Is the caption correct or foil (T1)? If it is foil, where is the mistake (T2) and which is the word to correct the foil one (T3)?

Such results indicate that in current datasets, *language provides priors* that make LaVi models successful without truly understanding and integrating language and vision. But problems do not stop at biases. Johnson et al. (2016) also point out that current data 'conflate multiple sources of error, making it hard to pinpoint model weaknesses', thus highlighting the need for *diagnostic datasets*. Thirdly, existing IC *evaluation metrics* are sensitive to n-gram overlap and there is a need for measures that better simulate human judgments (Hodosh et al., 2013; Elliott and Keller, 2014; Anderson et al., 2016).

Our paper tackles the identified issues by proposing an automatic method for creating a

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 255–265
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1024

large dataset of real images with *minimal language bias* and some *diagnostic* abilities. Our dataset, FOIL (Find One mismatch between Image and Language caption),[1] consists of images associated with incorrect captions. The captions are produced by introducing one single error (or 'foil') per caption in existing, human-annotated data (Figure 1). This process results in a challenging error-detection/correction setting (because the caption is 'nearly' correct). It also provides us with a ground truth (we know where the error is) that can be used to objectively measure the performance of current models.

We propose three tasks based on widely accepted evaluation measures: we test the ability of the system to a) compute whether a caption is compatible with the image (T1); b) when it is incompatible, highlight the mismatch in the caption (T2); c) correct the mistake by replacing the foil word (T3).

The dataset presented in this paper (Section 3) is built on top of MS-COCO (Lin et al., 2014), and contains 297,268 datapoints and 97,847 images. We will refer to it as FOIL-COCO. We evaluate two state-of-the-art VQA models: the popular one by Antol et al. (2015), and the attention-based model by Lu et al. (2016), and one popular IC model by (Wang et al., 2016). We show that those models perform close to chance level, while humans can perform the tasks accurately (Section 4). Section 5 provides an analysis of our results, allowing us to diagnose three failures of LaVi models. First, their coarse representations of language and visual input do not encode suitably structured information to spot mismatches between an utterance and the corresponding scene (tested by T1). Second, their language representation is not fine-grained enough to identify the part of an utterance that causes a mismatch with the image as it is (T2). Third, their visual representation is also too poor to spot and name the visual area that corresponds to a captioning error (T3).

2 Related Work

The image captioning (IC) and visual question answering (VQA) tasks are the most relevant to our work. In IC (Fang et al., 2015; Chen and Lawrence Zitnick, 2015; Donahue et al., 2015; Karpathy and Fei-Fei, 2015; Vinyals et al., 2015; Wang et al., 2016), the goal is to generate a caption for a given image, such that it is both semantically and syntactically correct, and properly describes the content of that image. In VQA (Antol et al., 2015; Malinowski and Fritz, 2014; Malinowski et al., 2015; Gao et al., 2015; Ren et al., 2015), the system attempts to answer open-ended questions related to the content of the image. There is a wealth of literature on both tasks, but we only discuss here the ones most related to our work and refer the reader to the recent surveys by (Bernardi et al., 2016; Wu et al., 2016).

Despite their success, it remains unclear whether state-of-the-art LaVi models capture vision and language in a truly integrative fashion. We could identify three types of arguments surrounding the high performance of LaVi models:

(i) Triviality of the LaVi tasks: Recent work has shown that LaVi models heavily rely on language priors (Ren et al., 2015; Agrawal et al., 2016; Kafle and Kanan, 2016). Even simple correlation and memorisation can result in good performance, without the underlying models truly understanding visual content (Zhou et al., 2015; Jabri et al., 2016; Hodosh and Hockenmaier, 2016). Zhang et al. (2016) first unveiled that there exists a huge bias in the popular VQA dataset by Antol et al. (2015): they showed that almost half of all the questions in this dataset could be answered correctly by using the question alone and ignoring the image completely. In the same vein, Zhou et al. (2015) proposed a simple baseline for the task of VQA. This baseline simply concatenates the Bag of Words (BoW) features from the question and Convolutional Neural Networks (CNN) features from the image to predict the answer. They showed that such a simple method can achieve comparable performance to complex and deep architectures. Jabri et al. (2016) proposed a similar model for the task of multiple choice VQA, and suggested a cross-dataset generalization scheme as an evaluation criterion for VQA systems. We complement this research by introducing three new tasks with different levels of difficulty, on which LaVi models can be evaluated sequentially.

(ii) Need for diagnostics: To overcome the bias uncovered in previous datasets, several research groups have started proposing tasks which involve distinguishing distractors from a ground-truth caption for an image. Zhang et al. (2016) introduced a binary VQA task along with a dataset

[1]The dataset is available from https://foilunitn.github.io/

composed of sets of similar artificial images, allowing for more precise diagnostics of a system's errors. Goyal et al. (2016a) balanced the dataset of Antol et al. (2015), collecting a new set of complementary natural images which are similar to existing items in the original dataset, but result in different answers to a common question. Hodosh and Hockenmaier (2016) also proposed to evaluate a number of state-of-the-art LaVi algorithms in the presence of distractors. Their evaluation was however limited to a small dataset (namely, Flickr30K (Young et al., 2014)) and the caption generation was based on a hand-crafted scheme using only inter-dataset distractors.

Most related to our paper is the work by Ding et al. (2016). Like us, they propose to extend the MS-COCO dataset by generating decoys from human-created image captions. They also suggest an evaluation apparently similar to our T1, requiring the LaVi system to detect the true target caption amongst the decoys. Our efforts, however, differ in some substantial ways. First, their technique to create incorrect captions (using BLEU to set an upper similarity threshold) is so that many of those captions will differ from the gold description in more than one respect. For instance, the caption *two elephants standing next to each other in a grass field* is associated with the decoy *a herd of giraffes standing next to each other in a dirt field* (errors: *herd*, *giraffe*, *dirt*) or with *animals are gathering next to each other in a dirt field* (error: *dirt*; infelicities: *animals* and *gathering*, which are both pragmatically odd). Clearly, the more the caption changes in the decoy, the easier the task becomes. In contrast, the foil captions we propose only differ from the gold description by *one* word and are thus more challenging. Secondly, the automatic caption generation of Ding et al means that 'correct' descriptions can be produced, resulting in some confusion in human responses to the task. We made sure to prevent such cases, and human performance on our dataset is thus close to 100%. We note as well that our task does not require any complex instructions for the annotation, indicating that it is intuitive to human beings (see §4). Thirdly, their evaluation is a multiple-choice task, where the system has to compare all captions to understand which one is *closest* to the image. This is arguably a simpler task than the one we propose, where a caption is given and the system is asked to classify it as correct or foil: as we show in §4, detecting a *correct* caption is much easier than detecting foils. So evaluating precision on both gold and foil items is crucial.

Finally, (Johnson et al., 2016) proposed CLEVR, a dataset for the diagnostic evaluation of VQA systems. This dataset was designed with the explicit goal of enabling detailed analysis of different aspects of visual reasoning, by minimising dataset biases and providing rich ground-truth representations for both images and questions.

(iii) Lack of objective evaluation metrics: The evaluation of Natural Language Generation (NLG) systems is known to be a hard problem. It is further unclear whether the quality of LaVi models should be measured using metrics designed for language-only tasks. Elliott and Keller (2014) performed a sentence-level correlation analysis of NLG evaluation measures against expert human judgements in the context of IC. Their study revealed that most of those metrics were only weakly correlated with human judgements. In the same line of research, Anderson et al. (2016) showed that the most widely-used metrics for IC fail to capture semantic propositional content, which is an essential component of human caption evaluation. They proposed a semantic evaluation metric called SPICE, that measures how effectively image captions recover objects, attributes and the relations between them. In this paper, we tackle this problem by proposing tasks which can be evaluated based on objective metrics for classification/detection error.

3 Dataset

In this section, we describe how we automatically generate FOIL-COCO datapoints, i.e. image, original and foil caption triples. We used the training and validation Microsoft's Common Objects in Context (MS-COCO) dataset (Lin et al., 2014) (2014 version) as our starting point. In MS-COCO, each image is described by at least five descriptions written by humans via Amazon Mechanical Turk (AMT). The images contains 91 common object categories (e.g. *dog, elephant, bird, ...* and *car, bicycle, airplane, ...*), from 11 supercategories (*Animal*, *Vehicle*, resp.), with 82 of them having more than 5K labeled instances. In total there are 123,287 images with captions (82,783 for training and 40,504 for validation).[2]

Our data generation process consists of four

[2]The MS-COCO test set is not available for download.

	nr. of datapoints	nr. unique images	nr. of tot. captions	nr. target::foil pairs
Train	197,788	65,697	395,576	256
Test	99,480	32,150	198,960	216

Table 1: Composition of FOIL-COCO.

main steps, as described below. The last two steps are illustrated in Figure 2.

1. Generation of replacement word pairs We want to replace one noun in the original caption (the *target*) with an incorrect but similar word (the *foil*). To do this, we take the labels of MS-COCO categories, and we pair together words belonging to the same supercategory (e.g., bicycle::motorcycle, bicycle::car, bird::dog). We use as our vocabulary 73 out of the 91 MS-COCO categories, leaving out those categories that are multi-word expressions (e.g. traffic light). We thus obtain 472 target::foil pairs.

2. Splitting of replacement pairs into training and testing To avoid the models learning trivial correlations due to replacement frequency, we randomly split, within each supercategory, the candidate target::foil pairs which are used to generate the captions of the training vs. test sets. We obtain 256 pairs, built out of 72 target and 70 foil words, for the training set, and 216 pairs, containing 73 target and 71 foil words, for the test set.

3. Generation of foil captions We would like to generate foil captions by replacing only target words which refer to *visually salient objects*. To this end, given an image, we replace only those target words that occur in more than one MS-COCO caption associated with that image. Moreover, we want to use foils which are *not visually present*, i.e. that refer to visual content not present in the image. Hence, given an image, we only replace a word with foils that are not among the labels (objects) annotated in MS-COCO for that image. We use the images from the MS-COCO training and validation sets to generate our training and test sets, respectively. We obtain 2,229,899 for training and 1,097,012 captions for testing.

4. Mining the hardest foil caption for each image To eliminate possible visual-language dataset bias, out of all foil captions generated in step 3, we select only the hardest one. For this purpose, we need to model the visual-language bias of the dataset. To this end, we use Neuraltalk[3] (Karpathy and Fei-Fei, 2015), one of the state-of-the-art image captioning systems, pre-trained on MS-COCO. Neuraltalk is based on an LSTM which takes as input an image and generates a sentence describing its content. We obtain a neural network $\mathcal{N}$ that implicitly represents the visual-language bias through its weights. We use $\mathcal{N}$ to approximate the conditional probability of a caption C given a dataset T and and an image I ($P(C|I,T)$). This is obtained by simply using the loss $l(C,\mathcal{N}(I))$ i.e., the error obtained by comparing the pseudo-ground truth C with the sentence predicted by $\mathcal{N}$: $P(C|I,T) = 1 - l(C,\mathcal{N}(I))$ (we refer to (Karpathy and Fei-Fei, 2015) for more details on how $l()$ is computed). $P(C|I,T)$ is used to select the hardest foil among all the possible foil captions, i.e. the one with the highest probability according to the dataset bias learned by $\mathcal{N}$. Through this process, we obtain 197,788 and 99,480 original::foil caption pairs for the training and test sets, respectively. None of the target::foil word pairs are filtered out by this mining process.

The final FOIL-COCO dataset consists of 297,268 datapoints (197,788 in training and 99,480 in test set). All the 11 MS-COCO supercategories are represented in our dataset and contain 73 categories from the 91 MS-COCO ones (4.8 categories per supercategory on average.) Further details are reported in Table 1.

4 Experiments and Results

We conduct three tasks, as presented below:

Task 1 (T1): Correct vs. foil classification Given an image and a caption, the model is asked to mark whether the caption is correct or wrong. The aim is to understand whether LaVi models can spot mismatches between their coarse representations of language and visual input.

Task 2 (T2): Foil word detection Given an image and a foil caption, the model has to detect the foil word. The aim is to evaluate the understanding of the system at the word level. In order to systematically check the system's performance with different prior information, we test two different set-

[3] https://github.com/karpathy/neuraltalk

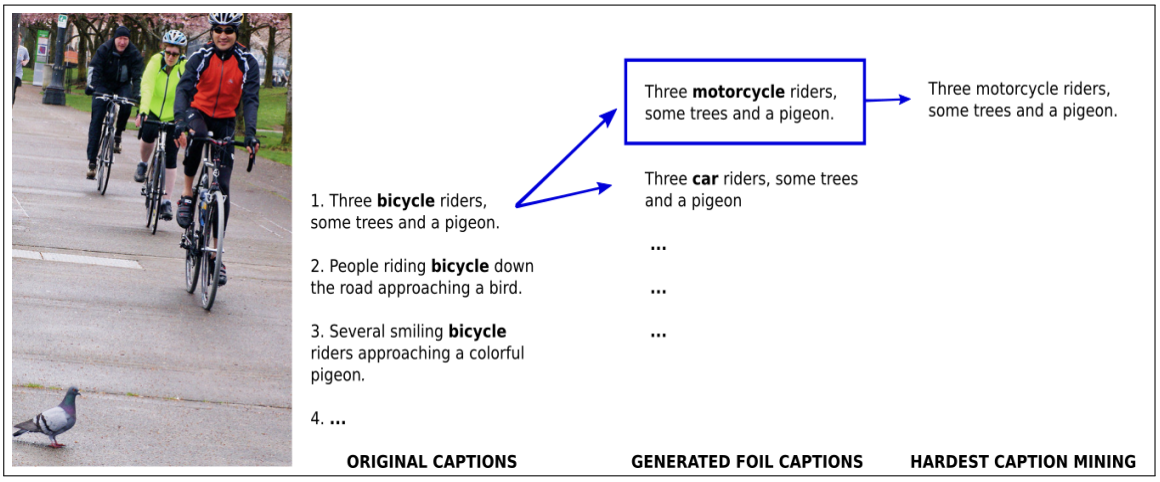

Figure 2: The main aspects of the foil caption generation process. Left column: some of the original COCO captions associated with an image. In bold we highlight one of the target words (bicycle), chosen because it is mentioned by more than one annotator. Middle column: For each original caption and each chosen target word, different foil captions are generated by replacing the target word with all possible candidate foil replacements. Right column: A single caption is selected amongst all foil candidates. We select the 'hardest' caption, according to Neuraltalk model, trained using only the original captions.

tings: the foil has to be selected amongst (a) only the nouns or (b) all content words in the caption.

Task 3 (T3): Foil word correction Given an image, a foil caption and the foil word, the model has to detect the foil and provide its correction. The aim is to check whether the system's visual representation is fine-grained enough to be able to extract the information necessary to correct the error. For efficiency reasons, we operationalise this task by asking models to select a correction from the set of target words, rather than the whole dataset vocabulary (viz. more than 10K words).

4.1 Models

We evaluate both VQA and IC models against our tasks. For the former, we use two of the three models evaluated in (Goyal et al., 2016a) against a balanced VQA dataset. For the latter, we use the multimodal bi-directional LSTM, proposed in (Wang et al., 2016), and adapted for our tasks.

LSTM + norm I: We use the best performing VQA model in (Antol et al., 2015) (deeper LSTM + norm I). This model uses a two stack Long-Short Term Memory (LSTM) to encode the questions and the last fully connected layer of VGGNet to encode images. Both image embedding and caption embedding are projected into a 1024-dimensional feature space. Following (Antol et al., 2015), we have normalised the image feature before projecting it. The combination of these two projected embeddings is performed by a point-wise multiplication. The multi-model representation thus obtained is used for the classification, which is performed by a multi-layer perceptron (MLP) classifier.

HieCoAtt: We use the Hierarchical Co-Attention model proposed by (Lu et al., 2016) that co-attends to both the image and the question to solve the task. In particular, we evaluate the 'alternate' version, i.e. the model that sequentially alternates between generating some attention over the image and question. It does so in a hierarchical way by starting from the word-level, then going to the phrase and then to the entire sentence-level. These levels are combined recursively to produce the distribution over the foil vs. correct captions.

IC-Wang: Amongst the IC models, we choose the multimodal bi-directional LSTM (Bi-LSTM) model proposed in (Wang et al., 2016). This model predicts a word in a sentence by considering both the past and future context, as sentences are fed to the LSTM in forward and backward order. The model consists of three modules: a CNN for encoding image inputs, a Text-LSTM (T-LSTM) for encoding sentence inputs, a Multimodal LSTM (M-LSTM) for embedding visual and textual vectors to a common semantic space and decoding to sentence. The bidirectional LSTM is implemented with two separate LSTM layers.

Baselines: We compare the SoA models above against two baselines. For the classification task, we use a **Blind** LSTM model followed by a fully connected layer and softmax and train it only on captions as input to predict the answer. In addition, we evaluate the **CNN+LSTM** model, where visual and textual features are simply concatenated.

The models at work on our three tasks For the *classification task* (T1), the baselines and VQA models can be applied directly. We adapt the generative IC model to perform the classification task as follows. Given a test image I and a test caption, for each word w_t in the test caption, we remove the word and use the model to generate new captions in which the w_t has been replaced by the word v_t predicted by the model (w_1,...,w_{t-1}, v_t, w_{t-1},...,w_n). We then compare the conditional probability of the test caption with all the captions generated from it by replacing w_t with v_t. When all the conditional probabilities of the generated captions are lower than the one assigned to the test caption the latter is classified as good, otherwise as foil. For the other tasks, the models have been trained on T1. To perform the *foil word detection task* (T2), for the VQA models, we apply the occlusion method. Following (Goyal et al., 2016b), we systematically occlude subsets of the language input, forward propagate the masked input through the model, and compute the change in the probability of the answer predicted with the unmasked original input. For the IC model, similarly to T1, we sequentially generate new captions from the foil one by replacing, one by one, the words in it and computing the conditional probability of the foil caption and the one generated from it. The word whose replacement generate the caption with the highest conditional probabilities is taken to be the foil word. Finally, to evaluate the models on the *error correction task* (T3), we apply the linear regression method over all the target words and select the target word which has the highest probability of making that wrong caption correct with respect to the given image.

Upper-bound Using Crowdflower, we collected human answers from 738 native English speakers for 984 image-caption pairs randomly selected from the test set. Subjects were given an image and a caption and had to decide whether it was correct or wrong (T1). If they thought it was wrong, they were required to mark the error in the caption (T2). We collected 2952 judgements (i.e. 3 judgements per pair and 4 judgements per rater) and computed human accuracy in T1 when considering as answer (a) the one provided by at least 2 out of 3 annotators (*majority*) and (b) the one provided by all 3 annotators (*unanimity*). The same procedure was adopted for computing accuracies in T2. Accuracies in both T1 an T2 are reported in Table 2. As can be seen, in the *majority* setting annotators are quasi-perfect in classifying captions (92.89%) and detecting foil words (97.00%). Though lower, accuracies in the *unanimity* setting are still very high, with raters providing the correct answer in 3 out of 4 cases in both tasks. Hence, although we have collected human answers only on a rather small subset of the test set, we believe their results are representative of how easy the tasks are for humans.

4.2 Results

As shown in Table 2, the FOIL-COCO dataset is challenging. On T1, for which the chance level is 50.00%, the 'blind', language-only model, does badly with an accuracy of 55.62% (25.04% on foil captions), demonstrating that language bias is minimal. By adding visual information, CNN+LSTM, the overall accuracy increases by 5.45% (7.94% on foil captions.) reaching 61.07% (resp. 32.98%). Both SoA VQA and IC models do significantly worse than humans on both T1 and T2. The VQA systems show a strong bias towards correct captions and poor overall performance. They only identify 34.51% (LSTM +norm I) and 36.38% (HieCoAtt) of the incorrect captions (T1). On the other hand, the IC model tends to be biased toward the foil captions, on which it achieves an accuracy of 45.44%, higher than the VQA models. But the overall accuracy (42.21%) is poorer than the one obtained by the two baselines. On the foil word detection task, when considering only nouns as possible foil word, both the IC and the LSTM+norm I models perform close to chance level, and the HieCoAtt performs somewhat better, reaching 38.79%. Similar results are obtained when considering all words in the caption as possible foil. Finally, the VQA models' accuracy on foil word correction (T3) is extremely low, at 4.7% (LSTM +norm I) and 4.21% (HieCoAtt). The result on T3 makes it clear that the VQA systems are unable to extract from the image rep-

resentation the information needed to correct the foil: despite being told which element in the caption is wrong, they are not able to zoom into the correct part of the image to provide a correction, or if they are, cannot name the object in that region. The IC model performs better compared to the other models, having an accuracy that is 20,78% higher than chance level.

T1: Classification task			
	Overall	Correct	Foil
Blind	55.62	86.20	25.04
CNN+LSTM	61.07	89.16	32.98
IC-Wang	42.21	38.98	45.44
LSTM + norm I	63.26	**92.02**	34.51
HieCoAtt	**64.14**	91.89	**36.38**
Human (*majority*)	92.89	91.24	94.52
Human (*unanimity*)	76.32	73.73	78.90

T2: Foil word detection task		
	nouns	all content words
Chance	23.25	15.87
IC-Wang	27.59	23.32
LSTM + norm I	26.32	24.25
HieCoAtt	**38.79**	**33.69**
Human (*majority*)		97.00
Human (*unanimity*)		73.60

T3: Foil word correction task	
	all target words
Chance	1.38
IC-Wang	**22.16**
LSTM + norm I	4.7
HieCoAtt	4.21

Table 2: **T1:** Accuracy for the *classification* task, relatively to all image-caption pairs (overall) and by type of caption (correct vs. foil); **T2:** Accuracy for the *foil word detection* task, when the foil is known to be among the nouns only or when it is known to be among all the content words; **T3:** Accuracy for the *foil word correction* task when the correct word has to be chosen among any of the target words.

5 Analysis

We performed a mixed-effect logistic regression analysis in order to check whether the behavior of the best performing models in T1, namely the VQA models, can be predicted by various linguistic variables. We included: 1) semantic similarity between the original word and the foil (computed as the cosine between the two corresponding `word2vec` embeddings (Mikolov et al., 2013)); 2) frequency of original word in FOIL-COCO captions; 3) frequency of the foil word in FOIL-COCO captions; 4) length of the caption (number of words). The mixed-effect model was performed to get rid of possible effects due to either object supercategory (indoor, food, vehicle, etc.) or target::foil pair (e.g., zebra::giraffe, boat::airplane, etc.). For both LSTM + norm I and HieCoAtt, `word2vec` similarity, frequency of the original word, and frequency of the foil word turned out to be highly reliable predictors of the model's response. The higher the values of these variables, the more the models tend to provide the wrong output. That is, when the foil word (e.g. *cat*) is semantically very similar to the original one (e.g. *dog*), the models tend to wrongly classify the caption as 'correct'. The same holds for frequency values. In particular, the higher the frequency of both the original word and the foil one, the more the models fail. This indicates that systems find it difficult to distinguish related concepts at the text-vision interface, and also that they may tend to be biased towards frequently occurring concepts, 'seeing them everywhere' even when they are not present in the image. Caption length turned out to be only a partially reliable predictor in the LSTM + norm I model, whereas it is a reliable predictor in HieCoAtt. In particular, the longer the caption, the harder for the model to spot that there is a foil word that makes the caption wrong.

As revealed by the fairly high variance explained by the random effect related to target::foil pairs in the regression analysis, both models perform very well on some target::foil pairs, but fail on some others (see leftmost part of Table 4 for same examples of easy/hard target::foil pairs). Moreover, the variance explained by the random effect related to object supercategory is reported in Table 3. As can be seen, for some supercategories accuracies are significatively higher than for others (compare, e.g., 'electronic' and 'outdoor').

In a separate analysis, we also checked whether there was any correlation between results and the position of the foil in the sentence, to ensure the models did not profit from any undesirable artifacts of the data. We did not find any such correlation.

Super-category	No. of object	No. of foil captions	Acc. using LSTM + norm I	Acc. using HieCoAtt
outdoor	2	107	2.80	0.93
food	9	10407	22.00	26.59
indoor	6	4911	30.74	27.97
appliance	5	2811	32.72	34.54
sports	10	16276	31.57	31.61
animal	10	21982	39.03	43.18
vehicle	8	16514	34.38	40.09
furniture	5	13625	33.27	33.13
accessory	5	3040	49.53	31.80
electronic	6	5615	45.82	43.47
kitchen	7	4192	38.19	45.34

Table 3: Classification Accuracy of foil captions by Super Categories (T1). The No. of the objects and the No. of foil captions refer to the test set. The training set has a similar distribution.

Top-5		Bottom-5		Top-5		Bottom-5	
T1: LSTM + norm I				T2: LSTM + norm I			
racket::glove	100	motorcycle::airplane	0	drier::scissors	100	glove::skis	0
racket::kite	97.29	bicycle::airplane	0	zebra::giraffe	88.98	snowboard::racket	0
couch::toilet	97.11	drier::scissors	0	boat::airplane	87.87	donut::apple	0
racket::skis	95.23	bus::airplane	0.35	truck::airplane	85.71	glove::surfboard	0
giraffe::sheep	95.09	zebra::giraffe	0.43	train::airplane	81.93	spoon::bottle	0
T1: HieCoAtt				T2: HieCoAtt			
tie::handbag	100	drier::scissors	0	zebra::elephant	94.92	drier::scissors	0
snowboard::glove	100	fork::glass	0	backpack::handbag	94.44	handbag::tie	0
racket::skis	100	handbag::tie	0	cow::zebra	93.33	broccoli:orange	1.47
racket::glove	100	motorcycle::airplane	0	bird::sheep	93.11	zebra::giraffe	1.96
backpack::handbag	100	train::airplane	0	orange::carrot	92.37	boat::airplane	2.09

Table 4: Easiest and hardest target::foil pairs: T1 (caption classification) and T2 (foil word detection).

To better understand results on T2, we performed an analysis investigating the performance of the VQA models on different target::foil pairs. As reported in Table 4 (right), both models perform nearly perfectly with some pairs and very badly with others. At first glance, it can be noticed that LSTM + norm I is very effective with pairs involving vehicles (*airplane*, *truck*, etc.), whereas HieCoAtt seems more effective with pairs involving animate nouns (i.e. animals), though more in depth analysis is needed on this point. More interestingly, some pairs that are found to be predicted almost perfectly by LSTM + I norm, namely boat::airplane, zebra::giraffe, and drier::scissors, turn out to be among the Bottom-5 cases in HieCoAtt. This suggests, on the one hand, that the two VQA models use different strategies to perform the task. On the other hand, it shows that our dataset does not contain cases that are a priori easy for any model.

The results of IC-Wang on T3 are much higher than LSTM + norm I and HieCoAtt, although it is outperformed by or is on par with HieCoAtton on T1-T2. Our interpretation is that this behaviour is related to the discriminative/generative nature of our tasks. Specifically, T1 and T2 are discriminative tasks and LSTM + norm I and HieCoAtt are discriminative models. Conversely, T3 is a generative task (a word needs to be generated) and IC-Wang is a generative model. It would be interesting to test other IC models on T3 and compare their results against the ones reported here. However, note that IC-Wang is 'tailored' for T3 because it takes as input the whole sentence (minus the word to be generated), while common sequential IC approaches can only generate a word depending on the previous words in the sentence.

As far as human performance is concerned, both T1 and T2 turn out to be extremely easy. In T1, image-caption pairs were correctly judged as correct/wrong in overall 914 out of 984 cases (92.89%) in the *majority* setting. In the *unanim-*

ity setting, the correct response was provided in 751 out of 984 cases (76.32%). Judging foil captions turns out to be slightly easier than judging correct captions in both settings, probably due to the presence of typos and misspellings that sometimes occur in the original caption (e.g. raters judge as wrong the original caption *People playing ball with a drown and white dog*, where 'brown' was misspelled as 'drown'). To better understand which factors contribute to make the task harder, we qualitatively analyse those cases where all annotators provided a wrong judgement for an image-caption pair. As partly expected, almost all cases where original captions (thus correct for the given image) are judged as being wrong are cases where the original caption is indeed incorrect. For example, a caption using the word 'motorcycle' to refer to a bicycle in the image is judged as wrong. More interesting are those cases where all raters agreed in considering as correct image-caption pairs that are instead foil. Here, it seems that vagueness as well as certain metaphorical properties of language are at play: human annotators judged as correct a caption describing *Blue and banana large birds on tree with metal pot* (see Fig 3, left), where 'banana' replaced 'orange'. Similarly, all raters judged as correct the caption *A cat laying on a bed next to an opened keyboard* (see Fig 3, right), where the cat is instead laying next to an opened laptop.

Focusing on T2, it is interesting to report that among the correctly-classified foil cases, annotators provided the target word in 97% and 73.6% of cases in the *majority* and *unanimity* setting, respectively. This further indicates that finding the foil word in the caption is a rather trivial task for humans.

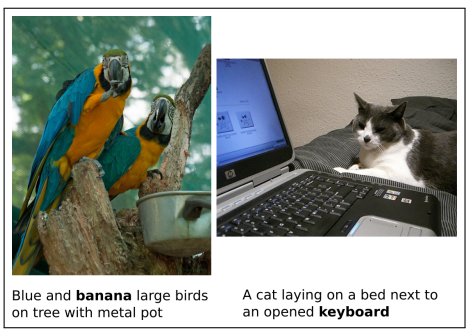

Figure 3: Two cases of foil image-caption pairs that are judged as correct by all annotators.

6 Conclusion

We have introduced FOIL-COCO, a large dataset of images associated with both correct and foil captions. The error production is automatically generated, but carefully thought out, making the task of spotting foils particularly challenging. By associating the dataset with a series of tasks, we allow for diagnosing various failures of current LaVi systems, from their coarse understanding of the correspondence between text and vision to their grasp of language and image structure.

Our hypothesis is that systems which, like humans, deeply integrate the language and vision modalities, should spot foil captions quite easily. The SoA LaVi models we have tested fall through that test, implying that they fail to integrate the two modalities. To complete the analysis of these results, we plan to carry out a further task, namely ask the system to detect in the image the area that produces the mismatch with the foil word (the red box around the bird in Figure 1.) This extra step would allow us to fully diagnose the failure of the tested systems and confirm what is implicit in our results from task 3: that the algorithms are unable to map particular elements of the text to their visual counterparts. We note that the addition of this extra step will move this work closer to the textual/visual explanation research (e.g., (Park et al., 2016; Selvaraju et al., 2016)). We will then have a pipeline able to not only test whether a mistake can be detected, but also whether the system can explain its decision: 'the wrong word is *dog* because the cyclists are in fact approaching a bird, there, in the image'.

LaVi models are a great success of recent research, and we are impressed by the amount of ideas, data and models produced in this stimulating area. With our work, we would like to push the community to think of ways that models can better merge language and vision modalites, instead of merely using one to supplement the other.

Acknowledgments

We are greatful to the Erasmus Mundus European Master in Language and Communication Technologies (EM LCT) for the scholarship provided to the third author. Moreover, we gratefully acknowledge the support of NVIDIA Corporation with the donation of the GPUs used in our research.

VERB PHYSICS: Relative Physical Knowledge of Actions and Objects

Maxwell Forbes **Yejin Choi**

University of Washington
{mbforbes,yejin}@cs.washington.edu

Abstract

Learning commonsense knowledge from natural language text is nontrivial due to *reporting bias*: people rarely state the obvious, e.g., "My house is *bigger* than me." However, while rarely stated explicitly, this trivial everyday knowledge does influence the way people talk about the world, which provides indirect clues to reason about the world. For example, a statement like, "Tyler *entered* his house" implies that his house is *bigger* than Tyler.

In this paper, we present an approach to infer relative physical knowledge of actions and objects along five dimensions (e.g., size, weight, and strength) from unstructured natural language text. We frame knowledge acquisition as joint inference over two closely related problems: learning (1) relative physical knowledge of object pairs and (2) physical implications of actions when applied to those object pairs. Empirical results demonstrate that it is possible to extract knowledge of actions and objects from language and that joint inference over different types of knowledge improves performance.

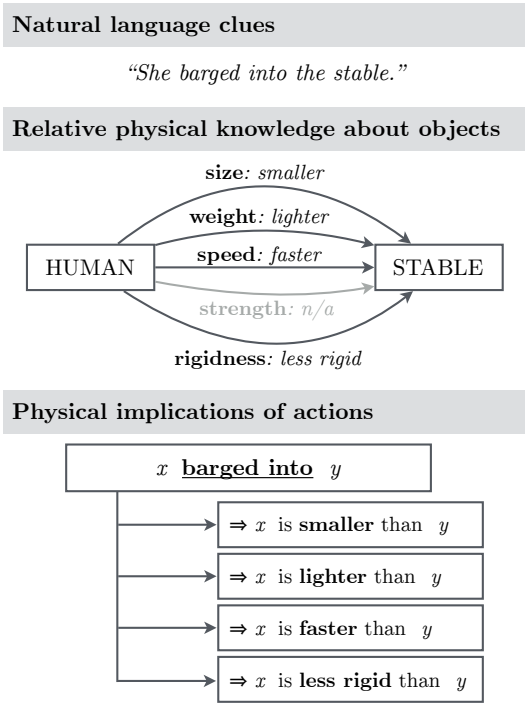

Figure 1: An overview of our approach. A verb's usage in language (top) implies physical relations between objects it takes as arguments. This allows us to reason about properties of specific objects (middle), as well as the knowledge implied by the verb itself (bottom).

1 Introduction

Reading and reasoning about natural language text often requires trivial knowledge about everyday physical actions and objects. For example, given a sentence *"Shanice could fit the trophy into the suitcase,"* we can trivially infer that the trophy must be smaller than the suitcase even though it is not stated explicitly. This reasoning requires knowledge about the action *"fit"*—in particular, typical preconditions that need to be satisfied in order to perform the action. In addition, reasoning about the applicability of various physical actions in a given situation often requires background knowledge about objects in the world, for example, that people are usually *smaller* than houses, that cars generally move *faster* than humans walk, or that a brick probably is *heavier* than a feather.

In fact, the potential use of such knowledge about everyday actions and objects can go beyond language understanding and reasoning. Many open challenges in computer vision and robotics may also benefit from such knowledge, as shown

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 266–276
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1025

in recent work that requires visual reasoning and entailment (Izadinia et al., 2015; Zhu et al., 2014). Ideally, an AI system should acquire such knowledge through direct physical interactions with the world. However, such a physically interactive system does not seem feasible in the foreseeable future.

In this paper, we present an approach to acquire trivial physical knowledge from unstructured natural language text as an alternative knowledge source. In particular, we focus on acquiring relative physical knowledge of actions and objects organized along five dimensions: size, weight, strength, rigidness, and speed. Figure 1 illustrates example knowledge of (1) relative physical relations of object pairs and (2) physical implications of actions when applied to those object pairs.

While natural language text is a rich source to obtain broad knowledge about the world, compiling trivial commonsense knowledge from unstructured text is a nontrivial feat. The central challenge lies in *reporting bias*: people rarely states the obvious (Gordon and Van Durme, 2013; Sorower et al., 2011; Misra et al., 2016; Zhang et al., 2017), since it goes against Grice's conversational maxim on the quantity of information (Grice, 1975).

In this work, we demonstrate that it is possible to overcome reporting bias and still extract the unspoken knowledge from language. The key insight is this: there is consistency in the way people describe how they interact with the world, which provides vital clues to reverse engineer the common knowledge shared among people. More concretely, we frame knowledge acquisition as joint inference over two closely related puzzles: inferring relative physical knowledge about object pairs while simultaneously reasoning about physical implications of actions.

Importantly, four of five dimensions of knowledge in our study—weight, strength, rigidness, and speed—are either not visual or not easily recognizable by image recognition using currently available computer vision techniques. Thus, our work provides unique value to complement recent attempts to acquire commonsense knowledge from web images (Izadinia et al., 2015; Bagherinezhad et al., 2016; Sadeghi et al., 2015).

In sum, our contributions are threefold:

- We introduce a new task in the domain of commonsense knowledge extraction from language, focusing on the physical implications of actions and the relative physical relations among objects, organized along five dimensions.
- We propose a model that can infer relations over grounded object pairs together with first order relations implied by physical verbs.
- We develop a new dataset VERBPHYSICS that compiles crowdsourced knowledge of actions and objects.[1]

The rest of the paper is organized as follows. We first provide the formal definition of knowledge we aim to learn in Section 2. We then describe our data collection in Section 3 and present our inference model in Section 4. Empirical results are given in Section 5 and discussed in Section 6. We review related work in Section 7 and conclude in Section 8.

2 Representation of Relative Physical Knowledge

2.1 Knowledge Dimensions

We consider five dimensions of relative physical knowledge in this work: *size, weight, strength, rigidness,* and *speed.* "Strength" in our work refers to the physical durability of an object (e.g., "diamond" is stronger than "glass"), while "rigidness" refers to the physical flexibility of an object (e.g., "glass" is more rigid than a "wire"). When considered in verb implications, *size, weight, strength,* and *rigidness* concern individual-level semantics; the relative properties implied by verbs in these dimensions are true in general. On the other hand, *speed* concerns stage-level semantics; its implied relations hold only during a window surrounding the verb.[2]

2.2 Relative physical knowledge

Let us first consider the problem of representing relative physical knowledge between two objects. We can write a single piece of knowledge like "A person is larger than a basketball" as

$$\texttt{person} >^{\text{size}} \texttt{basketball}$$

Any propositional statement can have exceptions and counterexamples. Moreover, we need to cope

[1] https://uwnlp.github.io/verbphysics/

[2] We thank reviewer two for pointing us to this terminology and for the illustrative example: "When a person throws a ball, the ball is faster than the person (stage-level) but it's not true in general that balls are faster than people (individual-level)."

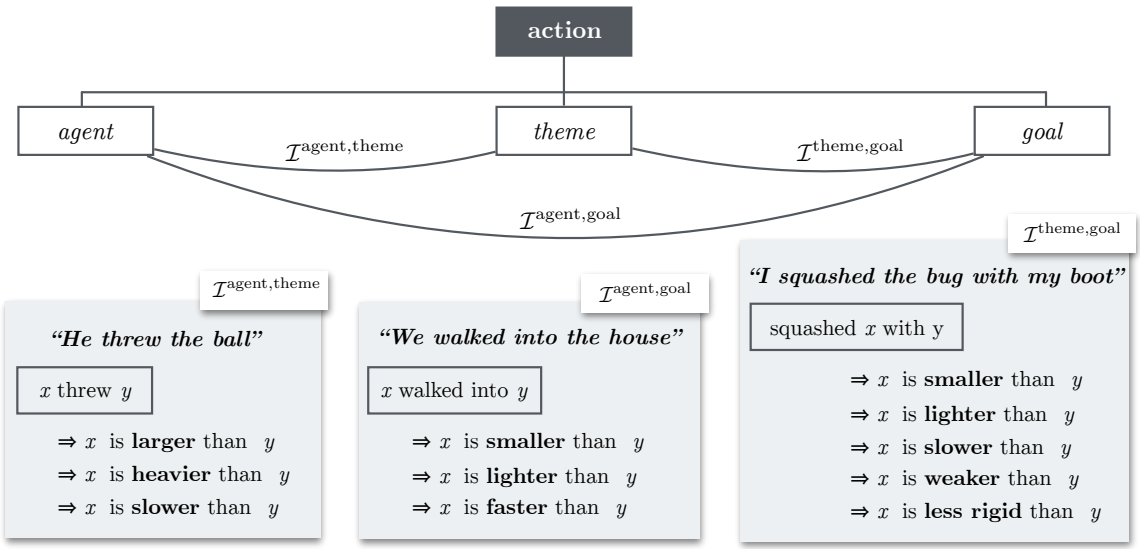

Figure 2: Example physical implications represented as frame relations between a pair of arguments.

with uncertainties involved in knowledge acquisition. Therefore, we assume each piece of knowledge is associated with a probability distribution. More formally, given objects x and y, we define a random variable $O^a_{x,y}$ whose range is $\{\boxed{>}, \boxed{<}, \boxed{\simeq}\}$ with respect to a knowledge dimension $a \in \{\text{SIZE}, \text{WEIGHT}, \text{STRENGTH}, \text{RIGIDNESS}, \text{SPEED}\}$ so that:

$$\mathbb{P}(O^a_{x,y} = r), r \in \{\boxed{>}, \boxed{<}, \boxed{\simeq}\}.$$

This immediately provides two simple properties:

$$\mathbb{P}(O_{x,y} = \boxed{>}) = \mathbb{P}(O_{y,x} = \boxed{<})$$
$$\mathbb{P}(O_{x,x} = \boxed{\simeq}) = 1$$

2.3 Physical Implications of Verbs

Next we consider representing relative physical implications of actions applied over two objects. For example, consider an action frame "x threw y." In general, following implications are likely to be true:

$$\text{“}x \text{ threw } y\text{”} \implies x >^{\text{size}} y$$
$$\text{“}x \text{ threw } y\text{”} \implies x >^{\text{weight}} y$$
$$\text{“}x \text{ threw } y\text{”} \implies x <^{\text{speed}} y$$

Again, in order to cope with exceptions and uncertainties, we assume a probability distribution associated with each implication. More formally, we define a random variable F^a_v to denote the implication of the action verb v when applied over its arguments x and y with respect to a knowledge dimension a so that:

$$\mathbb{P}(F^{\text{size}}_{\text{threw}} = \boxed{>}) := \mathbb{P}(\text{“}x \text{ threw } y\text{”} \Rightarrow x >^{\text{size}} y)$$
$$\mathbb{P}(F^{\text{wgt}}_{\text{threw}} = \boxed{>}) := \mathbb{P}(\text{“}x \text{ threw } y\text{”} \Rightarrow x >^{\text{wgt}} y)$$

where the range of F^{size}_{threw} is $\{\boxed{>}, \boxed{<}, \boxed{\simeq}\}$. Intuitively, F^{size}_{threw} represents the likely first order relation implied by "throw" over ungrounded (i.e., variable) object pairs.

The above definition assumes that there is only a single implication relation for any given verb with respect to a specific knowledge dimension. This is generally not true, since a verb, especially a common action verb, can often invoke a number of different frames according to frame semantics (Fillmore, 1976). Thus, given a number of different frame relations $v_1 ... v_T$ associated with a verb v, we define random variables F with respect to a specific frame relation v_t, i.e., $F^a_{v_t}$. We use this notation going forward.

Frame Perspective on Verb Implications: Figure 2 illustrates the frame-centric view of physical implication knowledge we aim to learn. Importantly, the key insight of our work is inspired by Fillmore's original manuscript on frame semantics (Fillmore, 1976). Fillmore has argued that "frames"—the contexts in which utterances are situated—should be considered as a third primitive of describing a language, along with a grammar and lexicon. While existing frame annotations such as FrameNet (Baker et al., 1998), PropBank (Palmer et al., 2005), and VerbNet (Kipper et al., 2000) provide rich frame knowledge associated

with a predicate, none of them provide the exact kind of physical implications we consider in our paper. Thus, our work can potentially contribute to these resources by investigating new approaches to automatically recover richer frame knowledge from language. In addition, our work is motivated by the formal semantics of Dowty (1991), as the task of learning verb implications is essentially that of extracting lexical entailments for verbs.

3 Data and Crowdsourced Knowledge

Action Verbs: We pick 50 classes of Levin verbs from both "alternation classes" and "verb classes" (Levin, 1993), which corresponds to about 1100 unique verbs. We sort this list by frequency of occurrence in our frame patterns in the Google Syntax Ngrams corpus (Goldberg and Orwant, 2013) and pick the top 100 verbs.

Action Frames: Figure 2 illustrates examples of action frame relations. Because we consider implications over pairwise argument relations for each frame, there are sometimes multiple frame relations we consider for a single frame. To enumerate action frame relations for each verb, we use syntactic patterns based on dependency parse by extracting the core components (subject, verb, direct object, prepositional object) of an action, then map the subject to an agent, the direct object to a theme, and the prepositional object to a goal.[3] For those frames that involve an argument in a prepositional phrase, we create a separate frame for each preposition based on the statistics observed in the Google Syntax Ngram corpus.

Because the syntax ngram corpus provides only tree snippets without context, this way of enumerating potential frame patterns tend to overgenerate. Thus we refine our prepositions for each frame by taking either the intersection or union with the top 5 Google Surface Ngrams (Michel et al., 2011), depending on whether the frame was under- or over-generating. We also add an additional crowdsourcing step where we ask crowd workers to judge whether a frame pattern with a particular verb and preposition could plausibly be found in a sentence. This process results in 813 frame templates, an average of 8.13 per verb.

[3]Future research could use an SRL parser instead. We use dependency parse to benefit from the Google Syntax Ngram dataset that provides language statistics over an extremely large corpus, which does not exist for SRL.

Data collected		
	Total	**Seed / dev / test**
$\text{Verbs}_{5\%}$	100	5 / 45 / 50
$\text{Verbs}_{20\%}$	"	20 / 30 / 50
$\text{Frames}_{5\%}$	813	65 / 333 / 415
$\text{Frames}_{20\%}$	"	188 / 210 / 415
$\text{Object pairs}_{5\%}$	3656	183 / 1645 / 1828
$\text{Object pairs}_{20\%}$	"	733 / 1096 / 1828

Per attribute frame statistics				
	Agreement		*Counts (usable)*	
	2/3	**3/3**	**Verbs**	**Frames**
size	0.91	0.41	96	615
weight	0.90	0.33	97	562
strength	0.88	0.25	95	465
rigidness	0.87	0.26	89	432
speed	0.93	0.36	88	420

Per attribute object pair statistics				
	Agreement		*Counts (usable)*	
	2/3	**3/3**	**Distinct objs**	**Pairs**
size	0.95	0.59	210	2552
weight	0.95	0.56	212	2586
strength	0.92	0.43	208	2335
rigidness	0.91	0.39	212	2355
speed	0.90	0.38	209	2184

Table 1: Statistics of crowdsourced knowledge. Frames are partitioned by verb. Counts are shown for *usable* data, which includes only $\geq$ 2/3 agreement and removes all with "no relation." Each prediction task (frames or object pairs) is given 5% of that domain's data as seed. We compare models using either 5% or 20% of the *other* domain's data as seed.

Object Pairs: To provide a source of ground truth relations between objects, we select the object pairs that occur in the 813 frame templates with positive pointwise mutual information (PMI) across the Google Syntax Ngram corpus. After replacing a small set of "human" nouns with a generic HUMAN object, filtering out nouns labeled as abstract by WordNet (Miller, 1995), and distilling all surface forms to their lemmas (also with WordNet), the result is 3656 object pairs.

3.1 Crowdsourcing Knowledge

We collect human judgements of the frame knowledge implications to use as a small set of seed knowledge (5%), a development set (45%), and a test set (50%). Crowd workers are given with a frame template such as "**x** threw **y**," and then asked to list a few plausible objects (including people and animals) for the missing slots (e.g., **x** and **y**).[4]

[4]This step is to prime them for thinking about the particular template; we do not use the objects they provided.

We then ask them to rate the general relationship that the arguments of the frame exhibit with respect to all knowledge dimensions (size, weight, etc.). For each knowledge dimension, or attribute, a, workers select an answer from (1) $\mathbf{x} >^a \mathbf{y}$, (2) $\mathbf{x} <^a \mathbf{y}$, (3) $\mathbf{x} \simeq^a \mathbf{y}$, or (4) no general relation.

We conduct a similar crowdsourcing step for the set of object pairs. We ask crowd workers to compare each of the 3656 object pairs along the five knowledge dimensions we consider, selecting an answer from the same options above as with frames. We reserve 50% of the data as a test set, and split the remainder up either 5% / 45% or 20% / 30% (seed / development) to investigate the effects of different seed knowledge sizes on the model.

Statistics for the dataset are provided in Table 1. About 90% of the frames as well as object pairs had 2/3 agreement between workers. After removing frame/attribute combinations and object pairs that received less than 2/3 agreement, or were selected by at least 2/3 workers to have no relation, we end up with roughly 400–600 usable frames and 2100–2500 usable object pairs per attribute.

4 Model

We model knowledge acquisition as probabilistic inference over a factor graph of knowledge. As shown in Figure 3, the graph consists of multiple substrates (page-wide boxes) corresponding to different knowledge dimensions (shown only three of them —strength, size, weight—for brevity). Each substrate consists of two types of sub-graphs: verb subgraphs and object subgraphs, which are connected through factors that quantify action–object compatibilities. Connecting across substrates are factors that model inter-dependencies across different knowledge dimensions. In what follows, we describe each graph component.

4.1 Nodes

The factor graph contains two types of nodes in order to capture two classes of knowledge. The first type of nodes are object pair nodes. Each object pair node is a random variable $O^a_{x,y}$ which captures the relative strength of an attribute a between objects x and y.

The second type of nodes are frame nodes. Each frame node is a random variable $F^a_{v_t}$. This corresponds to the verb v used in a particular type of frame t, and captures the implied knowledge the frame v_t holds along an attribute a.

All random variables take on the values $\{\boxed{>}, \boxed{<}, \boxed{\simeq}\}$. For an object pair node $O^a_{x,y}$, the value represents the belief about the relation between x and y along the attribute a. For a frame node $F^a_{v_t}$, the value represents the belief about the relation along the attribute a between *any* two objects that might be used in the frame v_t.

We denote the sets of all object pair and frame random variables $\mathcal{O}$ and $\mathcal{F}$, respectively.

4.2 Action–Object Compatibility

The key aspect of our work is to reason about two types of knowledge simultaneously: relative knowledge of grounded object pairs, and implications of actions related to those objects. Thus we connect the verb subgraphs and object subgraphs through selectional preference factors ψ_s between two such nodes $O^a_{x,y}$ and $F^a_{v_t}$ if we find evidence from text that suggests objects x and y are used in the frame v_t. These factors encourage both random variables to agree on the same value.

As an example, consider a node $O^{size}_{p,b}$ which represents the relative size of a person and a basketball, and a node $F^{size}_{threw_{dobj}}$ which represents the relative size implied by an *"x threw y"* frame. If we find significant evidence in text that *"[person] threw [basketball]"* occurs, we would add a selectional preference factor to connect $O^{size}_{p,b}$ with $F^{size}_{threw_{dobj}}$ and encourage them towards the same value. This means that if it is discovered that people are larger than basketballs (the value $\boxed{>}$), then we would expect the frame *"x threw y"* to entail $x >^{size} y$ (also the value $\boxed{>}$).

4.3 Semantic Similarities

Some frames have relatively sparse text evidences to support their corresponding knowledge acquisition. Thus, we include several types of factors based on semantic similarities as described below.

Cross-Verb Frame Similarity: We add a group of factors ψ_v between two verbs v and u (to connect a specific frame of v with a corresponding frame of u) based on the verb-level similarities.

Within-Verb Frame Similarity: Within each verb v, which consists of a set of frame relations $v_1, ...v_T$, we also include frame-level similarity factors ψ_f between v_i and v_j. This gives us more evidence over a broader range of frames when textual evidence might be sparse.

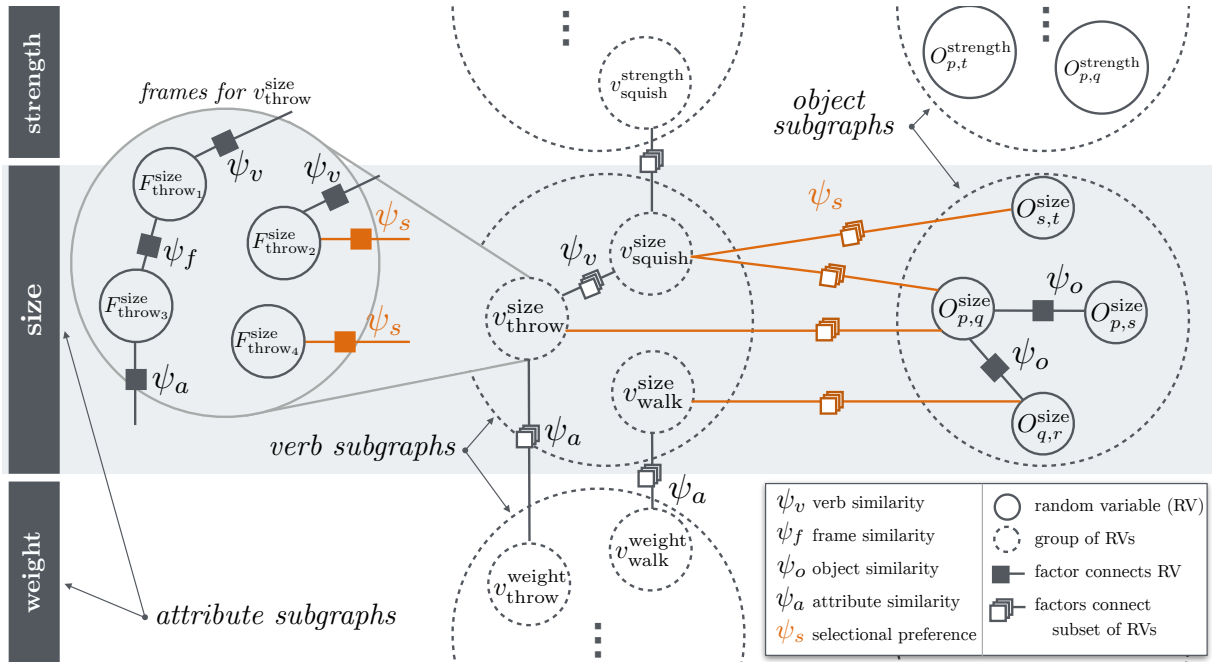

Figure 3: High level view of the factor graph model. Performance on both learning relative knowledge about objects (right), as well as entailed knowledge from verbs (center) via realized frames (left), is improved by modeling their interplay (orange). Unary seed (ψ_{seed}) and embedding (ψ_{emb}) factors are omitted for clarity.

Object Similarity: As with verbs, we add factors ψ_o that encourage similar pairs of objects to take the same value. Given that each node represents a pair of objects, finding that x and y are similar yields two main cases in how to add factors (aside from the trivial case where the variable $O^a_{x,y}$ is given a unary factor to encourage the value $\boxed{\simeq}$).

1. If nodes $O_{x,z}$ and $O_{y,z}$ exist, we expect objects x and y to both have a similar relation to z. We add a factor that encourages $O_{x,z}$ and $O_{y,z}$ to take the same value. The same is true if nodes $O_{z,x}$ and $O_{z,y}$ exist.
2. On the other hand, if nodes $O_{x,z}$ and $O_{z,y}$ exist, we expect these two nodes to reach the opposite decision. In this case, we add a factor that encourages one node to take the value $\boxed{>}$ if the other prefers the value $\boxed{<}$, and vice versa. (For the case of $\boxed{\simeq}$, if one prefers that value, then both should.)

4.4 Cross-Knowledge Correlation

Some knowledge dimensions, such as size and weight, have a significant correlation in their implied relations. For two such attributes a and b, if the same frame $F^a_{v_i}$ and $F^b_{v_i}$ exists in both graphs, we add a factor ψ_a between them to push them towards taking the same value.

4.5 Seed Knowledge

In order to kick off learning, we provide a small set of seed knowledge among the random variables in $\{\mathcal{O}, \mathcal{F}\}$ with seed factors ψ_{seed}. These unary seed factors push the belief for its associated random variable strongly towards the seed label.

4.6 Potential Functions

Unary Factors: For all frame and object pair random variables in the training set, we train a maximum entropy classifier to predict the value of the variable. We then use the probabilities of the classifier as potentials for seed factors given to all random variables in their class (frame or object pair). Each log-linear classifier is trained separately per attribute on a featurized vector of the variable:

$$\mathbb{P}(r|X^a) \propto e^{w_a \cdot f(X^a)}$$

The feature function is defined differently according to the node type:

$$f(O^a_{p,q}) := \langle g(p), g(q) \rangle$$
$$f(F^a_{v_t}) := \langle h(t), g(v), g(t) \rangle$$

Table 2: Accuracy of baselines and our model on both tasks. Top: frame prediction task; bottom: object pair prediction task. In both tasks 5% of in-domain data (frames or object pairs, respectively) are available as seed data. We compare providing the other type of data (object pairs or frames, respectively) as seed knowledge, trying 5% (OUR MODEL (A)) and 20% (OUR MODEL (B)).

Here $g(x)$ is the GloVe word embedding (Pennington et al., 2014) for the word x (t is the frame relation's preposition, and $g(t)$ is simply set to the zero vector if there is no preposition) and $h(t)$ is a one-hot vector of the frame relation type. We use GloVe vectors of 100 dimensions for verbs and 50 dimensions for objects and prepositions (the dimensions picked based on development set).

Binary Factors: In the case of all other factors, we use a "soft 1" agreement matrix with strong signal down the diagonals:

$$\begin{bmatrix} & > & \simeq & < \\ > & \mathbf{0.7} & 0.1 & 0.2 \\ \simeq & 0.15 & \mathbf{0.7} & 0.15 \\ < & 0.2 & 0.1 & \mathbf{0.7} \end{bmatrix}$$

4.7 Inference

After our full graph is constructed, we use belief propagation to infer the assignments of frames and object pairs not in our training data. Each message μ is a vector where each element is the probability that a random variable takes on each value $x \in \{\boxed{>}, \boxed{<}, \boxed{\simeq}\}$. A message passed from a random variable v to a neighboring factor f about the value x is the product of the messages from its other neighboring factors about x:

$$\mu_{v \to f}(x) \propto \prod_{f' \in N(v) \setminus \{f\}} \mu_{f' \to v}(x)$$

A message passed from a factor f with potential ψ to a random variable v about its value x is a marginalized belief about v taking value x from the other neighboring random variables combined with its potential:

$$\mu_{f \to v}(x) \propto \sum_{\mathbf{x}: \mathbf{x}[v]=x} \psi(\mathbf{x}) \prod_{v' \in N(f) \setminus \{v\}} \mu_{v' \to f}(\mathbf{x}[v'])$$

After stopping belief propagation, the marginals for a node can be computed and used as a decision for that random variable. The marginal for v taking value x is the product of its surrounding factors' messages:

$$v(x) \propto \prod_{f \in N(v)} \mu_{f \to v}(x)$$

5 Experimental Results

Factor Graph Construction: We first need to pick a set of frames and objects to determine our set of random variables. The frames are simply the subset of the frames that were crowdsourced in the given configuration (e.g., seed + dev), with "soft 1" unary seed factors (the gold label indexed row of the binary factor matrix) given only to those in the seed set. The same selection criteria and seed factors are applied to the crowdsourced object pairs.

For lexical similarity factors (ψ_v, ψ_o), we pick connections based on the cosine similarity scores of GloVe vectors thresholded above a value chosen based on development set performance. Attribute similarity factors (ψ_a) are chosen based on sets of frames that reach largely the same decisions on the seed data (95%). Frame similarity factors (ψ_f) are added to pairs of frames with linguistically similar constructions. Finally, selectional preference

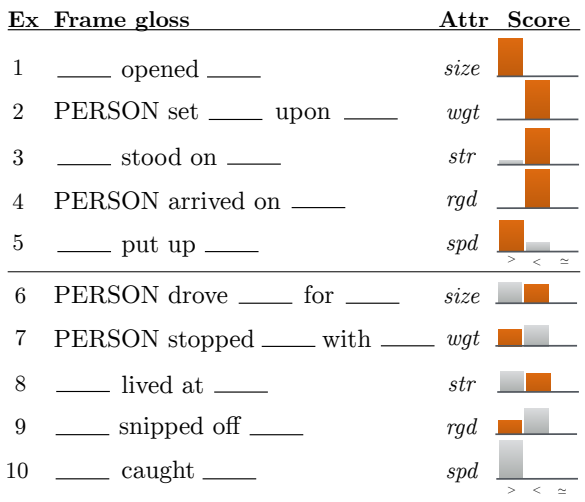

Figure 4: Example model predictions on dev set frames. The model's confidence is shown by the bars on the right. The correct relation is highlighted in orange (6–10 are failure cases for the model). If there are two blanks, the relation is between them. If there is only one blank, the relation is between PERSON and the blank. Note that $\boxed{\simeq}$ receives miniscule weight because it is never the correct value for frames in the seed set.

factors (ψ_s) are picked by using a threshold (also tuned on the development set) of pointwise mutual information (PMI) between the frames and the object pairs' occurrences in the Google Syntax Ngram corpus.

For each task, we consider the set of factors to include in each model a hyperparameter, which is also tuned on the development set.

Baselines: Baselines include making a RANDOM choice, picking between $\boxed{>}$, $\boxed{<}$, and $\boxed{\simeq}$), picking the MAJORITY label, and a maximum entropy classifier based on the embedding representations (EMB-MAXENT) defined in Section 4.6.

Inferring Knowledge of Actions: Our first experiment is to predict knowledge implied by new frames. In this task, 5% of the frames are available as seed knowledge. We experiment with two different sets of seed knowledge for the object pair data: OUR MODEL (A) uses only 5% of the object pair data as seed, and OUR MODEL (B) uses 20%.

The full results for the baseline methods and our model are given in the upper half of Table 2. Our model outperforms the baselines on all attributes except for the speed, which has a highly skewed label distribution to allow the majority baseline to perform well. Ablations are given in Table 3, and sample correct predictions from the development set are shown in examples 1–5 of Figure 4.

Ablated (or added) component	Accuracy
– Verb similarity	0.69
+ Frame similarity	0.62
– Action-object compatibility	0.62
– Object similarity	0.70
+ Attribute similarity	0.62
– Frame embeddings	0.63
– Frame seeds	0.62
– Object embeddings	0.62
– Object seeds	0.62
OUR MODEL (A)	**0.71**

Table 3: Ablation results on *size* attribute for the frame prediction task on the development dataset for OUR MODEL (A) (5% of the object pairs as seed data). We find that different graph configurations improve performance for different tasks and data amounts. In this setting, frame and attribute similarity factors hindered performance.

Inferring Knowledge of Objects: Our second experiment is to predict the correct relations of new object pairs. The data for this task is the inverse of before: 5% of the object pairs are available as seed knowledge, and we experiment with both 5% (OUR MODEL (A)) and 20% (OUR MODEL (B)) frames given as seed data. Again, both are independently tuned on the development data. Results for this task are presented in the lower half of Table 2. While OUR MODEL (A) is competitive with the strongest baseline, introducing the additional frame data allows OUR MODEL (B) to reach the highest accuracy.

6 Discussion

Metaphorical Language: While our frame patterns are intended to capture action verbs, our templates also match senses of those verbs that can be used with abstract or metaphorical arguments, rather than directly physical ones. One example from the development set is "x contained y." While x and y can be real objects, more abstract senses of "contained" could involve y as a "forest fire" or even a "revolution." In these instances, $x >^{\text{size}} y$ is plausible as an abstract notion: if some entity can contain a revolution, we might think that entity as "larger" or "stronger" than the revolution.

Error analysis: Examples 6–10 in Figure 4 highlight failure cases for the model. Example

6 shows a case where the comparison is nonsensical because *"for"* would naturally be followed by a purpose (*"He drove the car for work."*) or a duration (*"She drove the car for hours."*) rather than a concrete object whose size is measurable. Example 7 highlights an underspecified frame. One crowd worker provided the example, "PERSON *stopped the fly with {the jar / a swatter},"* where $\text{fly} <^{\text{weight}} \{\text{jar}, \text{swatter}\}$. However, two crowd workers provided examples like "PERSON *stopped their car with the brake,"* where clearly $\text{car} >^{\text{weight}} \text{brake}$. This example illustrates complex underlying physics we do not model: a brake—the pedal itself—is used to stop a car, but it does so by applying significant force through a separate system.

The next two examples are cases where the model nearly predicts correctly (8, e.g., *"She lived at the office."*) and is just clearly wrong (9, e.g., *"He snipped off a locket of hair"*). Example 10 demonstrates a case of polysemy where the model picks the wrong side. In the phrase, *"She caught the runner in first,"*, it is correct that $\text{she} >^{\text{speed}} \text{runner}$. However, the sense chosen by the crowd workers is that of, *"She caught the baseball,"* where indeed $\text{she} <^{\text{speed}} \text{baseball}$.

7 Related work

Several works straddle the gap between IE, knowledge base completion, and learning commonsense knowledge from text. Earlier works in these areas use large amounts of text to try to extract general statements like "A THING CAN BE READABLE" (Gordon et al., 2010) and frequencies of events (Gordon and Schubert, 2012). Our work focuses on specific domains of knowledge rather than general statements or occurrence statistics, and develops a frame-centric approach to circumvent reporting bias. Other work uses a knowledge base and scores unseen tuples based on similarity to existing ones (Angeli and Manning, 2013; Li et al., 2016). Relatedly, previous work uses natural language inference to infer new facts from a dataset of commonsense facts that can be extracted from unstructured text (Angeli and Manning, 2014). In contrast, we focus on a small number of specific types of knowledge without access to an existing database of knowledge.

A number of recent works combine multimodal input to learn visual attributes (Bruni et al., 2012; Silberer et al., 2013), extract commonsense knowledge from web images (Tandon et al., 2016), and overcome reporting bias (Misra et al., 2016). In contrast, we focus on natural language evidence to reason about attributes that are both in (size) and out (weight, rigidness, etc.) of the scope of computer vision. Yet other works mine numerical attributes of objects (Narisawa et al., 2013; Takamura and Tsujii, 2015; Davidov and Rappoport, 2010) and comparative knowledge from the web (Tandon et al., 2014). Our work uniquely learns verb-centric lexical entailment knowledge.

A handful of works have attempted to learn the types of knowledge we address in this work. One recent work tried to directly predict several binary attributes (such "is large" and "is yellow") from on off-the-shelf word embeddings, noting that accuracy was very low (Rubinstein et al., 2015). Another line of work addressed grounding verbs in the context of robotic tasks. One paper in this line acquires verb meanings by observing state changes in the environment (She and Chai, 2016). Another work in this line does a deep investigation of eleven verbs, modeling their physical effect via annotated images along eighteen attributes (Gao et al., 2016). These works are encouraging investigations into multimodal groundings of a small set of verbs. Our work instead grounds into a fixed set of attributes but leverages language on a broader scale to learn about more verbs in more diverse set of frames.

8 Conclusion

We presented a novel take on verb-centric frame semantics to learn implied physical knowledge latent in verbs. Empirical results confirm that by modeling changes in physical attributes entailed by verbs together with objects that exhibit these properties, we are able to better infer new knowledge in both domains.

Abstract

We propose a new A* CCG parsing model in which the probability of a tree is decomposed into factors of CCG categories and its syntactic dependencies both defined on bi-directional LSTMs. Our factored model allows the precomputation of all probabilities and runs very efficiently, while modeling sentence structures explicitly via dependencies. Our model achieves the state-of-the-art results on English and Japanese CCG parsing.[1]

1 Introduction

Supertagging in lexicalized grammar parsing is known as *almost parsing* (Bangalore and Joshi, 1999), in that each supertag is syntactically informative and most ambiguities are resolved once a correct supertag is assigned to every word. Recently this property is effectively exploited in A* Combinatory Categorial Grammar (CCG; Steedman (2000)) parsing (Lewis and Steedman, 2014; Lewis et al., 2016), in which the probability of a CCG tree $\boldsymbol{y}$ on a sentence $\boldsymbol{x}$ of length N is the product of the probabilities of supertags (categories) c_i (locally factored model):

$$P(\boldsymbol{y}|\boldsymbol{x}) = \prod_{i \in [1,N]} P_{tag}(c_i|\boldsymbol{x}). \quad (1)$$

By not modeling every combinatory rule in a derivation, this formulation enables us to employ efficient A* search (see Section 2), which finds the most probable supertag sequence that can build a well-formed CCG tree.

Although much ambiguity is resolved with this supertagging, some ambiguity still remains. Figure 1 shows an example, where the two CCG parses are derived from the same supertags. Lewis et al.'s approach to this problem is resorting to some deterministic rule. For example, Lewis et al. (2016) employ the attach low heuristics, which is motivated by the right-branching tendency of English, and always prioritizes (b) for this type of ambiguity. Though for English it empirically works well, an obvious limitation is that it does not always derive the correct parse; consider a phrase "*a house in Paris with a garden*", for which the correct parse has the structure corresponding to (a) instead.

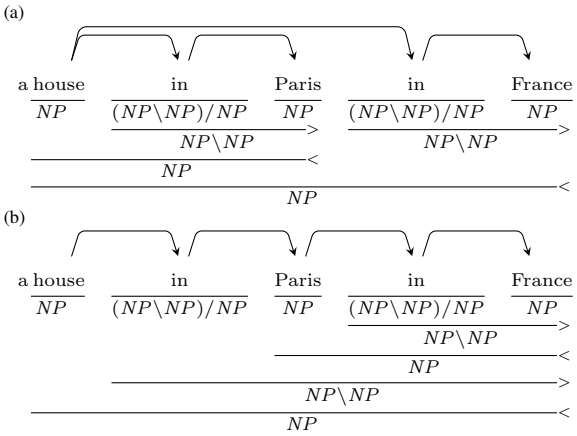

Figure 1: CCG trees that are equally likely under Eq. 1. Our model resolves this ambiguity by modeling the head of every word (dependencies).

In this paper, we provide a way to resolve these remaining ambiguities under the locally factored model, by explicitly modeling bilexical dependencies as shown in Figure 1. Our joint model is still locally factored so that an efficient A* search can be applied. The key idea is to predict the head of every word independently as in Eq. 1 with a strong unigram model, for which we utilize the scoring model in the recent successful graph-based dependency parsing on LSTMs (Kiperwasser and Goldberg, 2016; Dozat and Manning, 2016). Specif-

ically, we extend the bi-directional LSTM (bi-LSTM) architecture of Lewis et al. (2016) predicting the supertag of a word to predict the head of it at the same time with a bilinear transformation.

The importance of modeling structures beyond supertags is demonstrated in the performance gain in Lee et al. (2016), which adds a recursive component to the model of Eq. 1. Unfortunately, this formulation loses the efficiency of the original one since it needs to compute a recursive neural network every time it searches for a new node. Our model does not resort to the recursive networks while modeling tree structures via dependencies.

We also extend the tri-training method of Lewis et al. (2016) to learn our model with dependencies from unlabeled data. On English CCGbank test data, our model with this technique achieves 88.8% and 94.0% in terms of labeled and unlabeled F1, which mark the best scores so far.

Besides English, we provide experiments on Japanese CCG parsing. Japanese employs freer word order dominated by the case markers and a deterministic rule such as the attach low method may not work well. We show that this is actually the case; our method outperforms the simple application of Lewis et al. (2016) in a large margin, 10.0 points in terms of clause dependency accuracy.

2 Background

Our work is built on A* CCG parsing (Section 2.1), which we extend in Section 3 with a head prediction model on bi-LSTMs (Section 2.2).

2.1 Supertag-factored A* CCG Parsing

CCG has a nice property that since every category is highly informative about attachment decisions, assigning it to every word (*supertagging*) resolves most of its syntactic structure. Lewis and Steedman (2014) utilize this characteristics of the grammar. Let a CCG tree $\boldsymbol{y}$ be a list of categories $\langle c_1, \ldots, c_N \rangle$ and a derivation on it. Their model looks for the most probable $\boldsymbol{y}$ given a sentence $\boldsymbol{x}$ of length N from the set $Y(\boldsymbol{x})$ of possible CCG trees under the model of Eq. 1:

$$\hat{\boldsymbol{y}} = \arg\max_{\boldsymbol{y} \in Y(\boldsymbol{x})} \sum_{i \in [1,N]} \log P_{tag}(c_i | \boldsymbol{x}).$$

Since this score is factored into each supertag, they call the model a *supertag-factored* model.

Exact inference of this problem is possible by A* parsing (Klein and D. Manning, 2003), which uses the following two scores on a chart:

$$b(C_{i,j}) = \sum_{c_k \in \boldsymbol{c}_{i,j}} \log P_{tag}(c_k | \boldsymbol{x}),$$

$$a(C_{i,j}) = \sum_{k \in [1,N] \setminus [i,j]} \max_{c_k} \log P_{tag}(c_k | \boldsymbol{x}),$$

where $C_{i,j}$ is a chart item called an *edge*, which abstracts parses spanning interval $[i, j]$ rooted by category C. The chart maps each edge to the derivation with the highest score, i.e., the Viterbi parse for $C_{i,j}$. $\boldsymbol{c}_{i,j}$ is the sequence of categories on such Viterbi parse, and thus b is called the Viterbi inside score, while a is the approximation (upper bound) of the Viterbi outside score.

A* parsing is a kind of CKY chart parsing augmented with an agenda, a priority queue that keeps the edges to be explored. At every step it pops the edge e with the highest priority $b(e) + a(e)$ and inserts that into the chart, and enqueue any edges that can be built by combining e with other edges in the chart. The algorithm terminates when an edge $C_{1,N}$ is popped from the agenda.

A* search for this model is quite efficient because both b and a can be obtained from the unigram category distribution on every word, which can be precomputed before search. The heuristics a gives an upper bound on the true Viterbi outside score (i.e., admissible). Along with this the condition that the inside score never increases by expansion (monotonicity) guarantees that the first found derivation on $C_{1,N}$ is always optimal. $a(C_{i,j})$ matches the true outside score if the one-best category assignments on the outside words ($\arg\max_{c_k} \log P_{tag}(c_k | \boldsymbol{x})$) can comprise a well-formed tree with $C_{i,j}$, which is generally not true.

Scoring model For modeling P_{tag}, Lewis and Steedman (2014) use a log-linear model with features from a fixed window context. Lewis et al. (2016) extend this with bi-LSTMs, which encode the complete sentence and capture the long range syntactic information. We base our model on this bi-LSTM architecture, and extend it to modeling a head word at the same time.

Attachment ambiguity In A* search, an edge with the highest priority $b + a$ is searched first, but as shown in Figure 1 the same categories (with the same priority) may sometimes derive more than

one tree. In Lewis and Steedman (2014), they prioritize the parse with longer dependencies, which they judge with a conversion rule from a CCG tree to a dependency tree (Section 4). Lewis et al. (2016) employ another heuristics prioritizing low attachments of constituencies, but inevitably these heuristics cannot be flawless in any situations. We provide a simple solution to this problem by explicitly modeling bilexical dependencies.

2.2 Bi-LSTM Dependency Parsing

For modeling dependencies, we borrow the idea from the recent graph-based neural dependency parsing (Kiperwasser and Goldberg, 2016; Dozat and Manning, 2016) in which each dependency arc is scored directly on the outputs of bi-LSTMs. Though the model is first-order, bi-LSTMs enable conditioning on the entire sentence and lead to the state-of-the-art performance. Note that this mechanism is similar to modeling of the supertag distribution discussed above, in that for each word the distribution of the head choice is unigram and can be precomputed. As we will see this keeps our joint model still locally factored and A* search tractable. For score calculation, we use an extended bilinear transformation by Dozat and Manning (2016) that models the prior headness of each token as well, which they call *biaffine*.

3 Proposed Method

3.1 A* parsing with Supertag and Dependency Factored Model

We define a CCG tree $\boldsymbol{y}$ for a sentence $\boldsymbol{x} = \langle x_i, \ldots, x_N \rangle$ as a triplet of a list of CCG categories $\boldsymbol{c} = \langle c_1, \ldots, c_N \rangle$, dependencies $\boldsymbol{h} = \langle h_1, \ldots, h_N \rangle$, and the derivation, where h_i is the head index of x_i. Our model is defined as follows:

$$P(\boldsymbol{y}|\boldsymbol{x}) = \prod_{i \in [1,N]} P_{tag}(c_i|\boldsymbol{x}) \prod_{i \in [1,N]} P_{dep}(h_i|\boldsymbol{x}). \tag{2}$$

The added term P_{dep} is a unigram distribution of the head choice.

A* search is still tractable under this model. The search problem is changed as:

$$\hat{\boldsymbol{y}} = \arg\max_{\boldsymbol{y} \in Y(\boldsymbol{x})} \left(\sum_{i \in [1,N]} \log P_{tag}(c_i|\boldsymbol{x}) + \sum_{i \in [1,N]} \log P_{dep}(h_i|\boldsymbol{x}) \right),$$

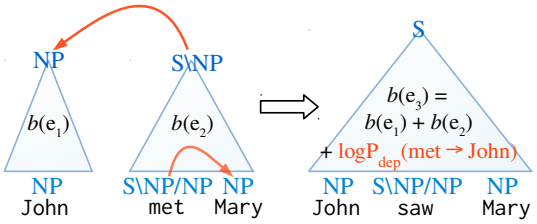

Figure 2: Viterbi inside score for edge e_3 under our model is the sum of those of e_1 and e_2 and the score of dependency arc going from the head of e_2 to that of e_1 (the head direction changes according to the child categories).

and the inside score is given by:

$$b(C_{i,j}) = \sum_{c_k \in \boldsymbol{c}_{i,j}} \log P_{tag}(c_k|\boldsymbol{x}) + \sum_{k \in [i,j] \setminus \{root(\boldsymbol{h}^C_{i,j})\}} \log P_{dep}(h_k|\boldsymbol{x}), \tag{3}$$

where $\boldsymbol{h}^C_{i,j}$ is a dependency subtree for the Viterbi parse on $C_{i,j}$ and $root(\boldsymbol{h})$ returns the root index. We exclude the head score for the subtree root token since it cannot be resolved inside $[i, j]$. This causes the mismatch between the goal inside score $b(C_{1,N})$ and the true model score (log of Eq. 2), which we adjust by adding a special unary rule that is always applied to the popped goal edge $C_{1,N}$.

We can calculate the dependency terms in Eq. 3 on the fly when expanding the chart. Let the currently popped edge be $A_{i,k}$, which will be combined with $B_{k,j}$ into $C_{i,j}$. The key observation is that only one dependency arc (between $root(\boldsymbol{h}^A_{i,k})$ and $root(\boldsymbol{h}^B_{k,j})$) is resolved at every combination (see Figure 2). For every rule $C \to A\ B$ we can define the head direction (see Section 4) and P_{dep} is obtained accordingly. For example, when the right child B becomes the head, $b(C_{i,j}) = b(A_{i,k}) + b(B_{k,j}) + \log P_{dep}(h_l = m|\boldsymbol{x})$, where $l = root(\boldsymbol{h}^A_{i,k})$ and $m = root(\boldsymbol{h}^B_{k,j})$ ($l < m$).

The Viterbi outside score is changed as:

$$a(C_{i,j}) = \sum_{k \in [1,N] \setminus [i,j]} \max_{c_k} \log P_{tag}(c_k|\boldsymbol{x}) + \sum_{k \in L} \max_{h_k} \log P_{dep}(h_k|\boldsymbol{x}),$$

where $L = [1, N] \setminus [k' | k' \in [i, j], root(\boldsymbol{h}^C_{i,j}) \neq k']$. We regard $root(\boldsymbol{h}^C_{i,j})$ as an outside word since its head is undefined yet. For every outside word we independently assign the weight of its argmax

head, which may not comprise a well-formed dependency tree. We initialize the agenda by adding an item for every supertag C and word x_i with the score $a(C_{i,i}) = \sum_{k \in I \setminus \{i\}} \max \log P_{tag}(c_k|\boldsymbol{x}) + \sum_{k \in I} \max \log P_{dep}(h_k|\boldsymbol{x})$. Note that the dependency component of it is the same for every word.

3.2 Network Architecture

Following Lewis et al. (2016) and Dozat and Manning (2016), we model P_{tag} and P_{dep} using bi-LSTMs for exploiting the entire sentence to capture the long range phenomena. See Figure 3 for the overall network architecture, where P_{tag} and P_{dep} share the common bi-LSTM hidden vectors.

First we map every word x_i to their hidden vector $\boldsymbol{r}_i$ with bi-LSTMs. The input to the LSTMs is word embeddings, which we describe in Section 6. We add special start and end tokens to each sentence with the trainable parameters following Lewis et al. (2016). For P_{dep}, we use the biaffine transformation in Dozat and Manning (2016):

$$\begin{aligned} \boldsymbol{g}_i^{dep} &= MLP_{child}^{dep}(\boldsymbol{r}_i), \\ \boldsymbol{g}_{h_i}^{dep} &= MLP_{head}^{dep}(\boldsymbol{r}_{h_i}), \\ &P_{dep}(h_i|\boldsymbol{x}) \\ &\quad \propto \exp((\boldsymbol{g}_i^{dep})^{\mathrm{T}} W_{dep} \boldsymbol{g}_{h_i}^{dep} + \boldsymbol{w}_{dep} \boldsymbol{g}_{h_i}^{dep}), \end{aligned} \tag{4}$$

where MLP is a multilayered perceptron. Though Lewis et al. (2016) simply use an MLP for mapping $\boldsymbol{r}_i$ to P_{tag}, we additionally utilize the hidden vector of the most probable head $h_i = \arg\max_{h'_i} P_{dep}(h'_i|\boldsymbol{x})$, and apply $\boldsymbol{r}_i$ and $\boldsymbol{r}_{h_i}$ to a bilinear function:[2]

$$\begin{aligned} \boldsymbol{g}_i^{tag} &= MLP_{child}^{tag}(\boldsymbol{r}_i), \\ \boldsymbol{g}_{h_i}^{tag} &= MLP_{head}^{tag}(\boldsymbol{r}_{h_i}), \\ \boldsymbol{\ell} &= (\boldsymbol{g}_i^{tag})^{\mathrm{T}} \boldsymbol{U}_{tag} \boldsymbol{g}_{h_i}^{tag} + W_{tag} \begin{bmatrix} \boldsymbol{g}_i^{tag} \\ \boldsymbol{g}_{h_i}^{tag} \end{bmatrix} + \boldsymbol{b}_{tag}, \\ P_{tag}(c_i|\boldsymbol{x}) &\propto \exp(\ell_c), \end{aligned} \tag{5}$$

where $\boldsymbol{U}_{tag}$ is a third order tensor. As in Lewis et al. these values can be precomputed before search, which makes our A* parsing quite efficient.

4 CCG to Dependency Conversion

Now we describe our conversion rules from a CCG tree to a dependency one, which we use in two purposes: 1) creation of the training data for the dependency component of our model; and 2) extraction of a dependency arc at each combinatory rule during A* search (Section 3.1). Lewis and Steedman (2014) describe one way to extract dependencies from a CCG tree (LEWISRULE). Below in addition to this we describe two simpler alternatives (HEADFIRST and HEADFINAL), and see the effects on parsing performance in our experiments (Section 6). See Figure 4 for the overview.

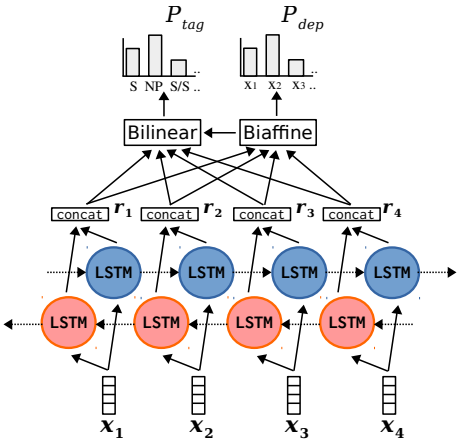

Figure 3: Neural networks of our supertag and dependency factored model. First we map every word x_i to a hidden vector $\boldsymbol{r}_i$ by bi-LSTMs, and then apply biaffine (Eq. 4) and bilinear (Eq. 5) transformations to obtain the distributions of dependency heads (P_{dep}) and supertags (P_{tag}).

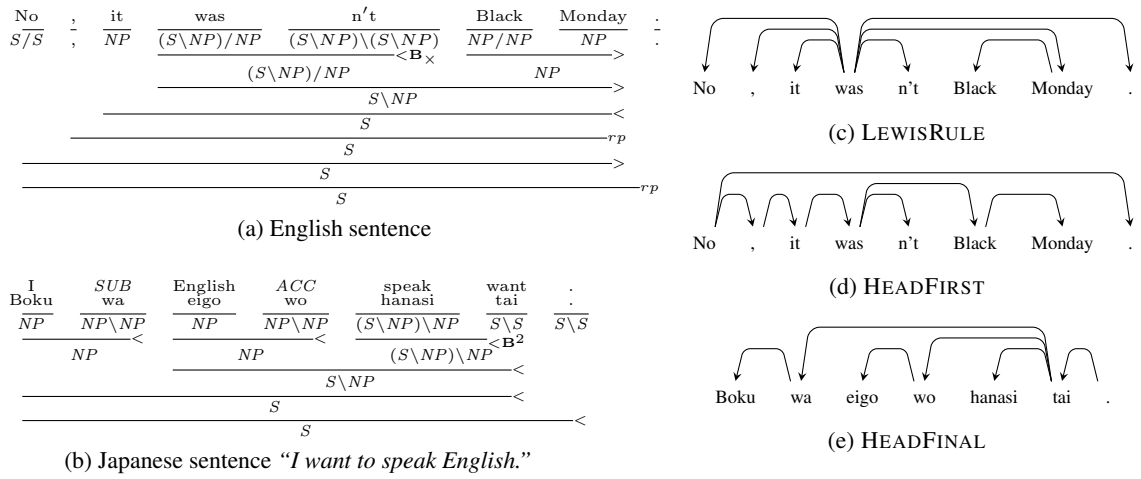
LEWISRULE This is the same as the conversion rule in Lewis and Steedman (2014). As shown in Figure 4c the output looks a familiar English dependency tree.

For forward application and (generalized) forward composition, we define the head to be the left argument of the combinatory rule, unless it matches either X/X or $X/(X\backslash Y)$, in which case the right argument is the head. For example, on *"Black Monday"* in Figure 4a we choose *Monday* as the head of *Black*. For the backward rules, the conversions are defined as the reverse of the corresponding forward rules. For other rules, *RemovePunctuation* (*rp*) chooses the non punctuation argument as the head, while *Conjunction* (Φ) chooses the right argument.[3]

[2] This is inspired by the formulation of label prediction in Dozat and Manning (2016), which performs the best among other settings that remove or reverse the dependence between the head model and the supertag model.

[3] When applying LEWISRULE to Japanese, we ignore the feature values in determining the head argument, which we find often leads to a more natural dependency structure. For example, in "tabe ta" (eat *PAST*), the category of auxiliary verb "ta" is $S_{f_1}\backslash S_{f_2}$ with $f_1 \neq f_2$, and thus $S_{f_1} \neq S_{f_2}$. We choose "tabe" as the head in this case by removing the feature values, which makes the category $X\backslash X$.



(a) English sentence

(b) Japanese sentence *"I want to speak English."*

(c) LEWISRULE

(d) HEADFIRST

(e) HEADFINAL

Figure 4: Examples of applying conversion rules in Section 4 to English and Japanese sentences.

One issue when applying this method for obtaining the training data is that due to the mismatch between the rule set of our CCG parser, for which we follow Lewis and Steedman (2014), and the grammar in English CCGbank (Hockenmaier and Steedman, 2007) we cannot extract dependencies from some of annotated CCG trees.[4] For this reason, we instead obtain the training data for this method from the original dependency annotations on CCGbank. Fortunately the dependency annotations of CCGbank matches LEWISRULE above in most cases and thus they can be a good approximation to it.

HEADFINAL Among SOV languages, Japanese is known as a strictly head final language, meaning that the head of every word always follows it. Japanese dependency parsing (Uchimoto et al., 1999; Kudo and Matsumoto, 2002) has exploited this property explicitly by only allowing left-to-right dependency arcs. Inspired by this tradition, we try a simple HEADFINAL rule in Japanese CCG parsing, in which we always select the right argument as the head. For example we obtain the head final dependency tree in Figure 4e from the Japanese CCG tree in Figure 4b.

HEADFIRST We apply the similar idea as HEADFINAL into English. Since English has the opposite, SVO word order, we define the simple "head first" rule, in which the left argument always becomes the head (Figure 4d).

Though this conversion may look odd at first sight it also has some advantages over LEWISRULE. First, since the model with LEWISRULE is trained on the CCGbank dependencies, at inference, occasionally the two components P_{dep} and P_{tag} cause some conflicts on their predictions. For example, the true Viterbi parse may have a lower score in terms of dependencies, in which case the parser slows down and may degrade the accuracy. HEADFIRST, in contract, does not suffer from such conflicts. Second, by fixing the direction of arcs, the prediction of heads becomes easier, meaning that the dependency predictions become more reliable. Later we show that this is in fact the case for existing dependency parsers (see Section 5), and in practice, we find that this simple conversion rule leads to the higher parsing scores than LEWISRULE on English (Section 6).

5 Tri-training

We extend the existing tri-training method to our models and apply it to our English parsers.

Tri-training is one of the semi-supervised methods, in which the outputs of two parsers on unlabeled data are intersected to create (silver) new training data. This method is successfully applied to dependency parsing (Weiss et al., 2015) and CCG supertagging (Lewis et al., 2016).

We simply combine the two previous approaches. Lewis et al. (2016) obtain their silver data annotated with the high quality supertags. Since they make this data publicly available [5], we obtain our silver data by assigning dependency

[4] For example, the combinatory rules in Lewis and Steedman (2014) do not contain $N_{conj} \rightarrow N\ N$ in CCGbank. Another difficulty is that in English CCGbank the name of each combinatory rule is not annotated explicitly.

[5] https://github.com/uwnlp/taggerflow

structures on top of them.[6]

We train two very different dependency parsers from the training data extracted from CCGbank Section 02-21. This training data differs depending on our dependency conversion strategies (Section 4). For LEWISRULE, we extract the original dependency annotations of CCGbank. For HEADFIRST, we extract the head first dependencies from the CCG trees. Note that we cannot annotate dependency labels so we assign a dummy "none" label to every arc. The first parser is graph-based `RBGParser` (Lei et al., 2014) with the default settings except that we train an unlabeled parser and use word embeddings of Turian et al. (2010). The second parser is transition-based `lstm-parser` (Dyer et al., 2015) with the default parameters.

On the development set (Section 00), with LEWISRULE dependencies `RBGParser` shows 93.8% unlabeled attachment score while that of `lstm-parser` is 92.5% using gold POS tags. Interestingly, the parsers with HEADFIRST dependencies achieve higher scores: 94.9% by `RBGParser` and 94.6% by `lstm-parser`, suggesting that HEADFIRST dependencies are easier to parse. For both dependencies, we obtain more than 1.7 million sentences on which two parsers agree.

Following Lewis et al. (2016), we include 15 copies of CCGbank training set when using these silver data. Also to make effects of the tri-train samples smaller we multiply their loss by 0.4.

6 Experiments

We perform experiments on English and Japanese CCGbanks.

6.1 English Experimental Settings

We follow the standard data splits and use Sections 02-21 for training, Section 00 for development, and Section 23 for final evaluation. We report labeled and unlabeled F1 of the extracted CCG semantic dependencies obtained using `generate` program supplied with `C&C` parser.

For our models, we adopt the pruning strategies in Lewis and Steedman (2014) and allow at most 50 categories per word, use a variable-width beam with $\beta = 0.00001$, and utilize a tag dictionary, which maps frequent words to the possible supertags[7]. Unless otherwise stated, we only allow normal form parses (Eisner, 1996; Hockenmaier and Bisk, 2010), choosing the same subset of the constraints as Lewis and Steedman (2014).

We use as word representation the concatenation of word vectors initialized to GloVe[8] (Pennington et al., 2014), and randomly initialized prefix and suffix vectors of the length 1 to 4, which is inspired by Lewis et al. (2016). All affixes appearing less than two times in the training data are mapped to "UNK".

Other model configurations are: 4-layer bi-LSTMs with left and right 300-dimensional LSTMs, 1-layer 100-dimensional MLPs with ELU non-linearity (Clevert et al., 2015) for all MLP^{dep}_{child}, MLP^{dep}_{head}, MLP^{tag}_{child} and MLP^{tag}_{head}, and the Adam optimizer with $\beta_1 = 0.9, \beta_2 = 0.9$, L2 norm ($1e^{-6}$), and learning rate decay with the ratio 0.75 for every 2,500 iteration starting from $2e^{-3}$, which is shown to be effective for training the biaffine parser (Dozat and Manning, 2016).

6.2 Japanese Experimental Settings

We follow the default train/dev/test splits of Japanese CCGbank (Uematsu et al., 2013). For the baselines, we use an existing shift-reduce CCG parser implemented in an NLP tool Jigg[9] (Noji and Miyao, 2016), and our implementation of the supertag-factored model using bi-LSTMs.

For Japanese, we use as word representation the concatenation of word vectors initialized to Japanese Wikipedia Entity Vector[10], and 100-dimensional vectors computed from randomly initialized 50-dimensional character embeddings through convolution (dos Santos and Zadrozny, 2014). We do not use affix vectors as affixes are less informative in Japanese. All characters appearing less than two times are mapped to "UNK". We use the same parameter settings as English for bi-LSTMs, MLPs, and optimization.

One issue in Japanese experiments is evaluation. The Japanese CCGbank is encoded in a different format than the English bank, and no standalone script for extracting semantic dependencies is available yet. For this reason, we evaluate the parser outputs by converting them to *bunsetsu*

[6] We annotate POS tags on this data using Stanford POS tagger (Toutanova et al., 2003).

[7] We use the same tag dictionary provided with their bi-LSTM model.

Table 2: Parsing results (F1) on English development set when excluding the normal form constraints. # violations is the number of combinations violating the constraints on the outputs.

dependencies, the syntactic representation ordinary used in Japanese NLP (Kudo and Matsumoto, 2002). Given a CCG tree, we obtain this by first segment a sentence into bunsetsu (chunks) using CaboCha[11] and extract dependencies that cross a bunsetsu boundary after obtaining the word-level, head final dependencies as in Figure 4b. For example, the sentence in Figure 4e is segmented as "*Boku wa* | *eigo wo* | *hanashi tai*", from which we extract two dependencies (*Boku wa*) ← (*hanashi tai*) and (*eigo wo*) ← (*hanashi tai*). We perform this conversion for both gold and output CCG trees and calculate the (unlabeled) attachment accuracy. Though this is imperfect, it can detect important parse errors such as attachment errors and thus can be a good proxy for the performance as a CCG parser.

6.3 English Parsing Results

Effect of Dependency We first see how the dependency components added in our model affect the performance. Table 1 shows the results on the development set with the several configurations, in which "w/o dep" means discarding the dependency terms of the model and applying the attach low heuristics (Section 1) instead (i.e., a supertag-factored model; Section 2.1). We can see that for both LEWISRULE and HEADFIRST, adding dependency terms improves the performance.

EasySRL (Lewis et al., 2016)	87.2	-
EasySRL_reimpl	86.8	92.3
HEADFIRST w/o NF (Ours)	87.7	**93.4**
Tri-training		
EasySRL (Lewis et al., 2016)	88.0	92.9
neuralccg (Lee et al., 2016)	88.7	93.7
HEADFIRST w/o NF (Ours)	**88.8**	**94.0**

Table 3: Parsing results (F1) on English test set (Section 23).

Choice of Dependency Conversion Rule To our surprise, our simple HEADFIRST strategy always leads to better results than the linguistically motivated LEWISRULE. The absolute improvements by tri-training are equally large (about 1.0 points), suggesting that our model with dependencies can also benefit from the silver data.

Excluding Normal Form Constraints One advantage of HEADFIRST is that the direction of arcs is always right, making the structures simpler and more parsable (Section 5). From another viewpoint, this fixed direction means that the constituent structure behind a (head first) dependency tree is unique. Since the constituent structures of CCGbank trees basically follow the normal form (NF), we hypothesize that the model learned with HEADFIRST has an ability to force the outputs in NF automatically. We summarize the results without the NF constraints in Table 2, which shows that the above argument is correct; the number of violating NF rules on the outputs of HEADFIRST is much smaller than that of LEWISRULE (89 vs. 283). Interestingly the scores of HEADFIRST slightly increase from the models with NF (e.g., 86.8 vs. 86.6 for CCGbank), suggesting that the NF constraints hinder the search of HEADFIRST models occasionally.

Results on Test Set Parsing results on the test set (Section 23) are shown in Table 3, where we compare our best performing HEADFIRST dependency model without NF constraints with the several existing parsers. In the CCGbank experi-

	EasySRL_reimpl	neuralccg	Ours
Tagging	24.8	21.7	16.6
A Search*	185.2	16.7	114.6
Total	21.9	9.33	14.5

Table 4: Results of the efficiency experiment, where each number is the number of sentences processed per second. We compare our proposed parser against neuralccg and our reimplementation of EasySRL.

ment, our parser shows the better result than all the baseline parsers except C&C with an LSTM supertagger (Vaswani et al., 2016). Our parser outperforms EasySRL by 0.5% and our reimplementation of that parser (EasySRL_reimpl) by 0.9% in terms of labeled F1. In the tri-training experiment, our parser shows much increased performance of 88.8% labeled F1 and 94.0% unlabeled F1, outperforming the current state-of-the-art neuralccg (Lee et al., 2016) that uses recursive neural networks by 0.1 point and 0.3 point in terms of labeled and unlabeled F1. This is the best reported F1 in English CCG parsing.

Efficiency Comparison We compare the efficiency of our parser with neuralccg and EasySRL_reimpl.[12] The results are shown in Table 4. For the overall speed (the third row), our parser is faster than neuralccg although lags behind EasySRL_reimpl. Inspecting the details, our supertagger runs slower than those of neuralccg and EasySRL_reimpl, while in A* search our parser processes over 7 times more sentences than neuralccg. The delay in supertagging can be attributed to several factors, in particular the differences in network architectures including the number of bi-LSTM layers (4 vs. 2) and the use of bilinear transformation instead of linear one. There are also many implementation differences in our parser (C++ A* parser with neural network model implemented with Chainer (Tokui et al., 2015)) and neuralccg (Java parser with C++ TensorFlow (Abadi et al., 2015) supertagger and recursive neural model in C++ DyNet (Neubig et al., 2017)).

6.4 Japanese Parsing Result

We show the results of the Japanese parsing experiment in Table 5. The simple application of Lewis et al. (2016) (Supertag model) is not effective for Japanese, showing the lowest attachment score of 81.5%. We observe a performance boost with our method, especially with HEADFINAL dependencies, which outperforms the baseline shift-reduce parser by 1.1 points on category assignments and 4.0 points on bunsetsu dependencies.

[12] This experiment is performed on a laptop with 4-thread 2.0 GHz CPU.

Method	Category	Bunsetsu Dep.
Noji and Miyao (2016)	93.0	87.5
Supertag model	93.7	81.5
LEWISRULE (Ours)	93.8	90.8
HEADFINAL (Ours)	**94.1**	**91.5**

Table 5: Results of Japanese CCGbank.

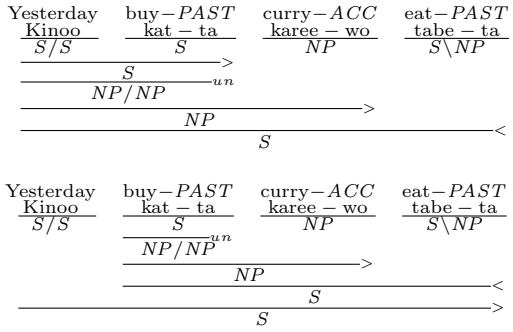

Figure 5: Examples of ambiguous Japanese sentence given fixed supertags. The English translation is *"I ate the curry I bought yesterday"*.

The degraded results of the simple application of the supertag-factored model can be attributed to the fact that the structure of a Japanese sentence is still highly ambiguous given the supertags (Figure 5). This is particularly the case in constructions where phrasal adverbial/adnominal modifiers (with the supertag S/S) are involved. The result suggests the importance of modeling dependencies in some languages, at least Japanese.

7 Related Work

There is some past work that utilizes dependencies in lexicalized grammar parsing, which we review briefly here.

For Head-driven Phrase Structure Grammar (HPSG; Pollard and Sag (1994)), there are studies to use the predicted dependency structure to improve HPSG parsing accuracy. Sagae et al. (2007) use dependencies to constrain the form of the output tree. As in our method, for every rule (schema) application they define which child becomes the head and impose a soft constraint that these dependencies agree with the output of the dependency parser. Our method is different

in that we do not use the one-best dependency structure alone, but rather we search for a CCG tree that is optimal in terms of dependencies and CCG supertags. Zhang et al. (2010) use the syntactic dependencies in a different way, and show that dependency-based features are useful for predicting HPSG supertags.

In the CCG parsing literature, some work optimizes a *dependency model*, instead of supertags or a derivation (Clark and Curran, 2007; Xu et al., 2014). This approach is reasonable given that the objective matches the evaluation metric. Instead of modeling dependencies alone, our method finds a CCG derivation that has a higher dependency score. Lewis et al. (2015) present a joint model of CCG parsing and semantic role labeling (SRL), which is closely related to our approach. They map each CCG semantic dependency to an SRL relation, for which they give the A* upper bound by the score from a predicate to the most probable argument. Our approach is similar; the largest difference is that we instead model syntactic dependencies from each token to its head, and this is the key to our success. Since dependency parsing can be formulated as independent head selections similar to tagging, we can build the entire model on LSTMs to exploit features from the whole sentence. This formulation is not straightforward in the case of multi-headed semantic dependencies in their model.

8 Conclusion

We have presented a new A* CCG parsing method, in which the probability of a CCG tree is decomposed into local factors of the CCG categories and its dependency structure. By explicitly modeling the dependency structure, we do not require any deterministic heuristics to resolve attachment ambiguities, and keep the model locally factored so that all the probabilities can be precomputed before running the search. Our parser efficiently finds the optimal parse and achieves the state-of-the-art performance in both English and Japanese parsing.

Acknowledgments

We are grateful to Mike Lewis for answering our questions and your Github repository from which we learned many things. We also thank Yuichiro Sawai for the faster LSTM implementation. This work was in part supported by JSPS KAKENHI Grant Number 16H06981, and also by JST CREST Grant Number JPMJCR1301.

Abstract

Restricted non-monotonicity has been shown beneficial for the projective arc-eager dependency parser in previous research, as posterior decisions can repair mistakes made in previous states due to the lack of information. In this paper, we propose a novel, fully non-monotonic transition system based on the non-projective Covington algorithm. As a non-monotonic system requires exploration of erroneous actions during the training process, we develop several non-monotonic variants of the recently defined dynamic oracle for the Covington parser, based on tight approximations of the loss. Experiments on datasets from the CoNLL-X and CoNLL-XI shared tasks show that a non-monotonic dynamic oracle outperforms the monotonic version in the majority of languages.

1 Introduction

Greedy transition-based dependency parsers are widely used in different NLP tasks due to their speed and efficiency. They parse a sentence from left to right by greedily choosing the highest-scoring transition to go from the current parser configuration or state to the next. The resulting sequence of transitions incrementally builds a parse for the input sentence. The scoring of the transitions is provided by a statistical model, previously trained to approximate an *oracle*, a function that selects the needed transitions to parse a gold tree.

Unfortunately, the greedy nature that grants these parsers their efficiency also represents their main limitation. McDonald and Nivre (2007) show that greedy transition-based parsers lose accuracy to error propagation: a transition erroneously chosen by the greedy parser can place it in an incorrect and unknown configuration, causing more mistakes in the rest of the transition sequence. Training with a dynamic oracle (Goldberg and Nivre, 2012) improves robustness in these situations, but in a monotonic transition system, erroneous decisions made in the past are permanent, even when the availability of further information in later states might be useful to correct them.

Honnibal et al. (2013) show that allowing some degree of non-monotonicity, by using a limited set of non-monotonic actions that can repair past mistakes and replace previously-built arcs, can increase the accuracy of a transition-based parser. In particular, they present a modified arc-eager transition system where the Left-Arc and Reduce transitions are non-monotonic: the former is used to repair invalid attachments made in previous states by replacing them with a leftward arc, and the latter allows the parser to link two words with a rightward arc that were previously left unattached due to an erroneous decision. Since the Right-Arc transition is still monotonic and leftward arcs can never be repaired because their dependent is removed from the stack by the arc-eager parser and rendered inaccessible, this approach can only repair certain kinds of mistakes: namely, it can fix erroneous rightward arcs by replacing them with a leftward arc, and connect a limited set of unattached words with rightward arcs. In addition, they argue that non-monotonicity in the training oracle can be harmful for the final accuracy and, therefore, they suggest to apply it only as a fallback component for a monotonic oracle, which is given priority over the non-monotonic one. Thus, this strategy will follow the path dictated by the monotonic oracle the majority of the time. Honnibal and Johnson (2015) present an extension of this transition system with an Unshift transition allowing it some extra flexibility to correct past errors. However, the restriction that only rightward

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 288–298
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1027

arcs can be deleted, and only by replacing them with leftward arcs, is still in place. Furthermore, both versions of the algorithm are limited to projective trees.

In this paper, we propose a non-monotonic transition system based on the non-projective Covington parser, together with a dynamic oracle to train it with erroneous examples that will need to be repaired. Unlike the system developed in (Honnibal et al., 2013; Honnibal and Johnson, 2015), we work with full non-monotonicity. This has a twofold meaning: (1) our approach can repair previous erroneous attachments regardless of their original direction, and it can replace them either with a rightward or leftward arc as both arc transitions are non-monotonic;[1] and (2) we use exclusively a non-monotonic oracle, without the interferences of monotonic decisions. These modifications are feasible because the non-projective Covington transition system is less rigid than the arc-eager algorithm, as words are never deleted from the parser's data structures and can always be revisited, making it a better option to exploit the full potencial of non-monotonicity. To our knowledge, the presented system is the first non-monotonic parser that can produce non-projective dependency analyses. Another novel aspect is that our dynamic oracle is *approximate*, i.e., based on efficiently-computable approximations of the loss due to the complexity of calculating its actual value in a non-monotonic and non-projective scenario. However, this is not a problem in practice: experimental results show how our parser and oracle can use non-monotonic actions to repair erroneous attachments, outperforming the monotonic version developed by Gómez-Rodríguez and Fernández-González (2015) in a large majority of the datasets tested.

2 Preliminaries

2.1 Non-Projective Covington Transition System

The non-projective Covington parser was originally defined by Covington (2001), and then recast by Nivre (2008) under the transition-based parsing framework.

[1]The only restriction is that parsing must still proceed in left-to-right order. For this reason, a leftward arc cannot be repaired with a rightward arc, because this would imply going back in the sentence. The other three combinations (replacing leftward with leftward, rightward with leftward or rightward with rightward arcs) are possible.

The transition system that defines this parser is as follows: each parser configuration is of the form $c = \langle \lambda_1, \lambda_2, B, A \rangle$, such that λ_1 and λ_2 are lists of partially processed words, B is another list (called the buffer) containing currently unprocessed words, and A is the set of dependencies that have been built so far. Suppose that our input is a string $w_1 \cdots w_n$, whose word occurrences will be identified with their indices $1 \cdots n$ for simplicity. Then, the parser will start at an initial configuration $c_s(w_1 \dots w_n) = \langle [], [], [1 \dots n], \emptyset \rangle$, and execute transitions chosen from those in Figure 1 until a terminal configuration of the form $\{\langle \lambda_1, \lambda_2, [], A \rangle \in C\}$ is reached. At that point, the sentence's parse tree is obtained from A.[2]

These transitions implement the same logic as the double nested loop traversing word pairs in the original formulation by Covington (2001). When the parser's configuration is $\langle \lambda_1 | i, \lambda_2, j | B, A \rangle$, we say that it is considering the **focus words** i and j, located at the end of the first list and at the beginning of the buffer. At that point, the parser must decide whether these two words should be linked with a leftward arc $i \leftarrow j$ (Left-Arc transition), a rightward arc $i \rightarrow j$ (Right-Arc transition), or not linked at all (No-Arc transition). However, the two transitions that create arcs will be disallowed in configurations where this would cause a violation of the **single-head constraint** (a node can have at most one incoming arc) or the **acyclicity constraint** (the dependency graph cannot have cycles). After applying any of these three transitions, i is moved to the second list to make $i - 1$ and j the focus words for the next step. As an alternative, we can instead choose to execute a Shift transition which lets the parser read a new input word, placing the focus on j and $j + 1$.

The resulting parser can generate any possible dependency tree for the input, including arbitrary non-projective trees. While it runs in quadratic worst-case time, in theory worse than linear-time transition-based parsers (e.g. (Nivre, 2003; Gómez-Rodríguez and Nivre, 2013)), it has been shown to outspeed linear algorithms in practice, thanks to feature extraction optimizations that cannot be implemented in other parsers (Volokh and Neumann, 2012). In fact, one of the fastest dependency parsers ever reported uses this algorithm

[2]In general A is a forest, but it can be converted to a tree by linking headless nodes as dependents of an artificial root node at position 0. When we refer to parser outputs as trees, we assume that this transformation is being implicitly made.

Shift:	$\langle \lambda_1, \lambda_2, j\|B, A\rangle \Rightarrow \langle \lambda_1 \cdot \lambda_2\|j, [], B, A\rangle$
No-Arc:	$\langle \lambda_1\|i, \lambda_2, B, A\rangle \Rightarrow \langle \lambda_1, i\|\lambda_2, B, A\rangle$
Left-Arc:	$\langle \lambda_1\|i, \lambda_2, j\|B, A\rangle \Rightarrow \langle \lambda_1, i\|\lambda_2, j\|B, A \cup \{j \rightarrow i\}\rangle$ only if $\nexists k \mid k \rightarrow i \in A$ (single-head) and $i \rightarrow^* j \notin A$ (acyclicity).
Right-Arc:	$\langle \lambda_1\|i, \lambda_2, j\|B, A\rangle \Rightarrow \langle \lambda_1, i\|\lambda_2, j\|B, A \cup \{i \rightarrow j\}\rangle$ only if $\nexists k \mid k \rightarrow j \in A$ (single-head) and $j \rightarrow^* i \notin A$ (acyclicity).

Figure 1: Transitions of the monotonic Covington non-projective dependency parser. The notation $i \rightarrow^* j \in A$ means that there is a (possibly empty) directed path from i to j in A.

(Volokh, 2013).

2.2 Monotonic Dynamic Oracle

A dynamic oracle is a function that maps a configuration c and a gold tree t_G to the set of transitions that can be applied in c and lead to some parse tree t minimizing the Hamming loss with respect to t_G (the amount of nodes whose head is different in t and t_G). Following Goldberg and Nivre (2013), we say that an arc set A is **reachable** from configuration c, and we write $c \rightsquigarrow A$, if there is some (possibly empty) path of transitions from c to some configuration $c' = \langle \lambda_1, \lambda_2, B, A'\rangle$, with $A \subseteq A'$. Then, we can define the loss of configuration c as

$$\ell(c) = \min_{t|c \rightsquigarrow t} \mathcal{L}(t, t_G),$$

and therefore, a correct dynamic oracle will return the set of transitions

$$o_d(c, t_G) = \{\tau \mid \ell(c) - \ell(\tau(c)) = 0\},$$

i.e., the set of transitions that do not increase configuration loss, and thus lead to the best parse (in terms of loss) reachable from c. Hence, implementing a dynamic oracle reduces to computing the loss $\ell(c)$ for each configuration c.

Goldberg and Nivre (2013) show a straightforward method to calculate loss for parsers that are **arc-decomposable**, i.e., those where every arc set A that can be part of a well-formed parse verifies that if $c \rightsquigarrow (i \rightarrow j)$ for every $i \rightarrow j \in A$ (i.e., each of the individual arcs of A is reachable from a given configuration c), then $c \rightsquigarrow A$ (i.e., the set A as a whole is reachable from c). If this holds, then the loss of a configuration c equals the number of gold arcs that are *not* individually reachable from c, which is easy to compute in most parsers.

Gómez-Rodríguez and Fernández-González (2015) show that the non-projective Covington parser is not arc-decomposable because sets of individually reachable arcs may form cycles together with already-built arcs, preventing them from being jointly reachable due to the acyclicity constraint. In spite of this, they prove that a dynamic oracle for the Covington parser can be efficiently built by counting individually unreachable arcs, and correcting for the presence of such cycles. Concretely, the loss is computed as:

$$\ell(c) = |\mathcal{U}(c, t_G)| + n_c(A \cup \mathcal{I}(c, t_G))$$

where $\mathcal{I}(c, t_G) = \{x \rightarrow y \in t_G \mid c \rightsquigarrow (x \rightarrow y)\}$ is the set of **individually reachable arcs** of t_G from configuration c; $\mathcal{U}(c, t_G)$ is the set of **individually unreachable arcs** of t_G from c, computed as $t_G \backslash \mathcal{I}(c, t_G)$; and $n_c(G)$ denotes the number of cycles in a graph G.

Therefore, to calculate the loss of a configuration c, we only need to compute the two terms $|\mathcal{U}(c, t_G)|$ and $n_c(A \cup \mathcal{I}(c, t_G))$. To calculate the first term, given a configuration c with focus words i and j (i.e., $c = \langle \lambda_1|i, \lambda_2, j|B, A\rangle$), an arc $x \rightarrow y$ will be in $\mathcal{U}(c, t_G)$ if it is not in A, and at least one of the following holds:

- $j > \max(x, y)$, (i.e., we have read too far in the string and can no longer get $\max(x, y)$ as right focus word),
- $j = \max(x, y) \wedge i < \min(x, y)$, (i.e., we have $\max(x, y)$ as the right focus word but the left focus word has already moved left past $\min(x, y)$, and we cannot go back),
- there is some $z \neq 0, z \neq x$ such that $z \rightarrow y \in A$, (i.e., we cannot create $x \rightarrow y$ because it would violate the single-head constraint),
- x and y are on the same weakly connected component of A (i.e., we cannot create $x \rightarrow y$ due to the acyclicity constraint).

The second term of the loss, $n_c(A \cup \mathcal{I}(c, t_G))$, can be computed by first obtaining $\mathcal{I}(c, t_G)$ as $t_G \setminus \mathcal{U}(c, t_G)$. Since the graph $\mathcal{I}(c, t_G)$ has in-degree 1, the algorithm by Tarjan (1972) can then be used to find and count the cycles in $O(n)$ time.

Algorithm 1 Computation of the loss of a configuration in the monotonic oracle.

function LOSS($c = \langle \lambda_1 | i, \lambda_2, j | B, A \rangle, t_G$)
  $U \leftarrow \emptyset$ ▷ Variable U is for $\mathcal{U}(c, t_G)$
  for each $x \rightarrow y \in (t_G \setminus A)$ **do**
    $left \leftarrow \min(x, y)$
    $right \leftarrow \max(x, y)$
    if $j > right \vee$
      $(j = right \wedge i < left) \vee$
      $(\exists z > 0, z \neq x : z \rightarrow y \in A) \vee$
      WEAKLYCONNECTED(A, x, y) **then**
        $U \leftarrow u \cup \{x \rightarrow y\}$
  $I \leftarrow t_G \setminus U$ ▷ Variable I is for $\mathcal{I}(c, t_G)$
  return $|U| +$ COUNTCYCLES$(A \cup I)$

Algorithm 1 shows the resulting loss calculation algorithm, where COUNTCYCLES is a function that counts the number of cycles in the given graph and WEAKLYCONNECTED returns whether two given nodes are weakly connected in A.

3 Non-Monotonic Transition System for the Covington Non-Projective Parser

We now define a non-monotonic variant of the Covington non-projective parser. To do so, we allow the Right-Arc and Left-Arc transitions to create arcs between any pair of nodes without restriction. If the node attached as dependent already had a previous head, the existing attachment is discarded in favor of the new one. This allows the parser to correct erroneous attachments made in the past by assigning new heads, while still enforcing the single-head constraint, as only the most recent head assigned to each node is kept.

To enforce acyclicity, one possibility would be to keep the logic of the monotonic algorithm, forbidding the creation of arcs that would create cycles. However, this greatly complicates the definition of the set of individually unreachable arcs, which is needed to compute the loss bounds that will be used by the dynamic oracle. This is because a gold arc $x \rightarrow y$ may superficially seem unreachable due to forming a cycle together with arcs in A, but it might in fact be reachable if there is some transition sequence that first breaks the cycle using non-monotonic transitions to remove arcs from A, to then create $x \rightarrow y$. We do not know of a way to characterize the conditions under which such a transition sequence exists, and thus cannot estimate the loss efficiently.

Instead, we enforce the acyclicity constraint in a similar way to the single-head constraint: Right-Arc and Left-Arc transitions are always allowed, even if the prospective arc would create a cycle in A. However, if the creation of a new arc $x \rightarrow y$ generates a cycle in A, we immediately remove the arc of the form $z \rightarrow x$ from A (which trivially exists, and is unique due to the single-head constraint). This not only enforces the acyclicity constraint while keeping the computation of $\mathcal{U}(c, t_G)$ simple and efficient, but also produces a straightforward, coherent algorithm (arc transitions are always allowed, and both constraints are enforced by deleting a previous arc) and allows us to exploit non-monotonicity to the maximum (we can not only recover from assigning a node the wrong head, but also from situations where previous errors together with the acyclicity constraint prevent us from building a gold arc, keeping with the principle that later decisions override earlier ones).

In Figure 2, we can see the resulting non-monotonic transition system for the non-projective Covington algorithm, where, unlike the monotonic version, all transitions are allowed at each configuration, and the single-head and acyclicity constraints are kept in A by removing offending arcs.

4 Non-Monotonic Approximate Dynamic Oracle

To successfully train a non-monotonic system, we need a dynamic oracle with error exploration, so that the parser will be put in erroneous states and need to apply non-monotonic transitions in order to repair them. To achieve that, we modify the dynamic oracle defined by Gómez-Rodríguez and Fernández-González (2015) so that it can deal with non-monotonicity. Our modification is an **approximate** dynamic oracle: due to the extra flexibility added to the algorithm by non-monotonicity, we do not know of an efficient way of obtaining an exact calculation of the loss of a given configuration. Instead, we use upper or lower bounds on the loss, which we empirically show to be very tight (less that 1% relative error with respect to the real loss) and are sufficient for the algorithm to provide better accuracy than the exact monotonic oracle.

First of all, we adapt the computation of the set of **individually unreachable arcs** $\mathcal{U}(c, t_G)$ to the new algorithm. In particular, if c has focus words i and j (i.e., $c = \langle \lambda_1 | i, \lambda_2, j | B, A \rangle$), then an arc $x \rightarrow y$ is in $\mathcal{U}(c, t_G)$ if it is not in A, and at least one of the following holds:

- $j > \max(x, y)$, (i.e., we have read too far in the string and can no longer get $\max(x, y)$ as

Shift:	$\langle \lambda_1, \lambda_2, j\|B, A\rangle \Rightarrow \langle \lambda_1 \cdot \lambda_2\|j, [], B, A\rangle$
No-Arc:	$\langle \lambda_1\|i, \lambda_2, B, A\rangle \Rightarrow \langle \lambda_1, i\|\lambda_2, B, A\rangle$
Left-Arc:	$\langle \lambda_1\|i, \lambda_2, j\|B, A\rangle \Rightarrow \langle \lambda_1, i\|\lambda_2, j\|B, (A \cup \{j \rightarrow i\}) \setminus \{x \rightarrow i \in A\} \setminus \{k \rightarrow j \in A \mid i \rightarrow^* k \in A\}\rangle$
Right-Arc:	$\langle \lambda_1\|i, \lambda_2, j\|B, A\rangle \Rightarrow \langle \lambda_1, i\|\lambda_2, j\|B, A \cup \{i \rightarrow j\} \setminus \{x \rightarrow j \in A\} \setminus \{k \rightarrow i \in A \mid j \rightarrow^* k \in A\}\rangle$

Figure 2: Transitions of the non-monotonic Covington non-projective dependency parser. The notation $i \rightarrow^* j \in A$ means that there is a (possibly empty) directed path from i to j in A.

right focus word),

- $j = \max(x, y) \wedge i < \min(x, y)$ (i.e., we have $\max(x, y)$ as the right focus word but the left focus word has already moved left past $\min(x, y)$, and we cannot move it back).

Note that, since the head of a node can change during the parsing process and arcs that produce cycles in A can be built, the two last conditions present in the monotonic scenario for computing $\mathcal{U}(c, t_G)$ are not needed when we use non-monotonicity and, as a consequence, the set of **individually reachable arcs** $\mathcal{I}(c, t_G)$ is larger: due to the greater flexibility provided by non-monotonicity, we can reach arcs that would be unreachable for the monotonic version.

Since arcs that are in this new $\mathcal{U}(c, t_G)$ are unreachable even by the non-monotonic parser, $|\mathcal{U}(c, t_G)|$ is trivially a **lower bound** of the loss $\ell(c)$. It is worth noting that there always exists at least one transition sequence that builds every arc in $\mathcal{I}(c, t_G)$ at some point (although not all of them necessarily appear in the final tree, due to non-monotonicity). This can be easily shown based on the fact that the non-monotonic parser does not forbid transitions at any configuration. Thanks to this, we can can generate one such sequence by just applying the original Covington (2001) criteria (choose an arc transition whenever the focus words are linked in $\mathcal{I}(c, t_G)$, and otherwise Shift or No-Arc depending on whether the left focus word is the first word in the sentence or not), although this sequence is not necessarily optimal in terms of loss. In such a transition sequence, the gold arcs that are missed are (1) those in $\mathcal{U}(c, t_G)$, and (2) those that are removed by the cycle-breaking in Left-Arc and Right-Arc transitions. In practice configurations where (2) is needed are uncommon, so this lower bound is a very close approximation of the real loss, as will be seen empirically below.

This reasoning also helps us calculate an upper bound of the loss: in a transition sequence as described, if we *only* build the arcs in $\mathcal{I}(c, t_G)$ and none else, the amount of arcs removed by breaking cycles (2) cannot be larger than the number of cycles in $A \cup \mathcal{I}(c, t_G)$. This means that $|\mathcal{U}(c, t_G)| + n_c(A \cup \mathcal{I}(c, t_G))$ is an **upper bound** of the loss $\ell(c)$. Note that, contrary to the monotonic case, this expression does not always give us the exact loss, for several reasons: firstly, $A \cup \mathcal{I}(c, t_G)$ can have non-disjoint cycles (a node may have different heads in A and $\mathcal{I}$ since attachments are not permanent, contrary to the monotonic version) and thus removing a single arc may break more than one cycle; secondly, the removed arc can be a non-gold arc of A and therefore not incur loss; and thirdly, there may exist alternative transition sequences where a cycle in $A \cup \mathcal{I}(c, t_G)$ is broken early by non-monotonic configurations that change the head of a wrongly-attached node in A to a different (and also wrong) head,[3] removing the cycle before the cycle-breaking mechanism needs to come into play without incurring in extra errors. Characterizing the situations where such an alternative exists is the main difficulty for an exact calculation of the loss.

However, it is possible to obtain a closer upper bound to the real loss if we consider the following: for each cycle in $A \cup \mathcal{I}(c, t_G)$ that will be broken by the transition sequence described above, we can determine exactly which is the arc removed by cycle-breaking (if $x \rightarrow y$ is the arc that will close the cycle according to the Covington arc-building order, then the affected arc is the one of the form $z \rightarrow x$). The cycle can only cause the loss of a gold arc if that arc $z \rightarrow x$ is gold, which can be trivially checked. Hence, if we call cycles where that holds **problematic cycles**, then the expression

[3] Note that, in this scenario, the new head must also be wrong because otherwise the newly created arc would be an arc of $\mathcal{I}(c, t_G)$ (and therefore, would not be breaking a cycle in $A \cup \mathcal{I}(c, t_G)$). However, replacing a wrong attachment with another wrong attachment need not increase loss.

Table 1: Average value of the different bounds and the loss, and of the relative differences from each bound to the loss, on CoNLL-XI (first block) and CoNLL-X (second block) datasets during 100,000 transitions. For each language, we show in boldface the average value and relative difference of the bound that is closer to the loss.

$|\mathcal{U}(c, t_G)| + n_{pc}(A \cup \mathcal{I}(c, t_G))$, where "pc" stands for problematic cycles, is a closer **upper bound** to the loss $\ell(c)$ and the following holds:

$$|\mathcal{U}(c, t_G)| \leq \ell(c) \leq |\mathcal{U}(c, t_G)| + n_{pc}(A \cup \mathcal{I}(c, t_G))$$

$$\leq |\mathcal{U}(c, t_G)| + n_c(A \cup \mathcal{I}(c, t_G))$$

As mentioned before, unlike the monotonic approach, a node can have a different head in A than in $\mathcal{I}(c, t_G)$ and, as a consequence, the resulting graph $A \cup \mathcal{I}(c, t_G)$ has maximum in-degree 2 rather than 1, and there can be overlapping cycles. Therefore, the computation of the non-monotonic terms $n_c(A \cup \mathcal{I}(c, t_G))$ and $n_{pc}(A \cup \mathcal{I}(c, t_G))$ requires an algorithm such as the one by Johnson (1975) to find all elementary cycles in a directed graph. This runs in $O((n + e)(c + 1))$, where n is the number of vertices, e is the number of edges and c is the number of elementary cycles in the graph. This implies that the calculation of the two non-monotonic upper bounds is less efficient than the linear loss computation in the monotonic scenario. However, a non-monotonic algorithm that uses the lower bound as loss expression is the fastest option (even faster than the monotonic approach) as the oracle does not need to compute cycles at all, speeding up the training process.

Algorithm 2 shows the non-monotonic variant of Algorithm 1, where CountRelevantCycles is a function that counts the number of cycles or problematic cycles in the given graph, depending on the upper bound implemented, and will return 0 in case we use the lower bound.

Algorithm 2 Computation of the approximate loss of a non-monotonic configuration.

```
1: function Loss(c = ⟨λ1|i, λ2, j|B, A⟩, t_G)
2:     U ← ∅                          ▷ Variable U is for U(c, t_G)
3:     for each x → y ∈ (t_G \ A) do
4:         left ← min(x, y)
5:         right ← max(x, y)
6:         if j > right ∨
7:           (j = right ∧ i < left) then
8:             U ← u ∪ {x → y}
9:     I ← t_G \ U                    ▷ Variable I is for I(c, t_G)
10:    return |U| + CountRelevantCycles(A ∪ I)
```

5 Evaluation of the Loss Bounds

To determine how close the lower bound $|\mathcal{U}(c, t_G)|$ and the upper bounds $|\mathcal{U}(c, t_G)| + n_{pc}(A \cup \mathcal{I}(c, t_G))$ and $|\mathcal{U}(c, t_G)| + n_c(A \cup \mathcal{I}(c, t_G))$ are to the actual loss in practical scenarios, we use exhaustive search to calculate the real loss of a given configuration, to then compare it with the bounds. This is feasible because the lower and upper bounds allow us to prune the search space: if an upper and a lower bound coincide for a configuration we already know the loss and need not keep searching, and if we can branch to two configurations such that the lower bound of one is greater or equal than an upper bound of the other, we can discard the former as it will never lead to smaller loss than the latter. Therefore, this ex-

Table 2: Feature templates. L_0 and R_0 denote the left and right focus words; $L_1, L_2, \ldots$ are the words to the left of L_0 and $R_1, R_2, \ldots$ those to the right of R_0. X_{ih} means the head of X_i, X_{ih2} the grandparent, X_{il} and $X_{il'}$ the farthest and closest left dependents, and X_{ir} and $X_{ir'}$ the farthest and closest right dependents, respectively. CL and CR are the first and last words between L_0 and R_0 whose head is not in the interval $[L_0, R_0]$. Finally, w stands for word form; p for PoS tag; l for dependency label; d is the distance between L_0 and R_0; v_l, v_r are the left/right valencies (number of left/right dependents); and s_l, s_r the left/right label sets (dependency labels of left/right dependents).

haustive search with pruning guarantees to find the exact loss.

Due to the time complexity of this process, we undertake the analysis of only the first 100,000 transitions on each dataset of the nineteen languages available from CoNLL-X and CoNLL-XI shared tasks (Buchholz and Marsi, 2006; Nivre et al., 2007). In Table 1, we present the average values for the lower bound, both upper bounds and the loss, as well as the relative differences from each bound to the real loss. After those experiments, we conclude that the lower and the closer upper bounds are a tight approximation of the loss, with both bounds incurring relative errors below 0.8% in all datasets. If we compare them, the real loss is closer to the upper bound $|\mathcal{U}(c, t_G)| + n_{pc}(A \cup \mathcal{I}(c, t_G))$ in the majority of datasets (12 out of 18 languages, excluding Japanese where both bounds were exactly equal to the real loss in the whole sample of configurations). This means that the term $n_{pc}(A \cup \mathcal{I}(c, t_G))$ provides a close approximation of the gold arcs missed by the presence of cycles in A. Regarding the upper bound $|\mathcal{U}(c, t_G)| + n_c(A \cup \mathcal{I}(c, t_G))$, it presents a more variable relative error, ranging from 0.1% to 4.0%.

Thus, although we do not know an algorithm to obtain the exact loss which is fast enough to be practical, any of the three studied loss bounds can be used to obtain a feasible approximate dynamic oracle with full non-monotonicity.

6 Experiments

To prove the usefulness of our approach, we implement the static, dynamic monotonic and non-monotonic oracles for the non-projective Covington algorithm and compare their accuracies on nine datasets[4] from the CoNLL-X shared task (Buchholz and Marsi, 2006) and all datasets from the CoNLL-XI shared task (Nivre et al., 2007). For the non-monotonic algorithm, we test the three different loss expressions defined in the previous section. We train an averaged perceptron model for 15 iterations and use the same feature templates for all languages[5] which are listed in detail in Table 2.

6.1 Results

The accuracies obtained by the non-projective Covington parser with the three available oracles are presented in Table 3, in terms of Unlabeled (UAS) and Labeled Attachment Score (LAS). For the non-monotonic dynamic oracle, three variants are shown, one for each loss expression implemented. As we can see, the novel non-monotonic oracle improves over the accuracy of the monotonic version on 14 out of 19 languages (0.32 in UAS on average) with the best loss calculation being $|\mathcal{U}(c, t_G)| + n_c(A \cup \mathcal{I}(c, t_G))$, where 6 of these improvements are statistically significant at the .05 level (Yeh, 2000). The other two loss calculation methods also achieve good results, outperforming the monotonic algorithm on 12 out of 19 datasets tested.

The loss expression $|\mathcal{U}(c, t_G)| + n_c(A \cup \mathcal{I}(c, t_G))$ obtains greater accuracy on average than the other two loss expressions, including the more adjusted upper bound that is provably closer to the real loss. This could be explained by the fact that

[4] We excluded the languages from CoNLL-X that also appeared in CoNLL-XI, i.e., if a language was present in both shared tasks, we used the latest version.

[5] No feature optimization is performed since our priority in this paper is not to compete with state-of-the-art systems, but to prove, under uniform experimental settings, that our approach outperforms the baseline system.

Table 3: Parsing accuracy (UAS and LAS, including punctuation) of the Covington non-projective parser with static, and dynamic monotonic and non-monotonic oracles on CoNLL-XI (first block) and CoNLL-X (second block) datasets. For the dynamic non-monotonic oracle, we show the performance with the three loss expressions, where *lower* stands for the lower bound $|\mathcal{U}(c, t_G)|$, *pc upper* for the upper bound $|\mathcal{U}(c, t_G)| + n_{pc}(A \cup \mathcal{I}(c, t_G))$, and *upper* for the upper bound $|\mathcal{U}(c, t_G)| + n_c(A \cup \mathcal{I}(c, t_G))$. For each language, we run five experiments with the same setup but different seeds and report the averaged accuracy. Best results for each language are shown in boldface. Statistically significant improvements ($\alpha = .05$) of both dynamic oracles are marked with * if they are only over the static oracle, and with † if they are over the opposite dynamic oracle too.

identifying problematic cycles is a difficult task to learn for the parser, and for this reason a more straightforward approach, which tries to avoid all kinds of cycles (regardless of whether they will cost gold arcs or not), can perform better. This also leads us to hypothesize that, even if it were feasible to build an oracle with the exact loss, it would not provide practical improvements over these approximate oracles; as it appears difficult for a statistical model to learn the situations where replacing a wrong arc with another indirectly helps due to breaking prospective cycles.

It is also worth mentioning that the non-monotonic dynamic oracle with the best loss expression accomplishes an average improvement over the static version (1.26 UAS) greater than that obtained by the monotonic oracle (0.98 UAS), resulting in 13 statistically significant improvements achieved by the non-monotonic variant over the static oracle in comparison to the 12 obtained by the monotonic system. Finally, note that, despite this remarkable performance, the non-monotonic version (regardless of the loss expression implemented) has an inexplicable drop in accuracy in Basque in comparison to the other two oracles.

6.2 Comparison

In order to provide a broader contextualization of our approach, Table 4 presents a comparison of the average accuracy and parsing speed obtained by some well-known transition-based systems with dynamic oracles. Concretely, we include in this comparison both monotonic (Goldberg and Nivre, 2012) and non-monotonic (Honnibal et al., 2013) versions of the arc-eager parser, as well as the original monotonic Covington system (Gómez-Rodríguez and Fernández-González, 2015). The three of them were ran with our own implementation so the comparison is homogeneous. We also report the published accuracy of the non-projective Attardi algorithm (Gómez-Rodríguez et al., 2014) on the nineteen datasets used in our experiments. From Table 4 we can see that our approach achieves the best average UAS score, but is slightly slower at parsing time than the monotonic Covington algorithm. This can be explained by the fact that the non-monotonic parser has to take into consideration the whole set of transitions at each configuration (since all are allowed), while the monotonic parser only needs to evaluate a limited set of transitions in some con-

Table 4: Comparison of the average Unlabeled and Labeled Attachment Scores (including punctuation) achieved by some widely-used transition-based algorithms with dynamic oracles on nine CoNLL-X datasets and all CoNLL-XI datatsets, as well as their average parsing speed (sentences per second across all datasets) measured on a 2.30GHz Intel Xeon processor. The first block corresponds to monotonic parsers, while the second gathers non-monotonic parsers. All algorithms are tested under our own implementation, except for the system developed by Gómez-Rodríguez et al. (2014) (marked with *) where we report the published results.

figurations, speeding up the parsing process.

6.3 Error Analysis

We also carry out some error analysis to provide some insights about how non-monotonicity is improving accuracy with respect to the original Covington parser. In particular, we notice that non-monotonicity tends to be more beneficial on projective than on non-projective arcs. In addition, the non-monotonic algorithm presents a notable performance on long arcs (which are more prone to error propagation): average precision on arcs with length greater than 7 goes from 58.41% in the monotonic version to 63.19% in the non-monotonic parser, which may mean that non-monotonicity is alleviating the effect of error propagation. Finally, we study the effectiveness of non-monotonic arcs (i.e., those that break a previously-created arc), obtaining that, on average across all datasets tested, 36.86% of the arc transitions taken were non-monotonic, replacing an existing arc with a new one. Out of these transitions, 60.31% created a gold arc, and only 5.99% were harmful (i.e., they replaced a previously-built gold arc with an incorrect arc), with the remaining cases creating non-gold arcs without introducing extra errors (replacing a non-gold arc with another). These results back up the usefulness of non-monotonicity in transition-based parsing.

7 Conclusion

We presented a novel, fully non-monotonic variant of the well-known non-projective Covington parser, trained with a dynamic oracle. Due to the unpredictability of a non-monotonic scenario, the real loss of each configuration cannot be computed. To overcome this, we proposed three different loss expressions that closely bound the loss and enable us to implement a practical non-monotonic dynamic oracle.

On average, our non-monotonic algorithm obtains better performance than the monotonic version, regardless of which of the variants of the loss calculation is used. In particular, one of the loss expressions developed proved very promising by providing the best average accuracy, in spite of being the farthest approximation from the actual loss. On the other hand, the proposed lower bound makes the non-monotonic oracle the fastest one among all dynamic oracles developed for the non-projective Covington algorithm.

To our knowledge, this is the first implementation of non-monotonicity for a non-projective parsing algorithm, and the first approximate dynamic oracle that uses close, efficiently-computable approximations of the loss, showing this to be a feasible alternative when it is not practical to compute the actual loss.

While we used a perceptron classifier for our experiments, our oracle could also be used in neural-network implementations of greedy transition-based parsing (Chen and Manning, 2014; Dyer et al., 2015), providing an interesting avenue for future work. We believe that gains from both techniques should be complementary, as they apply to orthogonal components of the parsing system (the scoring model vs. the transition system), although we might see a ”diminishing returns”effect.

Abstract

Despite sequences being core to NLP, scant work has considered how to handle noisy sequence labels from multiple annotators for the same text. Given such annotations, we consider two complementary tasks: (1) aggregating sequential crowd labels to infer a best single set of consensus annotations; and (2) using crowd annotations as training data for a model that can predict sequences in unannotated text. For aggregation, we propose a novel Hidden Markov Model variant. To predict sequences in unannotated text, we propose a neural approach using Long Short Term Memory. We evaluate a suite of methods across two different applications and text genres: Named-Entity Recognition in news articles and Information Extraction from biomedical abstracts. Results show improvement over strong baselines. Our source code and data are available online[1].

1 Introduction

Many important problems in Natural Language Processing (NLP) may be viewed as sequence labeling tasks, such as part-of-speech (PoS) tagging, named-entity recognition (NER), and Information Extraction (IE). As with other machine learning tasks, automatic sequence labeling typically requires annotated corpora on which to train predictive models. While such annotation was traditionally performed by domain experts, crowdsourcing has become a popular means to acquire large labeled datasets at lower cost, though annotations from laypeople may be lower quality than those from domain experts (Snow et al., 2008). It is therefore essential to model crowdsourced label quality, both to estimate individual annotator reliability and to aggregate individual annotations to induce a single set of "reference standard" consensus labels. While many models have been proposed for aggregating crowd labels for binary or multiclass classification problems (Sheshadri and Lease, 2013), far less work has explored crowd-based annotation of sequences (Finin et al., 2010; Hovy et al., 2014; Rodrigues et al., 2014).

In this paper, we investigate two complementary challenges in using sequential crowd labels: how to best aggregate them (Task 1); and how to accurately predict sequences in unannotated text given training data from the crowd (Task 2). For aggregation, one might want to induce a single set of high-quality consensus annotations for various purposes: (i) for direct use at run-time (when a given application requires human-level accuracy in identifying sequences); (ii) for sharing with others; or (iii) for training a predictive model.

When human-level accuracy in tagging of sequences is not crucial, automatic labeling of unannotated text is typically preferable, as it is more efficient, scalable, and cost-effective. Given a training set of crowd labels, how can we best predict sequences in unannotated text? Should we: (i) consider Task 1 as a pre-processing step and train the model using consensus labels; or (ii) instead directly train the model on all of the individual annotations, as done by Yang et al. (2010)? We investigate both directions in this work.

Our approach is to augment existing sequence labeling models such as HMMs (Rabiner and Juang, 1986) and LSTMs (Hochreiter and Schmidhuber, 1997; Lample et al., 2016) by introducing an explicit "crowd component". For HMMs, we model this crowd component by including additional parameters for worker label quality and crowd label variables. For the LSTM, we introduce a vector representation for each annotator. In

[1] Soure code and biomedical abstract data: www.github.com/thanhan/seqcrowd-acl17, www.byronwallace.com/EBM_abstracts_data

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 299–309
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1028

both cases, the crowd component models both the noise from labels and the label quality from each annotator. We find that principled combination of the "crowd component" with the "sequence component" yields strong improvement.

For evaluation, we consider two practical applications in two text genres: NER in news and IE from medical abstracts. Recognizing named-entities such as people, organizations or locations can be viewed as a sequence labeling task in which each label specifies whether each word is Inside, Outside or Beginning (IOB) a named-entity. For this task, we consider the English portion of the CoNLL-2003 dataset (Tjong Kim Sang and De Meulder, 2003), using crowd labels collected by Rodrigues et al. (2014).

For the IE application, we use a set of biomedical abstracts that describe Randomized Controlled Trials (RCTs). The crowdsourced annotations comprise labeled text spans that describe the patient populations enrolled in the corresponding RCTs. For example, an abstract may contain the text: *we recruited and enrolled diabetic patients*. Identifying these sequences is useful for downstream systems that process biomedical literature, e.g., clinical search engines (Huang et al., 2006; Schardt et al., 2007; Wallace et al., 2016).

Contributions. We present a systematic investigation and evaluation of alternative methods for handling and utilizing crowd labels for sequential annotation tasks. We consider both how to best aggregate sequential crowd labels (Task 1) and how to best predict sequences in unannotated text given a training set of crowd annotations (Task 2). As part of this work, we propose novel models for working with noisy sequence labels from the crowd. Reported experiments both benchmark existing state-of-the-art approaches (sequential and non-sequential) and show that our proposed models achieve best-in-class performance. As noted in the Abstract, we have also shared our sourcecode and data online for use by the community.

2 Related Work

We briefly review two separate threads of relevant prior work: (1) sequence labeling models; and (2) aggregation of crowdsourcing annotations.

Sequence labeling. Early work on learning for sequential tasks used HMMs (Bikel et al., 1997). HMMs are a class of generative probabilistic models comprising two components: an emission model from a hidden state to an observation and a transition model from a hidden state to the next hidden state. Later work focused on discriminative models such as Maximum Entropy Models (Chieu and Ng, 2002) and Conditional Random Fields (CRFs) (Lafferty et al., 2001). These were able to achieve strong predictive performance by exploiting arbitrary features, but they may not be the best choice for label aggregation. Also, compared to the simple HMM model, discriminative sequentially structured models require more complex optimization and are generally more difficult to extend. Here we argue for the generative HMMs for our first task of aggregating crowd labels. The generative nature of HMMs is a good fit for existing crowd modeling techniques and also enables very efficient parameter estimation.

In addition to the supervised setting, previous work has studied unsupervised HMMs, e.g., for PoS induction (Goldwater and Griffiths, 2007; Johnson, 2007). These works are similar to our work in trying to infer the hidden states without labeled data. Our graphical model is different in incorporating signal from the crowd labels.

For Task 2 (training predictive models), we consider CRFs and LSTMs. CRFs are undirected, conditional models that can exploit arbitrary features. They have achieved strong performance on many sequence labeling tasks (McCallum and Li, 2003), but they depend on hand-crafted features. Recent work has considered end-to-end neural architectures that *learn* features, e.g., Convolutional Neural Networks (CNNs) (Collobert et al., 2011; Kim, 2014; Zhang and Wallace, 2015) and LSTMs (Lample et al., 2016). Here we modify the LSTM model proposed by Lample et al. (2016) by augmenting the network with '*crowd worker vectors*'.

Crowdsourcing. Acquiring labeled data is critical for training supervised models. Snow et al. (2008) proposed using Amazon Mechanical Turk to collect labels in NLP quickly and at low cost, albeit with some degradation in quality. Subsequent work has developed models for improving aggregate label quality (Raykar et al., 2010; Felt et al., 2015; Kajino et al., 2012; Bi et al., 2014; Liu et al., 2012; Hovy et al., 2013). Sheshadri and Lease (2013) survey and benchmark methods.

However, these models are almost all in the binary or multiclass classification setting; only a few have considered sequence labeling. Dredze et al. (2009) proposed a method for learning a CRF

model from multiple labels (although the identities of the annotators or workers were not used). Rodrigues et al. (2014) extended this approach to account for worker identities, providing a joint "crowd-CRF" model. They collected a dataset of crowdsourced labels for a portion of the CoNLL 2003 dataset. Using this, they showed that their model outperformed Dredze et al. (2009)'s model and other baselines. However, due to the technical difficulty of the joint approach with CRFs, they resorted to strong modeling assumptions. For example, their model assumes that for each word, only one worker provides the correct answer while all others label the word completely randomly. While this assumption captures some aspects of label quality, it is potentially problematic, such as for 'easy words' labeled correctly by all workers.

More recently, **?** proposed HMM models for aggregating crowdsourced discourse segmentation labels. However, they did not consider the general sequence labeling setting. Their method includes task-specific assumptions, e.g., that discourse segment lengths follow some empirical distribution estimated from data. In the absence of a gold standard, they evaluated by checking that workers accuracies are consistent and by comparing their two models to each other. We include their approach along with Rodrigues et al. (2014) as a baseline in our evaluation.

3 Methods

We present our Task 1 HMM approach in Section 3.1 and our Task 2 LSTM approach in Section 3.2.

3.1 HMMs with Crowd Workers

Model: We first define a standard HMM with hidden states h_i, observations v_i, transition parameter vectors $\boldsymbol{\tau}_{h_i}$ and emission parameter vectors $\boldsymbol{\Omega}_{h_i}$:

$$h_{i+1}|h_i \sim \text{Discrete}(\boldsymbol{\tau}_{h_i}) \quad (1)$$

$$v_i|h_i \sim \text{Discrete}(\boldsymbol{\Omega}_{h_i}) \quad (2)$$

The discrete distributions here are governed by Multinomials. In the context of our task, v_i is the word at position i and h_i is the true, latent class of v_i (e.g., entity or non-entity).

For the crowd component, assume there are n classes, and let l_{ij} be the label for word i provided by worker j. Further, let $\mathbf{C}^{(j)}$ be the confusion matrix for worker j, i.e., $\mathbf{C}^{(j)}_k$ is a vector of size n in which element k' is the probability of worker j providing the label k' for a word of true class k:

$$l_{ij}|h_i \sim \text{Discrete}(\mathbf{C}^{(j)}_{h_i}) \quad (3)$$

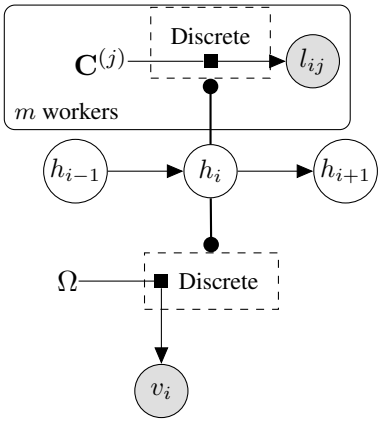

Figure 1: The factor graph for our HMM-Crowd model. Dotted rectangles are gates, where the value of h_i is used to select the parameters for the Multinomial governing the Discrete distribution.

Figure 1 shows the factor graph of this model, which we call HMM-Crowd. Note that we assume that individual crowdworker labels are conditionally independent given the (hidden) true label.

A common problem with crowdsourcing models is data sparsity. For workers who provide only a few labels, it is hard to derive a good estimate of their confusion matrices. This is exacerbated when the label distribution is imbalanced, e.g., most words are not part of a named entity, concentrating the counts in a few confusion matrix entries. Solutions for this problem include hierarchical models of 'worker communities' (Venanzi et al., 2014) or correlations between confusion matrix entries (Nguyen et al., 2016). Although effective, these methods are also quite computationally expensive. For our models, to keep parameter estimation efficient, we use a simpler solution of 'collapsing' the confusion matrix into a 'confusion vector'. For worker j, instead of having the $n \times n$ matrix $\mathbf{C}^{(j)}$, we use the $n \times 1$ vector $\mathbf{C'}^{(j)}$ where $\mathbf{C'}^{(j)}_k$ is the probability of worker j labeling a word with true class k correctly. We also smooth the estimate of $\mathbf{C'}$ with prior counts as in (Liu and Wang, 2012; Kim and Ghahramani, 2012).

Learning: We use the Expectation Maximization (EM) algorithm (Dempster et al., 1977) to learn the parameters $(\boldsymbol{\tau}, \boldsymbol{\Omega}, \mathbf{C'})$, given the observations (all the words $\mathbf{V}$ and all the worker labels $\mathbf{L}$).

In the E-step, given the current estimates of the parameters, we take a forward and a backward

pass in the HMM to infer the hidden states, i.e. to calculate $p(h_i|\mathbf{V},\mathbf{L})$ and $p(h_i, h_{i+1}|\mathbf{V},\mathbf{L})$ for all appropriate i. Let $\alpha(h_i) = p(h_i, v_{1:i}, l_{1:i})$ where $v_{1:i}$ are the words from position 1 to i and $l_{1:i}$ are the crowd labels for these words from all workers. Similarly, let $\beta(h_i) = p(v_{i+1:n}, l_{i+1:n}|h_i)$. We have the recursions:

$$\alpha(h_i) = \sum_{h_{i-1}} p(v_i|h_i)p(h_i|h_{i-1}) \prod_j p(l_{ij}|h_i)\alpha(h_{i-1}) \tag{4}$$

$$\beta(h_i) = \sum_{h_{i+1}} p(h_{i+1}|h_i)p(v_{i+1}|h_{i+1}) \prod_j p(l_{i+1,j}|h_{i+1})\beta(h_{i+1}) \tag{5}$$

These are the standard α and β recursions for HMMs augmented with the crowd model: the product $\prod_j$ over the workers j who have provided labels for word i (or $i+1$). The posteriors can then be easily evaluated: $p(h_i|\mathbf{V},\mathbf{L}) \propto \alpha(h_i)\beta(h_i)$ and $p(h_i, h_{i+1}|\mathbf{V},\mathbf{L}) \propto \alpha(h_i)p(h_{i+1}|h_i)p(v_{i+1}|h_{i+1})\beta(h_{i+1})$

In the standard M-step, the parameters are estimated using maximum likelihood. However, we found a Variational Bayesian (VB) update procedure for the HMM parameters similar to (Johnson, 2007; Beal, 2003) provides some improvement and stability. We first define the Dirichlet priors over the transition and emission parameters:

$$p(\boldsymbol{\tau}_{h_i}) = \mathrm{Dir}(a_t) \tag{6}$$

$$p(\boldsymbol{\Omega}_{h_i}) = \mathrm{Dir}(a_e) \tag{7}$$

With these priors, the variational M-step updates the parameters as follows[2]:

$$\boldsymbol{\tau}_{h'|h} = \frac{\exp\{\Psi(\mathbf{E}_{h'|h} + a_t)\}}{\exp\{\Psi(\mathbf{E}_h + na_t)\}} \tag{8}$$

$$\boldsymbol{\Omega}_{v|h} = \frac{\exp\{\Psi(\mathbf{E}_{v|h} + a_e)\}}{\exp\{\Psi(\mathbf{E}_h + ma_e)\}} \tag{9}$$

where Ψ is the Digamma function, n is the number of states and m is the number of observations. $\mathbf{E}$ denotes the expected counts, calculated from the posteriors inferred in the E-step. $\mathbf{E}_{h'|h}$ is the expected number of times the HMM transitioned from state h to state h', where the expectation is with respect to the posterior distribution $p(h_i, h_{i+1}|\mathbf{V},\mathbf{L})$ that we infer in the E step:

$$\mathbf{E}_{h'|h} = \sum_i p(h_i = h, h_{i+1} = h'|\mathbf{V},\mathbf{L}) \tag{10}$$

[2]See Beal (2003) for the derivation and Johnson (2007) for further discussion for the Variational Bayesian approach.

Similarly, $\mathbf{E}_h$ is the expected number of times the HMM is at state h: $\mathbf{E}_h = \sum_i p(h_i = h|\mathbf{V},\mathbf{L})$ and $\mathbf{E}_{v|h}$ is the expected number of times the HMM emits the observation v from the state h: $\mathbf{E}_{v|h} = \sum_{i,v_i=v} p(h_i = h|\mathbf{V},\mathbf{L})$.

For the crowd parameters $\mathbf{C}'^{(j)}$, we use the (smoothed) maximum likelihood estimate:

$$\mathbf{C}'^{(j)}_k = \frac{\mathbf{E}^{(j)}_{k|k} + a_c}{\mathbf{E}^{(j)}_k + na_c} \tag{11}$$

where a_c is the smoothing parameter and $\mathbf{E}^{(j)}_{k|k}$ is the expected number of times that worker j correctly labeled a word of true class k as k while $\mathbf{E}^{(j)}_k$ is the expected total number of words belonging to class k worker j has labeled. Again, the expectation in $\mathbf{E}$ is taken under the posterior distributions that we infer in the E step.

3.2 Long Short Term Memory with Crowds

For Task 2, we extend the LSTM architecture (Hochreiter and Schmidhuber, 1997) for NER (Lample et al., 2016) to account for noisy crowdsourced labels (this can be easily adapted to other sequence labeling tasks). In this model, the sentence input is first fed into an LSTM block (which includes character- and word-level bi-directional LSTM units). The LSTM block's output then becomes input to a (fully connected) hidden layer, which produces a vector of tags scores for each word. This *tag score* vector is the word-level prediction, representing the likelihood of the word being from each tag. All the tags scores are then fed into a 'CRF layer' that 'connects' the word-level predictions in the sentence and produces the final output: the most likely sequence of tags.

We introduce a crowd representation in which a worker vector represents the noise associated with her labels. In other words, the parameters in the original architecture learns the correct sequence labeling model while the crowd vectors add noise to its predictions to 'explain' the lower quality of the labels. We assume a perfect worker has a zero vector as her representation while an unreliable worker is represented by a large magnitude vector. At test time, we ignore the crowd component and make predictions by feeding the unlabeled sentence into the original LSTM architecture. At train time, an example consists of the labeled sentence and the ID of the worker who provided the labels. Worker IDs are mapped to vector representations and incorporated into the LSTM architecture.

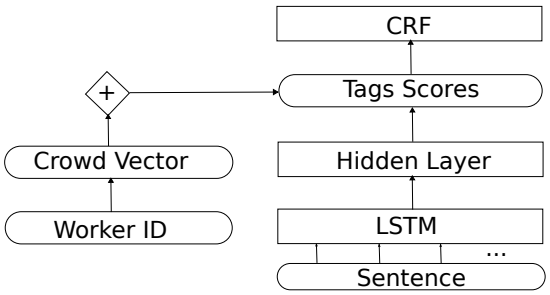

Figure 2: The LSTM-Crowd model. The Crowd Vector is added (element-wise) to the Tags Scores.

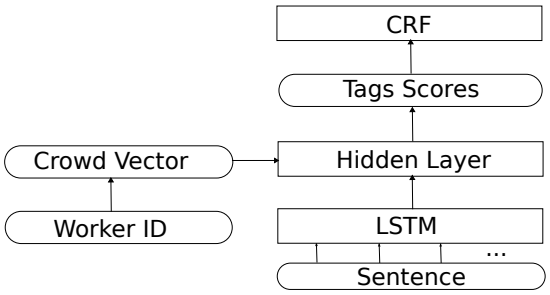

Figure 3: The LSTM-Crowd-cat model. The crowd vectors provide additional input for the Hidden Layer (they are effectively concatenated to the output of the LSTM block).

We propose two strategies for incorporating the crowd vector into the LSTM: (1) adding the crowd vector to the tags scores and (2) concatenating the crowd vector to the output of the LSTM block.

LSTM-Crowd. The first strategy is illustrated in **Figure 2**. We set the dimension of the crowd vectors to be equal to the number of tags and the addition is element-wise. In this strategy, the crowd vectors have a nice interpretation: the tag-conditional noise for the worker. This is useful for worker evaluation and intelligent task routing (i.e. assigning the right work to the right worker).

LSTM-Crowd-cat. The second strategy is illustrated in **Figure 3**. We set the crowd vectors to be additional inputs for the Hidden Layer (along with the LSTM block output). In this way, we are free to set the dimension of the crowd vectors and we have a more flexible model of worker noise. This comes with a cost of reduced interpretability and additional parameters in the hidden layer.

For both strategies, the crowd vectors are randomly initialized and learned in the same LSTM architecture using Back Propagation (Rumelhart et al., 1985) and Stochastic Gradient Descent (SGD) (Bottou, 2010).

Dataset	Application	Size	Gold	Crowd
CoNLL'03	NER	1393	All	400
Medical	IE	5000	200	All

Table 1: Datasets used for each application. We list the total number of articles/abstracts and the number which have Gold/Crowd labels.

4 Evaluation Setup

4.1 Datasets & Tuning

NER. We use the English portion of the CoNLL-2003 dataset (Tjong Kim Sang and De Meulder, 2003), which includes over 21,000 annotated sentences from 1,393 news articles split into 3 sets: train, validation and test. We also use crowd labels collected by Rodrigues et al. (2014) for 400 articles in the train set[3]. For Task 1 (aggregating crowd labels), to avoid overfitting, we split these 400 articles into 50% validation and 50% test[4]. For Task 2 (predicting sequences on unannotated text), we follow Rodrigues et al. (2014) in using the CoNLL validation and test sets.

Biomedical IE. We use 5,000 medical paper abstracts describing randomized control trials (RCTs) involving people. Each abstract is annotated by roughly 5 Amazon Mechanical Turk workers. Annotators were asked to mark all text spans in a given abstract which identify the population enrolled in the clinical trial. The annotations are therefore binary: inside or outside a span. In addition to annotations collected from laypeople via Mechanical Turk, we also use gold annotations by medical students for a small set of 200 abstracts, which we split into 50% validation and 50% test. For Task 1, we run methods being compared on all 5,000 abstracts, but we evaluate them only using the validation/test set. For Task 2, the validation and test sets are held out. **Table 1** presents key statistics of datasets used.

Tuning: In all experiments, validation set results are used to tune the models hyper-parameters. For HMM-Crowd, we have a smoothing parameter and two Dirichlet priors. For our two LSTMs, we have a L2 regularization parameter. For LSTM-Crowd-cat, we also have the crowd vector dimen-

[3] http://www.fprodrigues.com/software/crf-ma-sequence-labeling-with-multiple-annotators/

[4] Rodrigues et al. (2014)'s results on the 'training set' are not directly comparable to ours since they do not partition the crowd labels into validation and test sets.

sion. For each hyper-parameter, we consider a few (less then 5) different parameter settings for light tuning. We report results achieved on the test set.

4.2 Baselines

Task 1. For aggregating crowd labels, we consider the following baselines:

- Majority Voting (MV) at the token level. Rodrigues et al. (2014) show that this generally performs better than MV at the entity level.
- Dawid and Skene (1979) weighted voting at the token level. We tested both a popular public implementation[5] of Dawid-Skene and our own and found that ours performed better (likely due to smoothing), so we report it.
- MACE (Hovy et al., 2013), using the authors' public implementation[6].
- *Dawid-Skene then HMM*. We propose a simple heuristic to aggregate sequential crowd labels: (1) use Dawid and Skene (1979) to induce consensus labels from individual crowd labels; (2) train a HMM using the input text and consensus labels; and then (3) use the trained HMM to predict and output labels for the input text. We also tried using a CRF or LSTM as the sequence labeler but found the HMM performed best. This is not surprising: CRFs and LSTM are good at predicting unseen sequences, whereas the predictions here are on the seen training sequences.
- Rodrigues et al. (2014)'s CRF with Multiple Annotators (CRF-MA). We use the source code provided by the authors.
- **?**'s Interval-dependent (ID) HMM using the authors' source code[7]. Since they assume binary labels, we can only apply this to the biomedical IE task.

For non-sequential aggregation baselines, we evaluate majority voting (MV) and Dawid and Skene (1979) as perhaps the most widely known and used in practice. A recent benchmark evaluation of aggregation methods for (non-sequential) crowd labels found that classic Dawid-Skene was the most consistently strong performing method among those considered, despite its age, while majority voting was often outperformed by other methods (Sheshadri and Lease, 2013).

Dawid and Skene (1979) models a confusion matrix for each annotator, using EM estimation of these matrices as parameters and the true token labels as hidden variables. This is roughly equivalent to our proposed HMM-Crowd model (Section 3), but without the HMM component.

Task 2. To predict sequences on unannotated text when trained on crowd labels, we consider two broad approaches: (1) directly train the model on all individual crowd annotations; and (2) induce consensus labels via Task 1 and train on them.

For approach (1), we report as baselines:

- Rodrigues et al. (2014)'s CRF-MA
- Lample et al. (2016)'s LSTM trained on all crowd labels (ignoring worker IDs)

For approach (2), we report as baselines:

- Majority Voting (MV) then Conditional Random Field (CRF). We train the CRF using the *CRF Suite* package (Okazaki, 2007) with the same features as in Rodrigues et al. (2014), who also report this baseline.
- Lample et al. (2016)'s LSTM trained on Dawid-Skene (DS) consensus labels.

4.3 Metrics

NER. We use the CoNLL 2003 metrics of entity-level precision, recall and F1. The predicted entity must match the gold entity exactly (i.e. no partial credit is given for partial matches).

Biomedical IE. The above metrics are overly strict for the biomedical IR task, in which annotated sequences are typically far longer than named-entities. We therefore 'relax' the metric to credit partial matches as follows. For each predicted positive contiguous text span, we calculate:

$$\text{Precision} = \frac{\text{\# true positive words}}{\text{\# words in this predicted span}}$$

For example, for a predicted span of 10 words, if 6 words are truly positive, the Precision is 60%. We evaluate this 'local' precision for each predicted span and then take the average as the 'global' precision. Similarly, for each gold span, we calculate:

$$\text{Recall} = \frac{\text{\# words in a predicted span}}{\text{\# words in this gold span}}$$

[5] https://github.com/ipeirotis/Get-Another-Label
[6] http://www.isi.edu/publications/licensed-sw/mace/
[7] https://academiccommons.columbia.edu/catalog/ac:199939

Method	Precision	Recall	F1
Majority Vote	78.35	56.57	65.71
MACE	65.10	69.81	67.37
Dawid-Skene (DS)	78.05	65.78	71.39
CRF-MA	**80.29**	51.20	62.53
DS then HMM	76.81	71.41	74.01
HMM-Crowd	77.40	**72.29**	**74.76**

Table 2: **NER** results for Task 1 (crowd label aggregation). Rows 1-3 show non-sequential methods while Rows 4-6 show sequential methods.

The recall scores for all the gold spans are again averaged to get a global recall score.

For the biomedical IE task, because we have gold labels for only a small set of 200 abstracts, we create 100 bootstrap re-samples of the (predicted and gold) spans and perform the evaluation for each re-sample. We then report the mean and standard deviation over these 100 re-samples.

5 Evaluation Results

5.1 Named-Entity Recognition (NER)

Table 2 presents Task 1 results for aggregating crowd labels. For the non-sequential aggregation baselines, we see that Dawid and Skene (1979) outperforms both majority voting and MACE (Hovy et al., 2013). For sequential methods, our heuristic 'Dawid-Skene then HMM' method performs surprisingly well, nearly as well as HMM-Crowd. However, we will see that this heuristic does not work as well for biomedical IR.

Rodrigues et al. (2014)'s CRF-MA achieves the highest Precision of all methods, but surprisingly the lowest F1. We use their public implementation but observe different results from what they report (we observed similar results when using all the crowd data without validation/test split as they do). We suspect their released source code may be optimized for Task 2, though we could not reach the authors to verify this.

Table 3 reports NER results for Task 2: predicting sequences on unannotated text when trained on crowd labels. Results for Rodrigues et al. (2014)'s CRF-MA are reproduced using their public implementation and match their reported results. While CRF-MA outperforms 'Majority Vote then CRF' as the authors reported, and achieves the highest Recall of all methods, its F1 results are generally not competitive with other methods.

Methods based on Lample et al. (2016)'s LSTM generally outperform the CRF methods. Adding a crowd component to the LSTM yields marked improvement of 2.5-3 points F1 vs. the LSTM trained on individual crowd annotations or consensus MV annotations. LSTM-Crowd (trained on individual labels) and 'HMM-Crowd then LSTM' (LSTM trained on HMM consensus labels) offer different paths to achieving comparable, best results.

5.2 Biomedical Information Extraction (IE)

Tables 4 and **5** present Biomedical IE results for Tasks 1 and 2, respectively. We were unable to run Rodrigues et al. (2014)'s CRF-MA public implementation on the Biomedical IE dataset (due to an 'Out of Memory Error' with 8gb max heapsize).

For Task 1, Majority Vote achieves nearly 92% Precision but suffers from very low Recall. As with NER, HMM-Crowd achieves the highest Recall and F1, showing 2 points F1 improvement here over non-sequential Dawid and Skene (1979). In contrast with the NER results, our heuristic 'Dawid-Skene then HMM' performs much worse for Biomedical IE. In general, we expect heuristics to be less robust than principled methods.

For Task 2, as with NER, we again see that LSTM-Crowd (trained on individual labels) and 'HMM-Crowd then LSTM' (LSTM trained on HMM consensus labels) offer different paths to achieving fairly comparable results. While LSTM-Crowd-cat again achieves slightly lower F1, simply training Lample et al. (2016)'s LSTM directly on all crowd labels performs much better than seen earlier with NER, likely due to the relatively larger size of this dataset (see Table 1). To further investigate, we study the performances of these LSTM models as a function of training data available. In **Figure 4**, we see that as the amount of training data decreases, our crowd-augmented LSTM models produce greater relative improvement compared to the original LSTM architecture.

Table 6 presents an example from Task 1 of a sentence with its gold span, annotations and the outputs from Dawid-Skene and HMM-Crowd. Dawid-Skene aggregates labels based only on the crowd labels while our HMM-Crowd combines that with a sequence model. HMM-Crowd is able to return the longer part of the correct span.

Method	Precision	Recall	F1
CRF-MA (Rodrigues et al., 2014)	49.40	**85.60**	62.60
LSTM (Lample et al., 2016)	**83.19**	57.12	67.73
LSTM-Crowd	82.38	62.10	70.82
LSTM-Crowd-cat	79.61	62.87	70.26
Majority Vote then CRF	45.50	80.90	58.20
Dawid-Skene then LSTM	72.30	61.17	66.27
HMM-Crowd then CRF	77.40	61.40	68.50
HMM-Crowd then LSTM	76.19	66.24	**70.87**
LSTM on Gold Labels (upper-bound)	85.27	83.19	84.22

Table 3: **NER** results on Task 2: predicting sequences on unannotated text when trained on crowd labels. Rows 1-4 train the predictive model using individual crowd labels, while Rows 5-8 first aggregate crowd labels then train the model on the induced consensus labels. The last row indicates an upper-bound from training on gold labels. LSTM-Crowd and LSTM-Crowd-cat are described in Section 3.

Method	Precision	Recall	F1	std
Majority Vote	**91.89**	48.03	63.03	2.6
MACE	45.01	88.49	59.63	1.7
Dawid-Skene	77.85	66.77	71.84	1.7
Dawid-Skene then HMM	72.49	58.77	64.86	2.0
ID HMM (**?**)	78.99	68.10	73.11	1.9
HMM-Crowd	72.81	**75.14**	**73.93**	1.8

Table 4: **Biomedical IE** results for Task 1: aggregating sequential crowd labels to induce consensus labels. Rows 1-3 indicate non-sequential baselines. Results are averaged over 100 bootstrap re-samples. We report the standard deviation of F1, *std*, due to this dataset having fewer gold labels for evaluation.

Method	Precision	Recall	F1	std
LSTM (Lample et al., 2016)	77.43	61.13	68.27	1.9
LSTM-Crowd	73.83	63.93	68.47	1.6
LSTM-Crowd-cat	68.08	**68.41**	68.20	1.8
Majority Vote then CRF	**93.71**	33.16	48.92	2.8
Dawid-Skene then LSTM	70.21	65.26	67.59	1.7
HMM-Crowd then CRF	79.54	54.76	64.81	2.0
HMM-Crowd then LSTM	73.65	64.64	**68.81**	1.9

Table 5: **Biomedical IE** results for Task 2. Rows 1-3 correspond to training on all labels, while Rows 4-7 first aggregate crowd labels then train the sequence labeling model on consensus annotations.

Gold	... was as safe and effective as ... for the empiric treatment of acute invasive diarrhea in ambulatory pediatric patients requiring an emergency room visit
Annotations (2 out of 5)	... was as safe and effective as ... for the empiric treatment of acute invasive diarrhea in ambulatory pediatric patients requiring an emergency room visit
Dawid-Skene	... was as safe and effective as ... for the empiric treatment of acute invasive diarrhea in ambulatory pediatric patients requiring an emergency room visit
HMM-Crowd	... was as safe and effective as ... for the empiric treatment of acute invasive diarrhea in ambulatory pediatric patients requiring an emergency room visit

Table 6: An example from the medical abstract dataset for task 1: inferring true labels. Out of 5 annotations, only 2 have identified a positive span (the other 3 are empty). Dawid-Skene is able to assign higher weights to the minority of 2 annotations to return a part of the correct span. HMM-Crowd returns a longer part of the span, which we believe is due to useful signal from its sequence model.

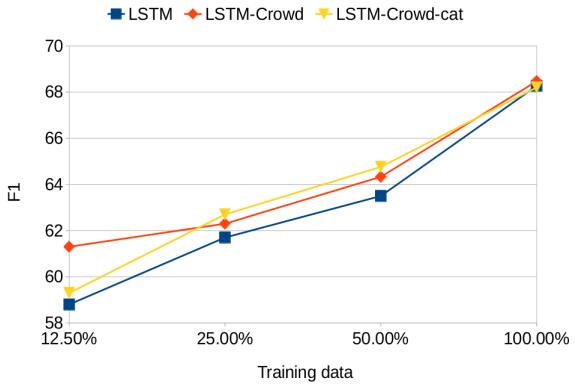

Figure 4: F1 scores in Task 2 for biomedical IE with varying percentages of training data.

6 Conclusions and Future Work

Given a dataset of crowdsourced sequence labels, we presented novel methods to: (1) aggregate sequential crowd labels to infer a best single set of consensus annotations; and (2) use crowd annotations as training data for a model that can predict sequences in unannotated text. We evaluated our approaches on two datasets representing different domains and tasks: general NER and biomedical IE. Results showed that our methods show improvement over strong baselines.

We expect our methods to be applicable to and similarly benefit other sequence labeling tasks, such as POS tagging and chunking (Hovy et al., 2014). Our methods also provide an estimate of each worker's label quality, which can be transfered between tasks and is useful for error analysis and intelligent task routing (Bragg et al., 2014). We also plan to investigate extension of the crowd component in our HMM method with hierarchical models, as well as a fully-Bayesian approach.

Multi-space Variational Encoder-Decoders for Semi-supervised Labeled Sequence Transduction

Chunting Zhou, Graham Neubig
Language Technologies Institute
Carnegie Mellon University
ctzhou,gneubig@cs.cmu.edu

Abstract

Labeled sequence transduction is a task of transforming one sequence into another sequence that satisfies desiderata specified by a set of labels. In this paper we propose *multi-space variational encoder-decoders*, a new model for labeled sequence transduction with semi-supervised learning. The generative model can use neural networks to handle both discrete and continuous latent variables to exploit various features of data. Experiments show that our model provides not only a powerful supervised framework but also can effectively take advantage of the unlabeled data. On the SIGMORPHON morphological inflection benchmark, our model outperforms single-model state-of-art results by a large margin for the majority of languages.[1]

1 Introduction

This paper proposes a model for labeled sequence transduction tasks, tasks where we are given an input sequence and a set of labels, from which we are expected to generate an output sequence that reflects the content of the input sequence and desiderata specified by the labels. Several examples of these tasks exist in prior work: using labels to moderate politeness in machine translation results (Sennrich et al., 2016), modifying the output language of a machine translation system (Johnson et al., 2016), or controlling the length of a summary in summarization (Kikuchi et al., 2016). In particular, however, we are motivated by the task of morphological reinflection (Cotterell et al., 2016), which we will use as an example in our description and test bed for our models.

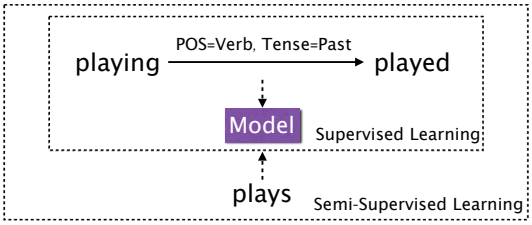

Figure 1: Standard supervised labeled sequence transduction, and our proposed semi-supervised method.

In morphologically rich languages, different affixes (i.e. prefixes, infixes, suffixes) can be combined with the lemma to reflect various syntactic and semantic features of a word. The ability to accurately analyze and generate morphological forms is crucial to creating applications such as machine translation (Chahuneau et al., 2013; Toutanova et al., 2008) or information retrieval (Darwish and Oard, 2007) in these languages. As shown in 1, *re*-inflection of an inflected form given the target linguistic labels is a challenging subtask of handling morphology as a whole, in which we take as input an inflected form (in the example, "playing") and labels representing the desired form ("`pos=Verb, tense=Past`") and must generate the desired form ("played").

Approaches to this task include those utilizing hand-crafted linguistic rules and heuristics (Taji et al., 2016), as well as learning-based approaches using alignment and extracted transduction rules (Durrett and DeNero, 2013; Alegria and Etxeberria, 2016; Nicolai et al., 2016). There have also been methods proposed using neural sequence-to-sequence models (Faruqui et al., 2016; Kann et al., 2016; Ostling, 2016), and currently ensembles of attentional encoder-decoder models (Kann and Schütze, 2016a,b) have achieved state-of-art results on this task. One feature of these neural models however, is that they are trained in a

[1] An implementation of our model are available at https://github.com/violet-zct/MSVED-morph-reinflection.

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 310–320
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1029

largely *supervised* fashion (top of Fig. 1), using data explicitly labeled with the input sequence and labels, along with the output representation. Needless to say, the ability to obtain this annotated data for many languages is limited. However, we can expect that for most languages we can obtain large amounts of unlabeled surface forms that may allow for *semi-supervised* learning over this unlabeled data (entirety of Fig. 1).[2]

In this work, we propose a new framework for labeled sequence transduction problems: multi-space variational encoder-decoders (**MSVED**, §3.3). MSVEDs employ continuous or discrete latent variables belonging to multiple separate probability distributions[3] to explain the observed data. In the example of morphological reinflection, we introduce a vector of continuous random variables that represent the lemma of the source and target words, and also one discrete random variable for each of the labels, which are on the source or the target side.

This model has the advantage of both providing a powerful modeling framework for supervised learning, and allowing for learning in an unsupervised setting. For labeled data, we maximize the variational lower bound on the marginal log likelihood of the data and annotated labels. For unlabeled data, we train an auto-encoder to reconstruct a word conditioned on its lemma and morphological labels. While these labels are unavailable, a set of discrete latent variables are associated with each unlabeled word. Afterwards we can perform posterior inference on these latent variables and maximize the variational lower bound on the marginal log likelihood of data.

Experiments on the SIGMORPHON morphological reinflection task (Cotterell et al., 2016) find that our model beats the state-of-the-art for a single model in the majority of languages, and is particularly effective in languages with more complicated inflectional phenomena. Further, we find that semi-supervised learning allows for significant further gains. Finally, qualitative evaluation of lemma representations finds that our model is able to learn lemma embeddings that match with human intuition.

[2]Faruqui et al. (2016) have attempted a limited form of semi-supervised learning by re-ranking with a standard n-gram language model, but this is not integrated with the learning process for the neural model and gains are limited.

[3]Analogous to multi-space hidden Markov models (Tokuda et al., 2002)

2 Labeled Sequence Transduction

In this section, we first present some notations regarding labeled sequence transduction problems in general, then describe a particular instantiation for morphological reinflection.

Notation: Labeled sequence transduction problems involve transforming a source sequence $\mathbf{x}^{(s)}$ into a target sequence $\mathbf{x}^{(t)}$, with some labels describing the particular variety of transformation to be performed. We use discrete variables $y_1^{(t)}, y_2^{(t)}, \cdots, y_K^{(t)}$ to denote the labels associated with each target sequence, where K is the total number of labels. Let $\mathbf{y}^{(t)} = [y_1^{(t)}, y_2^{(t)}, \cdots, y_K^{(t)}]$ denote a vector of these discrete variables. Each discrete variable $y_k^{(t)}$ represents a categorical feature pertaining to the target sequence, and has a set of possible labels. In the later sections, we also use $\mathbf{y}^{(t)}$ and $y_k^{(t)}$ to denote discrete latent variables corresponding to these labels.

Given a source sequence $\mathbf{x}^{(s)}$ and a set of associated target labels $\mathbf{y}^{(t)}$, our goal is to generate a target sequence $\mathbf{x}^{(t)}$ that exhibits the features specified by $\mathbf{y}^{(t)}$ using a probabilistic model $p(\mathbf{x}^{(t)}|\mathbf{x}^{(s)}, \mathbf{y}^{(t)})$. The best target sequence $\hat{\mathbf{x}}^{(t)}$ is then given by:

$$\hat{\mathbf{x}}^{(t)} = \arg\max_{\mathbf{x}^{(t)}} p(\mathbf{x}^{(t)}|\mathbf{x}^{(s)}, \mathbf{y}^{(t)}). \quad (1)$$

Morphological Reinflection Problem: In morphological reinflection, the source sequence $\mathbf{x}^{(s)}$ consists of the characters in an inflected word (e.g., "`played`"), while the associated labels $\mathbf{y}^{(t)}$ describe some linguistic features (e.g., $y_{\text{pos}}^{(t)} =$ `Verb`, $y_{\text{tense}}^{(t)} =$ `Past`) that we hope to realize in the target. The target sequence $\mathbf{x}^{(t)}$ is therefore the characters of the re-inflected form of the source word (e.g., "`played`") that satisfy the linguistic features specified by $\mathbf{y}^{(t)}$. For this task, each discrete variable $y_k^{(t)}$ has a set of possible labels (e.g. `pos=V`, `pos=ADJ`, etc) and follows a multinomial distribution.

3 Proposed Method

3.1 Preliminaries: Variational Autoencoder

As mentioned above, our proposed model uses probabilistic latent variables in a model based on neural networks. The variational autoencoder (Kingma and Welling, 2014) is an efficient way to handle (continuous) latent variables in neural

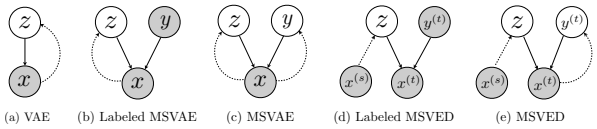

Figure 2: Graphical models of (a) VAE, (b) labeled MSVAE, (c) MSVAE, (d) labeled MSVED, and (e) MSVED. White circles are latent variables and shaded circles are observed variables. Dashed lines indicate the inference process while the solid lines indicate the generative process.

models. We describe it briefly here, and interested readers can refer to Doersch (2016) for details. The VAE learns a generative model of the probability $p(\mathbf{x}|\mathbf{z})$ of observed data $\mathbf{x}$ given a latent variable $\mathbf{z}$, and simultaneously uses a recognition model $q(\mathbf{z}|\mathbf{x})$ at learning time to estimate $\mathbf{z}$ for a particular observation $\mathbf{x}$ (Fig. 2(a)). $q(\cdot)$ and $p(\cdot)$ are modeled using neural networks parameterized by ϕ and θ respectively, and these parameters are learned by maximizing the variational lower bound on the marginal log likelihood of data:

$$\log p_\theta(\mathbf{x}) \geq \mathbb{E}_{\mathbf{z}\sim q_\phi(\mathbf{z}|\mathbf{x})}[\log p_\theta(\mathbf{x}|\mathbf{z})] - \mathrm{KL}(q_\phi(\mathbf{z}|\mathbf{x})||p(\mathbf{z})) \quad (2)$$

The KL-divergence term (a standard feature of variational methods) ensures that the distributions estimated by the recognition model $q_\phi(\mathbf{z}|\mathbf{x})$ do not deviate far from our prior probability $p(\mathbf{z})$ of the values of the latent variables. To optimize the parameters with gradient descent, Kingma and Welling (2014) introduce a reparameterization trick that allows for training using simple backpropagation w.r.t. the Gaussian latent variables $\mathbf{z}$. Specifically, we can express $\mathbf{z}$ as a deterministic variable $\mathbf{z} = g_\phi(\epsilon, \mathbf{x})$ where ϵ is an independent Gaussian noise variable $\epsilon \sim \mathcal{N}(0, 1)$. The mean μ and the variance σ^2 of $\mathbf{z}$ are reparameterized by the differentiable functions w.r.t. ϕ. Thus, instead of generating $\mathbf{z}$ from $q_\phi(\mathbf{z}|\mathbf{x})$, we sample the auxiliary variable ϵ and obtain $\mathbf{z} = \mu_\phi(x) + \sigma_\phi(x) \circ \epsilon$, which enables gradients to backpropagate through ϕ.

3.2 Multi-space Variational Autoencoders

As an intermediate step to our full model, we next describe a generative model for a single sequence with both continuous and discrete latent variables, the multi-space variational auto-encoder (MSVAE). MSVAEs are a combination of two threads of previous work: deep generative models with both continuous/discrete latent variables for classification problems (Kingma et al., 2014; Maaløe et al., 2016) and VAEs with only continuous variables for sequential data (Bowman et al., 2016; Chung et al., 2015; Zhang et al., 2016; Fabius and van Amersfoort, 2014; Bayer and Osendorfer, 2014). In MSVAEs, we have an observed sequence $\mathbf{x}$, continuous latent variables $\mathbf{z}$ like the VAE, as well as discrete variables $\mathbf{y}$.

In the case of the morphology example, $\mathbf{x}$ can be interpreted as an inflected word to be generated. $\mathbf{y}$ is a vector representing its linguistic labels, either annotated by an annotator in the observed case, or unannotated in the unobserved case. $\mathbf{z}$ is a vector of latent continuous variables, e.g. a latent embedding of the lemma that captures all the information about $\mathbf{x}$ that is not already represented in labels $\mathbf{y}$.

MSVAE: Because inflected words can be naturally thought of as "lemma+morphological labels", to interpret a word, we resort to discrete and continuous latent variables that represent the linguistic labels and the lemma respectively. In this case when the labels of the sequence $\mathbf{y}$ is not observed, we perform inference over possible linguistic labels and these inferred labels are referenced in generating $\mathbf{x}$.

The generative model $p_\theta(\mathbf{x}, \mathbf{y}, \mathbf{z}) = p(\mathbf{z})p_\pi(\mathbf{y})p_\theta(\mathbf{x}|\mathbf{y}, \mathbf{z})$ is defined as:

$$p(\mathbf{z}) = \mathcal{N}(\mathbf{z}|\mathbf{0}, \mathbf{I}) \quad (3)$$

$$p_\pi(\mathbf{y}) = \prod_k \mathrm{Cat}(y_k|\pi_k) \quad (4)$$

$$p_\theta(\mathbf{x}|\mathbf{y}, \mathbf{z}) = f(\mathbf{x}; \mathbf{y}, \mathbf{z}, \theta). \quad (5)$$

Like the standard VAE, we assume the prior of the latent variable $\mathbf{z}$ is a diagonal Gaussian distribution with zero mean and unit variance. We assume that each variable in $\mathbf{y}$ is independent, resulting in a factorized distribution in Eq. 4, where $\mathrm{Cat}(y_k|\pi_k)$ is a multinomial distribution with parameters π_k. For the purposes of this study, we set these to a uniform distribution $\pi_{k,j} = \frac{1}{|\pi_k|}$. $f(\mathbf{x}; \mathbf{y}, \mathbf{z}, \theta)$ calculates the likelihood of $\mathbf{x}$, a function parametrized by deep neural networks. Specifically, we employ an RNN decoder to generate the target word conditioned on the lemma variable $\mathbf{z}$ and linguistic labels $\mathbf{y}$, detailed in §5.

When inferring the latent variables from the given data $\mathbf{x}$, we assume the joint distribution of latent variables $\mathbf{z}$ and $\mathbf{y}$ has a factorized form, i.e. $q(\mathbf{z}, \mathbf{y}|\mathbf{x}) = q(\mathbf{z}|\mathbf{x})q(\mathbf{y}|\mathbf{x})$ as shown in Fig. 2(c).

The inference model is defined as follows:

$$q_\phi(\mathbf{z}|\mathbf{x}) = \mathcal{N}(\mathbf{z}|\mu_\phi(\mathbf{x}), \text{diag}(\sigma^2_\phi(\mathbf{x}))) \quad (6)$$

$$q_\phi(\mathbf{y}|\mathbf{x}) = \prod_k q_\phi(y_k|\mathbf{x}) = \prod_k \text{Cat}(y_k|\pi_\phi(\mathbf{x})) \quad (7)$$

where the inference distribution over $\mathbf{z}$ is a diagonal Gaussian distribution with mean and variance parameterized by neural networks. The inference model $q(\mathbf{y}|\mathbf{x})$ on labels $\mathbf{y}$ has the form of a discriminative classifier that generates a set of multinomial probability vectors $\pi_\phi(\mathbf{x})$ over all labels for each tag y_k. We represent each multinomial distribution $q(y_k|\mathbf{x})$ with an MLP.

The MSVAE is trained by maximizing the following variational lower bound $\mathcal{U}(\mathbf{x})$ on the objective for unlabeled data:

$$\begin{aligned}\log p_\theta(\mathbf{x}) &\geq \mathbb{E}_{(\mathbf{y},\mathbf{z})\sim q_\phi(\mathbf{y},\mathbf{z}|\mathbf{x})} \log \frac{p_\theta(\mathbf{x},\mathbf{y},\mathbf{z})}{q_\phi(\mathbf{y},\mathbf{z}|\mathbf{x})} \\ &= \mathbb{E}_{\mathbf{y}\sim q_\phi(\mathbf{y}|\mathbf{x})}[\mathbb{E}_{\mathbf{z}\sim q_\phi(\mathbf{z}|\mathbf{x})}[\log p_\theta(\mathbf{x}|\mathbf{z},\mathbf{y})] \\ &- \text{KL}(q_\phi(\mathbf{z}|\mathbf{x})||p(\mathbf{z})) + \log p_\pi(\mathbf{y}) \\ &- \log q_\phi(\mathbf{y}|\mathbf{x})] = \mathcal{U}(\mathbf{x}) \quad (8)\end{aligned}$$

Note that this introduction of discrete variables requires more sophisticated optimization algorithms, which we will discuss in §4.1.

Labeled MSVAE: When $\mathbf{y}$ is observed as shown in Fig. 2(b), we maximize the following variational lower bound on the marginal log likelihood of the data and the labels:

$$\begin{aligned}\log p_\theta(\mathbf{x},\mathbf{y}) &\geq \mathbb{E}_{\mathbf{z}\sim q_\phi(\mathbf{z}|\mathbf{x})} \log \frac{p_\theta(\mathbf{x},\mathbf{y},\mathbf{z})}{q_\phi(\mathbf{z}|\mathbf{x})} = \\ &\mathbb{E}_{\mathbf{z}\sim q_\phi(\mathbf{z}|\mathbf{x})}[\log p_\theta(\mathbf{x}|\mathbf{y},\mathbf{z}) + \log p_\pi(\mathbf{y})] \\ &- \text{KL}(q_\phi(\mathbf{z}|\mathbf{x})||p(\mathbf{z})) \quad (9)\end{aligned}$$

which is a simple extension to Eq. 2.

Note that when labels are not observed, the inference model $q_\phi(\mathbf{y}|\mathbf{x})$ has the form of a discriminative classifier, thus we can use observed labels as the supervision signal to learn a better classifier. In this case we also minimize the following cross entropy as the classification loss:

$$\mathcal{D}(\mathbf{x},\mathbf{y}) = \mathbb{E}_{(\mathbf{x},\mathbf{y})\sim p_l(\mathbf{x},\mathbf{y})}[-\log q_\phi(\mathbf{y}|\mathbf{x})] \quad (10)$$

where $p_l(\mathbf{x},\mathbf{y})$ is the distribution of labeled data. This is a form of multi-task learning, as this additional loss also informs the learning of our representations.

3.3 Multi-space Variational Encoder-Decoders

Finally, we discuss the full proposed method: the multi-space variational encoder-decoder (MSVED), which generates the target $\mathbf{x}^{(t)}$ from the source $\mathbf{x}^{(s)}$ and labels $\mathbf{y}^{(t)}$. Again, we discuss two cases of this model: labels of the target sequence are observed and not observed.

MSVED: The graphical model for the MSVED is given in Fig. 2 (e). Because the labels of target sequence are not observed, once again we treat them as discrete latent variables and make inference on the these labels conditioned on the target sequence. The generative process for the MSVED is very similar to that of the MSVAE with one important exception: while the standard MSVAE conditions the recognition model $q(\mathbf{z}|\mathbf{x})$ on $\mathbf{x}$, then generates $\mathbf{x}$ itself, the MSVED conditions the recognition model $q(\mathbf{z}|\mathbf{x}^{(s)})$ on the source $\mathbf{x}^{(s)}$, then generates the target $\mathbf{x}^{(t)}$. Because only the recognition model is changed, the generative equations for $p_\theta(\mathbf{x}^{(t)},\mathbf{y}^{(t)},\mathbf{z})$ are exactly the same as Eqs. 3–5 with $\mathbf{x}^{(t)}$ swapped for $\mathbf{x}$ and $\mathbf{y}^{(t)}$ swapped for $\mathbf{y}$. The variational lower bound on the conditional log likelihood, however, is affected by the recognition model, and thus is computed as:

$$\begin{aligned}&\log p_\theta(\mathbf{x}^{(t)}|\mathbf{x}^{(s)}) \\ &\geq \mathbb{E}_{(\mathbf{y}^{(t)},\mathbf{z})\sim q_\phi(\mathbf{y}^{(t)},\mathbf{z}|\mathbf{x}^{(s)},\mathbf{x}^{(t)})} \log \frac{p_\theta(\mathbf{x}^{(t)},\mathbf{y}^{(t)},\mathbf{z}|\mathbf{x}^{(s)})}{q_\phi(\mathbf{y}^{(t)},\mathbf{z}|\mathbf{x}^{(s)},\mathbf{x}^{(t)})} \\ &= \mathbb{E}_{\mathbf{y}^{(t)}\sim q_\phi(\mathbf{y}^{(t)}|\mathbf{x}^{(t)})}[\mathbb{E}_{\mathbf{z}\sim q_\phi(\mathbf{z}|\mathbf{x}^{(s)})}[\log p_\theta(\mathbf{x}^{(t)}|\mathbf{y}^{(t)},\mathbf{z})] \\ &- \text{KL}(q_\phi(\mathbf{z}|\mathbf{x}^{(s)})||p(\mathbf{z})) + \log p_\pi(\mathbf{y}^{(t)}) \\ &- \log q_\phi(\mathbf{y}^{(t)}|\mathbf{x}^{(t)})] = \mathcal{L}_u(\mathbf{x}^{(t)}|\mathbf{x}^{(s)}) \quad (11)\end{aligned}$$

Labeled MSVED: When the complete form of $\mathbf{x}^{(s)}$, $\mathbf{y}^{(t)}$, and $\mathbf{x}^{(t)}$ is observed in our training data, the graphical model of the labeled MSVED model is illustrated in Fig. 2 (d). We maximize the variational lower bound on the conditional log likelihood of observing $\mathbf{x}^{(t)}$ and $\mathbf{y}^{(t)}$ as follows:

$$\begin{aligned}&\log p_\theta(\mathbf{x}^{(t)},\mathbf{y}^{(t)}|\mathbf{x}^{(s)}) \\ &\geq \mathbb{E}_{\mathbf{z}\sim q_\phi(\mathbf{z}|\mathbf{x}^{(s)})} \log \frac{p_\theta(\mathbf{x}^{(t)},\mathbf{y}^{(t)},\mathbf{z}|\mathbf{x}^{(s)})}{q_\phi(\mathbf{z}|\mathbf{x}^{(s)})} \\ &= \mathbb{E}_{\mathbf{z}\sim q_\phi(\mathbf{z}|\mathbf{x}^{(s)})}[\log p_\theta(\mathbf{x}^{(t)}|\mathbf{y}^{(t)},\mathbf{z}) + \log p_\pi(\mathbf{y}^{(t)})] - \\ &\text{KL}(q_\phi(\mathbf{z}|\mathbf{x}^{(s)})||p(\mathbf{z})) = \mathcal{L}_l(\mathbf{x}^{(t)},\mathbf{y}^{(t)}|\mathbf{x}^{(s)}) \quad (12)\end{aligned}$$

4 Learning MSVED

Now that we have described our overall model, we discuss details of the learning process that prove

useful to its success.

4.1 Learning Discrete Latent Variables

One challenge in training our model is that it is not trivial to perform back-propagation through discrete random variables, and thus it is difficult to learn in the models containing discrete tags such as MSVAE or MSVED.[4] To alleviate this problem, we use the recently proposed Gumbel-Softmax trick (Maddison et al., 2014; Gumbel and Lieblein, 1954) to create a differentiable estimator for categorical variables.

The Gumbel-Max trick (Gumbel and Lieblein, 1954) offers a simple way to draw samples from a categorical distribution with class probabilities $\pi_1, \pi_2, \cdots$ by using the `argmax` operation as follows: $\text{one\_hot}(\arg\max_i[g_i + \log \pi_i])$, where $g_1, g_2, \cdots$ are i.i.d. samples drawn from the Gumbel(0,1) distribution.[5] When making inferences on the morphological labels $y_1, y_2, \cdots$, the Gumbel-Max trick can be approximated by the continuous softmax function with temperature τ to generate a sample vector $\hat{\mathbf{y}}_i$ for each label i:

$$\hat{y}_{ij} = \frac{\exp((\log(\pi_{ij}) + g_{ij})/\tau)}{\sum_{k=1}^{N_i} \exp((\log(\pi_{ik}) + g_{ik})/\tau} \quad (13)$$

where N_i is the number of classes of label i. When τ approaches zero, the generated sample $\hat{\mathbf{y}}_i$ becomes a one-hot vector. When $\tau > 0$, $\hat{\mathbf{y}}_i$ is smooth w.r.t π_i. In experiments, we start with a relatively large temperature and decrease it gradually.

4.2 Learning Continuous Latent Variables

MSVED aims at generating the target sequence conditioned on the latent variable $\mathbf{z}$ and the target labels $\mathbf{y}^{(t)}$. This requires the encoder to generate an informative representation $\mathbf{z}$ encoding the content of the $\mathbf{x}^{(s)}$. However, the variational lower bound in our loss function contains the KL-divergence between the approximate posterior $q_\phi(\mathbf{z}|\mathbf{x})$ and the prior $p(\mathbf{z})$, which is relatively easy to learn compared with learning to generate output from a latent representation. We observe that with the vanilla implementation the KL cost quickly decreases to near zero, setting $q_\phi(\mathbf{z}|\mathbf{x})$ equal to standard normal distribution. In this case, the RNN decoder can easily rely on the true output of last time step during training to decode the next token, which degenerates into an RNN language model. Hence, the latent variables are ignored by the decoder and cannot encode any useful information. The latent variable $\mathbf{z}$ learns an undesirable distribution that coincides with the imposed prior distribution but has no contribution to the decoder. To force the decoder to use the latent variables, we take the following two approaches which are similar to Bowman et al. (2016).

KL-Divergence Annealing: We add a coefficient λ to the KL cost and gradually anneal it from zero to a predefined threshold $\lambda_{\mathbf{m}}$. At the early stage of training, we set λ to be zero and let the model first figure out how to project the representation of the source sequence to a roughly right point in the space and then regularize it with the KL cost. Although we are not optimizing the tight variational lower bound, the model balances well between generation and regularization. This technique can also be seen in (Kočiskỳ et al., 2016; Miao and Blunsom, 2016).

Input Dropout in the Decoder: Besides annealing the KL cost, we also randomly drop out the input token with a probability of β at each time step of the decoder during learning. The previous ground-truth token embedding is replaced with a zero vector when dropped. In this way, the RNN decoder could not fully rely on the ground-truth previous token, which ensures that the decoder uses information encoded in the latent variables.

5 Architecture for Morphological Reinflection

Training details: For the morphological reinflection task, our supervised training data consists of source $\mathbf{x}^{(s)}$, target $\mathbf{x}^{(t)}$, and target tags $\mathbf{y}^{(t)}$. We test three variants of our model trained using different types of data and different loss functions. First, the single-directional supervised model (**SD-Sup**) is purely supervised: it only decodes the target word from the given source word with the loss function $\mathcal{L}_l(\mathbf{x}^{(t)}, \mathbf{y}^{(t)}|\mathbf{x}^{(s)})$ from Eq. 12. Second, the bi-directional supervised model (**BD-Sup**) is trained in both directions: decoding the target word from the source word and decoding the source word from the target word, which corresponds to the loss function $\mathcal{L}_l(\mathbf{x}^{(t)}, \mathbf{y}^{(t)}|\mathbf{x}^{(s)}) + \mathcal{L}_u(\mathbf{x}^{(s)}|\mathbf{x}^{(t)})$ using Eqs. 11–12. Finally, the semi-supervised model (**Semi-sup**) is trained to maxi-

[4] Kingma et al. (2014) solve this problem by marginalizing over all labels, but this is infeasible in our case where we have an exponential number of label combinations.

[5] The Gumbel (0,1) distribution can be sampled by first drawing $u \sim$ Uniform(0,1) and computing $g = -\log(-\log(u))$.

mize the variational lower bounds and minimize the classification cross-entropy error of 10.

$$\mathcal{L}(\mathbf{x^{(s)}}, \mathbf{x^{(t)}}, \mathbf{y^{(t)}}, \mathbf{x}) = \alpha \cdot \mathcal{U}(\mathbf{x}) + \mathcal{L}_u(\mathbf{x}^{(s)}|\mathbf{x}^{(t)}) + \mathcal{L}_l(\mathbf{x}^{(t)}, \mathbf{y}^{(t)}|\mathbf{x}^{(s)}) - \mathcal{D}(\mathbf{x}^{(t)}, \mathbf{y}^{(t)}) \quad (14)$$

The weight α controls the relative weight between the loss from unlabeled data and labeled data.

We use Monte Carlo methods to estimate the expectation over the posterior distribution $q(\mathbf{z}|\mathbf{x})$ and $q(\mathbf{y}|\mathbf{x})$ inside the objective function 14. Specifically, we draw Gumbel noise and Gaussian noise one at a time to compute the latent variables $\mathbf{y}$ and $\mathbf{z}$.

The overall model architecture is shown in Fig. 3. Each character and each label is associated with a continuous vector. We employ Gated Recurrent Units (GRUs) for the encoder and decoder. Let $\overrightarrow{h_t}$ and $\overleftarrow{h_t}$ denote the hidden state of the forward and backward encoder RNN at time step t. $\mathbf{u}$ is the hidden representation of $\mathbf{x}^{(s)}$ concatenating the last hidden state from both directions i.e. $[\overrightarrow{h_T}; \overleftarrow{h_T}]$ where T is the word length. $\mathbf{u}$ is used as the input for the inference model on $\mathbf{z}$. We represent $\mu(\mathbf{u})$ and $\sigma^2(\mathbf{u})$ as MLPs and sample $\mathbf{z}$ from $\mathcal{N}(\mu(\mathbf{u}), \text{diag}(\sigma^2(\mathbf{u})))$, using $\mathbf{z} = \mu + \sigma \circ \epsilon$, where $\epsilon \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$. Similarly, we can obtain the hidden representation of $\mathbf{x}^{(t)}$ and use this as input to the inference model on each label $\mathbf{y}_i^{(t)}$ which is also an MLP following a softmax layer to generate the categorical probabilities of target labels.

In decoding, we use 3 types of information in calculating the probability of the next character : (1) the current decoder state, (2) a tag context vector using attention (Bahdanau et al., 2015) over the tag embeddings, and (3) the latent variable $\mathbf{z}$. The intuition behind this design is that we would like the model to constantly consider the lemma represented by $\mathbf{z}$, and also reference the tag corresponding to the current morpheme being generated at this point. We do not marginalize over the latent variable $\mathbf{z}$ however, instead we use the mode μ of $\mathbf{z}$ as the latent representation for $\mathbf{z}$. We use beam search with a beam size of 8 to perform search over the character vocabulary at each decoding time step.

Other experimental setups: All hyperparameters are tuned on the validation set, and include the following: For KL cost annealing, λ_m is set to be 0.2 for all language settings. For character drop-out at the decoder, we empirically set β to be 0.4 for all languages. We set the dimension of character embeddings to be 300, tag label embeddings to be 200, RNN hidden state to be 256, and

latent variable $\mathbf{z}$ to be 150. We set α the weight for the unsupervised loss to be 0.8. We train the model with Adadelta (Zeiler, 2012) and use early-stop with a patience of 10.

6 Experiments

6.1 Background: SIGMORPHON 2016

SIGMORPHON 2016 is a shared task on morphological inflection over 10 different morphologically rich languages. There are a total of three tasks, the most difficult of which is task 3, which requires the system to output the reinflection of an inflected word.[6] The training data format in task 3 is in triples: (source word, target labels, target word). In the test phase, the system is asked to generate the target word given a source word and the target labels. There are a total of three tracks for each task, divided based the amount of supervised data that can be used to solve the problem, among which track 2 has the strictest limitation of only using data for the corresponding task. As this is an ideal testbed for our method, which can learn from unlabeled data, we choose track 2 and task 3 to test our our model's ability to exploit this data.

As a baseline, we compare our results with the MED system (Kann and Schütze, 2016a) which achieved state-of-the-art results in the shared task. This system used an encoder-decoder model with attention on the concatenated source word and target labels. Its best result is obtained from an ensemble of five RNN encoder-decoders (**Ensemble**). To make a fair comparison with our models, which don't use ensembling, we also calculated single model results (**Single**).

All models are trained using the labeled training data provided for task 3. For our semi-supervised model (**Semi-sup**), we also leverage unlabeled data from the training and validation data for tasks 1 and 2 to train variational auto-encoders.

6.2 Results and Analysis

From the results in Tab. 1, we can glean a number of observations. First, comparing the results of our full **Semi-sup** model, we can see that for all languages except Spanish, it achieves accuracies better than the single MED system, often by a large margin. Even compared to the MED ensembled model, our single-model system is quite competitive, achieving higher accuracies for Hungarian, Navajo, Maltese, and Arabic, as well as achieving average accuracies that are state-of-the-art.

[6]Task 1 is inflection of a lemma word and task 2 is reinflection but also provides the source word labels.

Language	Prefix	Stem	Suffix
Turkish	0.21	1.12	98.75
Hungarian	0.00	0.08	99.79
Spanish	0.09	3.25	90.74
Russian	0.66	7.70	85.00
Navajo	77.64	18.38	26.40
Maltese	48.81	11.05	98.74
Arabic	68.52	37.04	88.24
Georgian	4.46	0.41	92.47
German	0.84	3.32	89.19
Finnish	0.02	12.33	96.16

Table 2: Percentage of inflected word forms that have modified each part of the lemma (Cotterell et al., 2016) (some words can be inflected zero or multiple times, thus sums may not add to 100%).

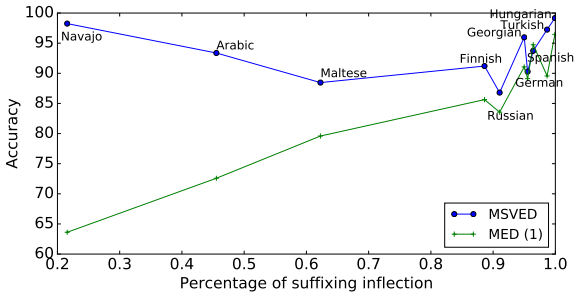

Figure 4: Performance on test data w.r.t. the percentage of suffixing inflection. Points with the same x-axis value correspond to the same language results.

Next, comparing the different varieties of our proposed models, we can see that the semi-supervised model consistently outperforms the bidirectional model for all languages. And similarly, the bidirectional model consistently outperforms the single direction model. From these results, we can conclude that the unlabeled data is beneficial to learn useful latent variables that can be used to decode the corresponding word.

Examining the linguistic characteristics of the models in which our model performs well provides even more interesting insights. Cotterell et al. (2016) estimate how often the inflection process involves prefix changes, stem-internal changes or suffix changes, the results of which are shown in Tab. 2. Among the many languages, the inflection processes of Arabic, Maltese and Navajo are relatively diverse, and contain a large amount of all three forms of inflection. By examining the experimental results together with the morphological inflection process of different languages, we found that among all the languages, Navajo, Maltese and Arabic obtain the largest gains in performance compared with the ensem-

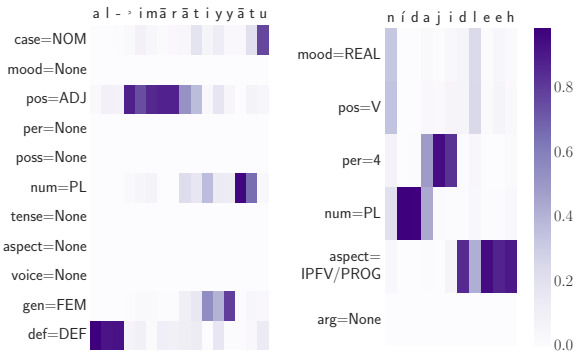

Figure 5: Two examples of attention weights on target linguistic labels: Arabic (**Left**) and Navajo (**Right**). When a tag equals `None`, it means the word does not have this tag.

bled MED system. To demonstrate this visually, in Fig. 4, we compare the semi-supervised MSVED with the MED single model w.r.t. the percentage of suffixing inflection of each language, showing this clear trend.

This strongly demonstrates that our model is agnostic to different morphological inflection forms whereas the conventional encoder-decoder with attention on the source input tends to perform better on suffixing-oriented morphological inflection. We hypothesize that for languages that the inflection mostly comes from suffixing, transduction is relatively easy because the source and target words share the same prefix and the decoder can copy the prefix of the source word via attention. However, for languages in which different inflections of a lemma go through different morphological processes, the inflected word and the target word may differ greatly and thus it is crucial to first analyze the lemma of the inflected word before generating the corresponding the reinflection form based on the target labels. This is precisely what our model does by extracting the lemma representation $\mathbf{z}$ learned by the variational inference model.

6.3 Analysis on Tag Attention

To analyze how the decoder attends to the linguistic labels associated with the target word, we randomly pick two words from the Arabic and Navajo test set and plot the attention weight in Fig. 5. The Arabic word "al-'imārātiyyātu" is an adjective which means "Emirati", and its source word in the test data is "'imārātiyyin" [7]. Both of these are declensions of "'imārātiyy". The source word is

[7] https://en.wiktionary.org/wiki/%D8%A5%D9%85%D8%A7%D8%B1%D8%A7%D8%AA%D9%8A

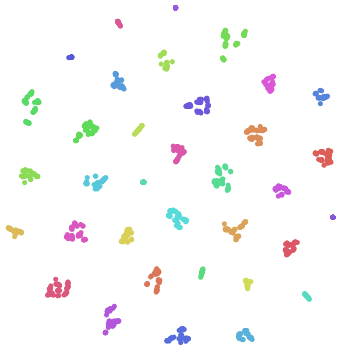

Figure 6: Visualization of latent variables $\mathbf{z}$ for Maltese with 35 pseudo-lemma groups in the figure.

singular, masculine, genitive and indefinite, while the required inflection is plural, feminine, nominative and definite. We can see from the left heat map that the attention weights are turned on at several positions of the word when generating corresponding inflections. For example, "al-" in Arabic is the definite article that marks definite nouns. The same phenomenon can also be observed in the Navajo example, as well as other languages, but due to space limitation, we don't provide detailed analysis here.

6.4 Visualization of Latent Lemmas

To investigate the learned latent representations, in this section we visualize the $\mathbf{z}$ vectors, examining whether the latent space groups together words with the same lemma. Each sample in SIGMORPHON 2016 contains source word and target words which share the same lemma. We run a heuristic process to assign pairs of words to groups that likely share a lemma by grouping together word pairs for which at least one of the words in each pair shares a surface form. This process is not error free – errors may occur in the case where multiple lemmas share the same surface form – but in general the groupings will generally reflect lemmas except in these rare erroneous cases, so we dub each of these groups a *pseudo-lemma*.

In Fig. 6, we randomly pick 1500 words from Maltese and visualize the continuous latent vectors of these words. We compute the latent vectors as $\mu_\phi(\mathbf{x})$ in the variational posterior inference (Eq. 6) without adding the variance. As expected, words that belong to the same pseudo-lemma (in the same color) are projected into adjacent points in the two-dimensional space. This demonstrates that the continuous latent variable captures the canonical form of a set of words and demonstrates the effectiveness of the proposed representation.

Table 3: Randomly picked output examples on the test data. Within each block, the first, second and third lines are outputs that ours is correct and MED's is wrong, ours is wrong and MED's is correct, both are wrong respectively.

6.5 Analyzing Effects of Size of Unlabeled Data

From Tab. 1, we can see that semi-supervised learning always performs better than supervised learning without unlabeled data. In this section, we investigate to what extent the size of unlabeled data can help with performance. We process a German corpus from a 2017 Wikipedia dump and obtain more than 100,000 German words. These words are ranked in order of occurrence frequency in Wikipedia. The data contains a certain amount of noise since we did not apply any special processing. We shuffle all unlabeled data from both the Wikipedia and the data provided in the shared task used in previous experiments, and increase the number of unlabeled words used in learning by 10,000 each time, and finally use all the unlabeled data (more than 150,000 words) to train the model. Fig. 7 shows that the performance on the test data improves as the amount of unlabeled data increases, which implies that the unsupervised learning continues to help improve the model's ability to model the latent lemma representation even as we scale to a noisy, real, and relatively large-scale dataset. Note that the growth rate of the performance grows slower as more data is added, because although the number of unlabeled data is increasing, the model has seen most word patterns in a relatively small vocabulary.

6.6 Case Study on Reinflected Words

In Tab. 3, we examine some model outputs on the test data from the MED system and our model respectively. It can be seen that most errors of MED and our models can be ascribed to either over-copy or under-copy of characters. In particular, from the complete outputs we observe that our model tends to be more aggressive in its changes, resulting in it performing more complicated transformations, both successfully (such as Maltese "ndammhomli" to "tindammhiex") and unsuccessfully ("tqożżx" to "qażżejtx"). In contrast, the attentional encoder-decoder model is more conservative in its changes, likely because it is less effective in learning an abstracted representation for the lemma, and instead copies characters directly from the input.

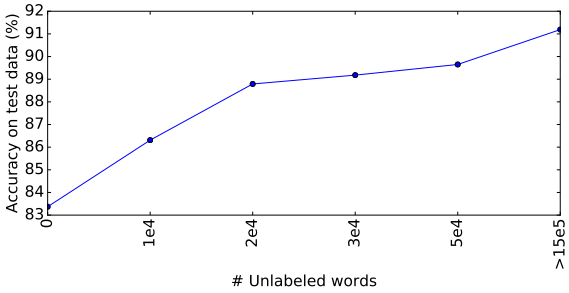

Figure 7: Performance on the German test data w.r.t. the amount of unlabeled Wikipedia data.

7 Conclusion and Future Work

In this work, we propose a multi-space variational encoder-decoder framework for labeled sequence transduction problem. The MSVED performs well in the task of morphological reinflection, outperforming the state of the art, and further improving with the addition of external unlabeled data. Future work will adapt this framework to other sequence transduction scenarios such as machine translation, dialogue generation, question answering, where continuous and discrete latent variables can be abstracted to guide sequence generation.

Abstract

Recurrent neural networks (RNNs) have shown promising performance for language modeling. However, traditional training of RNNs using back-propagation through time often suffers from overfitting. One reason for this is that stochastic optimization (used for large training sets) does not provide good estimates of model uncertainty. This paper leverages recent advances in stochastic gradient Markov Chain Monte Carlo (also appropriate for large training sets) to learn weight uncertainty in RNNs. It yields a principled Bayesian learning algorithm, adding gradient noise during training (enhancing exploration of the model-parameter space) and model averaging when testing. Extensive experiments on various RNN models and across a broad range of applications demonstrate the superiority of the proposed approach relative to stochastic optimization.

1 Introduction

Language modeling is a fundamental task, used for example to predict the next word or character in a text sequence given the context. Recently, recurrent neural networks (RNNs) have shown promising performance on this task (Mikolov et al., 2010; Sutskever et al., 2011). RNNs with Long Short-Term Memory (LSTM) units (Hochreiter and Schmidhuber, 1997) have emerged as a popular architecture, due to their representational power and effectiveness at capturing long-term dependencies.

RNNs are usually trained via back-propagation through time (Werbos, 1990), using stochastic optimization methods such as stochastic gradient descent (SGD) (Robbins and Monro, 1951); stochastic methods of this type are particularly important for training with large data sets. However, this approach often provides a *maximum a posteriori* (MAP) estimate of model parameters. The MAP solution is a single point estimate, ignoring weight uncertainty (Blundell et al., 2015; Hernández-Lobato and Adams, 2015). Natural language often exhibits significant variability, and hence such a point estimate may make over-confident predictions on test data.

To alleviate overfitting RNNs, good regularization is known as a key factor to successful applications. In the neural network literature, Bayesian learning has been proposed as a principled method to impose regularization and incorporate model uncertainty (MacKay, 1992; Neal, 1995), by imposing prior distributions on model parameters. Due to the intractability of posterior distributions in neural networks, Hamiltonian Monte Carlo (HMC) (Neal, 1995) has been used to provide sample-based approximations to the true posterior. Despite the elegant theoretical property of asymptotic convergence to the true posterior, HMC and other conventional Markov Chain Monte Carlo methods are not scalable to large training sets.

This paper seeks to scale up Bayesian learning of RNNs to meet the challenge of the increasing amount of "big" sequential data in natural language processing, leveraging recent advances in *stochastic* gradient Markov Chain Monte Carlo (SG-MCMC) algorithms (Welling and Teh, 2011; Chen et al., 2014; Ding et al., 2014; Li et al., 2016a,b). Specifically, instead of training a single network, SG-MCMC is employed to train an *ensemble* of networks, where each network has its parameters drawn from a shared posterior distribution. This is implemented by adding additional

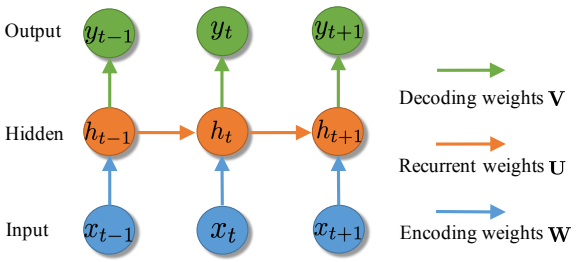

Figure 1: Illustration of different weight learning strategies in a single-hidden-layer RNN. Stochastic optimization used for MAP estimation puts fixed values on all weights. Naive dropout is allowed to put weight uncertainty only on encoding and decoding weights, and fixed values on recurrent weights. The proposed SG-MCMC scheme imposes distributions on all weights.

gradient noise during training and utilizing model averaging when testing.

This simple procedure has the following salutary properties for training neural networks: (i) When training, the injected noise encourages model-parameter trajectories to better explore the parameter space. This procedure was also empirically found effective in Neelakantan et al. (2016). (ii) Model averaging when testing alleviates overfitting and hence improves generalization, transferring uncertainty in the learned model parameters to subsequent prediction. (iii) In theory, both asymptotic and non-asymptotic consistency properties of SG-MCMC methods in posterior estimation have been recently established to guarantee convergence (Chen et al., 2015a; Teh et al., 2016). (iv) SG-MCMC is scalable; it shares the same level of computational cost as SGD in training, by only requiring the evaluation of gradients on a small mini-batch. To the authors' knowledge, RNN training using SG-MCMC has not been investigated previously, and is a contribution of this paper. We also perform extensive experiments on several natural language processing tasks, demonstrating the effectiveness of SG-MCMC for RNNs, including character/word-level language modeling, image captioning and sentence classification.

2 Related Work

Several scalable Bayesian learning methods have been proposed recently for neural networks. These come in two broad categories: stochastic variational inference (Graves, 2011; Blundell et al., 2015; Hernández-Lobato and Adams, 2015) and SG-MCMC methods (Korattikara et al., 2015; Li et al., 2016a). While prior work focuses on feed-forward neural networks, there has been little if any research reported for RNNs using SG-MCMC.

Dropout (Hinton et al., 2012; Srivastava et al., 2014) is a commonly used regularization method for training neural networks. Recently, several works have studied how to apply dropout to RNNs (Pachitariu and Sahani, 2013; Bayer et al., 2013; Pham et al., 2014; Zaremba et al., 2014; Bluche et al., 2015; Moon et al., 2015; Semeniuta et al., 2016; Gal and Ghahramani, 2016b). Among them, naive dropout (Zaremba et al., 2014) can impose weight uncertainty only on *encoding weights* (those that connect input to hidden units) and *decoding weights* (those that connect hidden units to output), but not the *recurrent weights* (those that connect consecutive hidden states). It has been concluded that noise added in the recurrent connections leads to model instabilities, hence disrupting the RNN's ability to model sequences.

Dropout has been recently shown to be a variational approximation technique in Bayesian learning (Gal and Ghahramani, 2016a; Kingma et al., 2015). Based on this, (Gal and Ghahramani, 2016b) proposed a new variant of dropout that can be successfully applied to recurrent layers, where the same dropout masks are shared along time for encoding, decoding and recurrent weights, respectively. Alternatively, we focus on SG-MCMC, which can be viewed as the Bayesian interpretation of dropout from the perspective of posterior sampling (Li et al., 2016c); this also allows imposition of model uncertainty on recurrent layers, enhancing performance. A comparison of naive dropout and SG-MCMC is illustrated in Fig. 1.

3 Recurrent Neural Networks

3.1 RNN as Bayesian Predictive Models

Consider data $\mathcal{D} = \{\mathbf{D}_1, \cdots, \mathbf{D}_N\}$, where $\mathbf{D}_n \triangleq (\mathbf{X}_n, \mathbf{Y}_n)$, with input $\mathbf{X}_n$ and output $\mathbf{Y}_n$. Our goal is to learn model parameters $\boldsymbol{\theta}$ to best characterize the relationship from $\mathbf{X}_n$ to $\mathbf{Y}_n$, with corresponding data likelihood $p(\mathcal{D}|\boldsymbol{\theta}) = \prod_{n=1}^{N} p(\mathbf{D}_n|\boldsymbol{\theta})$. In Bayesian statistics, one sets a prior on $\boldsymbol{\theta}$ via distribution $p(\boldsymbol{\theta})$. The posterior $p(\boldsymbol{\theta}|\mathcal{D}) \propto p(\boldsymbol{\theta})p(\mathcal{D}|\boldsymbol{\theta})$ reflects the belief concerning the model parameter distribution after observing the data. Given a test input $\tilde{\mathbf{X}}$ (with missing output $\tilde{\mathbf{Y}}$), the uncertainty learned in training

is transferred to prediction, yielding the posterior predictive distribution:

$$p(\tilde{\mathbf{Y}}|\tilde{\mathbf{X}},\mathcal{D}) = \int_{\boldsymbol{\theta}} p(\tilde{\mathbf{Y}}|\tilde{\mathbf{X}},\boldsymbol{\theta})p(\boldsymbol{\theta}|\mathcal{D})\mathrm{d}\boldsymbol{\theta}\,. \quad (1)$$

When the input is a sequence, RNNs may be used to parameterize the input-output relationship. Specifically, consider input sequence $\mathbf{X} = \{\boldsymbol{x}_1,\ldots,\boldsymbol{x}_T\}$, where $\boldsymbol{x}_t$ is the input data vector at time t. There is a corresponding hidden state vector $\boldsymbol{h}_t$ at each time t, obtained by recursively applying the *transition function* $\boldsymbol{h}_t = \mathcal{H}(\boldsymbol{h}_{t-1},\boldsymbol{x}_t)$ (specified in Section 3.2; see Fig. 1). The output $\mathbf{Y}$ differs depending on the application: a sequence $\{\boldsymbol{y}_1,\ldots,\boldsymbol{y}_T\}$ in language modeling or a discrete label in sentence classification. In RNNs the corresponding *decoding function* is $p(\boldsymbol{y}|\boldsymbol{h})$, described in Section 3.3.

3.2 RNN Architectures

The transition function $\mathcal{H}(\cdot)$ can be implemented with a *gated* activation function, such as Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) or a Gated Recurrent Unit (GRU) (Cho et al., 2014). Both the LSTM and GRU have been proposed to address the issue of learning long-term sequential dependencies.

Long Short-Term Memory The LSTM architecture addresses the problem of learning long-term dependencies by introducing a *memory cell*, that is able to preserve the state over long periods of time. Specifically, each LSTM unit has a cell containing a state $\boldsymbol{c}_t$ at time t. This cell can be viewed as a memory unit. Reading or writing the cell is controlled through sigmoid gates: input gate $\boldsymbol{i}_t$, forget gate $\boldsymbol{f}_t$, and output gate $\boldsymbol{o}_t$. The hidden units $\boldsymbol{h}_t$ are updated as

$$\begin{aligned}
\boldsymbol{i}_t &= \sigma(\mathbf{W}_i\boldsymbol{x}_t + \mathbf{U}_i\boldsymbol{h}_{t-1} + \boldsymbol{b}_i)\,,\\
\boldsymbol{f}_t &= \sigma(\mathbf{W}_f\boldsymbol{x}_t + \mathbf{U}_f\boldsymbol{h}_{t-1} + \boldsymbol{b}_f)\,,\\
\boldsymbol{o}_t &= \sigma(\mathbf{W}_o\boldsymbol{x}_t + \mathbf{U}_o\boldsymbol{h}_{t-1} + \boldsymbol{b}_o)\,,\\
\tilde{\boldsymbol{c}}_t &= \tanh(\mathbf{W}_c\boldsymbol{x}_t + \mathbf{U}_c\boldsymbol{h}_{t-1} + \boldsymbol{b}_c)\,,\\
\boldsymbol{c}_t &= \boldsymbol{f}_t \odot \boldsymbol{c}_{t-1} + \boldsymbol{i}_t \odot \tilde{\boldsymbol{c}}_t\,,\\
\boldsymbol{h}_t &= \boldsymbol{o}_t \odot \tanh(\boldsymbol{c}_t)\,,
\end{aligned}$$

where $\sigma(\cdot)$ denotes the logistic sigmoid function, and $\odot$ represents the element-wise matrix multiplication operator. $\mathbf{W}_{\{i,f,o,c\}}$ are *encoding weights*, and $\mathbf{U}_{\{i,f,o,c\}}$ are *recurrent weights*, as shown in Fig. 1. $\boldsymbol{b}_{\{i,f,o,c\}}$ are bias terms.

Variants Similar to the LSTM unit, the GRU also has gating units that modulate the flow of information inside the hidden unit. It has been shown that a GRU can achieve similar performance to an LSTM in sequence modeling (Chung et al., 2014). We specify the GRU in the Supplementary Material.

The LSTM can be extended to the bidirectional LSTM and multilayer LSTM. A bidirectional LSTM consists of two LSTMs that are run in parallel: one on the input sequence and the other on the reverse of the input sequence. At each time step, the hidden state of the bidirectional LSTM is the concatenation of the forward and backward hidden states. In multilayer LSTMs, the hidden state of an LSTM unit in layer ℓ is used as input to the LSTM unit in layer $\ell+1$ at the same time step (Graves, 2013).

3.3 Applications

The proposed Bayesian framework can be applied to any RNN model; we focus on the following tasks to demonstrate the ideas.

Language Modeling In word-level language modeling, the input to the network is a sequence of words, and the network is trained to predict the next word in the sequence with a softmax classifier. Specifically, for a length-T sequence, denote $\boldsymbol{y}_t = \boldsymbol{x}_{t+1}$ for $t = 1,\ldots,T-1$. $\boldsymbol{x}_1$ and $\boldsymbol{y}_T$ are always set to a special START and END token, respectively. At each time t, there is a decoding function $p(\boldsymbol{y}_t|\boldsymbol{h}_t) = \mathrm{softmax}(\mathbf{V}\boldsymbol{h}_t)$ to compute the distribution over words, where $\mathbf{V}$ are the *decoding weights* (the number of rows of $\mathbf{V}$ corresponds to the number of words/characters). We also extend this basic language model to consider other applications: (i) a *character-level language model* can be specified in a similar manner by replacing words with characters (Karpathy et al., 2016). (ii) *Image captioning* can be considered as a conditional language modeling problem, in which we learn a generative language model of the caption conditioned on an image (Vinyals et al., 2015; Gan et al., 2017).

Sentence Classification Sentence classification aims to assign a semantic category label $\boldsymbol{y}$ to a whole sentence $\mathbf{X}$. This is usually implemented through applying the decoding function once at the end of sequence: $p(\boldsymbol{y}|\boldsymbol{h}_T) = \mathrm{softmax}(\mathbf{V}\boldsymbol{h}_T)$, where the final hidden state of a RNN $\boldsymbol{h}_T$ is often considered as the summary of the sentence (here

the number of rows of $\mathbf{V}$ corresponds to the number of classes).

4 Scalable Learning with SG-MCMC

4.1 The Pitfall of Stochastic Optimization

Typically there is no closed-form solution for the posterior $p(\boldsymbol{\theta}|\mathcal{D})$, and traditional Markov Chain Monte Carlo (MCMC) methods (Neal, 1995) scale poorly for large N. To ease the computational burden, stochastic optimization is often employed to find the MAP solution. This is equivalent to minimizing an objective of regularized loss function $U(\boldsymbol{\theta})$ that corresponds to a (non-convex) model of interest: $\boldsymbol{\theta}_{\text{MAP}} = \arg\min U(\boldsymbol{\theta})$, $U(\boldsymbol{\theta}) = -\log p(\boldsymbol{\theta}|\mathcal{D})$. The expectation in (1) is approximated as:

$$p(\tilde{\mathbf{Y}}|\tilde{\mathbf{X}}, \mathcal{D}) = p(\tilde{\mathbf{Y}}|\tilde{\mathbf{X}}, \boldsymbol{\theta}_{\text{MAP}}) \,. \tag{2}$$

Though simple and effective, this procedure largely loses the benefit of the Bayesian approach, because the uncertainty on weights is ignored. To more accurately approximate (1), we employ stochastic gradient (SG) MCMC (Welling and Teh, 2011).

4.2 Large-scale Bayesian Learning

The negative log-posterior is

$$U(\boldsymbol{\theta}) \triangleq -\log p(\boldsymbol{\theta}) - \sum_{n=1}^{N} \log p(\mathbf{D}_n|\boldsymbol{\theta}). \tag{3}$$

In optimization, $E = -\sum_{n=1}^{N} \log p(\mathbf{D}_n|\boldsymbol{\theta})$ is typically referred to as the loss function, and $R \propto -\log p(\boldsymbol{\theta})$ as a regularizer.

For large N, stochastic approximations are often employed:

$$\tilde{U}_t(\boldsymbol{\theta}) \triangleq -\log p(\boldsymbol{\theta}) - \frac{N}{M} \sum_{m=1}^{M} \log p(\mathbf{D}_{i_m}|\boldsymbol{\theta}), \tag{4}$$

where $\mathcal{S}_m = \{i_1, \cdots, i_M\}$ is a *random* subset of the set $\{1, 2, \cdots, N\}$, with $M \ll N$. The gradient on this mini-batch is denoted as $\tilde{\boldsymbol{f}}_t = \nabla \tilde{U}_t(\boldsymbol{\theta})$, which is an unbiased estimate of the true gradient. The evaluation of (4) is cheap even when N is large, allowing one to efficiently collect a sufficient number of samples in large-scale Bayesian learning, $\{\boldsymbol{\theta}_s\}_{s=1}^{S}$, where S is the number of samples (this will be specified later). These samples are used to construct a sample-based estimation to the expectation in (1):

Table 1: SG-MCMC algorithms and their optimization counterparts. Algorithms in the same row share similar characteristics.

Algorithms	SG-MCMC	Optimization
Basic	SGLD	SGD
Precondition	pSGLD	RMSprop/Adagrad
Momentum	SGHMC	momentum SGD
Thermostat	SGNHT	Santa

$$p(\tilde{\mathbf{Y}}|\tilde{\mathbf{X}}, \mathcal{D}) \approx \frac{1}{S} \sum_{s=1}^{S} p(\tilde{\mathbf{Y}}|\tilde{\mathbf{X}}, \boldsymbol{\theta}_s) \,. \tag{5}$$

The finite-time estimation errors of SG-MCMC methods are bounded (Chen et al., 2015a), which guarantees (5) is an unbiased estimate of (1) asymptotically under appropriate decreasing step-sizes.

4.3 SG-MCMC Algorithms

SG-MCMC and stochastic optimization are parallel lines of work, designed for different purposes; their relationship has recently been revealed in the context of deep learning. The most basic SG-MCMC algorithm has been applied to Langevin dynamics, and is termed SGLD (Welling and Teh, 2011). To help convergence, a momentum term has been introduced in SGHMC (Chen et al., 2014), a "thermostat" has been devised in SGNHT (Ding et al., 2014; Gan et al., 2015) and preconditioners have been employed in pSGLD (Li et al., 2016a). These SG-MCMC algorithms often share similar characteristics with their counterpart approaches from the optimization literature such as the momentum SGD, Santa (Chen et al., 2016) and RMSprop/Adagrad (Tieleman and Hinton, 2012; Duchi et al., 2011). The interrelationships between SG-MCMC and optimization-based approaches are summarized in Table 1.

SGLD Stochastic Gradient Langevin Dynamics (SGLD) (Welling and Teh, 2011) draws posterior samples, with updates

$$\boldsymbol{\theta}_t = \boldsymbol{\theta}_{t-1} - \eta_t \tilde{\boldsymbol{f}}_{t-1} + \sqrt{2\eta_t}\boldsymbol{\xi}_t \,, \tag{6}$$

where η_t is the learning rate, and $\boldsymbol{\xi}_t \sim \mathcal{N}(\mathbf{0}, \mathbf{I}_p)$ is a standard Gaussian random vector. SGLD is the SG-MCMC analog to stochastic gradient descent (SGD), whose parameter updates are given by:

$$\boldsymbol{\theta}_t = \boldsymbol{\theta}_{t-1} - \eta_t \tilde{\boldsymbol{f}}_{t-1} \,. \tag{7}$$

Algorithm 1: pSGLD

Input: Default hyperparameter settings:
$\eta_t = 1 \times 10^{-3}, \lambda = 10^{-8}, \beta_1 = 0.99.$
Initialize: $\boldsymbol{v}_0 \leftarrow \mathbf{0}, \boldsymbol{\theta}_1 \sim \mathcal{N}(0, \mathbf{I})$;
for $t = 1, 2, \ldots, T$ **do**
  % Estimate gradient from minibatch $\mathcal{S}_t$
  $\tilde{\boldsymbol{f}}_t = \nabla \tilde{U}_t(\boldsymbol{\theta})$;
  % Preconditioning
  $\boldsymbol{v}_t \leftarrow \beta_1 \boldsymbol{v}_{t-1} + (1-\beta_1)\tilde{\boldsymbol{f}}_t \odot \tilde{\boldsymbol{f}}_t$;
  $\mathbf{G}_t^{-1} \leftarrow \text{diag}\left(\mathbf{1} \oslash \left(\lambda \mathbf{1} + \boldsymbol{v}_t^{\frac{1}{2}}\right)\right)$;
  % Parameter update
  $\boldsymbol{\xi}_t \sim \mathcal{N}(0, \eta_t \mathbf{G}_t^{-1})$;
  $\boldsymbol{\theta}_{t+1} \leftarrow \boldsymbol{\theta}_t + \frac{\eta_t}{2}\mathbf{G}_t^{-1}\tilde{\boldsymbol{f}}_t + \boldsymbol{\xi}_t$;
end

SGD is guaranteed to converge to a local minimum under mild conditions (Bottou, 2010). The additional Gaussian term in SGLD helps the learning trajectory to explore the parameter space to approximate posterior samples, instead of obtaining a local minimum.

pSGLD Preconditioned SGLD (pSGLD) (Li et al., 2016a) was proposed recently to improve the mixing of SGLD. It utilizes magnitudes of recent gradients to construct a diagonal preconditioner to approximate the Fisher information matrix, and thus adjusts to the local geometry of parameter space by equalizing the gradients so that a constant stepsize is adequate for all dimensions. This is important for RNNs, whose parameter space often exhibits *pathological curvature* and *saddle points* (Pascanu et al., 2013), resulting in slow mixing. There are multiple choices of preconditioners; similar ideas in optimization include Adagrad (Duchi et al., 2011), Adam (Kingma and Ba, 2015) and RMSprop (Tieleman and Hinton, 2012). An efficient version of pSGLD, adopting RMSprop as the preconditioner $\mathbf{G}$, is summarized in Algorithm 1, where $\oslash$ denotes element-wise matrix division. When the preconditioner is fixed as the identity matrix, the method reduces to SGLD.

4.4 Understanding SG-MCMC

To further understand SG-MCMC, we show its close connection to dropout/dropConnect (Srivastava et al., 2014; Wan et al., 2013). These methods improve the generalization ability of deep models, by randomly adding binary/Gaussian noise to the local units or global weights. For neural networks with the nonlinear function $q(\cdot)$ and consecutive layers $\boldsymbol{h}_1$ and $\boldsymbol{h}_2$, dropout and dropConnect are denoted as:

$$\begin{aligned} \text{Dropout:} \quad & \boldsymbol{h}_2 = \boldsymbol{\xi}_0 \odot q(\boldsymbol{\theta}\boldsymbol{h}_1), \\ \text{DropConnect:} \quad & \boldsymbol{h}_2 = q((\boldsymbol{\xi}_0 \odot \boldsymbol{\theta})\boldsymbol{h}_1), \end{aligned}$$

where the injected noise $\boldsymbol{\xi}_0$ can be binary-valued with dropping rate p or its equivalent Gaussian form (Wang and Manning, 2013):

$$\begin{aligned} \text{Binary noise:} \quad & \boldsymbol{\xi}_0 \sim \text{Ber}(p), \\ \text{Gaussian noise:} \quad & \boldsymbol{\xi}_0 \sim \mathcal{N}(1, \frac{p}{1-p}). \end{aligned}$$

Note that $\boldsymbol{\xi}_0$ is defined as a vector for dropout, and a matrix for dropConnect. By combining dropConnect and Gaussian noise from the above, we have the update rule (Li et al., 2016c):

$$\boldsymbol{\theta}_{t+1} = \boldsymbol{\xi}_0 \odot \boldsymbol{\theta}_t - \frac{\eta}{2}\tilde{\boldsymbol{f}}_t = \boldsymbol{\theta}_t - \frac{\eta}{2}\tilde{\boldsymbol{f}}_t + \boldsymbol{\xi}_0' \,, \quad (8)$$

where $\boldsymbol{\xi}_0' \sim \mathcal{N}\left(0, \frac{p}{(1-p)}\text{diag}(\boldsymbol{\theta}_t^2)\right)$; (8) shows that dropout/ dropConnect and SGLD in (6) share the same form of update rule, with the distinction being that the level of injected noise is different. In practice, the noise injected by SGLD may not be enough. A better way that we find to improve the performance is to jointly apply SGLD and dropout. This method can be interpreted as using SGLD to sample the posterior distribution of a mixture of RNNs, with mixture probability controlled by the dropout rate.

5 Experiments

We present results on several tasks, including character/word-level language modeling, image captioning, and sentence classification. We do not perform any dataset-specific tuning other than early stopping on validation sets. When dropout is utilized, the dropout rate is set to 0.5. All experiments are implemented in Theano (Theano Development Team, 2016), using a NVIDIA GeForce GTX TITAN X GPU with 12GB memory.

The hyper-parameters for the proposed algorithm include step size, minibatch size, thinning interval, number of burn-in epochs and variance of the Gaussian priors. We list the specific values used in our experiments in Table 2. The explanation of these hyperparameters, the initialization of model parameters and model specifications on each dataset are provided in the Supplementary Material.

Table 2: Hyper-parameter settings of pSGLD for different datasets. For PTB, SGLD is used.

5.1 Language Modeling

We first test character-level and word-level language modeling. The setup is as follows.

- Following Karpathy et al. (2016), we test character-level language modeling on the *War and Peace* (WP) novel. The training/validation/test sets contain 260/32/33 batches, in which there are 100 characters. The vocabulary size is 87, and we consider a 2-hidden-layer RNN of dimension 128.
- The *Penn Treebank* (PTB) corpus (Marcus et al., 1993) is used for word-level language modeling. The dataset adopts the standard split (929K training words, 73K validation words, and 82K test words) and has a vocabulary of size 10K. We train LSTMs of three sizes; these are denoted the small/medium/large LSTM. All LSTMs have two layers and are unrolled for 20 steps. The small, medium and large LSTM has 200, 650 and 1500 units per layer, respectively.

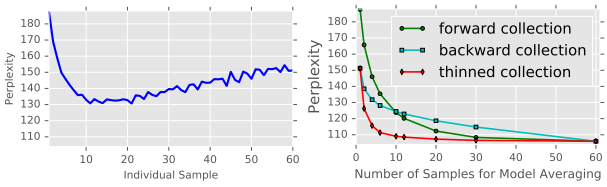
  We consider two types of training schemes on PTB corpus: (i) *Successive minibatches*: Following Zaremba et al. (2014), the final hidden states of the current minibatch are used as the initial hidden states of the subsequent minibatch (successive minibatches sequentially traverse the training set). (ii) *Random minibatches*: The initial hidden states of each minibatch are set to zero vectors, hence we can randomly sample minibatches in each update.

We study the effects of different types of architecture (LSTM/GRU/Vanilla RNN (Karpathy et al., 2016)) on the WP dataset, and effects of different learning algorithms on the PTB dataset. The comparison of test cross-entropy loss on WP is shown in Table 3. We observe that pSGLD consistently outperforms RMSprop. Table 4 summarizes the test set performance on PTB[1]. It is clear

[1]The results reported here do not match Zaremba et al. (2014) due to the implementation details. However, we provide a fair comparison to all methods.

Table 3: Test cross-entropy loss on WP dataset.

Methods	LSTM	GRU	RNN
RMSprop	1.3607	1.2759	1.4239
pSGLD	**1.3375**	**1.2561**	**1.4093**



(a) Single sample (b) Different collections

Figure 2: Effects of collected samples.

that our sampling-based method consistently outperforms the optimization counterpart, where the performance gain mainly comes from adding gradient noise and model averaging. When compared with dropout, SGLD performs better on the small LSTM model, but worse on the medium and large LSTM model. This may imply that dropout is suitable to regularizing large networks, while SGLD exhibits better regularization ability on small networks, partially due to the fact that dropout may inject a higher level of noise during training than SGLD. In order to inject a higher level of noise into SGLD, we empirically apply SGLD and dropout jointly, and found that this provided the best performace on the medium and large LSTM model.

We study three strategies to do model averaging, *i.e.*, *forward collection*, *backward collection* and *thinned collection*. Given samples $(\boldsymbol{\theta}_1, \cdots, \boldsymbol{\theta}_K)$ and the number of samples S used for averaging, *forward collection* refers to using $(\boldsymbol{\theta}_1, \cdots, \boldsymbol{\theta}_S)$ for the evaluation of a test function, *backward collection* refers to using $(\boldsymbol{\theta}_{K-S+1}, \cdots, \boldsymbol{\theta}_K)$, while *thinned collection* chooses samples from $\boldsymbol{\theta}_1$ to $\boldsymbol{\theta}_K$ with interval K/S. Fig. 2 plots the effects of these strategies, where Fig. 2(a) plots the perplexity of every single sample, Fig. 2(b) plots the perplexities using the three schemes. Only after 20

Table 4: Test perplexity on Penn Treebank.

Methods		Small	Medium	Large

	SGLD+Dropout	125.44	**82.71**	**78.91**
Literature	Moon et al. (2015)	–	97.0	118.7
	Moon et al. (2015)+ emb. dropout	–	86.5	86.0
	Zaremba et al. (2014)	–	82.7	78.4
	Gal and Ghahramani (2016b)	–	78.6	73.4

samples is a converged perplexity achieved in the thinned collection, while it requires 30 samples for forward collection or 60 samples for backward collection. This is unsurprising, because thinned collection provides a better way to select samples. Nevertheless, averaging of samples provides significantly lower perplexity than using single samples. Note that the overfitting problem in Fig. 2(a) is also alleviated by model averaging.

To better illustrate the benefit of model averaging, we visualize in Fig. 3 the probabilities of each word in a randomly chosen test sentence. The first 3 rows are the results predicted by 3 distinctive model samples, respectively; the bottom row is the result after averaging. Their corresponding perplexities for the test sentence are also shown on the right of each row. The 3 individual samples provide reasonable probabilities. For example, the consecutive words "New York", "stock exchange" and "did not" are assigned with a higher probability. After averaging, we can see a much lower perplexity, as the samples can complement each other. For example, though the second sample can yield the lowest single-model perplexity, its prediction on word "York" is still benefited from the other two via averaging.

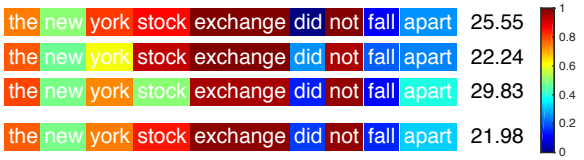

Figure 3: Predictive probabilities obtained by 3 samples and their average. Colors indicate normalized probability of each word. Best viewed in color.

Figure 4: Image captioning with different samples. Left are the given images, right are the corresponding captions. The captions in each box are from the same model sample.

5.2 Image Caption Generation

We next consider the problem of image caption generation, which is a conditional RNN model, where image features are extracted by residual network (He et al., 2016), and then fed into the RNN to generate the caption. We present results on two benchmark datasets, Flickr8k (Hodosh et al., 2013) and Flickr30k (Young et al., 2014). These datasets contain 8,000 and 31,000 images, respectively. Each image is annotated with 5 sentences. A single-layer LSTM is employed with the number of hidden units set to 512.

The widely used BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), ROUGE-L (Lin, 2004), and CIDEr-D (Vedantam et al., 2015) metrics are used to evaluate the performance. All the metrics are computed by using the code released by the COCO evaluation server (Chen et al., 2015b).

Table 5 presents results for pSGLD/RMSprop

Table 5: Performance on Flickr8k & Flickr30k: BLEU's, METEOR, CIDEr, ROUGE-L and perplexity.

Methods	B-1	B-2	B-3	B-4	METEOR	CIDEr	ROUGE-L	Perp.
Results on Flickr8k								
RMSprop	0.640	0.427	0.288	0.197	0.205	0.476	0.500	16.64

Results on Flickr30k								
RMSprop	0.644	0.422	0.279	0.184	0.180	0.372	0.476	17.80
RMSprop + Dropout	0.656	0.435	0.295	0.200	0.185	0.396	0.481	18.05
RMSprop + Gal's Dropout	0.636	0.429	0.290	0.197	0.190	0.408	0.480	17.27
pSGLD	0.657	0.438	0.300	0.206	**0.192**	**0.421**	**0.490**	**15.61**
pSGLD + Dropout	**0.666**	**0.448**	**0.308**	**0.209**	0.189	0.419	0.487	17.05

with or without dropout. In addition to (naive) dropout, we further compare pSGLD with the *Gal's dropout*, recently proposed in Gal and Ghahramani (2016b), which is shown to be applicable to recurrent layers. Consistent with the results in the basic language modeling, pSGLD yields improved performance compared to RMSprop. For example, pSGLD provides 2.7 BLEU-4 score improvement over RMSprop on the Flickr8k dataset. By comparing pSGLD with RMSprop with dropout, we conclude that pSGLD exhibits better regularization ability than dropout on these two datasets.

Apart from modeling weight uncertainty, different samples from our algorithm may capture different aspects of the input image. An example with two images is shown in Fig. 4, where 2 randomly chosen model samples are considered for each image. For each model sample, the top 3 generated captions are presented. We use the beam search approach (Vinyals et al., 2015) to generate captions, with a beam of size 5. In Fig. 4, the two samples for the first image mainly differ in the color and activity of the dog, *e.g.*, "tan" or "yellow", "playing" or "running", whereas for the second image, the two samples reflect different understanding of the image content.

5.3 Sentence Classification

We study the task of sentence classification on 5 datasets as in Kiros et al. (2015): *MR* (Pang and Lee, 2005), *CR* (Hu and Liu, 2004), *SUBJ* (Pang and Lee, 2004), *MPQA* (Wiebe et al., 2005) and *TREC* (Li and Roth, 2002). A single-layer bidirectional LSTM is employed with the number of hidden units set to 400. Table 6 shows the testing classification errors. 10-fold cross-validation is used for evaluation on the first 4 datasets, while TREC has a pre-defined training/test split, and we run each algorithm 10 times on TREC. The combination of pSGLD and dropout consistently provides the lowest errors.

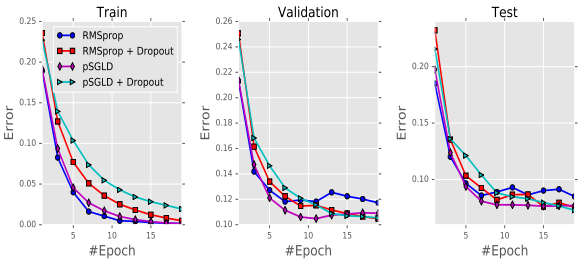

Figure 5: Learning curves on TREC dataset.

In the following, we focus on the analysis of TREC. Each sentence of TREC is a question, and the goal is to decide which topic type the question is most related to: *location*, *human*, *numeric*, *abbreviation*, *entity* or *description*. Fig. 5 plots the learning curves of different algorithms on the training, validation and testing sets of the TREC dataset. pSGLD and dropout have similar behavior: they explore the parameter space during learning, and thus coverge slower than RMSprop on the training dataset. However, the learned uncertainty alleviates overfitting and results in lower errors on the validation and testing datasets.

To further study the Bayesian nature of the proposed approach, in Fig. 6 we choose two testing sentences with high uncertainty (*i.e.*, standard derivation in prediction) from the TREC dataset. Interestingly, after embedding to 2d-space with tSNE (Van der Maaten and Hinton, 2008), the two

Table 6: Sentence classification errors on five benchmark datasets.

Methods	MR	CR	SUBJ	MPQA	TREC
RMSprop	21.86±1.19	20.20±1.35	8.13±1.19	10.60±1.28	8.14±0.63
RMSprop + Dropout	20.52±0.99	19.57±1.79	7.24±0.86	10.66±0.74	7.48±0.47
RMSprop + Gal's Dropout	20.22±1.12	19.29±1.93	7.52±1.17	10.59±1.12	7.34±0.66
pSGLD	20.36±0.85	18.72±1.28	7.00±0.89	10.54±0.99	7.48±0.82
pSGLD + Dropout	**19.33**±1.10	**18.18**±1.32	**6.61**±1.06	**10.22**±0.89	**6.88**±0.65

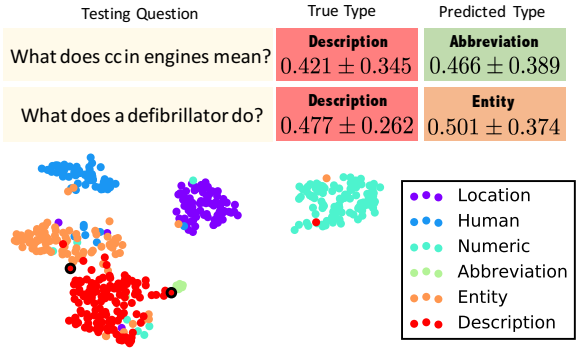

Figure 6: Visualization. Top two rows show selected ambiguous sentences, which correspond to the points with black circles in tSNE visualization of the testing dataset.

sentences correspond to points lying on the boundary of different classes. We use 20 model samples to estimate the prediction mean and standard derivation on the true type and predicted type. The classifier yields higher probability on the wrong types, associated with higher standard derivations. One can leverage the uncertainty information to make decisions: either manually make a human judgement when uncertainty is high, or automatically choose the one with lower standard derivations when both types exhibits similar prediction means. A more rigorous usage of the uncertainty information is left as future work.

5.4 Discussion

Ablation Study We investigate the effectivenss of each module in the proposed algorithm in Table 7 on two datasets: TREC and PTB. The small network size is used on PTB. Let M_1 denote only gradient noise, and M_2 denote only model averaging. As can be seen, The last sample in pSGLD (M_1) does not necessarily bring better results than RMSprop, but the model averaging over the samples of pSGLD indeed provide better results than model averaging of RMSprop (M_2). This indicates that both gradient noise and model averaging are crucial for good performance in pSGLD.

Table 7: Ablation study on TREC and PTB.

Datasets	RMSprop	M_1	M_2	pSGLD
TREC	8.14	8.34	7.54	7.48
PTB	120.45	122.14	114.86	109.44

Table 8: Running time on Flickr30k in seconds.

Stages	pSGLD	RMSprop+Dropout
Training	20324	12578
Testing	7047	1311

Running Time We report the training and testing time for image captioning on the Flickr30k dataset in Table 8. For pSGLD, the extra cost in training comes from adding gradient noise, and the extra cost in testing comes from model averaging. However, the cost in model averaging can be alleviated via the distillation methods: learning a single neural network that approximates the results of either a large model or an ensemble of models (Korattikara et al., 2015; Kim and Rush, 2016; Kuncoro et al., 2016). The idea can be incorporated with our SG-MCMC technique to achieve the same goal, which we leave for our future work.

6 Conclusion

We propose a scalable Bayesian learning framework using SG-MCMC, to model weight uncertainty in recurrent neural networks. The learning framework is tested on several tasks, including language models, image caption generation and sentence classification. Our algorithm outperforms stochastic optimization algorithms, indicating the importance of learning weight uncertainty in recurrent neural networks. Our algorithm requires little additional computational overhead in training, and multiple times of forward-passing for model averaging in testing.

Learning attention for historical text normalization by learning to pronounce

Abstract

Automated processing of historical texts often relies on pre-normalization to modern word forms. Training encoder-decoder architectures to solve such problems typically requires a lot of training data, which is not available for the named task. We address this problem by using several novel encoder-decoder architectures, including a multi-task learning (MTL) architecture using a grapheme-to-phoneme dictionary as auxiliary data, pushing the state-of-the-art by an absolute 2% increase in performance. We analyze the induced models across 44 different texts from Early New High German. Interestingly, we observe that, as previously conjectured, multi-task learning can learn to focus attention during decoding, in ways remarkably similar to recently proposed attention mechanisms. This, we believe, is an important step toward understanding how MTL works.

1 Introduction

There is a growing interest in automated processing of historical documents, as evidenced by the growing field of digital humanities and the increasing number of digitally available collections of historical documents. A common approach to deal with the high amount of variance often found in this type of data is to perform spelling normalization (Piotrowski, 2012), which is the mapping of historical spelling variants to standardized/modernized forms (e.g. *vnd* → *und* 'and').

Training data for supervised learning of historical text normalization is typically scarce, making it a challenging task for neural architectures, which typically require large amounts of labeled data. Nevertheless, we explore framing the spelling normalization task as a character-based sequence-to-sequence transduction problem, and use encoder–decoder recurrent neural networks (RNNs) to induce our transduction models. This is similar to models that have been proposed for neural machine translation (e.g., Cho et al. (2014)), so essentially, our approach could also be considered a specific case of character-based neural machine translation.

By basing our model on individual characters as input, we keep the vocabulary size small, which in turn reduces the model's complexity and the amount of data required to train it effectively. Using an encoder–decoder architecture removes the need for an explicit character alignment between historical and modern wordforms. Furthermore, we explore using an auxiliary task for which data is more readily available, namely grapheme-to-phoneme mapping (word pronunciation), to regularize the induction of the normalization models.

We propose several architectures, including multi-task learning architectures taking advantage of the auxiliary data, and evaluate them across 44 small datasets from Early New High German.

Contributions Our contributions are as follows:

- We are, to the best of our knowledge, the first to propose and evaluate encoder-decoder architectures for historical text normalization.
- We evaluate several such architectures across 44 datasets of Early New High German.
- We show that such architectures benefit from bidirectional encoding, beam search, and attention.
- We also show that MTL with pronunciation as an auxiliary task improves the performance of architectures without attention.

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 332–344
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1031

- We analyze the above architectures and show that the MTL architecture *learns* attention from the auxiliary task, making the attention mechanism largely redundant.

- We make our implementation publicly available at https://bitbucket.org/mbollmann/acl2017.

In sum, we both push the state-of-the-art in historical text normalization and present an analysis that, we believe, brings us a step further in understanding the benefits of multi-task learning.

2 Datasets

Normalization For the normalization task, we use a total of 44 texts from the Anselm corpus (Dipper and Schultz-Balluff, 2013) of Early New High German.[1] The corpus is a collection of manuscripts and prints of the same core text, a religious treatise. Although the texts are semi-parallel and share some vocabulary, they were written in different time periods (between the 14th and 16th century) as well as different dialectal regions, and show quite diverse spelling characteristics. For example, the modern German word *Frau* 'woman' can be spelled as *fraw/vraw* (Me), *frawe* (N2), *frauwe* (St), *fraüwe* (B2), *frow* (Stu), *vrowe* (Ka), *vorwe* (Sa), or *vrouwe* (B), among others.[2]

All texts in the Anselm corpus are manually annotated with gold-standard normalizations following guidelines described in Krasselt et al. (2015). For our experiments, we excluded texts from the corpus that are shorter than 4,000 tokens, as well as a few for which annotations were not yet available at the time of writing (mostly Low German and Dutch versions). Nonetheless, the remaining 44 texts are still quite short for machine-learning standards, ranging from about 4,200 to 13,200 tokens, with an average length of 7,350 tokens.

For all texts, we removed tokens that consisted solely of punctuation characters. We also lowercase all characters, since it helps keep the size of the vocabulary low, and uppercasing of words is usually not very consistent in historical texts. Tokenization was not an issue for pre-processing these texts, since modern token boundaries have already been marked by the transcribers.

[1] https://www.linguistics.rub.de/anselm/

[2] We refer to individual texts using the same internal IDs that are found in the Anselm corpus (cf. the website).

Grapheme-to-phoneme mappings We use learning to pronounce as our auxiliary task. This task consists of learning mappings from sequences of graphemes to the corresponding sequences of phonemes. We use the German part of the CELEX lexical database (Baayen et al., 1995), particularly the database of phonetic transcriptions of German wordforms. The database contains a total of 365,530 wordforms with transcriptions in DISC format, which assigns one character to each distinct phonological segment (including affricates and diphthongs). For example, the word *Jungfrau* 'virgin' is represented as `'jUN-frB`.

3 Model

3.1 Base model

We propose several architectures that are extensions of a base neural network architecture, closely following the sequence-to-sequence model proposed by Sutskever et al. (2014). It consists of the following:

- an embedding layer that maps one-hot input vectors to dense vectors;

- an encoder RNN that transforms the input sequence to an intermediate vector of fixed dimensionality;

- a decoder RNN whose hidden state is initialized with the intermediate vector, and which is fed the output prediction of one timestep as the input for the next one; and

- a final dense layer with a softmax activation which takes the decoder's output and generates a probability distribution over the output classes at each timestep.

For the encoder/decoder RNNs, we use long short-term memory units (LSTM) (Hochreiter and Schmidhuber, 1997). LSTMs are designed to allow recurrent networks to better learn long-term dependencies, and have proven advantageous to standard RNNs on many tasks. We found no significant advantage from stacking multiple LSTM layers for our task, so we use the simplest competitive model with only a single LSTM unit for both encoder and decoder.

By using this encoder–decoder model, we avoid the need to generate explicit alignments between the input and output sequences, which would bring up the question of how to deal with input/output

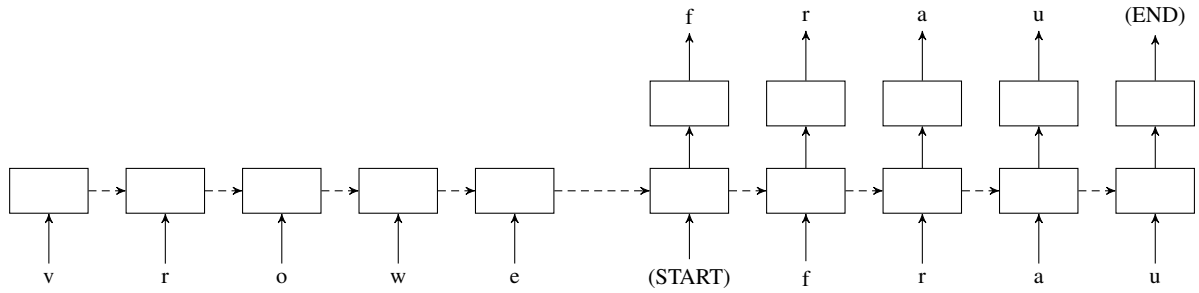

Figure 1: Flow diagram of the base model; left side is the encoder, right side the decoder, the latter of which has an additional prediction layer on top. Multi-task learning variants use two separate prediction layers for main/auxiliary tasks, while sharing the rest of the model. Embedding layers for the inputs are not explicitly shown.

pairs of different lengths. Another important property is that the model does not start to generate any output until it has seen the full input sequence, which in theory allows it to learn from any part of the input, without being restricted to fixed context windows. An example illustration of the unrolled network is shown in Fig. 1.

3.2 Training

During training, the encoder inputs are the historical wordforms, while the decoder inputs correspond to the correct modern target wordforms. We then train each model by minimizing the cross-entropy loss across all output characters; i.e., if $y = (y_1, ..., y_n)$ is the correct output word (as a list of one-hot vectors of output characters) and $\hat{y} = (\hat{y}_1, ..., \hat{y}_n)$ is the model's output, we minimize the mean loss $-\sum_{i=1}^{n} y_i \log \hat{y}_i$ over all training samples. For the optimization, we use the Adam algorithm (Kingma and Ba, 2015) with a learning rate of 0.003.

To reduce computational complexity, we also set a maximum word length of 14, and filter all training samples where either the input or output word is longer than 14 characters. This only affects 172 samples across the whole dataset, and is only done during training. In other words, we evaluate our models across all the test examples.

3.3 Decoding

For prediction, our base model generates output character sequences in a greedy fashion, selecting the character with the highest probability at each timestep. This works fairly well, but the greedy approach can yield suboptimal global picks, in which each individual character is sensibly derived from the input, but the overall word is nonsensical. We therefore also experiment with beam search decoding, setting the beam size to 5.

Finally, we also experiment with using a lexical filter during the decoding step. Here, before picking the next 5 most likely characters during beam search, we remove all characters that would lead to a string not covered by the lexicon. This is again intended to reduce the occurrence of nonsensical outputs. For the lexicon, we use all word forms from CELEX (cf. Sec. 2) plus the target word forms from the training set.[3]

3.4 Attention

In our base architecture, we assume that we can decode from a single vector encoding of the input sequence. This is a strong assumption, especially with long input sequences. Attention mechanisms give us more flexibility. The idea is that instead of encoding the entire input sequence into a fixed-length vector, we allow the decoder to "attend" to different parts of the input character sequence at each time step of the output generation. Importantly, we let the model learn what to attend to based on the input sequence and what it has produced so far.

Our implementation is identical to the decoder with soft attention described by Xu et al. (2015). If $a = (a_1, ..., a_n)$ is the encoder's output and h_t is the decoder's hidden state at timestep t, we first calculate a context vector $\hat{z}_t$ as a weighted combination of the output vectors a_i:

$$\hat{z}_t = \sum_{i=1}^{n} \alpha_i a_i \quad (1)$$

[3] We observe that due to this filtering, we cannot reach 2.25% of the targets in our test set, most of which are Latin word forms.

The weights α_i are derived by feeding the encoder's output and the decoder's hidden state from the previous timestep into a multilayer perceptron, called the attention model (f_{att}):

$$\alpha = softmax(f_{\text{att}}(a, h_{t-1})) \tag{2}$$

We then modify the decoder by conditioning its internal states not only on the previous hidden state h_{t-1} and the previously predicted output character y_{t-1}, but also on the context vector $\hat{z}_t$:

$$\begin{aligned} i_t &= \sigma(W_i[h_{t-1}, y_{t-1}, \hat{z}_t] + b_i) \\ f_t &= \sigma(W_f[h_{t-1}, y_{t-1}, \hat{z}_t] + b_f) \\ o_t &= \sigma(W_o[h_{t-1}, y_{t-1}, \hat{z}_t] + b_o) \\ g_t &= \tanh(W_g[h_{t-1}, y_{t-1}, \hat{z}_t] + b_g) \\ c_t &= f_t \odot c_{t-1} + i_t \odot g_t \\ h_t &= o_t \odot \tanh(c_t) \end{aligned} \tag{3}$$

In Eq. 3, we follow the traditional LSTM description consisting of input gate i_t, forget gate f_t, output gate o_t, cell state c_t and hidden state h_t, where W and b are trainable parameters.

For all experiments including an attentional decoder, we use a *bi-directional encoder*, comprised of one LSTM layer that reads the input sequence normally and another LSTM layer that reads it backwards, and attend over the concatenated outputs of these two layers.

While a precise alignment of input and output sequences is sometimes difficult, most of the time the sequences align in a sequential order, which can be exploited by an attentional component.

3.5 Multi-task learning

Finally, we introduce a variant of the base architecture, with or without beam search, that does multi-task learning (Caruana, 1993). The multi-task architecture only differs from the base architecture in having two classifier functions at the outer layer, one for each of our two tasks. Our auxiliary task is to predict a sequence of phonemes as the correct pronunciation of an input sequence of graphemes. This choice is motivated by the relationship between phonology and orthography, in particular the observation that spelling variation often stems from phonological variation.

We train our multi-task learning architecture by alternating between the two tasks, sampling one instance of the auxiliary task for each training sample of the main task. We use the encoder-decoder to generate a corresponding output sequence, whether a modern word form or a pronunciation. Doing so, we suffer a loss with respect to the true output sequence and update the model parameters. The update for a sample from a specific task affects the parameters of corresponding classifier function, as well as all the parameters of the shared hidden layers.

3.6 Hyperparameters

We used a single manuscript (B) for manually evaluating and setting the hyperparameters. This manuscript is left out of the averages reported below. We believe that using a single manuscript for development, and using the same hyperparameters across *all* manuscripts, is more realistic, as we often do not have enough data in historical text normalization to reliably tune hyperparameters.

For the final evaluation, we set the size of the embedding and the recurrent LSTM layers to 128, applied a dropout of 0.3 to the input of each recurrent layer, and trained the model on mini-batches with 50 samples each for a total of 50 epochs (in the multi-task learning setup, mini-batches contain 50 samples of each task, and epochs are counted by the size of the training set for the main task only). All these parameters were set on the B manuscript alone.

3.7 Implementation

We implemented all of the models in Keras (Chollet, 2015). Any parameters not explicitly described here were left at their default values in Keras v1.0.8.

4 Evaluation

We split up each text into three parts, using 1,000 tokens each for a test set and a development set (that is not currently used), and the remainder of the text (between 2,000 and 11,000 tokens) for training. We then train and evaluate on each of the 43 texts (excluding the B text that was used for hyper-parameter tuning) individually.

Baselines We compare our architectures to several competitive baselines. Our first baseline is an averaged perceptron model trained to predict output character n-grams for each input character, after using Levenshtein alignment with generated segment distances (Wieling et al., 2009, Sec. 3.3) to align input and output characters. Our second baseline uses the same alignment, but trains a

		Avg. Accuracy
Norma		77.89%
Averaged perceptron		75.72%
Bi-LSTM tagger		79.91%
MTL bi-LSTM tagger		79.56%
Base model	GREEDY	78.91%
	BEAM	79.27%
	BEAM+FILTER	80.46%
	BEAM+FILTER+ATTENTION	**82.72%**
MTL model	GREEDY	80.64%
	BEAM	81.13%
	BEAM+FILTER	**82.76%**
	BEAM+FILTER+ATTENTION	82.02%

Table 1: Average word accuracy across 43 texts from the Anselm dataset, evaluated on the first 1,000 tokens of each text. Evaluation on the base encoder-decoder model (Sec. 3.1) with greedy search, beam search ($k = 5$) and/or lexical filtering (Sec. 3.3), with attentional decoder (Sec. 3.4), and the multi-task learning (MTL) model using grapheme-to-phoneme mappings (Sec. 3.5).

deep bi-LSTM sequential tagger, following Bollmann and Søgaard (2016). We evaluate this tagger using both standard and multi-task learning. Finally, we compare our model to the rule-based and Levenshtein-based algorithms provided by the Norma tool (Bollmann, 2012).[4]

4.1 Word accuracy

We use word-level accuracy as our evaluation metric. While we also measure character-level metrics, minor differences on character level can cause large differences in downstream applications, so we believe that perfectly matching the output sequences is more useful. Average scores across all 43 texts are presented in Table 1 (see Appendix A for individual scores).

We first see that almost all our encoder-decoder architectures perform significantly better than the four state-of-the-art baselines. All our architectures perform better than Norma and the averaged perceptron, and all the MTL architectures outperform Bollmann and Søgaard (2016).

We also see that beam search, filtering, and attention lead to cumulative gains in the context of the single-task architecture – with the best architecture outperforming the state-of-the-art by almost 3% in absolute terms.

For our multi-task architecture, we also observe gains when we add beam search and filtering, but importantly, adding attention does not help. In fact, attention hurts the performance of our multi-task architecture quite significantly. Also note that the multi-task architecture *without* attention performs on-par with the single-task architecture *with* attention.

We hypothesize that the reason for this pattern, which is not only observed in the average scores in Table 1, but also quite consistent across the individual results in Appendix A, is that our multi-task learning already learns how to focus attention.

This is the hypothesis that we will try to validate in Sec. 5: *That multi-task learning can induce strategies for focusing attention comparable to attention strategies for recurrent neural networks.*

Sample predictions A small selection of predictions from our models is shown in Table 2. They serve to illustrate the effects of the various settings; e.g., the base model with greedy search tends to produce more nonsense words (*ters*, *ünsget*) than the others. Using a lexical filter helps the most in this regard: the base model with filtering correctly normalizes *ergieng* to *erging* '(he) fared', while decoding without a filter produces the non-word *erbiggen*. Even for *herczenlichen* (modern *herzlichen* 'heartfelt'), where no model finds the correct target form, only the model with filtering produces a somewhat reasonable alternative (*herzgeliebtes* 'heartily loved').

In some cases (such as *gewarnet* 'warned'),

[4] https://github.com/comphist/norma

Input	Target	Base model				MTL model
		GREEDY	BEAM	B+F	B+F+A	B+F
ergieng	erging	erbiggen	erbiggen	erging	erging	erging
herczenlichen	herzlichen	herrgelichen	herzgelichen	herzgeliebtes	herzel	herzel
tewr	teuer	ters	terter	terme	teurer	der
iüngst	jüngst	ünsget	pingst	fingst	fingst	jüngst
gewarnet	gewarnt	prandet	prandert	pranget	gewarnt	gewarnt
dick	oft	oft	oft	oft	dicke	dicke

Table 2: Selected predictions from some of our models on the M4 text; B = BEAM, F = FILTER, A = ATTENTION.

only the models with attention or multi-task learning produce the correct normalization, but even when they are wrong, they often agree on the prediction (e.g. *dicke*, *herzel*). We will investigate this property further in Sec. 5.

4.2 Learned vector representations

To gain further insights into our model, we created t-SNE projections (Maaten and Hinton, 2008) of vector representations learned on the M4 text.

Fig. 2 shows the learned character embeddings. In the representations from the base model (Fig. 2a), characters that are often normalized to the same target character are indeed grouped closely together: e.g., historical <*v*> and <*u*> (and, to a smaller extent, <*f*>) are often used interchangeably in the M4 text. Note the wide separation of <*n*> and <*m*>, which is a feature of M4 that does not hold true for all of the texts, as these do not always display a clear distinction between nasals. On the other hand, the MTL model shows a better generalization of the training data (Fig. 2b): here, <*u*> is grouped closer to other vowel characters and far away from <*v*>/<*f*>. Also, <*n*> and <*m*> are now in close proximity.

We can also visualize the internal word representations that are produced by the encoder (Fig. 3). Here, we chose words that demonstrate the interchangeable use of <*u*> and <*v*>. Historical *vnd, vns, vmb* become modern *und, uns, um*, changing the <*v*> to <*u*>. However, the representation of *vmb* learned by the base model is closer to forms like *von, vor, uor*, all starting with <*v*> in the target normalization. In the MTL model, however, these examples are indeed clustered together.

5 Analysis: Multi-task learning helps focus attention

Table 1 shows that models which employ *either* an attention mechanism *or* multi-task learning obtain similar improvements in word accuracy. However, we observe a decline in word accuracy for models that *combine* multi-task learning with attention.

A possible interpretation of this counter-intuitive pattern might be that attention and MTL, to some degree, learn similar functions of the input data, a conjecture by Caruana (1998). We put this hypothesis to the test by closely investigating properties of the individual models below.

5.1 Model parameters

First, we are interested in the weight parameters of the final layer that transforms the decoder output to class probabilities. We consider these parameters for our standard encoder-decoder model and compare them to the weights that are learned by the attention and multi-task models, respectively.[5]

Note that hidden layer parameters are not necessarily comparable across models, but with a fixed seed, differences in parameters over a reference model *may* be (and are, in our case). With a fixed seed, and iterating over data points in the same order, it is conceivable the two non-baselines end up in roughly the same alternative local optimum (or at least take comparable routes).

We observe that the weight differences between the standard and the attention model correlate with the differences between the standard and multi-task model by a Pearson's r of 0.346, averaged across datasets, with a standard deviation of 0.315; on individual datasets, correlation coefficient is as

[5]For the multi-task models, this analysis disregards those dimensions that do not correspond to classes in the main task.

(a) Parameter changes for the attention model

(b) Parameter changes for the multi-task model

Figure 4: Heat map of parameter differences in the final dense layer between (a) the plain and the attention model as well as (b) the plain and the multi-task model, when trained on the N4 manuscript. The changes correlate by $\rho = 0.959$.

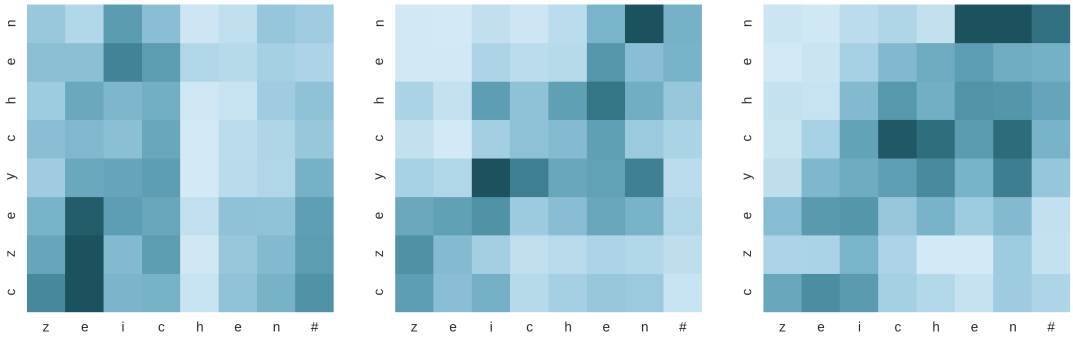

Figure 5: First-derivative saliency w.r.t. the input sequence, as calculated from the base model (left), the attentional model (center), and the MTL model (right). The scores for the attentional and the multi-task model correlate by $\rho = 0.615$, while the correlation of either one with the base model is $|\rho| < 0.12$.

high as 96. Figure 4 illustrates these highly parallel weight changes for the different models when trained on the N4 dataset.

5.2 Final output

Next, we compare the effect that employing either an attention mechanism or multi-task learning has on the actual output of our system. We find that out of the 210.9 word errors that the base model produces on average across all test sets (comprising 1,000 tokens each), attention resolves 47.7, while multi-task learning resolves an average of 45.4 errors. Crucially, the overlap of errors that are resolved by both the attention and the MTL model amounts to 27.7 on average.

Attention and multi-task also introduce new errors compared to the base model (26.6 and 29.5 per test set, respectively), and again we can observe a relatively high agreement of the models (11.8 word errors are introduced by both models).

Finally, the attention and multi-task models display a word-level agreement of κ=0.834 (Cohen's kappa), while either of these models is less strongly correlated with the base model (κ=0.817 for attention and κ=0.814 for multi-task learning).

5.3 Saliency analysis

Our last analysis regards the saliency of the input timesteps with respect to the predictions of our models. We follow Li et al. (2016) in calculating first-derivative saliency for given input/output pairs and compare the scores from the different models. The higher the saliency of an input timestep, the more important it is in determining the model's prediction at a given output timestep. Therefore, if two models produce similar saliency matrices for a given input/output pair, they have learned to focus on similar parts of the input during the prediction. Our hypothesis is that the attentional and the multi-task learning model should be more similar in terms of saliency scores than either of them compared to the base model.

Figure 5 shows a plot of the saliency matrices generated from the word pair *czeychen – zeichen* 'sign'. Here, the scores for the attentional and the MTL model indeed correlate by $\rho = 0.615$, while those for the base model do not correlate with either of them. A systematic analysis across 19,000 word pairs (where all models agree on the output) shows that this effect only holds for longer input sequences ($\geq$ 7 characters), with a mean $\rho = 0.303$ (± 0.177) for attentional vs. MTL model, while the base model correlates with either of them by $\rho < 0.21$.

6 Related Work

Many traditional approaches to spelling normalization of historical texts use edit distances or some form of character-level rewrite rules, handcrafted (Baron and Rayson, 2008) or learned automatically (Bollmann, 2013; Porta et al., 2013).

A more recent approach is based on character-based statistical machine translation applied to historical text (Pettersson et al., 2013; Sánchez-Martínez et al., 2013; Scherrer and Erjavec, 2013; Ljubešić et al., 2016) or dialectal data (Scherrer and Ljubešić, 2016). This is conceptually very similar to our approach, except that we substitute the classical SMT algorithms for neural networks. Indeed, our models can be seen as a form of character-based neural MT (Cho et al., 2014).

Neural networks have rarely been applied to

historical spelling normalization so far. Azawi et al. (2013) normalize old Bible text using bi-directional LSTMs with a layer that performs alignment between input and output wordforms. Bollmann and Søgaard (2016) also use bi-LSTMs to frame spelling normalization as a character-based sequence labelling task, performing character alignment as a preprocessing step.

Multi-task learning was shown to be effective for a variety of NLP tasks, such as POS tagging, chunking, named entity recognition (Collobert et al., 2011) or sentence compression (Klerke et al., 2016). It has also been used in encoder-decoder architectures, typically for machine translation (Dong et al., 2015; Luong et al., 2016), though so far not with attentional decoders.

7 Conclusion and Future Work

We presented an approach to historical spelling normalization using neural networks with an encoder-decoder architecture, and showed that it consistently outperforms several existing baselines. Encouragingly, our work proves to be fully competitive with the sequence-labeling approach by Bollmann and Søgaard (2016), without requiring a prior character alignment.

Specifically, we demonstrated the aptitude of multi-task learning to mitigate the shortage of training data for the named task. We included a multifaceted analysis of the effects that MTL introduces to our models and the resemblance that it bears to attention mechanisms. We believe that this analysis is a valuable contribution to the understanding of MTL approaches also beyond spelling normalization, and we are confident that our observations will stimulate further research into the relationship between MTL and attention.

Finally, many improvements to the presented approach are conceivable, most notably introducing some form of token context to the model. Currently, we only consider word forms in isolation, which is problematic for ambiguous cases (such as *jn*, which can normalize to *in* 'in' or *ihn* 'him') and conceivably makes the task harder for others. Reranking the predictions with a language model could be one possible way to improve on this. Ljubešić et al. (2016), for example, experiment with segment-based normalization, using a character-based SMT model with character input derived from segments (essentially, token n-grams) instead of single tokens, which also introduces context. Such an approach could also deal with the issue of tokenization differences between the historical and the modern text, which is another challenge often found in datasets of historical text.

Abstract

Kernel methods enable the direct usage of structured representations of textual data during language learning and inference tasks. Expressive kernels, such as Tree Kernels, achieve excellent performance in NLP. On the other side, deep neural networks have been demonstrated effective in automatically learning feature representations during training. However, their input is tensor data, i.e., they cannot manage rich structured information. In this paper, we show that expressive kernels and deep neural networks can be combined in a common framework in order to (*i*) explicitly model structured information and (*ii*) learn non-linear decision functions. We show that the input layer of a deep architecture can be pre-trained through the application of the Nyström low-rank approximation of kernel spaces. The resulting "kernelized" neural network achieves state-of-the-art accuracy in three different tasks.

1 Introduction

Learning for Natural Language Processing (NLP) requires to more or less explicitly account for trees or graphs to express syntactic and semantic information. A straightforward modeling of such information has been obtained in statistical language learning with Tree Kernels (TKs) (Collins and Duffy, 2001), or by means of structured neural models (Hochreiter and Schmidhuber, 1997; Socher et al., 2013). In particular, kernel-based methods (Shawe-Taylor and Cristianini, 2004) have been largely applied in language processing for alleviating the need of complex activities of manual feature engineering (e.g., (Moschitti et al., 2008)). Although *ad-hoc* features are adopted by many successful approaches to language learning (e.g., (Gildea and Jurafsky, 2002)), kernels provide a natural way to capture textual generalizations directly operating over (possibly complex) linguistic structures. Sequence (Cancedda et al., 2003) or tree kernels (Collins and Duffy, 2001) are of particular interest as the feature space they implicitly generate reflects linguistic patterns. On the other hand, Recursive Neural Networks (Socher et al., 2013) have been shown to learn dense feature representations of the nodes in a structure, thus exploiting similarities between nodes and sub-trees. Also, Long-Short Term Memory (Hochreiter and Schmidhuber, 1997) networks build intermediate representations of sequences, resulting in similarity estimates over sequences and their inner sub-sequences.

While such methods are highly effective and reach state-of-the-art results in many tasks, their adoption can be problematic. In kernel-based Support Vector Machine (SVM) the classification model corresponds to the set of support vectors (SVs) and weights justifying the maximal margin hyperplane: the classification cost crucially depends on their number, as classifying a new instance requires a kernel computation against all SVs, making their adoption in large data settings prohibitive. This scalability issue is evident in many NLP and Information Retrieval applications, such as in answer re-ranking in question answering (Severyn et al., 2013; Filice et al., 2016), where the number of SVs is typically very large. Improving the efficiency of kernel-based methods is a largely studied topic. The reduction of computational costs has been early designed by imposing a budget (Dekel and Singer, 2006; Wang and Vucetic, 2010), that is limiting the maximum number of SVs in a model. However, in complex tasks, such methods still require large budgets to reach

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 345–354
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1032

adequate accuracies. On the other hand, training complex neural networks is also difficult as no common design practice is established against complex data structures. In Levy et al. (2015), a careful analysis of neural word embedding models is carried out and the role of the hyper-parameter estimation is outlined. Different neural architectures result in the same performances, whenever optimal hyper-parameter tuning is applied. In this latter case, no significant difference is observed across different architectures, making the choice between different neural architectures a complex and empirical task.

A general approach to the large scale modeling of complex structures is a critical and open problem. A viable and general solution to this scalability issue is provided by the Nyström method (Williams and Seeger, 2001); it allows to approximate the Gram matrix of a kernel function and support the embedding of future input examples into a low-dimensional space. For example, if used over TKs, the Nyström projection corresponds to the embedding of any tree into a low-dimensional vector.

In this paper, we show that the Nyström based low-rank embedding of input examples can be used as the early layer of a deep feed-forward neural network. A standard NN back-propagation training can thus be applied to induce non-linear functions in the kernel space. The resulting deep architecture, called *Kernel-based Deep Architecture* (KDA), is a mathematically justified integration of expressive kernel functions and deep neural architectures, with several advantages: it (*i*) directly operates over complex non-tensor structures, e.g., trees, without any manual feature or architectural engineering, (*ii*) achieves a drastic reduction of the computational cost w.r.t. pure kernel methods, and (*iii*) exploits the non-linearity of NNs to produce accurate models. The experimental evaluation shows that the proposed approach achieves state-of-the-art results in three semantic inference tasks: Semantic Parsing, Question Classification and Community Question Answering.

In the rest of the paper, Section 2 surveys some of the investigated kernels. In Section 3 the Nyström methodology and KDA are presented. Experimental evaluations are described in Section 4. Finally, Section 5 derives the conclusions.

2 Kernel-based Semantic Inference

In almost all NLP tasks, explicit models of complex syntactic and semantic structures are required, such as in Paraphrase Detection: deciding whether two sentences are valid paraphrases involves learning grammatical rewriting rules, such as semantics preserving mappings among subtrees. Also in Question Answering, the syntactic information about input questions is crucial. While manual feature engineering is always possible, kernel methods on structured representations of data objects, e.g., sentences, have been largely applied. Since Collins and Duffy (2001), sentences can be modeled through their corresponding parse tree, and Tree Kernels (TKs) result in similarity metrics directly operating over tree fragments. Such kernels corresponds to dot products in the (implicit) feature space made of all possible tree fragments (Haussler, 1999). Notice that the number of tree fragments in a tree bank is combinatorial with the number of tree nodes and gives rise to billions of features, i.e., dimensions. In this high-dimensional space, kernel-based algorithms, such as SVMs, can implicitly learn robust prediction models (Shawe-Taylor and Cristianini, 2004), resulting in state-of-the-art approaches in several NLP tasks, e.g., Semantic Role Labeling (Moschitti et al., 2008), Question Classification (Croce et al., 2011) or Paraphrase Identification (Filice et al., 2015). As the feature space generated by the structural kernels depends on the input structures, different tree representations can be adopted to reflect more or less expressive syntactic/semantic feature spaces. While constituency parse trees have been early used (e.g., (Collins and Duffy, 2001)), dependency parse trees correspond to graph structures. TKs usually rely on their tree conversions, where grammatical edge labels corresponds to nodes. An expressive tree representation of dependency graphs is the Grammatical Relation Centered Tree (GRCT). As illustrated in Figure 1, PoS-Tags and grammatical functions correspond to nodes, dominating their associated lexicals.

Types of tree kernels. While a variety of TK functions have been studied, e.g., the *Partial Tree Kernel* (PTK) (Moschitti, 2006), the kernels used in this work model grammatical and semantic information, as triggered respectively by the dependency edge labels and lexical nodes. The latter is exploited through recent results in distributional models of lexical semantics, as proposed in

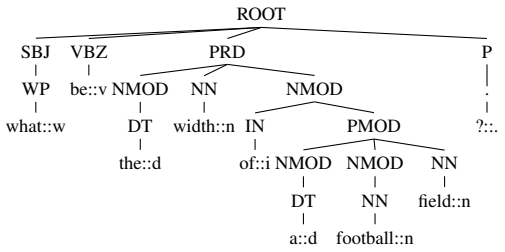

Figure 1: Grammatical Relation Centered Tree (GRCT) of *"What is the width of a football field?"*

word embedding methods (e.g., (Mikolov et al., 2013; Sahlgren, 2006). In particular, we adopt the *Smoothed Partial Tree Kernel* (SPTK) described in Croce et al. (2011): it extends the PTK formulation with a similarity function between lexical nodes in a GRCT, i.e., the cosine similarity between word vector representations based on word embeddings. We also use a further extension of the SPTK, called *Compositionally Smoothed Partial Tree Kernel* (CSPTK) (as in Annesi et al. (2014)). In CSPTK, the lexical information provided by the sentence words is propagated along the non-terminal nodes representing head-modifier dependencies. Figure 2 shows a compositionally-labeled tree, where the similarity function at the nodes can model lexical composition, i.e., capturing contextual information. For example, in the sentence, "*What instrument does Hendrix play?*", the role of the word *instrument* can be fully captured only if its composition with the verb *play* is considered. The CSPTK applies a composition function between nodes: while several algebraic functions can be adopted to compose two word vectors representing a head/modifier pair, here we refer to a simple additive function that assigns to each (h, m) pair the linear combination of the involved vectors, i.e., $(\mathbf{h}, \mathbf{m}) = A\mathbf{h} + B\mathbf{m}$: although simple and efficient, it actually produces very effective CSPTK functions.

Complexity. The training phase of an optimal maximum margin algorithm (such as SVM) requires a number of kernel operations that is more than linear (almost $\mathcal{O}(n^2)$) with respect to the number of training examples n, as discussed in Chang and Lin (2011). Also the classification phase depends on the size of the input dataset and the intrinsic complexity of the targeted task: classifying a new instance requires to evaluate the kernel function with respect to each support vector. For complex tasks, the number of selected support vectors tends to be very large, and using the resulting model can be impractical. This cost is also problematic as single kernel operations can be very expensive: the cost of evaluating the PTK on a single tree pair is almost linear in the number of nodes in the input trees, as shown in Moschitti (2006). When lexical semantics is considered, as in SPTKs and CSPTKs, it is more than linear in the number of nodes (Croce et al., 2011).

3 Deep Learning in Kernel Spaces

3.1 The Nyström method

Given an input training dataset D, a kernel $K(o_i, o_j)$ is a similarity function over $\mathcal{D}^2$ that corresponds to a dot product in the implicit kernel space, i.e., $K(o_i, o_j) = \Phi(o_i) \cdot \Phi(o_j)$. The advantage of kernels is that the projection function $\Phi(o) = \mathbf{x} \in \mathbb{R}^n$ is never explicitly computed (Shawe-Taylor and Cristianini, 2004). In fact, this operation may be prohibitive when the dimensionality n of the underlying kernel space is extremely large, as for Tree Kernels (Collins and Duffy, 2001). Kernel functions are used by learning algorithms, such as SVM, to operate only implicitly on instances in the kernel space, by never accessing their explicit definition. Let us apply the projection function Φ over all examples from $\mathcal{D}$ to derive representations, $\mathbf{x}$ denoting the rows of the matrix X. The Gram matrix can always be computed as $G = XX^\top$, with each single element corresponding to $G_{ij} = \Phi(o_i)\Phi(o_j) = K(o_i, o_j)$. The aim of the Nyström method is to derive a new low-dimensional embedding $\tilde{x}$ in a l-dimensional space, with $l \ll n$ so that $\tilde{G} = \tilde{X}\tilde{X}^\top$ and $\tilde{G} \approx G$. This is obtained by generating an approximation $\tilde{G}$ of G using a subset of l columns of the matrix, i.e., a selection of a subset $L \subset \mathcal{D}$ of the available examples, called *landmarks*. Suppose we randomly sample l columns of G, and let $C \in \mathbb{R}^{|D| \times l}$ be the matrix of these sampled columns. Then, we can rearrange the columns and rows of G and define $X = [X_1 \;\; X_2]$ such that:

$$G = XX^\top = \begin{bmatrix} W & X_1^\top X_2 \\ X_2^\top X_1 & X_2^\top X_2 \end{bmatrix}$$
$$\text{and} \quad C = \begin{bmatrix} W \\ X_2^\top X_1 \end{bmatrix} \tag{1}$$

where $W = X_1^\top X_1$, i.e., the subset of G that contains only landmarks. The Nyström approximation can be defined as:

$$G \approx \tilde{G} = CW^\dagger C^\top \tag{2}$$

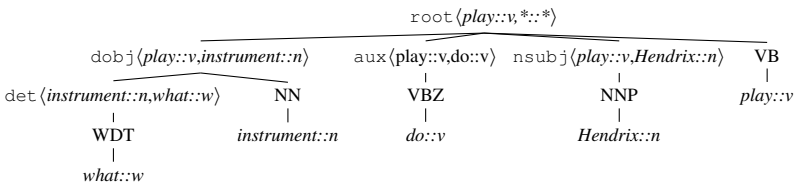

Figure 2: Compositional Grammatical Relation Centered Tree (CGRCT) of "*What instrument does Hendrix play?*"

where $W^\dagger$ denotes the Moore-Penrose inverse of W. The Singular Value Decomposition (SVD) is used to obtain $W^\dagger$ as it follows. First, W is decomposed so that $W = USV^\top$, where U and V are both orthogonal matrices, and S is a diagonal matrix containing the (non-zero) singular values of W on its diagonal. Since W is symmetric and positive definite $W = USU^\top$. Then $W^\dagger = US^{-1}U^\top = US^{-\frac{1}{2}}S^{-\frac{1}{2}}U^\top$ and the Equation 2 can be rewritten as

$$G \approx \tilde{G} = CUS^{-\frac{1}{2}}S^{-\frac{1}{2}}U^\top C^\top = (CUS^{-\frac{1}{2}})(CUS^{-\frac{1}{2}})^\top = \tilde{X}\tilde{X}^\top \quad (3)$$

Given an input example $o \in \mathcal{D}$, a new low-dimensional representation $\tilde{\mathbf{x}}$ can be thus determined by considering the corresponding item of C as

$$\tilde{\mathbf{x}} = \mathbf{c}US^{-\frac{1}{2}} \quad (4)$$

where $\mathbf{c}$ is the vector whose dimensions contain the evaluations of the kernel function between o and each landmark $o_j \in L$. Therefore, the method produces l-dimensional vectors. If k is the average number of basic operations required during a single kernel computation, the overall cost of a single projection is $\mathcal{O}(kl + l^2)$, where the first term corresponds to the cost of generating the vector $\mathbf{c}$, while the second term is needed for the matrix multiplications in Equation 4. Typically, the number of landmarks l ranges from hundreds to few thousands and, for complex kernels (such as Tree Kernels), the projection cost can be reduced to $\mathcal{O}(kl)$. Several policies have been defined to determine the best selection of landmarks to reduce the Gram Matrix approximation error. In this work the uniform sampling without replacement is adopted, as suggested by Kumar et al. (2012), where this policy has been theoretically and empirically shown to achieve results comparable with other (more complex) selection policies.

3.2 A Kernel-based Deep Architecture

The above introduced Nyström representation $\tilde{\mathbf{x}}$ of any input example o is linear and can be adopted to feed a neural network architecture. We assume a labeled dataset $\mathcal{L} = \{(o, y) \mid o \in \mathcal{D},\ y \in Y\}$ being available, where o refers to a generic instance and y is its associated class. In this Section, we define a Multi-Layer Perceptron (MLP) architecture, with a specific Nyström layer based on the Nyström embeddings of Eq. 4. We will refer to this architecture as Kernel-based Deep Architecture (KDA). KDA has an *input layer*, a *Nyström layer*, a possibly empty sequence of non-linear *hidden layers* and a final *classification layer*, which produces the output.

The *input* layer corresponds to the input vector $\mathbf{c}$, i.e., the row of the C matrix associated to an example o. Notice that, for adopting the KDA, the values of the matrix C should be all available. In the training stage, these values are in general cached. During the classification stage, the $\mathbf{c}$ vector corresponding to an example o is directly computed by l kernel computations between o and each one of the l landmarks.

The input layer is mapped to the *Nyström* layer, through the projection in Equation 4. Notice that the embedding provides also the proper weights, defined by $US^{-\frac{1}{2}}$, so that the mapping can be expressed through the Nyström matrix $H_{Ny} = US^{-\frac{1}{2}}$: it corresponds to a pre-trained stage derived through SVD, as discussed in Section 3.1. Equation 4 provides a static definition for H_{Ny} whose weights can be left invariant during the neural network training. However, the values of H_{Ny} can be made available for the standard back-propagation adjustments applied for training[1]. Formally, the low-dimensional embedding of an input example o, is $\tilde{\mathbf{x}} = \mathbf{c}\, H_{Ny} = \mathbf{c}\, US^{-\frac{1}{2}}$.

The resulting outcome $\tilde{\mathbf{x}}$ is the input to one or more non-linear *hidden* layers. Each t-th hidden layer is realized through a matrix $H_t \in \mathbb{R}^{h_{t-1} \times h_t}$ and a bias vector $\mathbf{b}_t \in \mathbb{R}^{1 \times h_t}$, whereas h_t denotes

[1] In our preliminary experiments, adjustments to the H_{Ny} matrix have been tested, but no significant effect was observed. Therefore, no adjustment has been used in any reported experiment, although more in depth exploration is needed on this aspect.

the desired hidden layer dimensionality. Clearly, given that $H_{Ny} \in \mathbb{R}^{l \times l}$, $h_0 = l$. The first hidden layer in fact receives in input $\tilde{\mathbf{x}} = \mathbf{c}H_{Ny}$, that corresponds to $t = 0$ layer input $\mathbf{x}_0 = \tilde{\mathbf{x}}$ and its computation is formally expressed by $\mathbf{x}_1 = f(\mathbf{x}_0 H_1 + \mathbf{b}_1)$, where f is a non-linear activation function. In general, the generic t-th layer is modeled as:

$$\mathbf{x}_t = f(\mathbf{x}_{t-1} H_t + \mathbf{b}_t) \quad (5)$$

The final layer of KDA is the *classification layer*, realized through the output matrix H_O and the output bias vector $\mathbf{b}_O$. Their dimensionality depends on the dimensionality of the last hidden layer (called O_{-1}) and the number $|Y|$ of different classes, i.e., $H_O \in \mathbb{R}^{h_{O_{-1}} \times |Y|}$ and $\mathbf{b}_O \in \mathbb{R}^{1 \times |Y|}$, respectively. In particular, this layer computes a linear classification function with a softmax operator so that $\hat{y} = softmax(\mathbf{x}_{O_{-1}} H_O + \mathbf{b}_O)$.

In order to avoid over-fitting, two different regularization schemes are applied. First, the dropout is applied to the input $\mathbf{x}_t$ of each hidden layer ($t \geq 1$) and to the input $\mathbf{x}_{O_{-1}}$ of the final classifier. Second, a L_2 regularization is applied to the norm of each layer[2] H_t and H_O.

Finally, the KDA is trained by optimizing a loss function made of the sum of two factors: first, the cross-entropy function between the gold classes and the predicted ones; second the L_2 regularization, whose importance is regulated by a meta-parameter λ. The final loss function is thus

$$L(y, \hat{y}) = \sum_{(o,y) \in \mathcal{L}} y \, log(\hat{y}) + \lambda \sum_{H \in \{H_t\} \cup \{H_O\}} ||H||^2$$

where $\hat{y}$ are the softmax values computed by the network and y are the true one-hot encoding values associated with the example from the labeled training dataset $\mathcal{L}$.

4 Empirical Investigation

The proposed KDA has been applied adopting the same architecture but with different kernels to three NLP tasks, i.e., Question Classification, Community Question Answering, and Automatic Boundary Detection in Semantic Role Labeling. The Nyström projector has been implemented in the KeLP framework[3]. The neural network has been implemented in Tensorflow[4], with 2 hidden layers whose dimensionality corresponds to the number of involved Nyström landmarks. The *rectified linear unit* is the non-linear activation function in each layer. The dropout has been applied in each hidden layer and in the final classification layer. The values of the dropout parameter and the λ parameter of the L_2-regularization have been selected from a set of values via grid-search. The Adam optimizer with a learning rate of 0.001 has been applied to minimize the loss function, with a multi-epoch (500) training, each fed with batches of size 256. We adopted an early stop strategy, where the best model was selected according to the performance over the development set. Every performance measure is obtained against a specific sampling of the Nyström landmarks. Results averaged against 5 such samplings are always hereafter reported.

4.1 Question Classification

Question Classification (QC) is the task of mapping a question into a closed set of answer types in a Question Answering system. We used the UIUC dataset (Li and Roth, 2006), including a training and test set of $5,452$ and 500 questions, respectively, organized in 6 classes (like `ENTITY` or `HUMAN`). TKs resulted very effective, as shown in Croce et al. (2011); Annesi et al. (2014). In Annesi et al. (2014), QC is mapped into a One-vs-All multi-classification schema, where the CSPTK achieves state-of-the-art results of 95%: it acts directly over compositionally labeled trees without relying on any manually designed feature.

In order to proof the benefits of the KDA architecture, we generated Nyström representation of the CSPTK kernel function[5] with default parameters (i.e., $\mu = \lambda = 0.4$). The SVM formulation by Chang and Lin (2011), fed with the CSPTK (hereafter KSVM), is here adopted to determine the reachable upper bound in classification quality, i.e., a 95% of accuracy, at higher computational costs. It establishes the state-of-the-art over the UIUC dataset. The resulting model includes 3,873 support vectors: this corresponds to the number of kernel operations required to classify any input test question. The Nyström method based on a number of landmarks ranging from 100 to 1,000 is adopted for modeling input vectors in

[2] The input layer and the Nyström layer are not modified during the learning process, and they are not regularized.

[3] http://www.kelp-ml.org

[4] https://www.tensorflow.org/

[5] The lexical vectors used in the CSPTK are generated again using the Word2vec tool with a Skip-gram model.

the CSPTK kernel space. Results are reported in Table 1: computational saving refers to the percentage of avoided kernel computations with respect to the application of the KSVM to each test instance. To justify the need of the Neural Network, we compared the proposed KDA to an efficient linear SVM that is directly trained over the Nyström embeddings. This SVM implements the Dual Coordinate Descent method (Hsieh et al., 2008) and will be referred as SVM_{DCD}. We also measured the state-of-the-art Convolutional Neural Network[6] (CNN) of Kim (2014), achieving the remarkable accuracy of 93.6%. Notice that the linear classifier SVM_{DCD} operating over the approximated kernel space achieves the same classification quality of the CNN when just 1,000 landmarks are considered. KDA improves this results, achieving 94.3% accuracy even with fewer landmarks (only 600), showing the effectiveness of non-linear learning over the Nyström input. Although KSVM improves to 95%, KDA provides a saving of more than 84% kernel computations at classification time. This result is straightforward as it confirms that **linguistic information encoded in a tree is important in the analysis of questions** and can be used as a pre-training strategy. Figure 3 shows the accuracy curves according to various approximations of the kernel space, i.e., number of landmarks.

Table 1: Results in terms of Accuracy and saving in the Question Classification task

Model	#Land.	Accuracy	Saving
CNN	-	93.6%	-
KSVM	-	95.0%	0.0%
KDA (SVM_{DCD})	100	88.5% (84.1%)	97.4%
	200	92.2% (88.7%)	94.8%
	400	93.7% (91.6%)	89.7%
	600	**94.3%** (92.8%)	**84.5%**
	800	94.3% (93.0%)	79.3%
	1,000	94.2% (93.6%)	74.2%

4.2 Community Question-Answering

In the SemEval-2016 task 3, participants were asked to automatically provide good answers in a community question answering setting (Nakov et al., 2016). We focused on the subtask A: given a question and a large collection of question-comment threads created by a user community, the task consists in (re-)ranking the comments w.r.t. their utility in answering the question. Subtask A can be modeled as a binary classification problem, where instances are (question, comment) pairs. Each pair generates an example for a binary SVM, where the positive label is associated to a *good* comment and the negative label refers to *potentially useful* and *bad* comments. The classification score achieved over different (question, comment) pairs is used to sort instances and produce the final ranking over comments. The above setting results in a train and test dataset made of 20,340 and 3,270 examples, respectively. In Filice et al. (2016), a Kernel-based SVM classifier (KSVM) achieved state-of-the-art results by adopting a kernel combination that exploited (*i*) feature vectors containing linguistic similarities between the texts in a pair; (*ii*) shallow syntactic trees that encode the lexical and morpho-syntactic information shared between text pairs; (*iii*) feature vectors capturing task-specific information.

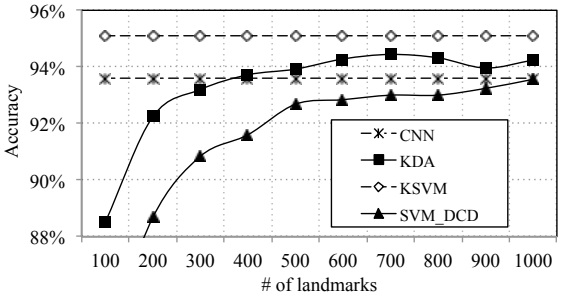

Figure 3: QC task - accuracy curves w.r.t. the number of landmarks.

Table 2: Results in terms of F_1 and savings in the Community Question Answering task

Model	#Land.	F_1	Saving
KSVM	-	0.644	0.0%
ConvKN	-	0.662	-
KDA (SVM_{DCD})	100	0.638 (0.596)	99.1%
	200	0.635 (0.627)	98.2%
	400	0.657 (0.637)	96.5%
	600	0.669 (0.645)	94.7%
	800	**0.680** (0.653)	**92.9%**
	1,000	0.674 (0.644)	91.2%

Such model includes 11,322 support vectors. We investigated the KDA architecture, trained by maximizing the F_1 measure, based on a Nyström layer initialized using the same kernel functions as KSVM. We varied the Nyström dimensions from 100 to 1,000 landmarks, i.e., a much lower number than the support vectors of KSVM.

Table 2 reports the results: very high F_1 scores

[6]The deep architecture presented in Kim (2014) outperforms several NN models, including the Recursive Neural Tensor Network or Tree-LSTM presented in (Socher et al., 2013; Tai et al., 2015) which presents a semantic compositionality model that exploits parse trees.

are observed with impressive savings in terms of kernel computations (between 91.2% and 99%). Also on the cQA task, the F_1 obtained by the SVM_{DCD} is significantly lower than the KDA one. Moreover, with 800 landmarks KDA achieves the remarkable results of 0.68 of F_1, that is the state-of-the-art against other convolutional systems, e.g., ConvKN (Barrón-Cedeño et al., 2016): this latter combines convolutional tree kernels with kernels operating on sentence embeddings generated by a convolutional neural network.

4.3 Argument Boundary Detection

Semantic Role Labeling (SRL) consists of the detection of the semantic arguments associated with the predicate of a sentence (called Lexical Unit) and their classification into their specific roles (Fillmore, 1985). For example, given the sentence "*Bootleggers then copy the film onto hundreds of tapes*" the task would be to recognize the verb *copy* as representing the DUPLICATION frame with roles, CREATOR for *Bootleggers*, ORIGINAL for *the film* and GOAL for *hundreds of tapes*.

Argument Boundary Detection (ABD) corresponds to the SRL subtask of detecting the sentence fragments spanning individual roles. In the previous example the phrase "*the film*" represents a role (i.e., ORIGINAL), while "*of tapes*" or "*film onto hundreds*" do not, as they just partially cover one or multiple roles, respectively. The ABD task has been successfully tackled using TKs since Moschitti et al. (2008). It can be modeled as a binary classification task over each parse tree node n, where the argument span reflects words covered by the sub-tree rooted at n. In our experiments, Grammatical Relation Centered Tree (GRCT) derived from dependency grammar (Fig. 4) are employed, as shown in Fig. 5. Each node is considered as a candidate in covering a possible *argument*. In particular, the structure in Fig. 5a is a positive example. On the contrary, in Fig. 5b the NMOD node only covers the phrase "*of tapes*", i.e., a subset of the correct role, and it represents a negative example[7].

We selected all the sentences whose predicate word (lexical unit) is a verb (they are about

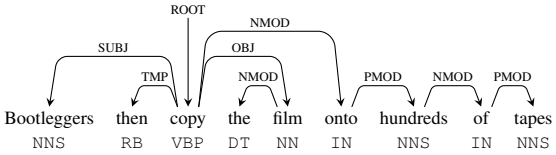

Figure 4: Example of dependency parse tree

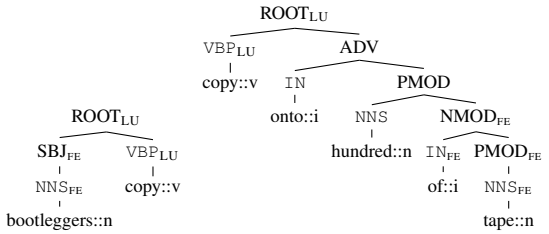

Figure 5: Conversion from dependency graph to GRCT. Tree in Fig. 5a is a positive example, while in Fig. 5b a negative one.

60,000), from the 1.3 version of the Framenet dataset (Baker et al., 1998). This gives rise to about 1,400,000 sub-trees, i.e., the positive and negative instances. The dataset is split in train and test according to the 90/10 proportion (as in (Johansson and Nugues, 2008)). This size makes the application of a traditional kernel-based method unfeasible, unless a significant instance sub-sampling is performed.

We firstly experimented standard SVM learning over a sampled training set of 10,000 examples, a typical size for annotated datasets in computational linguistics tasks. We adopted the Smoothed Partial Tree Kernel (Croce et al., 2011) with standard parameters (i.e., $\mu = \lambda = 0.4$) and lexical nodes expressed through 250-dimensional vectors obtained by applying Word2Vec (Mikolov et al., 2013) to the entire Wikipedia. When trained over this 10k instances dataset, the kernel-based SVM (KSVM) achieves an F_1 of 70.2%, over the same test set used in Croce and Basili (2016) that includes 146,399 examples. The KSVM learning produces a model including $2,994$ support vectors, i.e., the number of kernel operations required to classify each new test instance. We then apply the Nyström linearization to a larger dataset made of 100k examples, and trained a classifier using both the Dual Coordinate Descent method (Hsieh et al., 2008), SVM_{DCD}, and the KDA proposed in this work. Table 3 presents the results in terms of F_1 and saved kernel operation. Although SVM_{DCD} with 500 landmarks already achieves 0.713 F_1, a score higher than KSVM, it is signif-

[7]The nodes of the subtree covering the words to be verified as possible argument are marked with a FE tag. The word evoking the frame and its ancestor nodes are also marked with the LU tag. The other nodes are pruned out, except the ones connecting the LU nodes to the FE ones.

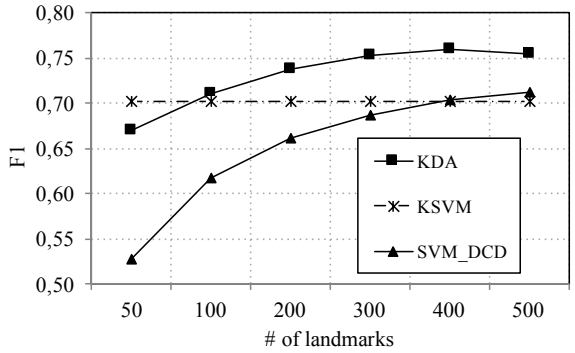

Figure 6: ABD task: F_1 measure curves w.r.t. the number of landmarks.

icantly improved by the KDA. KDA achieves up to 0.76 F_1 with only 400 landmarks, resulting in a huge step forward w.r.t. the KSVM. This result is straightforward considering (*i*) the reduction of required kernel operations, i.e., more than 86% are saved and (*ii*) the quality achieved since 100 landmarks (i.e., 0.711, higher than the KSVM).

Table 3: Results in terms of F_1 and saving in the Argument Boundary Detection task.

Model	Land.	Tr.Size	F_1	Saving
KSVM	-	10k	0.702	0.0%
KDA (SVM_{DCD})	100	100k	0.711 (0.618)	96.7%
	200	100k	0.737 (0.661)	93.3%
	300	100k	0.753 (0.686)	90.0%
	400	100k	**0.760** (0.704)	**86.6%**
	500	100k	0.754 (0.713)	83.3%

5 Discussion and Conclusions

In this work, we promoted a methodology to embed structured linguistic information within NNs, according to mathematically rich semantic similarity models, based on kernel functions. Structured data, such as trees, are transformed into dense vectors according to the Nyström methodology, and the NN is effective in capturing non-linearities in these representations, but still improving generalization at a reasonable complexity.

At the best our knowledge, this work is one of the few attempts to systematically integrate linguistic kernels within a deep neural network architecture. The problem of combining such methodologies has been studied in specific works, such as (Baldi et al., 2011; Cho and Saul, 2009; Yu et al., 2009). In Baldi et al. (2011) the authors propose a hybrid classifier, for bridging kernel methods and neural networks. In particular, they use the output of a kernelized k-nearest neighbors algorithm as input to a neural network. Cho and Saul (2009) introduced a family of kernel functions that mimic the computation of large multilayer neural networks. However, such kernels can be applied only on vector inputs. In Yu et al. (2009), deep neural networks for rapid visual recognition are trained with a novel regularization method taking advantage of kernels as an oracle representing prior knowledge. The authors transform the kernel regularizer into a loss function and carry out the neural network training by gradient descent. In Zhuang et al. (2011) a different approach has been promoted: a multiple (two) layer architecture of kernel functions, inspired by neural networks, is studied to find the best kernel combination in a Multiple Kernel Learning setting. In Mairal et al. (2014) the invariance properties of convolutional neural networks (LeCun et al., 1998) are modeled through kernel functions, resulting in a Convolutional Kernel Network. Other effort for combining NNs and kernel methods is described in Tymoshenko et al. (2016), where a SVM adopts a tree kernels combinations with embeddings learned through a CNN.

The approach here discussed departs from previous approaches in different aspects. First, a general framework is promoted: it is largely applicable to any complex kernel, e.g., structural kernels or combinations of them. The efficiency of the Nyström methodology encourages its adoption, especially when complex kernel computations are required. Notice that other low-dimensional approximations of kernel functions have been studied, as for example the randomized feature mappings proposed in Rahimi and Recht (2008). However, these assume that (*i*) instances have vectorial form and (*ii*) shift-invariant kernels are adopted. The Nyström method adopted here does not suffer of such limitations: as our target is the application to structured (linguistic) data, more general kernels, i.e., non-shift-invariant convolution kernels are needed.

Given the Nyström approximation, the learning setting corresponds to a general well-known neural network architecture, i.e., a multilayer perceptron, and does not require any manual feature engineering or the design of ad-hoc network architectures. The success in three different tasks confirms its large applicability without major changes or adaptations. Second, we propose a novel learning strategy, as the capability of kernel methods to represent complex search spaces is combined with the ability of neural networks to find non-linear so-

lutions to complex tasks. Last, the suggested KDA framework is *fully scalable*, as (*i*) the network can be parallelized on multiple machines, and (*ii*) the computation of the Nyström reconstruction vector $\mathbf{c}$ can be easily parallelized on multiple processing units, ideally l, as each unit can compute one c_i value. Future work will address experimentations with larger scale datasets; moreover, it is interesting to experiment with more landmarks in order to better understand the trade-off between the representation capacity of the Nyström approximation of the kernel functions and the over-fitting that can be introduced in a neural network architecture. Finally, the optimization of the KDA methodology through the suitable parallelization on multicore architectures, as well as the exploration of mechanisms for the dynamic reconstruction of kernel spaces (e.g., operating over H_{Ny}) also constitute interesting future research directions on this topic.

Abstract

Language models are typically applied at the sentence level, without access to the broader document context. We present a neural language model that incorporates document context in the form of a topic model-like architecture, thus providing a succinct representation of the broader document context outside of the current sentence. Experiments over a range of datasets demonstrate that our model outperforms a pure sentence-based model in terms of language model perplexity, and leads to topics that are potentially more coherent than those produced by a standard LDA topic model. Our model also has the ability to generate related sentences for a topic, providing another way to interpret topics.

1 Introduction

Topic models provide a powerful tool for extracting the macro-level content structure of a document collection in the form of the latent topics (usually in the form of multinomial distributions over terms), with a plethora of applications in NLP (Hall et al., 2008; Newman et al., 2010a; Wang and McCallum, 2006). A myriad of variants of the classical LDA method (Blei et al., 2003) have been proposed, including recent work on neural topic models (Cao et al., 2015; Wan et al., 2012; Larochelle and Lauly, 2012; Hinton and Salakhutdinov, 2009).

Separately, language models have long been a foundational component of any NLP task involving generation or textual normalisation of a noisy input (including speech, OCR and the processing of social media text). The primary purpose of a language model is to predict the probability of a span of text, traditionally at the sentence level, under the assumption that sentences are independent of one another, although recent work has started using broader local context such as the preceding sentences (Wang and Cho, 2016; Ji et al., 2016).

In this paper, we combine the benefits of a topic model and language model in proposing a topically-driven language model, whereby we jointly learn topics and word sequence information. This allows us to both sensitise the predictions of the language model to the larger document narrative using topics, and to generate topics which are better sensitised to local context and are hence more coherent and interpretable.

Our model has two components: a language model and a topic model. We implement both components using neural networks, and train them jointly by treating each component as a sub-task in a multi-task learning setting. We show that our model is superior to other language models that leverage additional context, and that the generated topics are potentially more coherent than LDA topics. The architecture of the model provides an extra dimensionality of topic interpretability, in supporting the generation of sentences from a topic (or mix of topics). It is also highly flexible, in its ability to be supervised and incorporate side information, which we show to further improve language model performance. An open source implementation of our model is available at: https://github.com/jhlau/topically-driven-language-model.

2 Related Work

Griffiths et al. (2004) propose a model that learns topics and word dependencies using a Bayesian framework. Word generation is driven by either LDA or an HMM. For LDA, a word is generated based on a sampled topic in the document. For the

https://doi.org/10.18653/v1/P17-1033

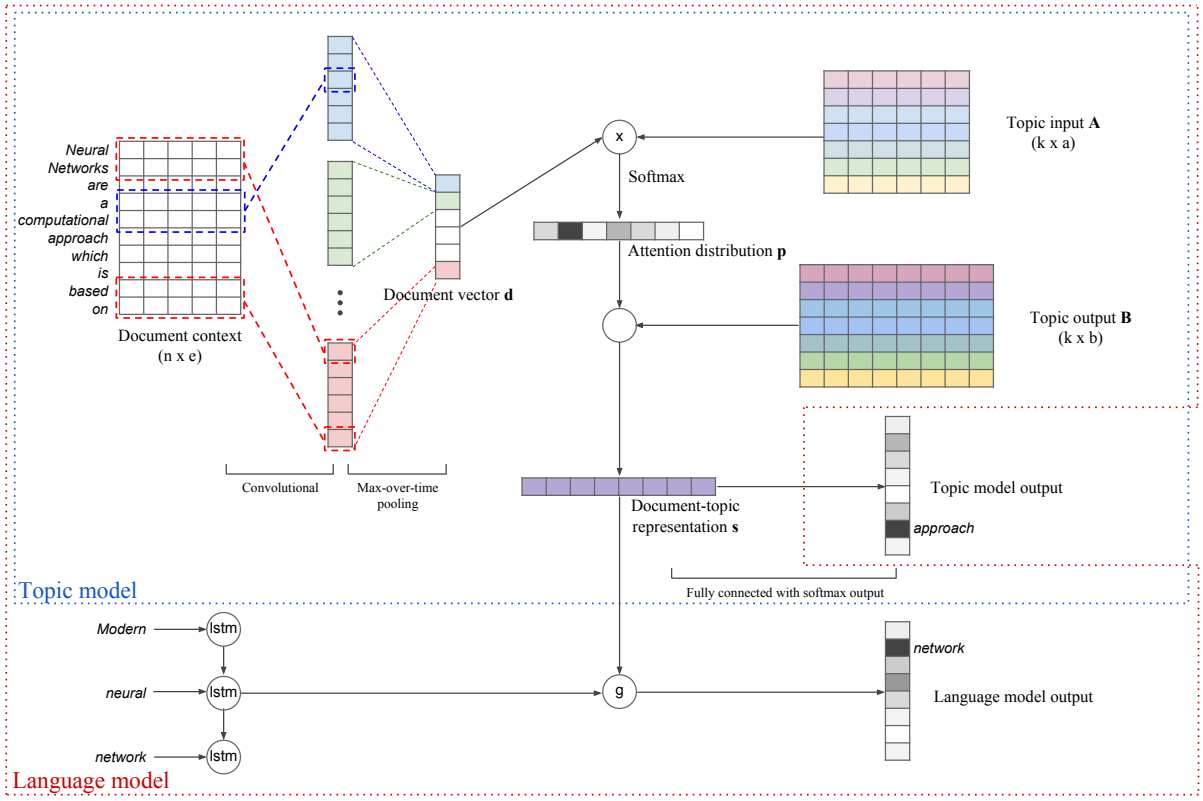

Figure 1: Architecture of `tdlm`. Scope of the models are denoted by dotted lines: blue line denotes the scope of the topic model, red the language model.

HMM, a word is conditioned on previous words. A key difference over our model is that their language model is driven by an HMM, which uses a fixed window and is therefore unable to track long-range dependencies.

Cao et al. (2015) relate the topic model view of documents and words — documents having a multinomial distribution over topics and topics having a multinomial distributional over words — from a neural network perspective by embedding these relationships in differentiable functions. With that, the model lost the stochasticity and Bayesian inference of LDA but gained non-linear complex representations. The authors further propose extensions to the model to do supervised learning where document labels are given.

Wang and Cho (2016) and Ji et al. (2016) relax the sentence independence assumption in language modelling, and use preceeding sentences as additional context. By treating words in preceeding sentences as a bag of words, Wang and Cho (2016) use an attentional mechanism to focus on these words when predicting the next word. The authors show that the incorporation of additional context helps language models.

3 Architecture

The architecture of the proposed topically-driven language model (henceforth "`tdlm`") is illustrated in Figure 1. There are two components in `tdlm`: a language model and a topic model. The language model is designed to capture word relations in sentences, while the topic model learns topical information in documents. The topic model works like an auto-encoder, where it is given the document words as input and optimised to predict them.

The topic model takes in word embeddings of a document and generates a document vector using a convolutional network. Given the document vector, we associate it with the topics via an attention scheme to compute a weighted mean of topic vectors, which is then used to predict a word in the document.

The language model is a standard LSTM language model (Hochreiter and Schmidhuber, 1997; Mikolov et al., 2010), but it incorporates the weighted topic vector generated by the topic model to predict succeeding words.

Marrying the language and topic models allows the language model to be topically driven, i.e. it models not just word contexts but also the document context where the sentence occurs, in the form of topics.

3.1 Topic Model Component

Let $\mathbf{x}_i \in \mathbb{R}^e$ be the e-dimensional word vector for the i-th word in the document. A document of n words is represented as a concatenation of its word vectors:

$$\mathbf{x}_{1:n} = \mathbf{x}_1 \oplus \mathbf{x}_2 \oplus ... \oplus \mathbf{x}_n$$

where $\oplus$ denotes the concatenation operator. We use a number of convolutional filters to process the word vectors, but for clarity we will explain the network with one filter.

Let $\mathbf{w}_v \in \mathbb{R}^{eh}$ be a convolutional filter which we apply to a window of h words to generate a feature. A feature c_i for a window of words $\mathbf{x}_{i:i+h-1}$ is given as follows:

$$c_i = I(\mathbf{w}_v^\intercal \mathbf{x}_{i:i+h-1} + b_v)$$

where b_v is a bias term and I is the identity function.[1] A feature map $\mathbf{c}$ is a collection of features computed from all windows of words:

$$\mathbf{c} = [c_1, c_2, ..., c_{n-h+1}]$$

where $\mathbf{c} \in \mathbb{R}^{n-h+1}$. To capture the most salient features in $\mathbf{c}$, we apply a max-over-time pooling operation (Collobert et al., 2011), yielding a scalar:

$$d = \max_i c_i$$

In the case where we use a filters, we have $\mathbf{d} \in \mathbb{R}^a$, and this constitutes the vector representation of the document generated by the convolutional and max-over-time pooling network.

The topic vectors are stored in two lookup tables $\mathbf{A} \in \mathbb{R}^{k \times a}$ (input vector) and $\mathbf{B} \in \mathbb{R}^{k \times b}$ (output vector), where k is the number of topics, and a and b are the dimensions of the topic vectors.

To align the document vector $\mathbf{d}$ with the topics, we compute an attention vector which is used to compute a document-topic representation:[2]

$$\mathbf{p} = \text{softmax}(\mathbf{A}\mathbf{d}) \quad (1)$$

$$\mathbf{s} = \mathbf{B}^\intercal \mathbf{p} \quad (2)$$

where $\mathbf{p} \in \mathbb{R}^k$ and $\mathbf{s} \in \mathbb{R}^b$. Intuitively, $\mathbf{s}$ is a weighted mean of topic vectors, with the weighting given by the attention $\mathbf{p}$. This is inspired by the generative process of LDA, whereby documents are defined as having a multinomial distribution over topics.

Finally $\mathbf{s}$ is connected to a dense layer with softmax output to predict each word in the document, where each word is generated independently as a unigram bag-of-words, and the model is optimised using categorical cross-entropy loss. In practice, to improve efficiency we compute loss for predicting a sequence of m_1 words in the document, where m_1 is a hyper-parameter.

3.2 Language Model Component

The language model is implemented using LSTM units (Hochreiter and Schmidhuber, 1997):

$$\begin{aligned}
\mathbf{i}_t &= \sigma(\mathbf{W}_i \mathbf{v}_t + \mathbf{U}_i \mathbf{h}_{t-1} + \mathbf{b}_i) \\
\mathbf{f}_t &= \sigma(\mathbf{W}_f \mathbf{v}_t + \mathbf{U}_f \mathbf{h}_{t-1} + \mathbf{b}_f) \\
\mathbf{o}_t &= \sigma(\mathbf{W}_o \mathbf{v}_t + \mathbf{U}_o \mathbf{h}_{t-1} + \mathbf{b}_i) \\
\hat{\mathbf{c}}_t &= \tanh(\mathbf{W}_c \mathbf{v}_t + \mathbf{U}_c \mathbf{h}_{t-1} + \mathbf{b}_c) \\
\mathbf{c}_t &= \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot \hat{\mathbf{c}}_t \\
\mathbf{h}_t &= \mathbf{o}_t \odot \tanh(\mathbf{c}_t)
\end{aligned}$$

where $\odot$ denotes element-wise product; $\mathbf{i}_t$, $\mathbf{f}_t$, $\mathbf{o}_t$ are the input, forget and output activations respectively at time step t; and $\mathbf{v}_t$, $\mathbf{h}_t$ and $\mathbf{c}_t$ are the input word embedding, LSTM hidden state, and cell state, respectively. Hereinafter $\mathbf{W}$, $\mathbf{U}$ and $\mathbf{b}$ are used to refer to the model parameters.

Traditionally, a language model operates at the sentence level, predicting the next word given its history of words in the sentence. The language model of `tdlm` incorporates topical information by assimilating the document-topic representation ($\mathbf{s}$) with the hidden output of the LSTM ($\mathbf{h}_t$) at each time step t. To prevent `tdlm` from memorising the next word via the topic model network, we exclude the current sentence from the document context.

[1] A non-linear function is typically used here, but preliminary experiments suggest that the identity function works best for `tdlm`.

[2] The attention mechanism was inspired by memory networks (Graves et al., 2014; Weston et al., 2014; Sukhbaatar et al., 2015; Tran et al., 2016). We explored various attention styles (including traditional schemes which use one vector for a topic), but found this approach to work best.

We use a gating unit similar to a GRU (Cho et al., 2014; Chung et al., 2014) to allow tdlm to learn the degree of influence of topical information on the language model:

$$\begin{aligned}\mathbf{z}_t &= \sigma(\mathbf{W}_z\mathbf{s} + \mathbf{U}_z\mathbf{h}_t + \mathbf{b}_z)\\ \mathbf{r}_t &= \sigma(\mathbf{W}_r\mathbf{s} + \mathbf{U}_r\mathbf{h}_t + \mathbf{b}_r)\\ \hat{\mathbf{h}}_t &= \tanh(\mathbf{W}_h\mathbf{s} + \mathbf{U}_h(\mathbf{r}_t \odot \mathbf{h}_t) + \mathbf{b}_h)\\ \mathbf{h}'_t &= (1 - \mathbf{z}_t) \odot \mathbf{h}_t + \mathbf{z}_t \odot \hat{\mathbf{h}}_t\end{aligned} \quad (3)$$

where $\mathbf{z}_t$ and $\mathbf{r}_t$ are the update and reset gate activations respectively at timestep t. The new hidden state $\mathbf{h}'_t$ is connected to a dense layer with linear transformation and softmax output to predict the next word, and the model is optimised using standard categorical cross-entropy loss.

3.3 Training and Regularisation

tdlm is trained using minibatches and SGD.[3] For the language model, a minibatch consists of a batch of sentences, while for the topic model it is a batch of documents (each predicting a sequence of m_1 words).

We treat the language and topic models as subtasks in a multi-task learning setting, and train them jointly using categorical cross-entropy loss. Most parameters in the topic model are shared by the language model, as illustrated by their scopes (dotted lines) in Figure 1.

Hyper-parameters of tdlm are detailed in Table 1. Word embeddings for the topic model and language model components are not shared, although their dimensions are the same (e).[4] For m_1, m_2 and m_3, sequences/documents shorter than these thresholds are padded. Sentences longer than m_2 are broken into multiple sequences, and documents longer than m_3 are truncated. Optimal hyper-parameter settings are tuned using the development set; the presented values are used for experiments in Sections 4 and 5.

To regularise tdlm, we use dropout regularisation (Srivastava et al., 2014). We apply dropout to $\mathbf{d}$ and $\mathbf{s}$ in the topic model, and to the input word embedding and hidden output of the LSTM in the language model (Pham et al., 2013; Zaremba et al., 2014).

4 Language Model Evaluation

We use standard language model perplexity as the evaluation metric. In terms of dataset, we use document collections from 3 sources: APNEWS, IMDB and BNC. APNEWS is a collection of Associated Press[5] news articles from 2009 to 2016. IMDB is a set of movie reviews collected by Maas et al. (2011). BNC is the written portion of the British National Corpus (BNC Consortium, 2007), which contains excerpts from journals, books, letters, essays, memoranda, news and other types of text. For APNEWS and BNC, we randomly sub-sample a set of documents for our experiments.

For preprocessing, we tokenise words and sentences using Stanford CoreNLP (Klein and Manning, 2003). We lowercase all word tokens, filter word types that occur less than 10 times, and exclude the top 0.1% most frequent word types.[6] We additionally remove stopwords for the topic model document context.[7] All datasets are partitioned into training, development and test sets; preprocessed dataset statistics are presented in Table 2.

We tune hyper-parameters of tdlm based on development set language model perplexity. In general, we find that optimal settings are fairly robust across collections, with the exception of m_3, as document length is collection dependent; optimal hyper-parameter values are given in Table 1. In terms of LSTM size, we explore 2 settings: a small model with 1 LSTM layer and 600 hidden units, and a large model with 2 layers and 900 hidden units.[8] For the topic number, we experiment with 50, 100 and 150 topics. Word embeddings are pre-trained 300-dimension word2vec Google News vectors.[9]

For comparison, we compare tdlm with:[10]

vanilla-lstm: A standard LSTM language model, using the same tdlm hyper-parameters where applicable. This is the baseline model.

lclm: A larger context language model that incorporates context from preceding sentences (Wang and Cho, 2016), by treating the preceding sentence as a bag of words, and using an

[3] We use Adam as the optimiser (Kingma and Ba, 2014).

[4] Word embeddings are updated during training.

[5] https://www.ap.org/en-gb/.

[6] For the topic model, we remove word tokens that correspond to these filtered word types; for the language model we represent them as ⟨unk⟩ tokens (as for unseen words in test).

[7] We use Mallet's stopword list: https://github.com/mimno/Mallet/tree/master/stoplists.

[8] Multi-layer LSTMs are vanilla stacked LSTMs without skip connections (Gers and Schmidhuber, 2000) or depth-gating (Yao et al., 2015).

[9] https://code.google.com/archive/p/word2vec/.

[10] Note that all models use the same pre-trained word2vec vectors.

Hyper-parameter	Value	Description
m_1	3	Output sequence length for topic model
m_2	30	Sequence length for language model
m_3	300,150,500	Maximum document length
n_{batch}	64	Minibatch size
n_{layer}	1,2	Number of LSTM layers
n_{hidden}	600,900	LSTM hidden size
n_{epoch}	10	Number of training epochs
k	100,150,200	Number of topics
e	300	Word embedding size
h	2	Convolutional filter width
a	20	Topic input vector size or number of features for convolutional filter
b	50	Topic output vector size
l	0.001	Learning rate of optimiser
p_1	0.4	Topic model dropout keep probability
p_2	0.6	Language model dropout keep probability

Table 1: `tdlm` hyper-parameters; we experiment with 2 LSTM settings and 3 topic numbers, and m_3 varies across the three domains (APNEWS, IMDB, and BNC).

Collection	Training		Development		Test	
	#Docs	#Tokens	#Docs	#Tokens	#Docs	#Tokens
APNEWS	50K	15M	2K	0.6M	2K	0.6M
IMDB	75K	20M	12.5K	0.3M	12.5K	0.3M
BNC	15K	18M	1K	1M	1K	1M

Table 2: Preprocessed dataset statistics.

attentional mechanism when predicting the next word. An additional hyper-parameter in `lclm` is the number of preceeding sentences to incorporate, which we tune based on a development set (to 4 sentences in each case). All other hyper-parameters (such as n_{batch}, e, n_{epoch}, k_2) are the same as `tdlm`.

`lstm+lda`: A standard LSTM language model that incorporates LDA topic information. We first train an LDA model (Blei et al., 2003; Griffiths and Steyvers, 2004) to learn 50/100/150 topics for APNEWS, IMDB and BNC.[11] For a document, the LSTM incorporates the LDA topic distribution ($\mathbf{q}$) by concatenating it with the output hidden state ($\mathbf{h}_t$) to predict the next word (i.e. $\mathbf{h}'_t = \mathbf{h}_t \oplus \mathbf{q}$). That is, it incorporates topical information into the language model, but unlike `tdlm` the language model and topic model are trained separately.

We present language model perplexity performance in Table 3. All models outperform the baseline `vanilla-lstm`, with `tdlm` performing the best across all collections. `lclm` is competitive over the BNC, although the superiority of `tdlm` for the other collections is substantial. `lstm+lda` performs relatively well over APNEWS and IMDB, but very poorly over BNC.

The strong performance of `tdlm` over `lclm` suggests that compressing document context into topics benefits language modelling more than using extra context words directly.[12] Overall, our results show that topical information can help language modelling and that joint inference of topic and language model produces the best results.

5 Topic Model Evaluation

We saw that `tdlm` performs well as a language model, but it is also a topic model, and like LDA it produces: (1) a probability distribution over topics for each document (Equation (1)); and (2) a probability distribution over word types for each topic.

[11] Based on Gibbs sampling; $\alpha = 0.1$, $\beta = 0.01$.

[12] The context size of `lclm` (4 sentences) is technically smaller than `tdlm` (full document), however, note that increasing the context size does not benefit `lclm`, as the context size of 4 gives the best performance.

Domain	LSTM Size	vanilla-lstm	lclm	lstm+lda			tdlm		
				50	100	150	50	100	150

(a) APNEWS (b) IMDB (c) BNC

Figure 2: Boxplots of topic coherence of all models; number of topics = 100.

Recall that $\mathbf{s}$ is a weighted mean of topic vectors for a document (Equation (2)). Generating the vocabulary distribution for a particular topic is therefore trivial: we can do so by treating $\mathbf{s}$ as having maximum weight (1.0) for the topic of interest, and no weight (0.0) for all other topics. Let $\mathbf{B}_t$ denote the topic output vector for the t-th topic. To generate the multinomial distribution over word types for the t-th topic, we replace $\mathbf{s}$ with $\mathbf{B}_t$ before computing the softmax over the vocabulary.

Topic models are traditionally evaluated using model perplexity. There are various ways to estimate test perplexity (Wallach et al., 2009), but Chang et al. (2009) show that perplexity does not correlate with the coherence of the generated topics. Newman et al. (2010b); Mimno et al. (2011); Aletras and Stevenson (2013) propose automatic approaches to computing topic coherence, and Lau et al. (2014) summarises these methods to understand their differences. We propose using automatic topic coherence as a means to evaluate the topic model aspect of `tdlm`.

Following Lau et al. (2014), we compute topic coherence using normalised PMI ("NPMI") scores. Given the top-n words of a topic, coherence is computed based on the sum of pairwise NPMI scores between topic words, where the word probabilities used in the NPMI calculation are based on co-occurrence statistics mined from English Wikipedia with a sliding window (Newman et al., 2010b; Lau et al., 2014).[13]

Based on the findings of Lau and Baldwin (2016), we average topic coherence over the top-5/10/15/20 topic words. To aggregate topic coherence scores for a model, we calculate the mean coherence over topics.

In terms of datasets, we use the same document collections (APNEWS, IMDB and BNC) as the language model experiments (Section 4). We use the same hyper-parameter settings for `tdlm` and do not tune them.

For comparison, we use the following topic models:

`lda`: We use a LDA model as a baseline topic model. We use the same LDA models as were used to learn topic distributions for `lstm+lda` (Section 4).

[13] We use this toolkit to compute topic coherence: https://github.com/jhlau/topic_interpretability.

	tdlm-large	.145	.091	.104

Table 4: Mean topic coherence of all models over APNEWS, IMDB and BNC. Boldface indicates the best performance for each dataset and topic setting.

ntm: ntm is a neural topic model proposed by Cao et al. (2015). The document-topic and topic-word multinomials are expressed from a neural network perspective using differentiable functions. Model hyper-parameters are tuned using development loss.

Topic model performance is presented in Table 4. There are two models of tdlm (tdlm-small and tdlm-large), which specify the size of its LSTM model (1 layer+600 hidden vs. 2 layers+900 hidden; see Section 4). tdlm achieves encouraging results: it has the best performance over APNEWS, and is competitive over IMDB. lda, however, produces more coherent topics over BNC. Interestingly, coherence appears to increase as the topic number increases for lda, but the trend is less pronounced for tdlm. ntm performs the worst of the 3 topic models, and manual inspection reveals that topics are in general not very interpretable. Overall, the results suggest that tdlm topics are competitive: at best they are more coherent than lda topics, and at worst they are as good as lda topics.

To better understand the spread of coherence scores and impact of outliers, we present box plots for all models (number of topics = 100) over the 3 domains in Figure 2. Across all domains, ntm has poor performance and larger spread of scores. The difference between lda and tdlm is small (tdlm > lda in APNEWS, but lda < tdlm in BNC), which is consistent with our previous observation that tdlm topics are competitive with lda topics.

Table 5: 20NEWS preprocessed statistics.

6 Extensions

One strength of tdlm is its flexibility, owing to it taking the form of a neural network. To showcase this flexibility, we explore two simple extensions of tdlm, where we: (1) build a supervised model using document labels (Section 6.1); and (2) incorporate additional document metadata (Section 6.2).

6.1 Supervised Model

In datasets where document labels are known, supervised topic model extensions are designed to leverage the additional information to improve modelling quality. The supervised setting also has an additional advantage in that model evaluation is simpler, since models can be quantitatively assessed via classification accuracy.

To incorporate supervised document labels, we treat document classification as another sub-task in tdlm. Given a document and its label, we feed the document through the topic model network to generate the document-topic representation $\mathbf{s}$, and connect it to another dense layer with softmax output to generate the probability distribution over classes.

During training, we have additional minibatches for the documents. We start the document classification training after the topic and language models have completed training in each epoch.

We use 20NEWS in this experiment, which is a popular dataset for text classification. 20NEWS is a collection of forum-like messages from 20 newsgroups categories. We use the "bydate" version of the dataset, where the train and test partition is separated by a specific date. We sample 2K documents from the training set to create the development set. For preprocessing we tokenise words and sentence using Stanford CoreNLP (Klein and Manning, 2003), and lowercase all words. As with previous experiments (Section 4) we additionally filter low/high frequency word types and stopwords. Preprocessed dataset statistics are presented in Table 5.

For comparison, we use the same two topic

Topic No.	System	Accuracy
50	lda	.567
	ntm	**.649**
	tdlm	.606
100	lda	.581
	ntm	**.639**
	tdlm	.602
150	lda	.597
	ntm	**.628**
	tdlm	.601

models as in Section 5: ntm and lda. Both ntm and lda have natural supervised extensions (Cao et al., 2015; McAuliffe and Blei, 2008) for incorporating document labels. For this task, we tune the model hyper-parameters based on development accuracy.[14] Classification accuracy for all models is presented in Table 6. We present tdlm results using only the small setting of LSTM (1 layer + 600 hidden), as we found there is little gain when using a larger LSTM.

ntm performs very strongly, outperforming both lda and tdlm by a substantial margin. Comparing lda and tdlm, tdlm achieves better performance, especially when there is a smaller number of topics. Upon inspection of the topics we found that ntm topics are much less coherent than those of lda and tdlm, consistent with our observations from Section 5.

[14]Most hyper-parameter values for tdlm are similar to those used in the language and topic model experiments; the only exceptions are: $a = 80$, $b = 100$, $n_{epoch} = 20$, $m_3 = 150$. The increase in parameters is unsurprising, as the additional supervision provides more constraint to the model.

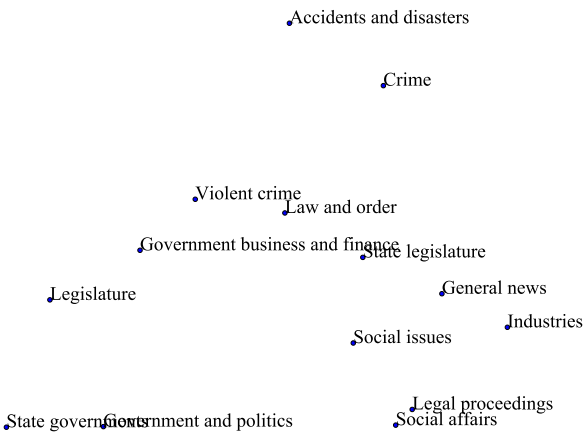

Figure 3: Scatter plots of tag embeddings (model=150 topics)

6.2 Incorporating Document Metadata

In APNEWS, each news article contains additional document metadata, including subject classification tags, such as "General News", "Accidents and Disasters", and "Military and Defense". We present an extension to incorporate document metadata in tdlm to demonstrate its flexibility in integrating this additional information.

As some of the documents in our original APNEWS sample were missing tags, we re-sampled a set of APNEWS articles of the same size as our original, all of which have tags. In total, approximately 1500 unique tags can be found among the training articles.

To incorporate these tags, we represent each of them as a learnable vector and concatenate it with the document vector before computing the attention distribution. Let $\mathbf{z}_i \in \mathbb{R}^f$ denote the f-dimension vector for the i-th tag. For the j-th document, we sum up all tags associated with it:

$$\mathbf{e} = \sum_{i=1}^{n_{tags}} \mathbb{I}(i,j)\mathbf{z}_i$$

where n_{tags} is the total number of unique tags, and function $\mathbb{I}(i,j)$ returns 1 is the i-th tag is in the j-th document or 0 otherwise. We compute $\mathbf{d}$ as before (Section 3.1), and concatenate it with the summed tag vector: $\mathbf{d}' = \mathbf{d} \oplus \mathbf{e}$.

We train two versions of tdlm on the new APNEWS dataset: (1) the vanilla version that ignores the tag information; and (2) the extended version which incorporates tag information.[15] We exper-

[15]Model hyper-parameters are the same as the ones used in the language (Section 4) and topic model (Section 5) experiments.

Table 8: Generated sentences for APNEWS topics.

imented with a few values for the tag vector size (f) and find that a small value works well; in the following experiments we use $f = 5$. We evaluate the models based on language model perplexity and topic model coherence, and present the results in Table 7.[16]

In terms of language model perplexity, we see a consistent improvement over different topic settings, suggesting that the incorporation of tags improves modelling. In terms of topic coherence, there is a small but encouraging improvement (with one exception).

To investigate whether the vectors learnt for these tags are meaningful, we plot the top-14 most frequent tags in Figure 3.[17] The plot seems reasonable: there are a few related tags that are close to each other, e.g. "State government" and "Government and politics"; "Crime" and "Violent Crime"; and "Social issues" and "Social affairs".

7 Discussion

Topics generated by topic models are typically interpreted by way of their top-N highest probability words. In `tdlm`, we can additionally generate sentences related to the topic, providing another way to understand the topics. To do this, we can constrain the topic vector for the language model to be the topic output vector of a particular topic (Equation (3)).

We present 4 topics from a APNEWS model ($k = 100$; LSTM size = "large") and 3 randomly generated sentences conditioned on each topic in Table 8.[18] The generated sentences highlight the content of the topics, providing another interpretable aspect for the topics. These results also reinforce that the language model is driven by topics.

8 Conclusion

We propose `tdlm`, a topically driven neural language model. `tdlm` has two components: a language model and a topic model, which are jointly trained using a neural network. We demonstrate that `tdlm` outperforms a state-of-the-art language model that incorporates larger context, and that its topics are potentially more coherent than LDA topics. We additionally propose simple extensions of `tdlm` to incorporate information such as document labels and metadata, and achieved encouraging results.

Handling Cold-Start Problem in Review Spam Detection by Jointly Embedding Texts and Behaviors

Abstract

Solving the cold-start problem in review spam detection is an urgent and significant task. It can help the on-line review websites to relieve the damage of spammers in time, but has never been investigated by previous work. This paper proposes a novel neural network model to detect review spam for the cold-start problem, by learning to represent the new reviewers' review with jointly embedded textual and behavioral information. Experimental results prove the proposed model achieves an effective performance and possesses preferable domain-adaptability. It is also applicable to a large-scale dataset in an unsupervised way.

1 Introduction

With the rapid growth of products reviews at the web, it has become common for people to read reviews before making a purchase decision. The reviews usually contain abundant consumers' personal experiences. It has led to a significant influence on financial gains and fame for businesses. Existing studies have shown that an extra half-star rating on Yelp causes restaurants to sell out 19% points more frequently (Anderson and Magruder, 2012), and a one-star increase in Yelp rating leads to a 5-9 % increase in revenue (Luca, 2011). This, unfortunately, gives strong incentives for imposters (called spammers) to game the system. They post fake reviews or opinions (called review spam) to promote or to discredit some targeted products and services. The news from BBC has shown that around 25% of Yelp reviews could be fake.[1] Therefore, it is urgent to detect review spam, to ensure that the online review continues to be trusted.

Jindal and Liu (2008) make the first step to detect review spam. Most efforts are devoted to exploring effective linguistic and behavioral features by subsequent work to distinguish such spam from the real reviews. However, to notice such patterns or form behavioral features, developers should take a long time to observe the data, because the features are based on statistics. For instance, the feature *activity window* proposed by Mukherjee et al. (2013c) is to measure the activity freshness of reviewers. It usually takes several months to count the difference of timestamps between the last and first reviews for reviewers. When the features show themselves finally, some major damages might have already been done. Thus, *it is important to design algorithms that can detect review spam as soon as possible, ideally, right after they are posted by the new reviewers*. It is a cold-start problem which is the focus of this paper.

In this paper, we assume that we must identify fake reviews immediately when a new reviewer posts just one review. Unfortunately, it is very difficult because the available information for detecting fake reviews is very poor. Traditional behavioral features based on the statistics can only work well on users' abundant behaviors. The more behavioral information obtained, the more effective the traditional behavioral features are (see experiments in Section 3). In the scenario of cold-start, a new reviewer only has a behavior: post a review. As a result, we can not get effective behavioral features from the data. Although, the linguistic features of reviews do not need to take much time to form, Mukherjee et al. (2013c) have proved that the linguistic features are not effective enough in detecting real-life fake reviews from the commercial websites, where we also obtain the same observation (the details are shown in Section 3).

[1] http://www.bbc.com/news/technology-24299742

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 366–376
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1034

Therefore, the main difficulty of the cold-start spam problem is that there are no sufficient behaviors of the new reviewers for constructing effective behavioral features. Nevertheless, there is ample textual and behavioral information contained in the abundant reviews posted by the existing reviewers (Figure 1). We could employ behavioral information of existing similar reviewers to a new reviewer to approximate his behavioral features. We argue that a reviewer's individual characteristics such as background information, motivation, and interactive behavior style have a great influence on a reviewer's textual and behavioral information. So the textual information and the behavioral information of a reviewer are correlated with each other (similar argument in Li et al. (2016)). For example, the students of the college are likely to choose the youth hostel during summer vacation and tend to comment the room price in their reviews. But the financial analysts on a business trip may tend to choose the business hotel, the environment and service are what they care about in their reviews.

To augment the behavioral information of the new reviewers in the cold-start problem, we first try to find the textual information which is similar with that of the new reviewer, from the existing reviews. There are several ways to model the textual information of the review spam, such as Unigram (Mukherjee et al., 2013c), POS (Ott et al., 2011) and LIWC (Linguistic Inquiry and Word Count) (Newman et al., 2003). We employ the CNN (Convolutional Neural Network) to model the review text, which has been proved that it can capture complex global semantic information that is difficult to express using traditional discrete manual features (Ren and Zhang, 2016). Then we employ the behavioral information which is correlated with the found textual information to approximate the behavioral information of the new reviewer. An intuitive approach is to search the most similar existing review for the new review, then take the found reviewer's behavioral features as the new reviewers' features (detailed in Section 5.3). However, there is abundant behavioral information in the review graph (Figure 1), it is difficult for the traditional discrete manual behavioral features to record the global behavioral information (Wang et al., 2016). Moreover, the traditional features can not capture the reviewer's individual characteristics, because there is no explicit characteristic tag available in the review system (experiments in Section 5.3). So, we propose a neural network model to jointly encode the textual and behavioral information into the review embeddings for detecting the review spam in the cold-start problem. By encoding the review graph structure (Figure 1), the proposed model can record the global footprints of the existing reviewers in an unsupervised way, and further record the reviewers' latent characteristic information in the footprints. The jointly learnt review embeddings can model the correlation of the reviewers' textual and behavioral information. When a new reviewer posts a review, the proposed model can represent the review with the similar textual information and the correlated behavioral information encoded in the word embeddings. Finally, the embeddings of the new review are fed into a classifier to identify whether it is spam or not.

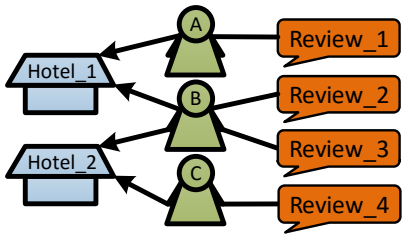

Figure 1: Part of review graph simplified from Yelp.

In summary, our major contributions include:

- To our best knowledge, this is the first work that explores the cold-start problem in review spam detection. We qualitatively and quantitatively prove that the traditional linguistic and behavioral features are not effective enough in detecting review spam for the cold-start task.
- We propose a neural network model to jointly encode the textual and behavioral information into the review embeddings for the cold-start spam detection task. It is an unsupervised distributional representation model which can learn from large scale unlabeled review data.
- Experimental results on two domains (hotel and restaurant) give good confidence that the proposed model performs effectively in the cold-start spam detection task.

2 Related Work

Jindal and Liu (2008) make the first step to detect review spam. Subsequent work devoted most

efforts to explore effective features and spammer-like clues.

Linguistic features: Ott et al. (2011) applied psychological and linguistic clues to identify review spam; Harris (2012) explored several writing style features. Syntactic stylometry for review spam detection was investigated in Feng et al. (2012a); Xu and Zhao (2012) using deep linguistic features for finding deceptive opinion spam; Li et al. (2013) studied the topics in the review spam; Li et al. (2014b) further analyzed the general difference of language usage. Fornaciari and Poesio (2014) proved the effectiveness of the N-grams in detecting deceptive Amazon book reviews. The effectiveness of the N-grams was also explored in Cagnina and Rosso (2015). Li et al. (2014a) proposed a positive-unlabeled learning method based on unigrams and bigrams; Kim et al. (2015) carried out a frame-based deep semantic analysis. Hai et al. (2016) exploited the relatedness of multiple review spam detection tasks and available unlabeled data to address the scarcity of labeled opinion spam data by using linguistic features. Besides, (Ren and Zhang, 2016) proved that the CNN model is more effective than the RNN and the traditional discrete manual linguistic features. Hovy (2016) used N-gram generative models to produce reviews and evaluated their effectiveness.

Behavioral features: Lim et al. (2010) analyzed reviewers' rating behavioral features; Jindal et al. (2010) identified unusual review patterns which can represent suspicious behaviors of reviews; Li et al. (2011) proposed a two-view semi-supervised co-training method base on behavioral features. Feng et al. (2012b) study the distributions of individual spammers' behaviors. The group spammers' behavioral features were studied in Mukherjee et al. (2012). Temporal patterns of spammers were investigated by Xie et al. (2012), Fei et al. (2013); Li et al. (2015) explored the temporal and spatial patterns. The review graph was analyzed by Wang et al. (2011), Akoglu et al. (2013); Mukherjee et al. (2013a) studied the spamicity of reviewers. Mukherjee et al. (2013c), Mukherjee et al. (2013b) proved that reviewers' behavioral features are more effective than reviews' linguistic features for detecting review spam. Based on this conclusion, recently, researchers (Rayana and Akoglu, 2015; KC and Mukherjee, 2016) have put more efforts in employing reviewers' behavioral features for detecting review spam, the intuition behind which is to capture the reviewers' actions and supposes that those reviews written with spammer-like behaviors would be spam. Wang et al. (2016) explored a method to learn the review representation with global behavioral information. Viviani and Pasi (2017) concentrated on the aggregation process with respect to each single veracity feature.

Both training and testing use balanced data (50:50).

3 Whether Traditional Features are Effective

As a new reviewer posted just one review and we have to identify it immediately, the major challenge of the cold-start task is that the available information about the new reviewer is very poor. The new reviewer only provides us with one review record. For most traditional features based on the statistics, they can not form themselves or make no sense, such as the *percentage of reviews written at weekends* (Li et al., 2015), the *entropy of rating distribution of user's review* (Rayana and Akoglu, 2015). To investigate whether traditional features are effective in the cold-start task, we conducted experiments on the Yelp dataset in Mukherjee et al. (2013c). We trained SVM models with different features on the existing reviews posted before January 1, 2012, and tested on the new reviews which just posted by the new reviewers after January 1, 2012. Results are shown in Table 1.

3.1 Linguistic Features' Poor Performance

The linguistic features need not take much time to form. But Mukherjee et al. (2013c) have proved that the linguistic features are not effective enough in detecting real-life fake reviews from the commercial websites, compared with the performances on the crowd source datasets (Ott et al., 2011). They showed that the word bigrams perform better than the other linguistic features, such as LIWC (Newman et al., 2003; Pennebaker et al., 2007), part-of-speech sequence patterns (Mukherjee and Liu, 2010), deep syntax (Feng et al., 2012a), information gain (Mukherjee et al., 2013c) and so on. So, we conduct experiments with the word bigrams feature. As shown in Table 1 (a, b) row 1, the word bigrams result in only around 55% in accuracy in both the hotel and restaurant domains. It indicates that the most effective traditional linguistic feature (i.e., the word bigrams) can't detect the review spam effectively in the cold start task.

3.2 Behavioral Features only Work Well with Abundant Information

Because there is not enough available information about the new reviewer, for most traditional behavioral features based on the statistical mechanism, they couldn't form themselves or make no sense. We investigated the previous work and found that there are three behavioral features can be applied to the cold-start task. They are proposed by Mukherjee et al. (2013b), i.e., 1.*Review length (RL)* : the length of the new review posted by the new reviewer; 2.*Reviewer deviation (RD)*: the absolute rating deviation of the new reviewer's review from other reviews on the same business; 3.*Maximum content similarity (MCS)* : the maximum content similarity (using cosine similarity) between the new reviewer's review with other reviews on the same business.

Table 1 (a, b) row 2 shows the experiment results by the combinations of the bigrams feature and the three behavioral features described above. The behavioral features make around 5% improvement in accuracy in the hotel domain (2.7% in the restaurant domain) as compared with only using bigrams. The accuracy is improved but it is just near 60% in average. It indicates that the traditional features are not effective enough with poor behavioral information. What's more, the behavioral features cause around 4.6% decrease in F1-score and around 19% decrease in Recall in both hotel and restaurant domains. It is obvious that there is more false-positive review spam caused by the behavioral features as compared to only using bigrams. It further indicates that the traditional behavioral features' discrimination for review spam gets to be weakened by the poor behavioral information.

To go a step further, we carried experiments with the three behavioral features which are formed on abundant behavioral information. When the new reviewers continue to post more reviews in after weeks, their behavioral information gets to be more. Then the review system could obtain sufficient data to extract behavior features as compared to the poor information in the cold-start period. So the behavioral features with abundant information make an obvious improvement in accuracy (6.4%) in the hotel domain (Table 1 (a) row 3) as compared with the results in Table 1 (a) row 2. But it is only 0.6% in the restaurant domain. By statistics on the datasets, we found that the new reviewers posted about 54.4 reviews in average after their first post in the hotel domain, but it is only 10 reviews in average for the new reviewers in the restaurant domain. The added behavioral information in the hotel domain is richer than that in the restaurant domain. It indicates that:

- the traditional behavioral features can only work well with abundant behavioral information;
- the more behavioral information can be obtained, the more effective the traditional behavioral features are.

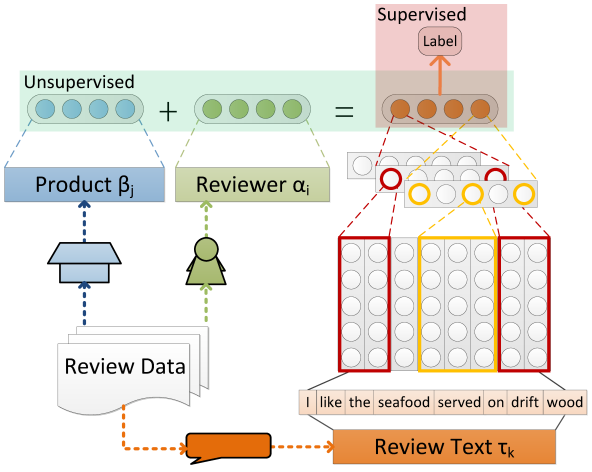

Figure 2: Illustration of our model.

4 The Proposed Model

The difficulty of detecting review spam in the cold-start task is that the available behavioral information of new reviewers is very poor. The new reviewer just posted one review and we have to filter it out immediately, there is not any historical review provided to us. As we argued, the textual information and the behavioral information of a reviewer are correlated with each other. So, to augment the behavioral information of new reviewers, we try to find the textual information which is similar with that of the new reviewer, from existing reviews. Then we take the behavioral information which is correlated with the found textual information as the most possible behavioral information of the new reviewer. For this purpose, we propose a neural network model to jointly encode the textual and behavioral information into the review embeddings for detecting the review spam in the cold-start problem (shown in Figure 2). When a new reviewer posts a review, the neural network can represent the review with the similar textual information and the correlated behavioral information encoded in the word embeddings. Finally, embeddings of the new review are fed into a classifier to identify whether it is spam or not.

4.1 Behavioral Information Encoding

In Figure 1, there is a part of review graph which is simplified from the Yelp website. As it shows, the review graph contains the global behavioral information (footprints) of the existing reviewers. Because the motivations of the spammers and the real reviewers are totally different, the distributions of the behavioral information of them are different (Mukherjee et al., 2013a). There are businesses (even highly reputable ones) paying people to write fake reviews for them to promote their products/services and/or to discredit their competitors (Liu, 2015). So the behavioral footprints of the spammers are decided by the demands of the businesses. But the real reviewers only post reviews to the product or services they have actually experienced. Their behavioral footprints are influenced by their own characteristics. Previous work extracts behavioral features for reviewers from these behavioral information. But it is impractical to the new reviewers in the cold-start task. Moreover, the traditional discrete features can not effectively record the global behavioral information (Wang et al., 2016). Besides, there is no explicit characteristic tag available in the review system, and we need to find a way to record the reviewers' latent characters information in footprints.

Therefore we encode these behavioral information into our model by utilizing an embedding learning model which is similar with TransE (Bordes et al., 2013). TransE is a model which can encode the graph structure, and represent the nodes and edges (head, translation/relation, tail) in low dimension vector space. TransE has been proved that it is good at describing the global information of the graph structure by the work about distributional representation for knowledge base (Guu et al., 2015). We consider that each reviewer in review graph describes the product in his/her own view and writes the review. When we represent the product, reviewer, and review in low dimension vector space, the reviewer embeddings can be taken as a translation vector, which has translated the product embeddings to the review embeddings. So, as shown in Figure 2, we take the products (hotels/restaurants) as the head part of the TransE network in our model, take the reviewers as the translation (relation) part and take the review as the tail part. By learning from the existing large scale unlabeled reviews of the review graph, we can encode the global behavioral information into our model without extracting any traditional behavioral feature, and record reviewers' latent characteristics information.

More formally, we minimize a margin-based criterion over the training set:

$$\mathcal{L} = \sum_{(\boldsymbol{\beta},\boldsymbol{\alpha},\boldsymbol{\tau})\in S} \sum_{(\boldsymbol{\beta}',\boldsymbol{\alpha},\boldsymbol{\tau}')\in S'} \max \{0, 1 + d(\boldsymbol{\beta}+\boldsymbol{\alpha},\boldsymbol{\tau}) - d(\boldsymbol{\beta}'+\boldsymbol{\alpha},\boldsymbol{\tau}')\} \quad (1)$$

S denotes the training set of triples $(\boldsymbol{\beta}, \boldsymbol{\alpha}, \boldsymbol{\tau})$ composed product $\boldsymbol{\beta}$ ($\boldsymbol{\beta} \in B$, products set (head part)), reviewer $\boldsymbol{\alpha}$ ($\boldsymbol{\alpha} \in A$, reviewers set (translation part)) and review text embeddings learnt by the CNN $\boldsymbol{\tau}$ ($\boldsymbol{\tau} \in T$, review texts set (tail part)).

$$S' = \{(\boldsymbol{\beta}', \boldsymbol{\alpha}, \boldsymbol{\tau}) | \boldsymbol{\beta}' \in B\} \cup \{(\boldsymbol{\beta}, \boldsymbol{\alpha}, \boldsymbol{\tau}') | \boldsymbol{\tau}' \in T\} \quad (2)$$

The set of corrupted triplets S' (Equation (2)), is composed of training triplets with either the product or review text replaced by a random chosen one (but not both at the same time).

$$d(\boldsymbol{\beta}+\boldsymbol{\alpha},\boldsymbol{\tau}) = \|\boldsymbol{\beta}+\boldsymbol{\alpha}-\boldsymbol{\tau}\|_2^2, \quad s.t. \|\boldsymbol{\beta}\|_2^2 = \|\boldsymbol{\alpha}\|_2^2 = \|\boldsymbol{\tau}\|_2^2 = 1 \quad (3)$$

Domain	Hotel	Restaurant

Table 2: Yelp Whole Dataset Statistics (Labeled and Unlabeled).

$d(\boldsymbol{\beta} + \boldsymbol{\alpha}, \boldsymbol{\tau})$ is the dissimilarity function with the squared euclidean distance.

4.2 Textual Information Encoding

To encode the textual information into our model, we adopt a convolutional neural network (CNN) to learn to represent the existing reviews. By statistics, we find that a review usually refers to several aspects of the products or services. For example, a hotel review may comment the room price, the free WiFi, and the bathroom at the same time. Compared with the recurrent neural network (RNN), the CNN can do a better job of modeling the different aspects of a review. Ren and Zhang (2016) have proved that the CNN can capture complex global semantic information and detect review spam more effectively, compared with traditional discrete manual features and the RNN model. As shown in Figure 2, we take the learnt embeddings τ of reviews by the CNN as the tail part.

Specifically, we denote the review text consisting of n words as $\{w_1, w_2, ..., w_n\}$, the word embeddings $\boldsymbol{e}(w_i) \in R^D$, D is the word vector dimension. We take the concatenation of the word embeddings in a fixed length window size Z as the input of the linear layer, which is denoted as $I_i \in R^{D \times Z}$. So the output of the linear layer H_i is calculated by $H_{k,i} = W_k \cdot I_i + b_i$, where $W_k \in R^{D \times Z}$ is the weight matrix of filter k. We utilize a max pooling layer to get the output of each filter. Then we take $tanh$ as the activation function and concatenate the outputs as the final review embeddings, which is denoted as $\boldsymbol{\tau}_i$.

4.3 Jointly Information Encoding

To model the correlation of the textual and behavioral information, we employ the jointly information encoding. By jointly learning from the global review graph, the textual and behavioral information of existing spammers and real reviewers are embedded into the word embeddings.

Domain	Hotel	Restaurant
fake	802	8368
non-fake	4876	50149

#reviews	14012	2368

(b) Restaurant

Table 4: The Balanced Datasets Statistics for Training and Testing the Classifier from Table 3.

In addition, the rating usually represents the sentiment polarity of a review, e.g., five star means 'like' and one star means 'dislike'. The spammers often review their target products with a low rating for discredited purpose, and with a high rating for promoted purpose. To encode the semantics of the sentiment polarity into the review embeddings, we learn the embeddings of 1-5 stars rating in our model at the same time. They are taken as the constraints of the review embeddings during the joint learning. They are calculated as:

$$\mathcal{C} = \sum_{(\boldsymbol{\tau},\boldsymbol{\gamma}) \in \Gamma} \sum_{(\boldsymbol{\tau},\boldsymbol{\gamma}') \in \Gamma'} \max\{0, 1 + g(\boldsymbol{\tau},\boldsymbol{\gamma}) - g(\boldsymbol{\tau},\boldsymbol{\gamma}')\} \quad (4)$$

The set of corrupted tuples Γ' is composed of training tuples Γ with the rating of review replaced by its opposite rating (i.e., 1 by 5, 2 by 4, 3 by 1 or 5). $g(\boldsymbol{\tau},\boldsymbol{\gamma}) = \|\boldsymbol{\tau} - \boldsymbol{\gamma}\|_2^2$, norm constraints: $\|\boldsymbol{\gamma}\|_2^2 = 1$.

The final joint loss function is as follows:

$$\mathcal{L}_{\mathcal{J}} = (1 - \theta)\mathcal{L} + \theta\mathcal{C} \quad (5)$$

where θ is a hyper-parameter.

Table 5: SVM classification results across linguistic features (LF, bigrams here (Mukherjee et al., 2013b)), behavioral features (BF: RL, RD, MCS (Mukherjee et al., 2013b)); the SVM classification results by the intuitive method that finding the most similar existing review by edit distance ratio and take the found reviewers' behavioral features as approximation (BF_EditSim+LF), and results by the intuitive method that finding the most similar existing review by averaged pre-trained word embeddings (using Word2Vec) (BF_W2Vsim+W2V); and the SVM classification results across the learnt review embeddings (RE), the learnt review's rating embeddings (RRE), the learnt product's average rating embeddings (PRE) by our model. Improvements of our model are statistically significant with $p<0.005$ based on paired *t*-test.

5 Experiments

5.1 Datasets and Evaluation Metrics

Datasets: To evaluate the proposed method, we conducted experiments on Yelp dataset that was used in (Mukherjee et al., 2013b,c; Rayana and Akoglu, 2015). The statistics of the Yelp dataset are listed in Table 2 and Table 3. The reviewed product here refers to a hotel or restaurant. We take the existing reviews posted before January 1, 2012 as the datasets for training our embedding learning model, and take the first new reviews which just posted by the new reviewers after January 1, 2012 as the test datasets. Table 4 displays the statistics of the balanced datasets for training and testing the classifier.

Evaluation Metrics: We select precision (P), recall (R), F1-Score (F1), accuracy (A) as metrics.

5.2 Our Model v.s. the Traditional Features

To illustrate the effectiveness of our model, we conduct experiments on the public datasets, and make comparison with the most effective traditional linguistic features, e.g., bigrams, and the three practicable traditional behavioral features (RL, RD, MCS (Mukherjee et al., 2013b)) referred in Section 3.2. The results are shown in Table 5. For our model, we set the dimension of embeddings to 100, the number of CNN filters to 100, θ to 0.1, Z to 2. The hyper-parameters are tuned by grid search on the development dataset. The product and reviewer embeddings are randomly initialized from a uniform distribution (Socher et al., 2013). The word embeddings are initialized with 100-dimensions vectors pre-trained by the CBOW model (Word2Vec) (Mikolov et al., 2013). As Table 5 showed, our model observably performs better in detecting review spam for the cold-start task in both hotel and restaurant domains.

Review Embeddings Compared with the traditional linguistic features, e.g., bigrams, using the review embeddings learnt by our model, results in around 3.4% improvement in F1 and around 7.4% improvement in A in the hotel domain (1.1% in F1 and 5.0% in A for the restaurant domain, shown in Tabel 5 (a,b) rows 1, 5). Compared with the combination of the bigrams and the traditional behavioral features, using the review embeddings learnt by our model, results in around 7.6% improvement in F1 and around 2.2% improvement in A in the hotel domain (6.1% in F1 and 2.3% in A for the restaurant domain, shown in Tabel 5 (a,b) rows 2, 5). The F1-Score (F1) of the classification under the balance distribution reflects the ability to detect the review spam. The accuracy (A) of the classification under the balance distribution reflects the ability to identify both the review spam and the real review. The experiment results indicate that our model performs significantly better than the traditional methods in F1 and A at the same time. The learnt review embeddings with encoded linguistic and behavioral information are more effective in detecting review

Features	P	R	F1	A

Ours_RE	62.1	68.3	**65.1**	**63.3**	3

(a) Hotel

P	R	F1	A	
53.8	80.8	64.6	55.8	1
56.9	58.8	57.8	57.1	2
58.4	75.1	**65.7**	**60.8**	3

(b) Restaurant

Table 6: SVM classification results across linguistic features (LF, bigrams here (Mukherjee et al., 2013b)), the learnt review embeddings (RE) ; and the classification results by only using our CNN. Both training and testing use balanced data (50:50). Improvements of our model are statistically significant with $p<0.005$ based on paired *t*-test.

spam for the cold-start task.

Rating Embeddings As we referred in Section 4.3, the rating of a review usually means the sentiment polarity of a real reviewer or the motivation of a spammer. As shown in Table 5 (a,b) rows 6, adding the rating embeddings of the products (hotel/restaurant) and reviews renders even higher F1 and A. We suppose that different rating embeddings are encoded with different semantic meanings. They reflect the semantic divergences between the average rating of the product and the review rating. In results, using RE+RRE+PRE which makes the best performance of our model, results in around 5.5% improvement in F1 and around 9.4% improvement in A in the hotel domain (2.9% in F1 and 6.2% in A for the restaurant domain, shown in Tabel 5 (a,b) rows 1, 6), compared with the LF. Using RE+RRE+PRE results in around 9.7% improvement in F1 and around 4.2% improvement in A in the hotel domain (7.9% in F1 and 3.5% in A for the restaurant domain, shown in Tabel 5 (a,b) rows 2, 6), compared with the LF+BF.

The experiment results prove that our model is effective. The improvements in both the F1 and A prove that our model performs well in both detecting the review spam and identifying the real review. Furthermore, the improvements in both the hotel and restaurant domains prove that our model possesses preferable domain-adaptability [2]. It can learn to represent the reviews with global linguistic and behavioral information from large-scale unlabeled existing reviews.

[2]The improvements in hotel domain are greater than that in restaurant domain. The possible reason is the proportion of the available training data in hotel domain is higher than that in restaurant domain (99.01% vs. 97.40% in Table 2).

5.3 Our Jointly Embeddings v.s. the Intuitive Methods

As mentioned in Section 1, to approximate the behavioral information of the new reviewers, there are other intuitive methods. So we conduct experiments with two intuitive methods as a comparison. One is finding the most similar existing review by edit distance ratio and taking the found reviewers' behavioral features as an approximation, and then training the classifier on the behavioral features and bigrams (BF_EditSim+LF). The other is finding the most similar existing review by cosine similarity of review embeddings which is the average of the pre-trained word embeddings (using Word2Vec), and then training the classifier on the behavioral features and review embeddings (BF_W2Vsim+W2V). As shown in Table 5, our joint embeddings (Ours_RE and Ours_RE+RRE+PRE) obviously perform better than the intuitive methods, such as the Ours_RE is 3.8% (Accuracy) and 3.2% (F1) better than BF_W2Vsim+W2V in the hotel domain. The experiments indicate that our joint embeddings do a better job in capturing the reviewer's characteristics and modeling the correlation of textual and behavioral information.

5.4 The Effectiveness of Encoding the Global Behavioral Information

To further evaluate the effectiveness of encoding the global behavioral information in our model, we build an independent supervised convolutional neural network which has the same structure and parameter settings with the CNN part of our model. There is not any review graphic or behavioral information in this independent supervised CNN (Tabel 6 (a,b) row 2). As shown in Tabel 6 (a,b) rows 2, 3, compared with the review embeddings learnt by the independent supervised CNN, using

the review embeddings learnt by our model results in around 9.0% improvement in F1 and around 3.8% improvement in A in the hotel domain (7.9% in F1 and 3.7% in A for the restaurant domain). The results show that our model can represent the new reviews posted by the new reviewers with the correlated behavioral information encoded in the word embeddings. The transE part of our model has effectively recorded the behavioral information of the review graph. Thus, our model is more effective by jointly embedding the textual and behavioral informations, it helps to augment the possible behavioral information of the new reviewer.

5.5 The Effectiveness of CNN

Compared with the the most effective linguistic features, e.g., bigrams, our independent supervised convolutional neural network performs better in A than F1 (shown in Tabel 5 (a,b) rows 1, 2). It indicates that the CNN do a better job in identifying the real review than the review spam. We suppose that the possible reason is that the CNN is good at modeling the different semantic aspects of a review. And the real reviewers usually tend to describe different aspects of a hotel or restaurant according to their real personal experiences, but the spammers can only forge fake reviews with their own infinite imagination. Mukherjee et al. (2013b) also proved that different psychological states of the minds of the spammers and non-spammers, lead to significant linguistic differences between review spam and non-spam.

6 Conclusion and Future Work

This paper analyzes the importance and difficulty of the cold-start challenge in review spam combat. We propose a neural network model that jointly embeds the existing textual and behavioral information for detecting review spam in the cold-start task. It can learn to represent the new review of the new reviewer with the similar textual information and the correlated behavioral information in an unsupervised way. Then, a classifier is applied to detect the review spam. Experimental results prove the proposed model achieves an effective performance and possesses preferable domain-adaptability. It is also applicable to a large-scale dataset in an unsupervised way. To our best knowledge, this is the first work to handle the cold-start problem in review spam detection. We are going to explore more effective models in future.

Abstract

Cognitive NLP systems- *i.e.*, NLP systems that make use of behavioral data - augment traditional text-based features with cognitive features extracted from eye-movement patterns, EEG signals, brain-imaging *etc.*. Such extraction of features is typically manual. We contend that manual extraction of features may not be the best way to tackle text subtleties that characteristically prevail in complex classification tasks like *sentiment analysis* and *sarcasm detection*, and that even the extraction and choice of features should be delegated to the learning system. We introduce a framework to automatically extract cognitive features from the *eye-movement / gaze* data of human readers reading the text and use them as features along with textual features for the tasks of sentiment polarity and sarcasm detection. Our proposed framework is based on Convolutional Neural Network (CNN). The CNN *learns* features from both gaze and text and uses them to classify the input text. We test our technique on published sentiment and sarcasm labeled datasets, enriched with gaze information, to show that using a combination of automatically learned text and gaze features often yields better classification performance over (i) CNN based systems that rely on text input alone and (ii) existing systems that rely on handcrafted gaze and textual features.

1 Introduction

Detection of sentiment and sarcasm in user-generated short reviews is of primary importance for social media analysis, recommendation and dialog systems. Traditional sentiment analyzers and sarcasm detectors face challenges that arise at *lexical*, *syntactic*, *semantic* and *pragmatic* levels (Liu and Zhang, 2012; Mishra et al., 2016c). Feature-based systems (Akkaya et al., 2009; Sharma and Bhattacharyya, 2013; Poria et al., 2014) can aptly handle lexical and syntactic challenges (*e.g.* learning that the word *deadly* conveys a strong positive sentiment in opinions such as *Shane Warne is a deadly bowler*, as opposed to *The high altitude Himalayan roads have deadly turns*). It is, however, extremely difficult to tackle subtleties at semantic and pragmatic levels. For example, the sentence *I really love my job. I work 40 hours a week to be this poor.* requires an NLP system to be able to understand that the opinion holder has not expressed a positive sentiment towards her / his job. In the absence of explicit clues in the text, it is difficult for automatic systems to arrive at a correct classification decision, as they often lack external knowledge about various aspects of the text being classified.

Mishra et al. (2016b) and Mishra et al. (2016c) show that NLP systems based on cognitive data (or simply, *Cognitive NLP* systems) , that leverage eye-movement information obtained from human readers, can tackle the semantic and pragmatic challenges better. The hypothesis here is that human gaze activities are related to the cognitive processes in the brain that combine the "external knowledge" that the reader possesses with textual clues that she / he perceives. While incorporating behavioral information obtained from gaze-data in NLP systems is intriguing and quite plausible, especially due to the availability of low cost eye-tracking machinery (Wood and Bulling, 2014; Yamamoto et al., 2013), few methods exist for text classification, and they rely on handcrafted features extracted from gaze data (Mishra et al., 2016b,c). These systems have limited capabilities due to two reasons: (a) Manually designed gaze based features may not adequately

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 377–387
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1035

capture all forms of textual subtleties (b) Eye-movement data is not as intuitive to analyze as text which makes the task of designing manual features more difficult. So, in this work, **instead of handcrafting the gaze based and textual features, we try to learn feature representations from both gaze and textual data using Convolutional Neural Network (CNN)**. We test our technique on two publicly available datasets enriched with eye-movement information, used for *binary classification* tasks of sentiment polarity and sarcasm detection. Our experiments show that the automatically extracted features often help to achieve significant classification performance improvement over (a) existing systems that rely on handcrafted gaze and textual features and (b) CNN based systems that rely on text input alone. The datasets used in our experiments, resources and other relevant pointers are available at http://www.cfilt.iitb.ac.in/cognitive-nlp

The rest of the paper is organized as follows. Section 2 discusses the motivation behind using readers' eye-movement data in a text classification setting. In Section 3, we argue why CNN is preferred over other available alternatives for feature extraction. The CNN architecture is proposed and discussed in Section 4. Section 5 describes our experimental setup and results are discussed in Section 6. We provide a detailed analysis of the results along with some insightful observations in Section 7. Section 8 points to relevant literature followed by Section 9 that concludes the paper.

Terminology

A *fixation* is a relatively long stay of gaze on a visual object (such as words in text) where as a *sacccade* corresponds to quick shifting of gaze between two positions of rest. Forward and backward saccades are called *progressions* and *regressions* respectively. A *scanpath* is a line graph that contains fixations as nodes and saccades as edges.

2 Eye-movement and Linguistic Subtleties

Presence of linguistic subtleties often induces (a) surprisal (Kutas and Hillyard, 1980; Malsburg et al., 2015), due to the underlying disparity /context incongruity or (b) higher cognitive load (Rayner and Duffy, 1986), due to the presence of lexically and syntactically complex structures. While surprisal accounts for irregular saccades (Malsburg et al., 2015), higher cognitive load results in longer fixation duration (Kliegl et al., 2004).

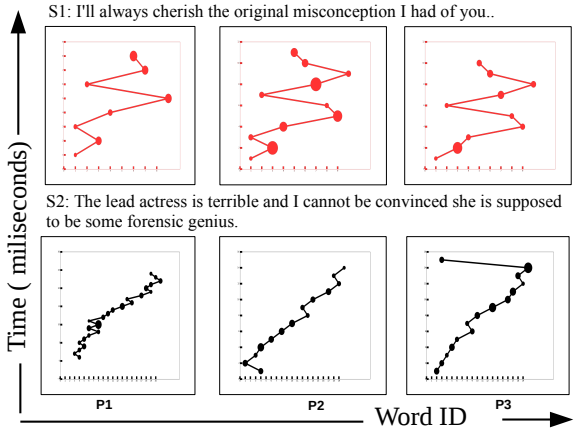

Figure 1: Scanpaths of three participants for two sentences (Mishra et al., 2016b). Sentence *S1* is sarcastic but *S2* is not. Length of the straight lines represents saccade distance and size of the circles represents fixation duration

Mishra et al. (2016b) find that presence of sarcasm in text triggers either *irregular saccadic patterns* or *unusually high duration fixations* than non-sarcastic texts (illustrated through example scanpath representations in Figure 1). For sentiment bearing texts, highly subtle eye-movement patterns are observed for semantically/pragmatically complex negative opinions (expressing irony, sarcasm, thwarted expectations, etc.) than the simple ones (Mishra et al., 2016b). The association between linguistic subtleties and eye-movement patterns could be captured through sophisticated feature engineering that considers both gaze and text inputs. In our work, CNN takes the onus of feature engineering.

3 Why Convolutional Neural Network?

CNNs have been quite effective in learning *filters* for image processing tasks, filters being used to transform the input image into more informative feature space (Krizhevsky et al., 2012). Filters learned at various CNN layers are quite similar to handcrafted filters used for detection of edges, contours, and removal of redundant backgrounds. We believe, a similar technique can also be applied to eye-movement data, where the learned filters will, hopefully, extract informative cognitive features. For instance, for sarcasm, we expect the network to learn filters that detect long distance saccades (refer to Figure 2 for an analogical il-

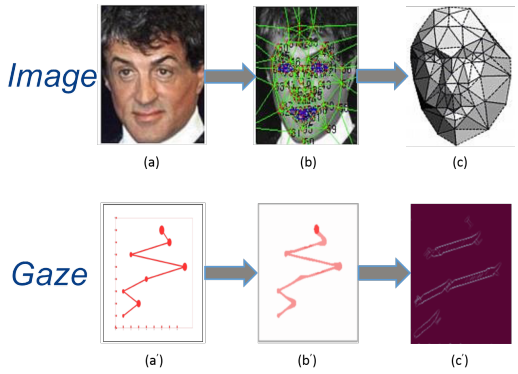

Figure 2: Illustrative analogy between CNN applied to images and scanpath representations showing why CNN can be useful for learning features from gaze patterns. Images partially taken from Taigman et al. (2014)

lustration). With more number of convolution filters of different dimensions, the network may extract multiple features related to different gaze attributes (such as fixations, progressions, regressions and skips) and will be free from any form of human bias that manually extracted features are susceptible to.

4 Learning Feature Representations: The CNN Architecture

Figure 3 shows the CNN architecture with two components for processing and extracting features from text and gaze inputs. The components are explained below.

4.1 Text Component

The text component is quite similar to the one proposed by Kim (2014) for sentence classification. Words (in the form of *one-hot* representation) in the input text are first replaced by their embeddings of dimension K (i^{th} word in the sentence represented by an embedding vector $x_i \in \mathbb{R}^K$). As per Kim (2014), a multi-channel variant of CNN (referred to as MULTICHANNELTEXT) can be implemented by using two channels of embeddings- one that remains static throughout training (referred to as STATICTEXT), and the other one that gets updated during training (referred to as NON-STATICTEXT). We separately experiment with static, non-static and multi-channel variants.

For each possible input channel of the text component, a given text is transformed into a tensor of fixed length N (padded with *zero-tensors* wherever necessary to tackle length variations) by concatenating the word embeddings.

$$x_{1:N} = x_1 \oplus x_2 \oplus x_3 \oplus ... \oplus x_N \quad (1)$$

where $\oplus$ is the concatenation operator. To extract *local features*[1], convolution operation is applied. Convolution operation involves a *filter*, $W \in \mathbb{R}^{HK}$, which is convolved with a window of H embeddings to produce a local feature for the H words. A local feature, c_i is generated from a window of embeddings $x_{i:i+H-1}$ by applying a non linear function (such as a hyperbolic tangent) over the convoluted output. Mathematically,

$$c_i = f(W.x_{i:i+H-1} + b) \quad (2)$$

where $b \in \mathbb{R}$ is the *bias* and f is the non-linear function. This operation is applied to each possible window of H words to produce a feature map (c) for the window size H.

$$c = [c_1, c_2, c_3, ..., c_{N-H+1}] \quad (3)$$

A global feature is then obtained by applying *max pooling* operation[2] (Collobert et al., 2011) over the feature map. The idea behind *max-pooling* is to capture the most important feature - one with the highest value - for each feature map.

We have described the process by which one feature is extracted from one filter (red bordered portions in Figure 3 illustrate the case of $H = 2$). The model uses multiple filters for each filter size to obtain multiple features representing the text. In the MULTICHANNELTEXT variant, for a window of H words, the convolution operation is separately applied on both the embedding channels. Local features learned from both the channels are concatenated before applying *max-pooling*.

4.2 Gaze Component

The gaze component deals with scanpaths of multiple participants annotating the same text. Scanpaths can be pre-processed to extract two sequences[3] of gaze data to form separate channels of input: (1) A sequence of normalized[4] durations of fixations (in milliseconds) in the order in which

[1] features specific to a region in case of images or window of words in case of text

[2] *mean pooling* does not perform well.

[3] like text-input, gaze sequences are padded where necessary

[4] scaled across participants using min-max normalization to reduce subjectivity

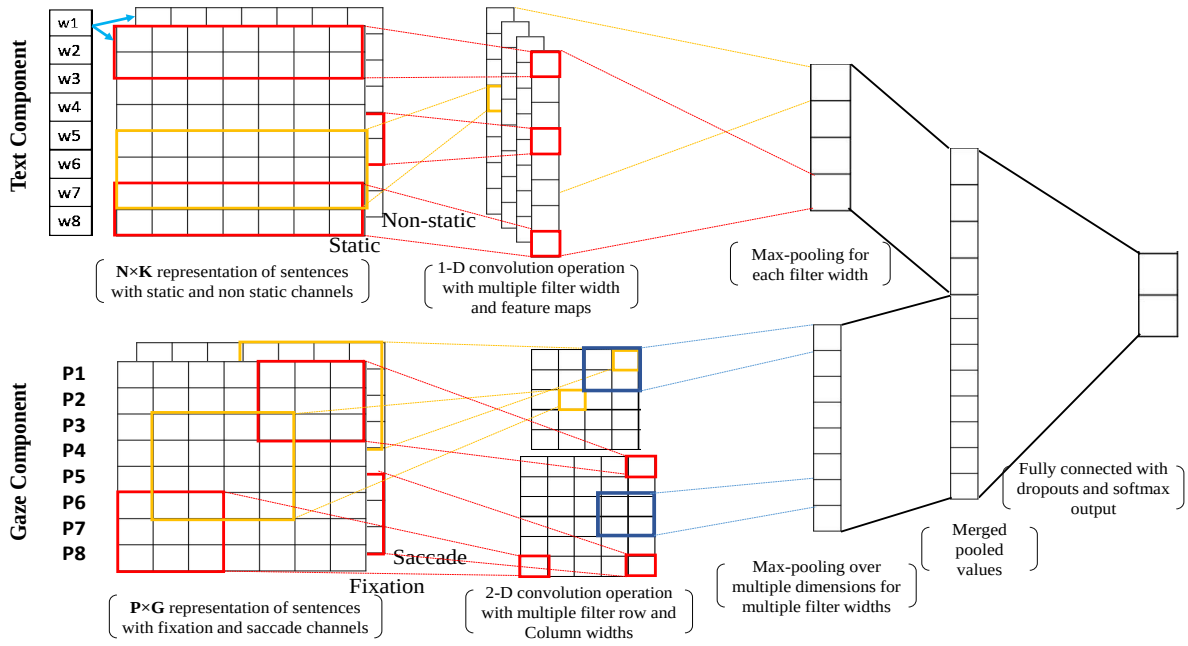

Figure 3: Deep convolutional model for feature extraction from both text and gaze inputs

they appear in the scanpath, and (2) A sequence of position of fixations (in terms of word id) in the order in which they appear in the scanpath. These channels are related to two fundamental gaze attributes such as fixation and saccade respectively. With two channels, we thus have three possible configurations of the gaze component such as (i) FIXATION, where the input is normalized fixation duration sequence, (ii) SACCADE, where the input is fixation position sequence, and (iii) MULTICHANNELGAZE, where both the inputs channels are considered.

For each possible input channel, the input is in the form of a $P \times G$ matrix (with $P \rightarrow$ number of participants and $G \rightarrow$ length of the input sequence). Each element of the matrix $g_{ij} \in \mathbb{R}$, with $i \in P$ and $j \in G$, corresponds to the j^{th} gaze attribute (either fixation duration or word id, depending on the channel) of the input sequence of the i^{th} participant. Now, unlike the text component, here we apply convolution operation across two dimensions *i.e.* choosing a two dimensional convolution filter $W \in \mathbb{R}^{JK}$ (for simplicity, we have kept $J = K$, thus , making the dimension of W, J^2). For the dimension size of J^2, a local feature c_{ij} is computed from the window of gaze elements $g_{ij:(i+J-1)(j+J-1)}$ by,

$$c_{ij} = f(W.g_{ij:(i+J-1)(j+J-1)} + b) \qquad (4)$$

where $b \in \mathbb{R}$ is the *bias* and f is a non-linear function. This operation is applied to each possible window of size J^2 to produce a feature map (c),

$$\begin{aligned} c = [&c_{11}, c_{12}, c_{13}, ..., c_{1(G-J+1)}, \\ &c_{21}, c_{22}, c_{23}, ..., c_{2(G-J+1)}, \\ &..., \\ &c_{(P-J+1)1}, c_{(P-J+1)2}, ..., c_{(P-J+1)(G-J+1)}] \end{aligned} \qquad (5)$$

A global feature is then obtained by applying *max pooling* operation. Unlike the text component, max-pooling operator is applied to a 2D window of local features size $M \times N$ (for simplicity, we set $M = N$, denoted henceforth as M^2). For the window of size M^2, the pooling operation on c will result in as set of global features $\hat{c_J} = max\{c_{ij:(i+M-1)(j+M-1)}\}$ for each possible i, j.

We have described the process by which one feature is extracted from one filter (of 2D window size J^2 and the max-pooling window size of M^2). In Figure 3, red and blue bordered portions illustrate the cases of $J^2 = [3, 3]$ and $M^2 = [2, 2]$ respectively. Like the text component, the gaze component also uses multiple filters for each filter size to obtain multiple features representing the gaze input. In the MULTICHANNELGAZE variant, for a 2D window of J^2, the convolution operation is separately applied on both fixation duration and saccade channels and local features learned from both the channels are concatenated before max-pooling is applied.

Once the global features are learned from both the text and gaze components, they are *merged*

and passed to a fully connected feed forward layer (with number of units set to 150) followed by a *SoftMax* layer that outputs the the probabilistic distribution over the class labels.

The gaze component of our network is not invariant of the order in which the scanpath data is given as input- *i.e.*, the P rows in the $P \times G$ can not be shuffled, even if each row is independent from others. The only way we can think of for addressing this issue is by applying convolution operations to all $P \times G$ matrices formed with all the permutations of P, capturing every possible ordering. Unfortunately, this makes the training process significantly less scalable, as the number of model parameters to be learned becomes huge. As of now, training and testing are carried out by keeping the order of the input constant.

5 Experiment Setup

We now share several details regarding our experiments below.

5.1 Dataset

We conduct experiments for two binary-classification tasks of sentiment and sarcasm using two publicly available datasets enriched with eye-movement information. Dataset 1 has been released by Mishra et al. (2016a). It contains 994 text snippets with 383 positive and 611 negative examples. Out of the 994 snippets, 350 are sarcastic. Dataset 2 has been used by Joshi et al. (2014) and it consists of 843 snippets comprising movie reviews and normalized tweets out of which 443 are positive, and 400 are negative. Eye-movement data of 7 and 5 readers is available for each snippet for dataset 1 and 2 respectively.

5.2 CNN Variants

With text component alone we have three variants such as STATICTEXT, NONSTATICTEXT and MULTICHANNELTEXT (refer to Section 4.1). Similarly, with gaze component we have variants such as FIXATION, SACCADE and MULTICHANNELGAZE (refer to Section 4.2). With both text and gaze components, 9 more variants could thus beexperimented with.

5.3 Hyper-parameters

For text component, we experiment with filter widths (H) of $[3, 4]$. For the gaze component, 2D filters (J^2) set to $[3 \times 3], [4 \times 4]$ respectively. The max pooling 2D window, M^2, is set to $[2 \times 2]$. In both gaze and text components, number of filters is set to 150, resulting in 150 feature maps for each window. These model hyper-parameters are fixed by trial and error and are possibly good enough to provide a first level insight into our system. Tuning of hyper-parameters might help in improving the performance of our framework, which is on our future research agenda.

5.4 Regularization

For regularization *dropout* is employed both on the embedding and the penultimate layers with a constraint on l_2-norms of the weight vectors (Hinton et al., 2012). Dropout prevents co-adaptation of hidden units by randomly dropping out - i.e., setting to zero - a proportion p of the hidden units during forward propagation. We set p to 0.25.

5.5 Training

We use ADADELTA optimizer (Zeiler, 2012), with a learning rate of 0.1. The input batch size is set to 32 and number of training iterations (epochs) is set to 200. 10% of the training data is used for validation.

5.6 Use of Pre-trained Embeddings:

Initializing the embedding layer with of pre-trained embeddings can be more effective than random initialization (Kim, 2014). In our experiments, we have used embeddings learned using the *movie reviews with one sentence per review* dataset (Pang and Lee, 2005). It is worth noting that, for a small dataset like ours, using a small data-set like the one from (Pang and Lee, 2005) helps in reducing the number model parameters resulting in faster learning of embeddings. The results are also quite close to the ones obtained using *word2vec* facilitated by Mikolov et al. (2013).

5.7 Comparison with Existing Work

For sentiment analysis, we compare our systems's accuracy (for both datasets 1 and 2) with Mishra et al. (2016c)'s systems that rely on handcrafted text and gaze features. For sarcasm detection, we compare Mishra et al. (2016b)'s sarcasm classifier with ours using dataset 1 (with available gold standard labels for sarcasm). We follow the same 10-fold train-test configuration as these existing works for consistency.

	Configuration	Dataset1			Dataset2		
		P	**R**	**F**	**P**	**R**	**F**
Traditional systems based on textual features	Näive Bayes	63.0	59.4	61.14	50.7	50.1	50.39

Table 1: Results for different traditional feature based systems and CNN model variants for the task of sentiment analysis. Abbreviations (P,R,F)→ Precision, Recall, F-score. SVM→Support Vector Machine

6 Results

In this section, we discuss the results for different model variants for sentiment polarity and sarcasm detection tasks.

6.1 Results for Sentiment Analysis Task

Table 1 presents results for sentiment analysis task. For dataset 1, different variants of our CNN architecture outperform the best systems reported by Mishra et al. (2016c), with a maximum F-score improvement of 3.8%. This improvement is statistically significant of $p < 0.05$ as confirmed by **McNemar test**. Moreover, we observe an F-score improvement of around 5% for CNNs with both gaze and text components as compared to CNNs with only text components (similar to the system by Kim (2014)), which is also statistically significant (with $p < 0.05$).

For dataset 2, CNN based approaches do not perform better than manual feature based approaches. However, variants with both text and gaze components outperform the ones with only text component (Kim, 2014), with a maximum F-score improvement of 2.9%. We observe that for dataset 2, training accuracy reaches 100 within 25 epochs with validation accuracy stable around 50%, indicating the possibility of overfitting. Tuning the regularization parameters specific to dataset 2 may help here. Even though CNN might not be proving to be a choice as good as handcrafted features for dataset 2, the bottom line remains that incorporation of gaze data into CNN consistently improves the performance over only-text-based CNN variants.

6.2 Results for Sarcasm Detection Task

For sarcasm detection, our CNN model variants outperform traditional systems by a maximum margin of 11.27% (Table 2). However, the improvement by adding the gaze component to the CNN network is just 1.34%, which is statistically insignificant over CNN with text component. While inspecting the sarcasm dataset, we observe a clear difference between the vocabulary of sarcasm and non-sarcasm classes in our dataset. This, perhaps, was captured well by the text component, especially the variant with only non-static embeddings.

7 Discussion

In this section, some important observations from our experiments are discussed.

7.1 Effect of Embedding Dimension Variation

Embedding dimension has proven to have a deep impact on the performance of neural systems (dos Santos and Gatti, 2014; Collobert et al., 2011).

	MultiChannelText + Fixation	87.03	86.92	**86.97**
	MultiChannelText + Saccade	81.98	81.08	81.53
	MultiChannelText + MultiChannelGaze	83.11	81.69	82.39

Table 2: Results for different traditional feature based systems and CNN model variants for the task of sarcasm detection on dataset 1. Abbreviations (P,R,F)→ Precision, Recall, F-score

We repeated our experiments by varying the embedding dimensions in the range of [50-300][5] and observed that reducing embedding dimension improves the F-scores by a little margin. Small embedding dimensions are probably reducing the chances of over-fitting when the data size is small. We also observe that for different embedding dimensions, performance of CNN with both gaze and text components is consistently better than that with only text component.

7.2 Effect of Static / Non-static Text Channels

Non-static embedding channel has a major role in tuning embeddings for sentiment analysis by bringing adjectives expressing similar sentiment close to each other (*e.g, good and nice*), where as static channel seems to prevent over-tuning of embeddings (over-tuning often brings verbs like *love* closer to the pronoun *I* in embedding space, purely due to higher co-occurrence of these two words in sarcastic examples).

7.3 Effect of Fixation / Saccade Channels

For sentiment detection, saccade channel seems to be handing text having semantic incongruity (due to the presence of irony / sarcasm) better. Fixation channel does not help much, may be because of higher variance in fixation duration. For sarcasm detection, fixation and saccade channels perform with similar accuracy when employed separately. Accuracy reduces with gaze multichannel, may be because of higher variation of both fixations and saccades across sarcastic and non-sarcastic classes, as opposed to sentiment classes.

7.4 Effectiveness of the CNN-learned Features

To examine how good the features learned by the CNN are, we analyzed the features for a few example cases. Figure 4 presents some of the example test cases for the task of sarcasm detection. Example 1 contains sarcasm while examples 2, 3 and 4 are non-sarcastic. To see if there is any difference in the automatically learned features between text-only and combined text and gaze variants, we examine the feature vector (of dimension 150) for the examples obtained from different model variants. Output of the hidden layer after *merge* layer is considered as features learned by the network. We plot the features, in the form of color-bars, following Li et al. (2016) - denser col-

[5] a standard range (Liu et al., 2015; Melamud et al., 2016)

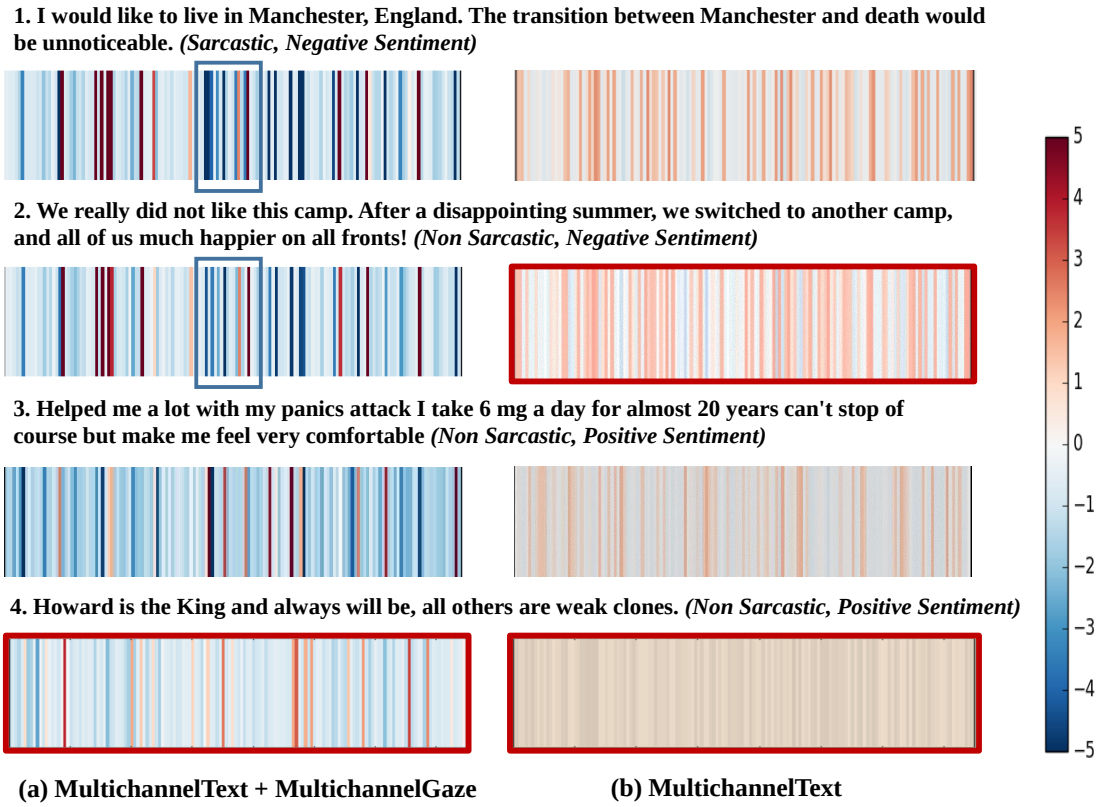

Figure 4: Visualization of representations learned by two variants of the network for sarcasm detection task. The output of the *Merge* layer (of dimension 150) are plotted in the form of colour-bars. Plots with thick red borders correspond to wrongly predicted examples.

ors representing feature with higher magnitude. In Figure 4, we show only two representative model variants *viz.,* MULTICHANNELTEXT and MULTICHANNELTEXT+ MULTICHANNELGAZE. As one can see, addition of gaze information helps to generate features with more subtle differences (marked by blue rectangular boxes) for sarcastic and non-sarcastic texts. It is also interesting to note that in the marked region, features for the sarcastic texts exhibit more intensity than the non-sarcastic ones - perhaps capturing the notion that *sarcasm typically conveys an intensified negative opinion*. This difference is not clear in feature vectors learned by text-only systems for instances like example 2, which has been incorrectly classified by MULTICHANNELTEXT. Example 4 is incorrectly classified by both the systems, perhaps due to lack of context. In cases like this, addition of gaze information does not help much in learning more distinctive features, as it becomes difficult for even humans to classify such texts.

8 Related Work

Sentiment and sarcasm classification are two important problems in NLP and have been the focus of research for many communities for quite some time. Popular sentiment and sarcasm detection systems are feature based and are based on unigrams, bigrams etc. (Dave et al., 2003; Ng et al., 2006), syntactic properties (Martineau and Finin, 2009; Nakagawa et al., 2010), semantic properties (Balamurali et al., 2011). For sarcasm detection, supervised approaches rely on **(a)** Unigrams and Pragmatic features (González-Ibánez et al., 2011; Barbieri et al., 2014; Joshi et al., 2015) **(b)** Stylistic patterns (Davidov et al., 2010) and patterns related to *situational disparity* (Riloff et al., 2013) and **(c)** Hastag interpretations (Liebrecht et al., 2013; Maynard and Greenwood, 2014). Recent systems are based on variants of deep neural network built on the top of embeddings. A few representative works in this direction for sentiment analysis are based on CNNs (dos Santos and Gatti, 2014; Kim, 2014; Tang et al., 2014), RNNs (Dong et al., 2014; Liu et al., 2015) and combined archi-

tecture (Wang et al., 2016). Few works exist on using deep neural networks for sarcasm detection, one of which is by (Ghosh and Veale, 2016) that uses a combination of RNNs and CNNs.

Eye-tracking technology is a relatively new NLP, with very few systems directly making use of gaze data in prediction frameworks. Klerke et al. (2016) present a novel multi-task learning approach for sentence compression using labeled data, while, Barrett and Søgaard (2015) discriminate between grammatical functions using gaze features. The closest works to ours are by Mishra et al. (2016b) and Mishra et al. (2016c) that introduce feature engineering based on both gaze and text data for sentiment and sarcasm detection tasks. These recent advancements motivate us to explore the cognitive NLP paradigm.

9 Conclusion and Future Directions

In this work, we proposed a multimodal ensemble of features, automatically learned using variants of CNNs from text and readers' eye-movement data, for the tasks of sentiment and sarcasm classification. On multiple published datasets for which gaze information is available, our systems could often achieve significant performance improvements over (a) systems that rely on handcrafted gaze and textual features and (b) CNN based systems that rely on text input alone. An analysis of the learned features confirms that the combination of automatically learned features is indeed capable of representing deep linguistic subtleties in text that pose challenges to sentiment and sarcasm classifiers. Our future agenda includes: (a) optimizing the CNN framework hyper-parameters (*e.g.*, filter width, dropout, embedding dimensions, *etc.*) to obtain better results, (b) exploring the applicability of our technique for document-level sentiment analysis and (c) applying our framework to related problems, such as emotion analysis, text summarization, and question-answering, where considering textual clues alone may not prove to be sufficient.

Abstract

Aspect extraction is an important and challenging task in aspect-based sentiment analysis. Existing works tend to apply variants of topic models on this task. While fairly successful, these methods usually do not produce highly coherent aspects. In this paper, we present a novel neural approach with the aim of discovering coherent aspects. The model improves coherence by exploiting the distribution of word co-occurrences through the use of neural word embeddings. Unlike topic models which typically assume independently generated words, word embedding models encourage words that appear in similar contexts to be located close to each other in the embedding space. In addition, we use an attention mechanism to de-emphasize irrelevant words during training, further improving the coherence of aspects. Experimental results on real-life datasets demonstrate that our approach discovers more meaningful and coherent aspects, and substantially outperforms baseline methods on several evaluation tasks.

1 Introduction

Aspect extraction is one of the key tasks in sentiment analysis. It aims to extract entity aspects on which opinions have been expressed (Hu and Liu, 2004; Liu, 2012). For example, in the sentence *"The beef was tender and melted in my mouth"*, the aspect term is *"beef"*. Two sub-tasks are performed in aspect extraction: (1) extracting all aspect terms (e.g., *"beef"*) from a review corpus, (2) clustering aspect terms with similar meaning into categories where each category represents a single aspect (e.g., cluster *"beef"*, *"pork"*, *"pasta"*, and *"tomato"* into one aspect *food*).

Previous works for aspect extraction can be categorized into three approaches: rule-based, supervised, and unsupervised. Rule-based methods usually do not group extracted aspect terms into categories. Supervised learning requires data annotation and suffers from domain adaptation problems. Unsupervised methods are adopted to avoid reliance on labeled data needed for supervised learning.

In recent years, Latent Dirichlet Allocation (LDA) (Blei et al., 2003) and its variants (Titov and McDonald, 2008; Brody and Elhadad, 2010; Zhao et al., 2010; Mukherjee and Liu, 2012) have become the dominant unsupervised approach for aspect extraction. LDA models the corpus as a mixture of topics (aspects), and topics as distributions over word types. While the mixture of aspects discovered by LDA-based models may describe a corpus fairly well, we find that the individual aspects inferred are of poor quality – aspects often consist of unrelated or loosely-related concepts. This may substantially reduce users' confidence in using such automated systems. There could be two primary reasons for the poor quality. Conventional LDA models do not directly encode word co-occurrence statistics which are the primary source of information to preserve topic coherence (Mimno et al., 2011). They implicitly capture such patterns by modeling word generation from the document level, assuming that each word is generated independently. Furthermore, LDA-based models need to estimate a distribution of topics for each document. Review documents tend to be short, thus making the estimation of topic distributions more difficult.

In this work, we present a novel neural approach to tackle the weaknesses of LDA-based methods. We start with neural word embeddings that al-

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 388–397
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1036

ready map words that usually co-occur within the same context to nearby points in the embedding space (Mikolov et al., 2013). We then filter the word embeddings within a sentence using an attention mechanism (Bahdanau et al., 2015) and use the filtered words to construct aspect embeddings. The training process for aspect embeddings is analogous to autoencoders, where we use dimension reduction to extract the common factors among embedded sentences and reconstruct each sentence through a linear combination of aspect embeddings. The attention mechanism de-emphasizes words that are not part of any aspect, allowing the model to focus on aspect words. We call our proposed model *Attention-based Aspect Extraction* (ABAE).

In contrast to LDA-based models, our proposed method explicitly encodes word-occurrence statistics into word embeddings, uses dimension reduction to extract the most important aspects in the review corpus, and uses an attention mechanism to remove irrelevant words to further improve coherence of the aspects.

We have conducted extensive experiments on large review data sets. The results show that ABAE is effective in discovering meaningful and coherent aspects. It substantially outperforms baseline methods on multiple evaluation tasks. In addition, ABAE is intuitive and structurally simple. It can also easily scale to a large amount of training data. Therefore, it is a promising alternative to LDA-based methods proposed previously.

2 Related Work

The problem of aspect extraction has been well studied in the past decade. Initially, methods were mainly based on manually defined rules. Hu and Liu (2004) proposed to extract different product features through finding frequent nouns and noun phrases. They also extracted opinion terms by finding the synonyms and antonyms of opinion seed words through WordNet. Following this, a number of methods have been proposed based on frequent item mining and dependency information to extract product aspects (Zhuang et al., 2006; Somasundaran and Wiebe, 2009; Qiu et al., 2011). These models heavily depend on predefined rules which work well only when the aspect terms are restricted to a small group of nouns.

Supervised learning approaches generally model aspect extraction as a standard sequence labeling problem. Jin and Ho (2009) and Li *et al.* (2010) proposed to use hidden Markov models (HMM) and conditional random fields (CRF), respectively with a set of manually-extracted features. More recently, different neural models (Yin et al., 2016; Wang et al., 2016) were proposed to automatically learn features for CRF-based aspect extraction. Rule-based models are usually not refined enough to categorize the extracted aspect terms. On the other hand, supervised learning requires large amounts of labeled data for training purposes.

Unsupervised approaches, especially topic models, have been proposed subsequently to avoid reliance on labeled data. Generally, the outputs of those models are word distributions or rankings for each aspect. Aspects are naturally obtained without separately performing extraction and categorization. Most existing works (Brody and Elhadad, 2010; Zhao et al., 2010; Mukherjee and Liu, 2012; Chen et al., 2014) are based on variants and extensions of LDA (Blei et al., 2003). Recently, Wang et al. (2015) proposed a restricted Boltzmann machine (RBM)-based model to simultaneously extract aspects and relevant sentiments of a given review sentence, treating aspects and sentiments as separate hidden variables in RBM. However, the RBM-based model proposed in (Wang et al., 2015) relies on a substantial amount of prior knowledge such as part-of-speech (POS) tagging and sentiment lexicons. A biterm topic model (BTM) that generates co-occurring word pairs was proposed in (Yan et al., 2013). We experimentally compare ABAE and BTM on multiple tasks in this paper.

Attention models (Mnih et al., 2014) have recently gained popularity in training neural networks and have been applied to various natural language processing tasks, including machine translation (Bahdanau et al., 2015; Luong et al., 2015), sentence summarization (Rush et al., 2015), sentiment classification (Chen et al., 2016; Tang et al., 2016), and question answering (Hermann et al., 2015). Rather than using all available information, attention mechanism aims to focus on the most pertinent information for a task. Unlike previous works, in this paper, we apply attention to an unsupervised neural model. Our experimental results demonstrate its effectiveness under an unsupervised setting for aspect extraction.

3 Model Description

We describe the Attention-based Aspect Extraction (ABAE) model in this section. The ultimate goal is to learn a set of aspect embeddings, where each aspect can be interpreted by looking at the nearest words (representative words) in the embedding space. We begin by associating each word w in our vocabulary with a feature vector $\mathbf{e}_w \in \mathbb{R}^d$. We use word embeddings for the feature vectors as word embeddings are designed to map words that often co-occur in a context to points that are close by in the embedding space (Mikolov et al., 2013). The feature vectors associated with the words correspond to the rows of a word embedding matrix $\mathbf{E} \in \mathbb{R}^{V \times d}$, where V is the vocabulary size. We want to learn embeddings of aspects, where aspects share the same embedding space with words. This requires an aspect embedding matrix $\mathbf{T} \in \mathbb{R}^{K \times d}$, where K, the number of aspects defined, is much smaller than V. The aspect embeddings are used to approximate the aspect words in the vocabulary, where the aspect words are filtered through an attention mechanism.

Each input sample to ABAE is a list of indexes for words in a review sentence. Given such an input, two steps are performed as shown in Figure 1. First, we filter away non-aspect words by down-weighting them using an attention mechanism, and construct a sentence embedding $\mathbf{z}_s$ from weighted word embeddings. Then, we try to reconstruct the sentence embedding as a linear combination of aspect embeddings from $\mathbf{T}$. This process of dimension reduction and reconstruction, where ABAE aims to transform sentence embeddings of the filtered sentences ($\mathbf{z}_s$) into their reconstructions ($\mathbf{r}_s$) with the least possible amount of distortion, preserves most of the information of the aspect words in the K embedded aspects. We next describe the process in detail.

3.1 Sentence Embedding with Attention Mechanism

We construct a vector representation $\mathbf{z}_s$ for each input sentence s in the first step. In general, we want the vector representation to capture the most relevant information with regards to the aspect (topic) of the sentence. We define the sentence embedding $\mathbf{z}_s$ as the weighted summation of word embeddings $\mathbf{e}_{w_i}$, $i = 1, ..., n$ corresponding to the word indexes in the sentence.

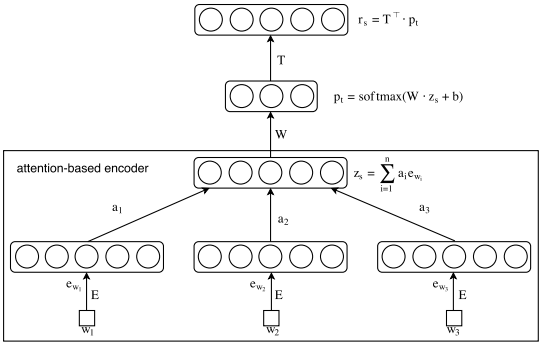

Figure 1: An example of the ABAE structure.

$$\mathbf{z}_s = \sum_{i=1}^{n} a_i \mathbf{e}_{w_i}. \tag{1}$$

For each word w_i in the sentence, we compute a positive weight a_i which can be interpreted as the probability that w_i is the right word to focus on in order to capture the main topic of the sentence. The weight a_i is computed by an attention model, which is conditioned on the embedding of the word $\mathbf{e}_{w_i}$ as well as the global context of the sentence:

$$a_i = \frac{\exp(d_i)}{\sum_{j=1}^{n} \exp(d_j)} \tag{2}$$

$$d_i = \mathbf{e}_{w_i}^{\top} \cdot \mathbf{M} \cdot \mathbf{y}_s \tag{3}$$

$$\mathbf{y}_s = \frac{1}{n} \sum_{i=1}^{n} \mathbf{e}_{w_i} \tag{4}$$

where $\mathbf{y}_s$ is simply the average of the word embeddings, which we believe captures the global context of the sentence. $\mathbf{M} \in \mathbb{R}^{d \times d}$ is a matrix mapping between the global context embedding $\mathbf{y}_s$ and the word embedding $\mathbf{e}_w$ and is learned as part of the training process. We can think of the attention mechanism as a two-step process. Given a sentence, we first construct its representation by averaging all the word representations. Then the weight of a word is assigned by considering two things. First, we filter the word through the transformation $\mathbf{M}$ which is able to capture the relevance of the word to the K aspects. Then we capture the relevance of the filtered word to the sentence by taking the inner product of the filtered word to the global context $\mathbf{y}_s$.

3.2 Sentence Reconstruction with Aspect Embeddings

We have obtained the sentence embedding. Now we describe how to compute the reconstruction of the sentence embedding. As shown in Figure 1, the reconstruction process consists of two steps of transitions, which is similar to an autoencoder. Intuitively, we can think of the reconstruction as a linear combination of aspect embeddings from $\mathbf{T}$:

$$\mathbf{r}_s = \mathbf{T}^\top \cdot \mathbf{p}_t \tag{5}$$

where $\mathbf{r}_s$ is the reconstructed vector representation, $\mathbf{p}_t$ is the weight vector over K aspect embeddings, where each weight represents the probability that the input sentence belongs to the related aspect. $\mathbf{p}_t$ can simply be obtained by reducing $\mathbf{z}_s$ from d dimensions to K dimensions and then applying a softmax non-linearity that yields normalized non-negative weights:

$$\mathbf{p}_t = softmax(\mathbf{W} \cdot \mathbf{z}_s + \mathbf{b}) \tag{6}$$

where $\mathbf{W}$, the weighted matrix parameter, and $\mathbf{b}$, the bias vector, are learned as part of the training process.

3.3 Training Objective

ABAE is trained to minimize the reconstruction error. We adopted the contrastive max-margin objective function used in previous work (Weston et al., 2011; Socher et al., 2014; Iyyer et al., 2016). For each input sentence, we randomly sample m sentences from our training data as negative samples. We represent each negative sample as $\mathbf{n}_i$ which is computed by averaging its word embeddings. Our objective is to make the reconstructed embedding $\mathbf{r}_s$ similar to the target sentence embedding $\mathbf{z}_s$ while different from those negative samples. Therefore, the unregularized objective J is formulated as a hinge loss that maximize the inner product between $\mathbf{r}_s$ and $\mathbf{z}_s$ and simultaneously minimize the inner product between $\mathbf{r}_s$ and the negative samples:

$$J(\theta) = \sum_{s \in D} \sum_{i=1}^{m} \max(0, 1 - \mathbf{r}_s \mathbf{z}_s + \mathbf{r}_s \mathbf{n}_i) \tag{7}$$

where D represents the training data set and $\theta = \{\mathbf{E}, \mathbf{T}, \mathbf{M}, \mathbf{W}, \mathbf{b}\}$ represents the model parameters.

Domain	#Reviews	#Labeled sentences
Restaurant	52,574	3,400
Beer	1,586,259	9,245

Table 1: Dataset description.

3.4 Regularization Term

We hope to learn vector representations of the most representative aspects for a review dataset. However, the aspect embedding matrix $\mathbf{T}$ may suffer from redundancy problems during training. To ensure the diversity of the resulting aspect embeddings, we add a regularization term to the objective function J to encourage the uniqueness of each aspect embedding:

$$U(\theta) = \|\mathbf{T}_n \cdot \mathbf{T}_n^\top - \mathbf{I}\| \tag{8}$$

where $\mathbf{I}$ is the identity matrix, and $\mathbf{T}_n$ is $\mathbf{T}$ with each row normalized to have length 1. Any non-diagonal element $t_{ij} (i \neq j)$ in the matrix $\mathbf{T}_n \cdot \mathbf{T}_n^\top$ corresponds to the dot product of two different aspect embeddings. U reaches its minimum value when the dot product between any two different aspect embeddings is zero. Thus the regularization term encourages orthogonality among the rows of the aspect embedding matrix $\mathbf{T}$ and penalizes redundancy between different aspect vectors. Our final objective function L is obtained by adding J and U:

$$L(\theta) = J(\theta) + \lambda U(\theta) \tag{9}$$

where λ is a hyperparameter that controls the weight of the regularization term.

4 Experimental Setup

4.1 Datasets

We evaluate our method on two real-word datasets. The detailed statistics of the datasets are summarized in Table 1.

(1) **Citysearch corpus**: This is a restaurant review corpus widely used by previous works (Ganu et al., 2009; Brody and Elhadad, 2010; Zhao et al., 2010), which contains over 50,000 restaurant reviews from Citysearch New York. Ganu et al. (2009) also provided a subset of 3,400 sentences from the corpus with manually labeled aspects. These annotated sentences are used for evaluation of aspect identification. There are six manually defined aspect labels: *Food, Staff, Ambience, Price, Anecdotes,* and *Miscellaneous*.

(2) **BeerAdvocate**: This is a beer review corpus introduced in (McAuley et al., 2012), containing over 1.5 million reviews. A subset of 1,000 reviews, corresponding to 9,245 sentences, are annotated with five aspect labels: *Feel, Look, Smell, Taste,* and *Overall*.

4.2 Baseline Methods

To validate the performance of ABAE, we compare it against a number of baselines:

(1) **LocLDA** (Brody and Elhadad, 2010): This method uses a standard implementation of LDA. In order to prevent the inference of global topics and direct the model towards rateable aspects, each sentence is treated as a separate document.

(2) **k-means**: We initialize the aspect matrix T by using the k-means centroids of the word embeddings. To show the power of ABAE, we compare its performance with using the k-means centroids directly.

(3) **SAS** (Mukherjee and Liu, 2012): This is a hybrid topic model that jointly discovers both aspects and aspect-specific opinions. This model has been shown to be competitive among topic models in discovering meaningful aspects (Mukherjee and Liu, 2012; Wang et al., 2015).

(4) **BTM** (Yan et al., 2013): This is a biterm topic model that is specially designed for short texts such as texts from social media and review sites. The major advantage of BTM over conventional LDA models is that it alleviates the problem of data sparsity in short documents by directly modeling the generation of unordered word-pair co-occurrences (biterms) over the corpus. It has been shown to perform better than conventional LDA models in discovering coherent topics.

4.3 Experimental Settings

Review corpora are preprocessed by removing punctuation symbols, stop words, and words appearing less than 10 times. For LocLDA, we use the open-source implementation GibbsLDA++[1] and for BTM, we use the implementation released by (Yan et al., 2013)[2]. We tune the hyperparameters of all topic model baselines on a held-out set with grid search using the topic coherence metric to be introduced later in Eq 10: for LocLDA, the Dirichlet priors $\alpha = 0.05$ and $\beta = 0.1$; for SAS and BTM, $\alpha = 50/K$ and $\beta = 0.1$. We run 1,000 iterations of Gibbs sampling for all topic models.

For the ABAE model, we initialize the word embedding matrix $\mathbf{E}$ with word vectors trained by word2vec with negative sampling on each dataset, setting the embedding size to 200, window size to 10, and negative sample size to 5. The parameters we use for training word embeddings are standard with no specific tuning to our data. We also initialize the aspect embedding matrix $\mathbf{T}$ with the centroids of clusters resulting from running k-means on word embeddings. Other parameters are initialized randomly. During the training process, we fix the word embedding matrix $\mathbf{E}$ and optimize other parameters using Adam (Kingma and Ba, 2014) with learning rate 0.001 for 15 epochs and batch size of 50. We set the number of negative samples per input sample m to 20, and the orthogonality penalty weight λ to 1 by tuning the hyperparameters on a held-out set with grid search. The results reported for all models are the average over 10 runs.

Following (Brody and Elhadad, 2010; Zhao et al., 2010), we set the number of aspects for the restaurant corpus to 14. We experimented with different number of aspects from 10 to 20 for the beer corpus. The results showed no major difference, so we also set it to 14. As in previous work (Brody and Elhadad, 2010; Zhao et al., 2010), we manually mapped each inferred aspect to one of the gold-standard aspects according to its top ranked representative words. In ABAE, representative words of an aspect can be found by looking at its nearest words in the embedding space using cosine as the similarity metric.

5 Evaluation and Results

We describe the evaluation tasks and report the experimental results in this section. We evaluate ABAE on two criteria:

- Is it able to find meaningful and semantically coherent aspects?
- Is it able to improve aspect identification performance on real-world review datasets?

5.1 Aspect Quality Evaluation

Table 2 presents all 14 aspects inferred by ABAE for the restaurant domain. Compared to gold-

[1] http://gibbslda.sourceforge.net
[2] http://code.google.com/p/btm/

Inferred Aspects	Representative Words	Gold Aspects
Main Dishes	beef, duck, pork, mahi, filet, veal	Food
Dessert	gelato, banana, caramel, cheesecake, pudding, vanilla	
Drink	bottle, selection, cocktail, beverage, pinot, sangria	
Ingredient	cucumber, scallion, smothered, stewed, chilli, cheddar	
General	cooking, homestyle, traditional, cuisine, authentic, freshness	
Physical Ambience	wall, lighting, ceiling, wood, lounge, floor	Ambience
Adjectives	intimate, comfy, spacious, modern, relaxing, chic	
Staff	waitstaff, server, staff, waitress, bartender, waiter	Staff
Service	unprofessional, response, condescending, aggressive, behavior, rudeness	
Price	charge, paid, bill, reservation, came, dollar	Price
Anecdotes	celebrate, anniversary, wife, fiance, recently, wedding	Anecdotes
Location	park, street, village, avenue, manhattan, brooklyn	Misc.
General	excellent, great, enjoyed, best, wonderful, fantastic	
Other	aged, reward, white, maison, mediocrity, principle	

Table 2: List of inferred aspects for restaurant reviews (left), with top representative words for each inferred aspect (middle), and the corresponding gold-standard aspect labels (right). Inferred aspect labels (left) were assigned manually.

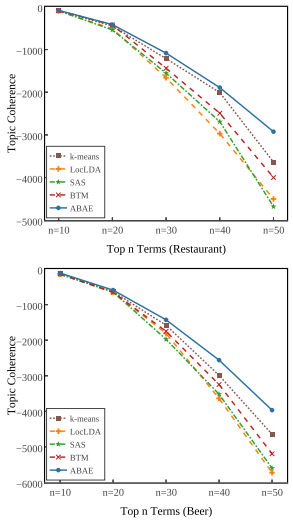

Figure 2: Average coherence score versus number of top n terms for the restaurant domain (top) and beer domain (bottom).

standard labels, the inferred aspects are more fine-grained. For example, it can distinguish main dishes from desserts, and drinks from food.

5.1.1 Coherence Score

In order to objectively measure the quality of aspects, we use *coherence score* as a metric which has been shown to correlate well with human judgment (Mimno et al., 2011). Given an aspect z and a set of top N words of z, $S^z = \{w_1^z, ..., w_N^z\}$, the coherence score is calculated as follows:

$$C(z; S^z) = \sum_{n=2}^{N} \sum_{l=1}^{n-1} log \frac{D_2(w_n^z, w_l^z) + 1}{D_1(w_l^z)} \quad (10)$$

where $D_1(w)$ is the document frequency of word w and $D_2(w_1, w_2)$ is the co-document frequency of words w_1 and w_2. A higher coherence score indicates a better aspect interpretability, i.e., more meaningful and semantically coherent.

Figure 2 shows the average *coherence score* of each model which is computed as $\frac{1}{K}\sum_{k=1}^{K} C(z_k; S^{z_k})$ on both the restaurant domain and beer domain. From the results, we make the following observations: (1) ABAE outperforms previous models for all ranked buckets. (2) BTM performs slightly better than LocLDA and SAS. This may be because BTM directly models the generation of biterms, while conventional LDA just implicitly captures such patterns by modeling word generation from the document level. (3) It is interesting to note that performing k-means on the word embeddings is sufficient to perform better than all topic model baselines, including BTM. This indicates that neural word embedding is a better model for capturing co-occurrence than LDA, even for BTM which specifically models the generation of co-occurring word pairs.

	k-means	LocLDA	SAS	BTM	ABAE
Restaurant	11	8	9	9	11
Beer	9	8	8	9	10

Table 3: Number of coherent aspects. K (number of aspects) = 14 for all models.

5.1.2 User Evaluation

As we want to discover a set of aspects that the human user finds agreeable, it is also necessary

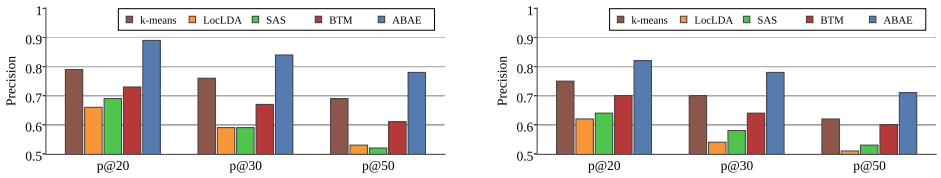

Figure 3: Average $p@n$ over all coherent aspects for the restaurant domain (left) and beer domain (right).

to carry out user evaluation directly. Following the experimental setting in (Chen et al., 2014), we recruited three human judges. Each aspect is labeled as coherent if the majority of judges assess that most of its top 50 terms coherently represent a product aspect. The numbers of coherent aspects discovered by each model are shown in Table 3. ABAE discovers the most number of coherent aspects compared with other models.

For a coherent aspect, each of its top terms is labeled as correct if and only if the majority of judges assess that it reflects the related aspect. We adopt *precision@n* (or $p@n$) to evaluate the results, which was also used in (Mukherjee and Liu, 2012; Chen et al., 2014). Figure 3 shows the average $p@n$ results over all coherent aspects for each domain. We can see that the user evaluation results correlate well with the coherence scores shown in Figure 2, where ABAE substantially outperforms all other models for all ranked buckets, especially for large values of n.

5.2 Aspect Identification

We evaluate the performance of sentence-level aspect identification on both domains using the annotated sentences shown in Table 1. The evaluation criterion is to judge how well the predictions match the true labels, measured by precision, recall, and F_1 scores. The results[4] are shown in Table 4 and Table 5.

Given a review sentence, ABAE first assigns an inferred aspect label which corresponds to the highest weight in $\mathbf{p}_t$ calculated as shown in Equation 6 . And we then assign the gold-standard label to the sentence according to the mapping between inferred aspects and gold-standard labels.

[3] k-means assigns a sentence an inferred aspect whose embedding is the closest to the averaged word embeddings of the sentence.

[4] Note that the values of P/R/F_1 reported are the average over 10 runs (except some values taken from published results in Table 4). Thus the F_1 values cannot be computed directly from corresponding P/R values

Aspect	Method	Precision	Recall	F_1
Food	LocLDA	0.898	0.648	0.753
	ME-LDA	0.874	0.787	0.828
	SAS	0.867	0.772	0.817
	BTM	0.933	0.745	0.816
	SERBM	0.891	**0.854**	**0.872**
	k-means[3]	0.931	0.647	0.755
	ABAE	**0.953**	0.741	0.828
Staff	LocLDA	0.804	0.585	0.677
	ME-LDA	0.779	0.540	0.638
	SAS	0.774	0.556	0.647
	BTM	**0.828**	0.579	0.677

	SAS	0.780	0.542	0.640
	BTM	0.813	0.599	0.685
	SERBM	0.805	0.592	0.682
	k-means	0.730	0.637	0.677
	ABAE	**0.815**	**0.698**	**0.740**

Table 4: Aspect identification results on the restaurant domain. The results of LocLDA and ME-LDA are taken from (Zhao et al., 2010); the results of SAS and SERBM are taken from (Wang et al., 2015).

For the restaurant domain, we follow the experimental settings of previous work (Brody and Elhadad, 2010; Zhao et al., 2010; Wang et al., 2015) to make our results comparable. To do that, (1) we only used the single-label sentences for evaluation to avoid ambiguity (about 83% of labeled sentences have a single label), and (2) we only evaluated on three major aspects, namely *Food*, *Staff*, and *Ambience*. The other aspects do not show clear patterns in either word usage or writing style, which makes these aspects very hard for even humans to identify. Besides the baseline models, we also compare the results with other published models, including MaxEnt-LDA (ME-LDA) (Zhao et al., 2010) and SERBM (Wang et al., 2015). SERBM has reported state-of-the-art results for aspect identification on the restaurant corpus to date. However, SERBM relies on a substantial amount of prior knowledge.

Aspect	Method	Precision	Recall	F_1

	ABAE	0.654	**0.828**	**0.725**

Table 5: Aspect identification results on the beer domain.

We make the following observations from Table 4: (1) ABAE outperforms all other models on F_1 score for aspects *Staff* and *Ambience*. (2) The F_1 score of ABAE for *Food* is worse than SERBM while its precision is very high. We analyzed the errors and found that most of the sentences we failed to recognize as *Food* are general descriptions without specific food words appearing. For example, the true label for the sentence "*The food is prepared quickly and efficiently.*" is *Food*. ABAE assigns *Staff* to it as the highly focused words according to the attention mechanism are *quickly* and *efficiently* which are more related to *Staff*. In fact, although this sentence contains the word *food*, we think it is a rather general description of service. (3) ABAE substantially outperforms k-means for this task although both methods perform well for extracting coherent aspects as shown in Figure 2 and Figure 3. This shows the power brought by the attention mechanism, which is able to capture the main topic of a sentence by only focusing on aspect-related words.

For the beer domain, in addition to the five gold-standard aspect labels, we also combined *Taste* and *Smell* to form a single aspect – *Taste+Smell*. This is because these two aspects are very similar

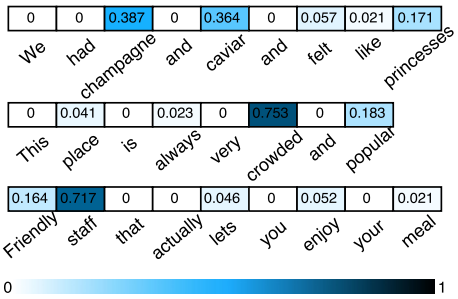

Figure 4: Visualization of the attention layer.

and many words can be used to describe both aspects. For example, the words *spicy*, *bitter*, *fresh*, *sweet*, etc. are top ranked representative words in both aspects, which makes it very hard even for humans to distinguish them. Since *Taste* and *Smell* are highly correlated and difficult to separate in real life, a natural way to evaluate is to treat them as a single aspect.

We can see from Table 5 that due to the issue described above, all models perform poorly on *Taste* and *Smell*. ABAE outperforms previous models in F_1 scores on all aspects except for *Taste*. The results demonstrate the capability of ABAE in identifying separable aspects.

Aspect	Method	Precision	Recall	F_1
Food	ABAE$^-$	0.898	0.739	0.791
	ABAE	**0.953**	**0.741**	**0.828**
Staff	ABAE$^-$	0.784	0.669	0.693
	ABAE	**0.802**	**0.728**	**0.757**
Ambience	ABAE$^-$	0.782	0.660	0.703
	ABAE	**0.815**	**0.698**	**0.740**

Table 6: Comparison between ABAE and ABAE$^-$ on aspect identification on the restaurant domain.

5.3 Validating the Effectiveness of Attention Model

Figure 4 shows the weights of words assigned by the attention model for some example sentences. As we can see, the weights learned by the model correspond very strongly with human intuition. In order to evaluate how attention model affects the overall performance of ABAE, we conduct experiments to compare ABAE and ABAE$^-$ on aspect identification, where ABAE$^-$ denotes the model in which the attention layer is switched off and sentence embedding is calculated by averaging its word embeddings: $z_s = \frac{1}{n}\sum_{i=1}^{n} e_{w_i}$. The results on the restaurant domain are shown in Table 6. ABAE achieves substantially higher precision and recall on all aspects compared with

ABAE$^-$, which demonstrates the effectiveness of the attention mechanism.

6 Conclusion

We have presented ABAE, a simple yet effective neural attention model for aspect extraction. In contrast to LDA models, ABAE explicitly captures word co-occurrence patterns and overcomes the problem of data sparsity present in review corpora. Our experimental results demonstrated that ABAE not only learns substantially higher quality aspects, but also more effectively captures the aspects of reviews than previous methods. To the best of our knowledge, we are the first to propose an unsupervised neural approach for aspect extraction. ABAE is intuitive and structurally simple, and also scales up well. All these benefits make it a promising alternative to LDA-based methods in practice.

Other Topics You May Also Agree or Disagree: Modeling Inter-Topic Preferences using Tweets and Matrix Factorization

Akira Sasaki, Kazuaki Hanawa, Naoaki Okazaki, and **Kentaro Inui**

{aki-s, hanawa, okazaki, inui}@ecei.tohoku.ac.jp

Abstract

We present in this paper our approach for modeling inter-topic preferences of Twitter users: for example, *those who agree with the Trans-Pacific Partnership (TPP) also agree with free trade*. This kind of knowledge is useful not only for stance detection across multiple topics but also for various real-world applications including public opinion surveys, electoral predictions, electoral campaigns, and online debates. In order to extract users' preferences on Twitter, we design linguistic patterns in which people agree and disagree about specific topics (e.g., "$\underline{A}$ is completely wrong"). By applying these linguistic patterns to a collection of tweets, we extract statements agreeing and disagreeing with various topics. Inspired by previous work on item recommendation, we formalize the task of modeling inter-topic preferences as matrix factorization: representing users' preferences as a user-topic matrix and mapping both users and topics onto a latent feature space that abstracts the preferences. Our experimental results demonstrate both that our proposed approach is useful in predicting missing preferences of users and that the latent vector representations of topics successfully encode inter-topic preferences.

1 Introduction

Social media have changed the way people shape public opinion. The latest survey by the Pew Research Center reported that a majority of US adults (62%) obtain news via social media, and of those, 18% do so often (Gottfried and Shearer, 2016). Given that news and opinions are shared and amplified by friend networks of individuals (Jamieson and Cappella, 2008), individuals are thereby isolated from information that does not fit well with their opinions (Pariser, 2011). Ironically, cutting-edge social media technologies promote ideological groups even with its potential to deliver diverse information.

A large number of studies already analyzed discussions, interactions, influences, and communities on social media along the political spectrum from liberal to conservative (Adamic and Glance, 2005; Zhou et al., 2011; Cohen and Ruths, 2013; Bakshy et al., 2015; Wong et al., 2016). Even though these studies provide intuitive visualizations and interpretations along the liberal-conservative axis, political analysts argue that the axis is flawed and insufficient for representing public opinion and ideologies (Kerlinger, 1984; Maddox and Lilie, 1984).

A potential solution for analyzing multiple axes of the political spectrum on social media is stance detection (Thomas et al., 2006; Somasundaran and Wiebe, 2009; Murakami and Raymond, 2010; Anand et al., 2011; Walker et al., 2012; Mohammad et al., 2016; Johnson and Goldwasser, 2016), whose task is to determine whether the author of a text is for, neutral, or against a topic (e.g., *free trade*, *immigration*, *abortion*). However, stance detection across different topics is extremely difficult. Anand et al. (2011) reported that a sophisticated method with topic-dependent features substantially improved the performance of stance detection within a topic, but such an approach could not outperform a baseline method with simple n-gram features when evaluated across topics. More recently, all participants of SemEval 2016 Task 6A (with five topics) could not outperform the baseline supervised method using n-gram features (Mohammad et al., 2016).

In addition, stance detection encounters dif-

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 398–408
Vancouver, Canada, July 30 - August 4, 2017.

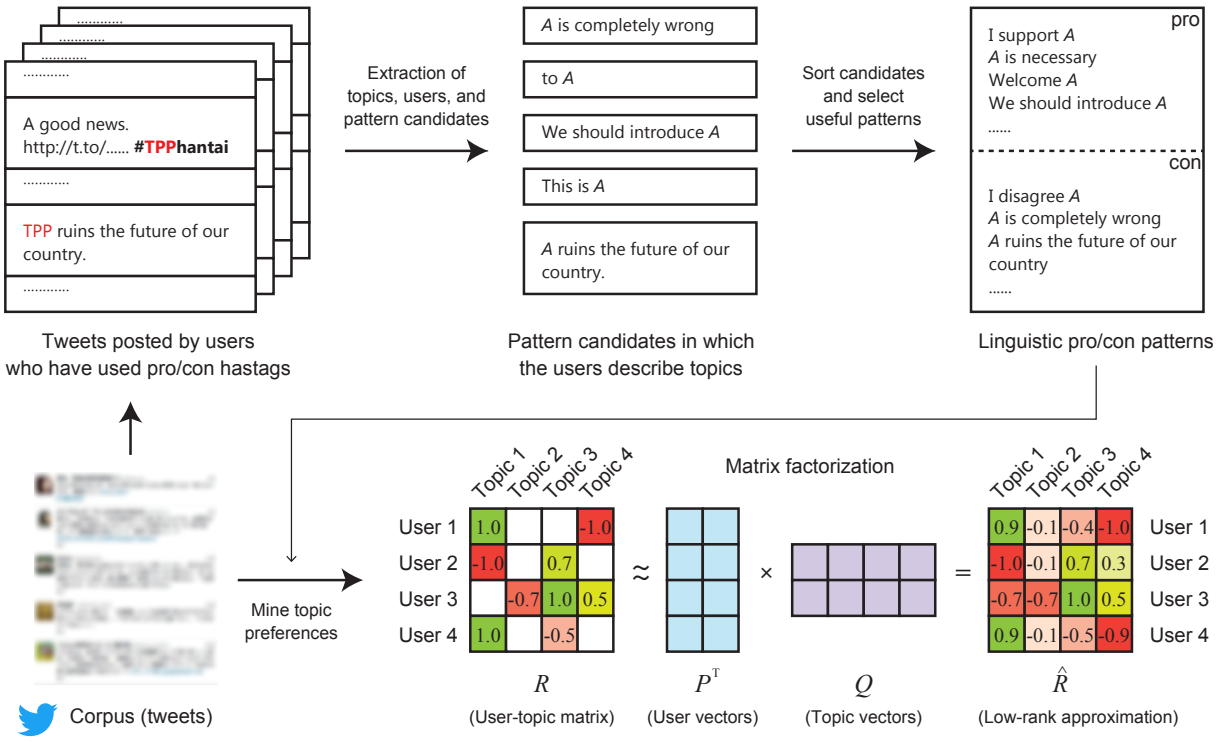

Figure 1: An overview of this study.

ficulties with different user types. Cohen and Ruths (2013) observed that existing methods on stance detection fail on "ordinary" users because such methods primarily obtain training and test data from politically vocal users (e.g., politicians); for example, they found that a stance detector trained on a dataset with politicians achieved 91% accuracy on other politicians but only achieved 54% accuracy on "ordinary" users. Establishing a bridge across different topics and users remains a major challenge not only in stance detection, but also in social media analytics.

An important component in establishing this bridge is commonsense knowledge about topics. For example, consider a topic *a revision of Article 96 of the Japanese Constitution*. We infer that the statement "we should maintain armed forces" tends to favor this topic even without any lexical overlap between the topic and the statement. This inference is reasonable because: the writer of the statement favors *armed forces*; those who favor *armed forces* also favor *a revision of Article 9*[1]; and those who favor *a revision of Article 9* also favor *a revision of Article 96*[2]. In general, this kind of commonsense knowledge can be expressed in the format: *those who agree/disagree with topic A also agree/disagree with topic B*. We call this kind of knowledge *inter-topic preference* throughout this paper.

We conjecture that previous work on stance detection indirectly learns inter-topic preferences within the same target through the use of n-gram features on a supervision data. In contrast, in the present paper, we directly acquire inter-topic preferences from an unlabeled corpus of tweets. This acquired knowledge regarding inter-topic preferences is useful not only for stance detection, but also for various real-world applications including public opinion survey, electoral campaigns, electoral predictions, and online debates.

Figure 1 provides an overview of this work. In our system, we extract linguistic patterns in which people agree and disagree about specific topics (e.g., "A is completely wrong"); to accomplish this, as described in Section 2.1, we make use of hashtags within a large collection of tweets. The patterns are then used to extract instances of users' preferences regarding various topics, as detailed in Section 2.2. Inspired by previous work on item recommendation, in Section 3, we formalize the task of modeling inter-topic preferences as a matrix factorization: representing a sparse user-topic matrix (i.e., the extracted instances) with the prod-

[1] Article 9 prohibits armed forces in Japan.

[2] Article 96 specifies high requirements for making amendments to Constitution of Japan (including Article 9).

uct of low-rank user and topic matrices. These low-rank matrices provide *latent vector representations* of both users and topics. This approach is also useful for completing preferences of "ordinary" (i.e., less vocal) users, which fills the gap between different types of users.

The contributions of this paper are threefold.

1. To the best of our knowledge, this is the first study that models inter-topic preferences for unlimited targets on real-world data.

2. Our experimental results show that this approach can accurately predict missing topic preferences of users accurately (80–94%).

3. Our experimental results also demonstrate that the latent vector representations of topics successfully encode inter-topic preferences, e.g., *those who agree with nuclear power plants also agree with nuclear fuel cycles*.

This study uses a Japanese Twitter corpus because of its availability from the authors, but the core idea is applicable to any language.

2 Mining Topic Preferences of Users

In this section, we describe how we collect statements in which users agree or disagree with various topics on Twitter, which then serves as source data for modeling inter-topic preferences. More formally, we are interested in acquiring a collection of tuples (u, t, v), where: $u \in U$ is a user; U is the set of all users on Twitter; $t \in T$ is a topic; T is the set of all topics; and $v \in \{+1, -1\}$ is $+1$ when the user u agrees with the topic t and -1 otherwise (i.e., disagreement).

Throughout this work, we use a corpus consisting of 35,328,745,115 Japanese tweets (7,340,730 users) crawled from February 6, 2013 to September 30, 2016. We removed retweets from the corpus.

2.1 Mining Linguistic Patterns of Agreement and Disagreement

We use linguistic patterns to extract tuples (u, t, v) from the aforementioned corpus. More specifically, when a tweet message matches to one of linguistic patterns of agreement (e.g., "$\underline{t}$ is necessary"), we regard that the author u of the tweet agrees with topic t. Conversely, a statement of disagreement is identified by linguistic patterns for disagreement (e.g., "$\underline{t}$ is unacceptable").

In order to design linguistic patterns, we focus on hashtags appearing in the corpus that have been popular clues for locating subjective statements such as sentiments (Davidov et al., 2010), emotions (Qadir and Riloff, 2014), and ironies (Van Hee et al., 2016). Hashtags are also useful for finding strong supporters and critics, as well as their target topics; for example, `#immigrantsWelcome` indicates that the author favors *immigrants*; and `#StopAbortion` is against *abortion*.

Based on this intuition, we design regular expressions for both *pro hashtags* "`#(.+)sansei`"[3] and *con hashtags* "`#(.+)hantai`"[4], where `(.+)` matches a target topic. These regular expressions can find users who have strong preferences to topics. Using this approach, we extracted 31,068 occurrences of pro/con hashtags used by 18,582 users for 4,899 topics. We regard the set of topics found using this procedure as set of target topics T in this study.

Each time we encounter a tweet containing a pro/con hashtag, we searched for corresponding textual statements as follows. Suppose that a tweet includes a hashtag (e.g., `#TPPsansei`) for a topic t (e.g., *TPP*). Assuming that the author of the given tweet does not change their attitude toward a topic over time, we search for other tweets posted by the same author that also have the topic keyword t. This process retrieves tweets like "I support TPP." Then, we replace the topic keyword into a variable A to extract patterns, e.g., "I support $\underline{A}$." Here, the definition of the pattern unit is language specific. For Japanese tweets, we simply recognize a pattern that starts with a variable (i.e., topic) and ends at the end of the sentence[5].

Because this procedure also extracts useless patterns such as "to A" and "this is A", we manually choose useful patterns in a systematic way: sort patterns in descending order of the number of users who use the pattern; and check the sorted list of patterns manually; and remove useless patterns.

[3] Unlike English hashtags, we systematically attach a noun *sansei*, which stands for *pro* (agreement) in Japanese, to a topic, for example, `#TPPsansei`. This paper uses the alphabetical expression `sansei` only for explanation; the actual pattern uses Chinese characters corresponding to *sansei*.

[4] A Japanese noun *hantai* stands for *con* (disagreement), for example, `#TPPhantai`. This paper uses the alphabetical expression `hantai` only for explanation; the actual pattern uses Chinese characters corresponding to *hantai*.

[5] In English, this treatment roughly corresponds to extracting a verb phrase with the variable A.

Using this approach, we obtained 100 pro patterns (e.g., "welcome A" and "A is necessary") and 100 con patterns ("do not let A" and "I don't want A").

2.2 Extracting Instances of Topic Preferences

By using the pro and con patterns acquired using the approach described in Section 2.1, we extract instances of (u, t, v) as follows. When a sentence in a tweet whose author is user u matches one of the pro patterns (e.g., "$\underline{t}$ *is necessary*") and the topic t is included in the set of target topics T, we recognize this as an instance of $(u, t, +1)$. Similarly, when a sentence matches one of the con patterns (e.g., "I don't want $\underline{t}$") and the topic t is included in the set of target topics T, we recognize this as an instance of $(u, t, -1)$. Using this approach, we collected 25,805,909 tuples corresponding to 3,302,613 users and 4,899 topics. Because these collected tuples included comparatively infrequent users and topics, we removed users and topics that appeared less than five times. In addition, there were also meaningless frequent topics such as "of" and "it". Therefore, we sorted topics in descending order of their co-occurrence frequencies with each of the pro patterns and con patterns, and then removed meaningless topics in the top 100 topics. This resulted in 9,961,509 tuples regarding 273,417 users and 2,323 topics.

3 Matrix Factorization

Using the methods described in Section 2, from the corpus, we collected a number of instances of users' preferences regarding various topics. However, Twitter users do not necessarily express preferences for all topics. In addition, it is by nature impossible to predict whether a new (i.e., nonexistent in the data) user agrees or disagrees with given topics. Therefore, in this section, we apply matrix factorization (Koren et al., 2009) in order to predict missing values, inspired by research regarding item recommendation (Bell and Koren, 2007; Dror et al., 2011). In essence, matrix factorization maps both users and topics onto a latent feature space that abstracts topic preferences of users.

Here, let R be a sparse matrix of $|U|\times|T|$. Only when a user u expresses a preference for topic t do we compute an element of the sparse matrix $r_{u,t}$,

$$r_{u,t} = \frac{\#(u,t,+1) - \#(u,t,-1)}{\#(u,t,+1) + \#(u,t,-1)} \quad (1)$$

Here, $\#(u,t,+1)$ and $\#(u,t,-1)$ represent the numbers of occurrences of instances $(u,t,+1)$ and $(u,t,-1)$, respectively. Thus, an element $r_{u,t}$ approaches $+1$ as the user u favors the topic t, and -1 otherwise. If the user u does not make any statement regarding the topic t (i.e., neither $(u,t,+1)$ nor $(u,t,-1)$ exists in the data), we do not fill the corresponding element, leaving it as a missing value.

Matrix factorization decomposes the sparse matrix R into low-dimensional matrices $P \in \mathbb{R}^{k\times|U|}$ and $Q \in \mathbb{R}^{k\times|T|}$, where k is a parameter that specifies the number of dimensions of the latent space. We minimize the following objective function to find the matrices P and Q,

$$\min_{P,Q} \sum_{(u,t)\in R} \Big((r_{u,t} - \boldsymbol{p}_u{}^\intercal \boldsymbol{q}_t)^2 + \lambda_P \|\boldsymbol{p}_u\|^2 + \lambda_Q \|\boldsymbol{q}_t\|^2 \Big). \quad (2)$$

Here, $(u,t) \in R$ is repeated for elements filled in the sparse matrix R, $\boldsymbol{p}_u \in \mathbb{R}^k$ and $\boldsymbol{q}_v \in \mathbb{R}^k$ are u column vectors of P and v column vectors of Q, respectively, and $\lambda_P \geq 0$ and $\lambda_Q \geq 0$ represent coefficients of regularization terms. We call $\boldsymbol{p}_u$ and $\boldsymbol{q}_t$ the *user vector* and *topic vector*, respectively.

Using these user and topic vectors, we can predict an element $\hat{r}_{u,t}$ that may be missing in the original matrix R,

$$\hat{r}_{u,t} \simeq \boldsymbol{p}_u{}^\intercal \boldsymbol{q}_t. \quad (3)$$

We use `libmf`[6] (Chin et al., 2015) to solve the optimization problem in Equation 2. We set regularization coefficients $\lambda_P = 0.1$ and $\lambda_Q = 0.1$ and use default values for the other parameters of `libmf`.

4 Evaluation

4.1 Determining the Dimension Parameter k

How good is the low-rank approximation found by matrix factorization? And can we find the "sweet spot" for the number of dimensions k of the latent space? We investigate the reconstruction error of matrix factorization using different values of k to answer these questions. We use Root Mean Squared Error (RMSE) to measure error,

$$RMSE = \sqrt{\frac{\sum_{(u,t)\in R} (\boldsymbol{p}_u{}^\intercal \boldsymbol{q}_t - r_{u,t})^2}{N}}. \quad (4)$$

[6] https://github.com/cjlin1/libmf

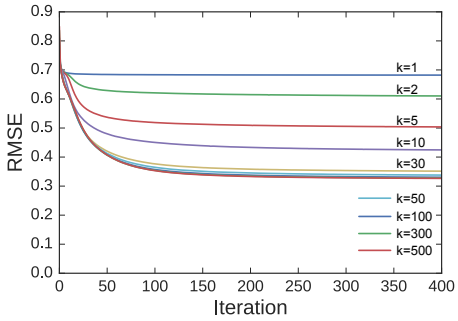

Figure 2: Reconstruction error (RMSE) of matrix factorization with different k.

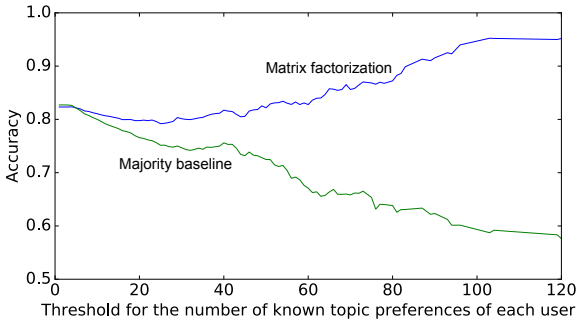

Figure 3: Prediction accuracy when changing the threshold for the number of known topic preferences of each user.

Here, N is the number of elements in the sparse matrix R (i.e., the number of known values).

Figure 2 shows RMSE values over iterations of `libmf` with the dimension parameter $k \in \{1, 2, 5, 10, 30, 50, 100, 300, 500\}$. We observed that the reconstruction error decreased as the iterative method of `libmf` progressed. The larger the number of dimensions k was, the smaller the reconstruction error became; the lowest reconstruction error was 0.3256 with $k = 500$. We also observed the error with $k = 1$, which corresponds to mapping users and topics onto one dimension similarly to the political spectrum of liberal and conservative. Judging from the relatively high RMSE values with $k = 1$, we conclude that it may be difficult to represent everything in the data using a one-dimensional axis. Based on this result, we concluded that matrix factorization with $k = 100$ is sufficient for reconstructing the original matrix R and therefore used this parameter value for the rest of our experiments.

4.2 Predicting Missing Topic Preferences

How accurately can the user and topic vectors predict missing topic preferences? To answer this question, we evaluate the accuracy in predicting hidden preferences in the matrix R as follows. First, we randomly selected 5% of existing elements in R and let Y represent the collection of the selected elements (test set). We then perform matrix factorization on the sparse matrix without the selected elements of Y, that is, only with the remaining 95% elements of R (training set). We define the accuracy of the prediction as

$$\frac{1}{|Y|} \sum_{u,t \in Y} \mathbb{1}\left(\text{sign}(\hat{r}_{u,t}) = \text{sign}(r_{u,t})\right) \quad (5)$$

Here, $r_{u,t}$ denotes the actual (i.e., self-declared) preference values, $\hat{r}_{u,t}$ represents the preference value predicted by Equation 3, $\text{sign}(.)$ represents the sign of the argument, and $\mathbb{1}(.)$ yields 1 only when the condition described in the argument holds and 0 otherwise. In other words, Equation 5 computes the proportion of correct predictions to all predictions, assuming zero to be the decision boundary between pro and con.

Figure 3 plots prediction accuracy values calculated from different sets of users. Here the x-axis represents a threshold θ, which filters out users whose declarations of topic preferences are no greater than θ topics. In other words, Figure 3 shows prediction accuracy when we know user preferences for at least θ topics. For comparison, we also include the majority baseline that predicts pro and con based on the majority of preferences regarding each topic in the training set.

Our proposed method was able to predict missing preferences with an 82.1% accuracy for users stating preferences for at least five topics. This accuracy increased as our method received more information regarding the users, reaching a 94.0% accuracy when $\theta = 100$. This result again indicates that our proposed method reasonably utilizes known preferences to complete missing preferences.

In contrast, the performance of the majority baseline decreased as it received more information regarding the users. Because this result was rather counter-intuitive, we examined the cause of this phenomenon. Consequently, this result turned out to be reasonable because preferences of vocal users deviated from those of the average users. Figure 4 illustrates this finding, showing the mean of variances of preference values $r_{u,t}$ across self-

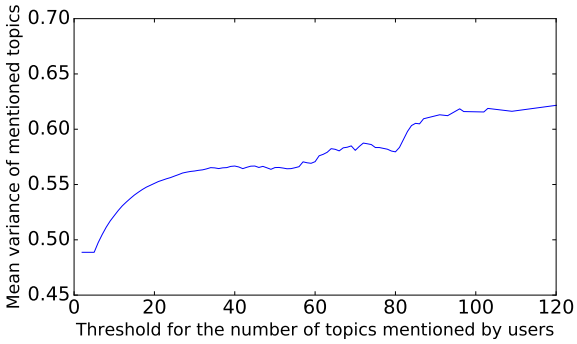

Figure 4: Mean variance of preference values of self-declared topics when changing the threshold for the number of self-declared topics.

declared topics. In the figure, the x-axis represents a threshold θ, which filters out users whose statements of topic preferences are no greater than θ topics. We observe that the mean variance increased as we focused on vocal users. Overall, these results demonstrate the usefulness of user and topic vectors in predicting missing preferences.

Table 1 shows examples in which missing preferences of two users were predicted from known statements of agreements and disagreements[7]. In the table, predicted topics are accompanied by the corresponding $\hat{r}_{u,t}$ value in parentheses. As an example, our proposed method predicted that the user A, who is positive toward *regime change* but negative toward *Okinawa US military base*, may also be positive toward *vote of non-confidence to Cabinet* but negative toward *construction of a new base*.

4.3 Inter-topic Preferences

Do the topic vectors obtained by matrix factorization capture inter-topic preferences, such as "People who agree with A also agree with B"?

Because no dataset exists for this evaluation, we created a dataset of pairwise inter-topic preferences by using a crowdsourcing service[8]. Sampling topic pairs randomly, we collected 150 topic pairs whose cosine similarities of topic vectors were below -0.6, 150 pairs whose cosine similarities were between -0.6 and 0.6, and 150 pairs whose cosine similarities were above 0.6. In this way, we obtained 450 topic pairs for evaluation.

Given a pair of topics A and B, a crowd worker was asked to choose a label from the following three options: (a) *those who agree/disagree with topic A may also agree/disagree with topic B*; (b) *those who agree/disagree with topic A may conversely disagree/agree with topic B*; (c) *otherwise (no association between A and B)*. Creating twenty pairs of topics as gold data, we removed labeling results from workers whose accuracy is less than 90%.

Consequently, we obtained 6–10 human judgements for every topic pair. Regarding (a) as $+1$ point, (b) as -1 point, and (c) as 0 point, we computed the mean of the points (i.e., average human judgements) for each topic pair. Spearman's rank correlation coefficient (ρ) between cosine similarity values of topic vectors and human judgements was 0.2210. We could observe a moderate correlation even though inter-topic preferences collected in this manner were highly subjective.

In addition to the quantitative evaluation, as summarized in Table 2, we also checked similar topics for three controversial topics, *Liberal Democratic Party (LDP)*, *constitutional amendment* and *right of foreigners to vote* (Table 2). Topics similar to LDP included synonymous ones (e.g., *Abe's LDP* and *Abe administration*) and other topics promoted by the *LDP* (e.g., *resuming nuclear power plant operations*, *bus rapid transit (BRT)* and *hate speech countermeasure law*). Considering that people who support the LDP may also tend to favor its policies, we found these results reasonable. As for the other example, *constitutional amendment* had a feature vector that was similar to that of *amendment of Article 9*, *enforcement of specific secret protection law* and *security related law*. From these results, we concluded that topic vectors were able to capture inter-topic preferences.

5 Related Work

In this section, we summarize the related work that spreads across various research fields.

Social Science and Political Science A number of of studies analyze social phenomena regarding political activities, political thoughts, and public opinions on social media. These studies

[7] We anonymized user names in these examples. In addition, we removed topics that are too discriminatory or aggressive to other countries and races. Even though the experimental results of this paper do not necessarily reflect our idea, we do not think it is a good idea to distribute politically incorrect ideas through this paper.

[8] We used Yahoo! Crowdsourcing, a Japanese online service for crowdsourcing.

User	Type	Topic
A	Agreement (declared)	regime change, capital relocation
	Disagreement (declared)	Okinawa US military base, nuclear weapons, TPP, Abe Cabinet, Abe government, nuclear cycle, right to collective defense, nuclear power plant, Abenomics
	Agreement (predicted)	same-sex partnership ordinance (0.9697), vote of non-confidence to Cabinet (0.9248), national people's government (0.9157), abolition of tax (0.8978)
	Disagreement (predicted)	steamrollering war bill (-1.0522), worsening dispatch law (-1.0301), Sendai nuclear power plant (-1.0269), war bill (-1.0190), construction of a new base (-1.0186), Abe administration (-1.0173), landfill Henoko (-1.0158), unreasonable arrest (-1.0113)
B	Agreement (declared)	visit shrine, marriage
	Disagreement(declared)	tax increase, conscription, amend Article 9
	Agreement (predicted)	national people's government (0.8467), abolition of tax (0.8300), same-sex partnership ordinance (0.7700), security bills (0.6736)
	Disagreement (predicted)	corporate tax cuts (-1.0439), Liberal Democratic Party's draft constitution (-1.0396), radioactivity (-1.0276), rubble (-1.0159), nuclear cycle (-1.0143)

Table 1: Examples of agreement/disagreement topics predicted for two sample users A and B, with predicted score $\hat{r}_{u,v}$ shown in parenthesis.

Topic	Topics with a high degree of cosine similarity
Liberal Democratic Party (LDP)	Abe's LDP (0.3937), resuming nuclear power plant operations (0.3765), bus rapid transit (BRT) (0.3410), hate speech countermeasure law (0.3373), Henoko relocation (0.3353), C-130 (0.3338), Abe administration (0.3248), LDP & Komeito (0.2898), Prime Minister Abe (0.2835)
constitutional amendment	amendment of Article 9 (0.4520), enforcement of specific secret protection law (0.4399), security related law (0.4242), specific confidentiality protection law (0.4022), security bill amendment (0.3977), defense forces (0.3962), my number law (0.3874), collective self-defense rights (0.3687), militarist revival (0.3567)
right of foreigners to vote	human rights law (0.5405), anti-discrimination law (0.5376), hate speech countermeasure law (0.5080), foreigner's life protection (0.4553), immigration refugee (0.4520), co-organized Olympics (0.4379)

Table 2: Topics identified as being similar to the three controversial topics shown in the left column.

model the political spectrum from liberal to conservative (Adamic and Glance, 2005; Zhou et al., 2011; Cohen and Ruths, 2013; Bakshy et al., 2015; Wong et al., 2016), political parties (Tumasjan et al., 2010; Boutet et al., 2013; Makazhanov and Rafiei, 2013), and elections (O'Connor et al., 2010; Conover et al., 2011).

Employing a single axis (e.g., liberal to conservative) or a few axes (e.g., political parties and candidates of elections), these studies provide intuitive visualizations and interpretations along the respective axes. In contrast, this study is the first attempt to recognize and organize various axes of topics on social media with no prior assumptions regarding the axes. Therefore, we think our study provides a new tool for computational social science and political science that enables researchers to analyze and interpret phenomena on social media.

Next, we describe previous research focused on acquiring lexical knowledge of politics. Sim et al. (2013) measured ideological positions of candidates in US presidential elections from their speeches. The study first constructs "cue lexicons" from political writings labeled with ideologies by domain experts, using sparse additive generative models (Eisenstein et al., 2011). These constructed cue lexicons were associated with such ideologies as *left*, *center*, and *right*. Representing each speech of a candidate with cue lexicons, they inferred the proportions of ideologies of the candidate. The study requires a predefined set of labels and text data associated with the labels.

Bamman and Smith (2015) presented an unsupervised method for assessing the political stance of a proposition, such as "global warming is a hoax," along the political spectrum of liberal to conservative. In their work, a proposition was represented by a tuple in the form $\langle \text{subject}, \text{predicate} \rangle$, for example, $\langle \textit{global warming}, \textit{hoax} \rangle$. They presented a generative model for users, subjects, and predicates to find a one-dimensional latent space that corresponded to the political spectrum.

Similar to our present work, their work (Bamman and Smith, 2015) did not require labeled data

to map users and topics (i.e., subjects) onto a latent feature space. In their paper, they reported that the generative model outperformed Principal Component Analysis (PCA), which is a method for matrix factorization. Empirical results here probably reflected the underlying assumptions that PCA treats missing elements as zero and not as missing data. In contrast, in the present work, we properly distinguish missing values from zero, excluding missing elements of the original matrix from the objective function of Equation 2. Further, this work demonstrated the usefulness of the latent space, that is, topic and user vectors, in predicting missing topic preferences of users and inter-topic preferences.

Fine-grained Opinion Analysis The method presented in Section 2 is an instance of fine-grained opinion analysis (Wiebe et al., 2005; Choi et al., 2006; Johansson and Moschitti, 2010; Yang and Cardie, 2013; Deng and Wiebe, 2015), which extracts a tuple of a subjective opinion, a holder of the opinion, and a target of the opinion from text. Although these previous studies have the potential to improve the quality of the user-topic matrix R, unfortunately, no corpus or resource is available for the Japanese language. We do not currently have a large collection of English tweets, but combining fine-grained opinion analysis with matrix factorization is an immediate future work.

Causality Relation Some of inter-topic preferences in this work can be explained by causality relation, for example, "TPP promotes free trade." A number of previous studies acquire instances of causal relation (Girju, 2003; Do et al., 2011) and promote/suppress relation (Hashimoto et al., 2012; Fluck et al., 2015) from text. The causality knowledge is useful for predicting (hypotheses of) future events (Radinsky et al., 2012; Radinsky and Davidovich, 2012; Hashimoto et al., 2015).

Inter-topic preferences, however, also include pairs of topics in which causality relation hardly holds. As an example, it is unreasonable to infer that *nuclear plant* and *railroading of bills* have a causal relation, but those who dislike *nuclear plant* also oppose *railroading of bills* because presumably they think the governing political parties rush the bill for resuming a nuclear plant. In this study, we model these inter-topic preferences based on preferences of the public. That said, we have as a promising future direction of our work plans to incorporate approaches to acquire causality knowledge.

6 Conclusion

In this paper, we presented a novel approach for modeling inter-topic preferences of users on Twitter. Designing linguistic patterns for identifying support and opposition statements, we extracted users' preferences regarding various topics from a large collection of tweets. We formalized the task of modeling inter-topic preferences as a matrix factorization that maps both users and topics onto a latent feature space that abstracts users' preferences. Through our experimental results, we demonstrated that our approach was able to accurately predict missing topic preferences of users (80–94%) and that our latent vector representations of topics properly encoded inter-topic preferences.

For our immediate future work, we plan to embed the topic and user vectors to create a cross-topic stance detector. It is possible to generalize our work to model heterogeneous signals, such as interests and behaviors of people, for example, "those who are interested in A also support B," and "those who favor A also vote for B". Therefore, we believe that our work will bring about new applications in the field of NLP and other disciplines.

Abstract

Modern models of event extraction for tasks like ACE are based on supervised learning of events from small hand-labeled data. However, hand-labeled training data is expensive to produce, in low coverage of event types, and limited in size, which makes supervised methods hard to extract large scale of events for knowledge base population. To solve the data labeling problem, we propose to automatically label training data for event extraction via world knowledge and linguistic knowledge, which can detect key arguments and trigger words for each event type and employ them to label events in texts automatically. The experimental results show that the quality of our large scale automatically labeled data is competitive with elaborately human-labeled data. And our automatically labeled data can incorporate with human-labeled data, then improve the performance of models learned from these data.

1 Introduction

Event Extraction (EE), a challenging task in Information Extraction, aims at detecting and typing events (Event Detection), and extracting arguments with different roles (Argument Identification) from natural-language texts. For example, in the sentence shown in Figure 1, an EE system is expected to identify an *Attack* event triggered by *threw* and extract the corresponding five augments with different roles: *Yesterday* (Role=*Time*), *demonstrators* (Role=*Attacker*), *stones* (Role=*Instrument*), *soldiers* (Role=*Target*), and *Israeli* (Role=*Place*).

To this end, so far most methods (Nguyen et al., 2016; Chen et al., 2015; Li et al., 2014; Hong et al., 2011; Ji and Grishman, 2008) usually adopted supervised learning paradigm which relies on elaborate human-annotated data, such as ACE 2005[1], to train extractors. Although this paradigm was widely studied, existing approaches still suffer from high costs for manually labeling training data and low coverage of predefined event types. In ACE 2005, all 33 event types are manually predefined and the corresponding event information (including triggers, event types, arguments and their roles) are manually annotated only in 599 English documents since the annotation process is extremely expensive. As Figure 2 shown, nearly 60% of event types in ACE 2005 have less than 100 labeled samples and there are even three event types which have less than ten labeled samples. Moreover, those predefined 33 event types are in low coverage for Natural Language Processing (NLP) applications on large-scale data.

Figure 1: This sentence expresses an *Attack* event triggered by *threw* and containing five arguments.

Therefore, for extracting large scale events, especially in open domain scenarios, how to automatically and efficiently generate sufficient training data is an important problem. This paper aims to automatically generate training data for EE, which involves labeling triggers, event types, arguments and their roles. Figure 1 shows an example of labeled sentence. Recent improvements of Distant Supervision (DS) have been proven to be effective to label training data for Relation Extraction (RE), which aims to predict semantic re-

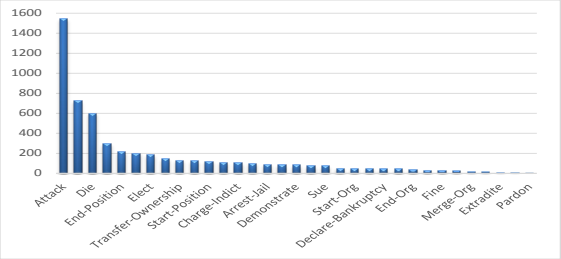

Figure 2: Statistics of ACE 2005 English Data.

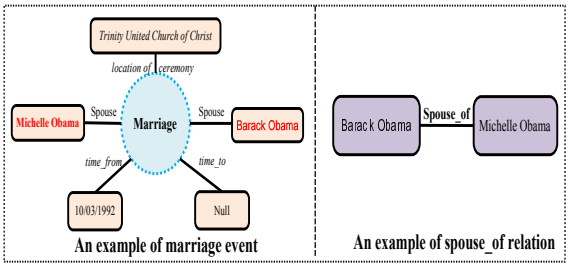

Figure 3: A comparison of events and relations.

lations between pairs of entities, formulated as $(entity_1, relation, entity_2)$. And DS for RE assumes that if two entities have a relationship in a known knowledge base, then all sentences that mention these two entities will express that relationship in some way (Mintz et al., 2009). However, when we use DS for RE to EE, we meet following challenges:

Triggers are not given out in existing knowledge bases. EE aims to detect an event instance of a specific type and extract their arguments and roles, formulated as $(event\ instance, event\ type; role_1, argument_1; role_2, argument_2; ...; role_n, argument_n)$, which can be regarded as a kind of multiple or complicated relational data. In Figure 3, the right part shows an example of $spouse\_of$ relation between $Barack\ Obama$ and $Michelle\ Obama$, where two rectangles represent two entities and the edge connecting them represents their relation. DS for RE uses two entities to automatically label training data; In comparison, the left part in Figure 3 shows a *marriage* event of $Barack\ Obama$ and $Michelle\ Obama$, where the dash circle represents the *marriage* event instance of $Barack\ Obama$ and $Michelle\ Obama$, rectangles represent arguments of the event instance, and each edge connecting an argument and the event instance expresses the role of the argument. For example, $Barack\ Obama$ plays a $Spouse$ role in this marriage event instance. It seems that we could use an event instance and an argument to automatically generate training data for argument identification just like DS for RE. However, an event instance is a virtual node in existing knowledge bases and mentioned implicitly in texts. For example, in Freebase, the aforementioned marriage event instance is represented as $m.02nqglv$ (see details in Section 2). Thus we cannot directly use an event instance and an argument, like $m.02nqglv$ and $Barack\ Obama$, to label back in sentences. In ACE event extraction program, an event instance is represented as a trigger word, which is the main word that most clearly represents an event occurrence in sentences, like *threw* in Figure 1. Following ACE, we can use trigger words to represent event instance, like *married* for *people.marriage* event instance. Unfortunately, triggers are not given out in existing knowledge bases.

To resolve the trigger missing problem mentioned above, we need to discover trigger words before employing distant supervision to automatically label event arguments. Following DS in RE, we could naturally assume that a sentence contains all arguments of an event in the knowledge base tend to express that event, and the verbs occur in these sentences tend to evoke this type of events. However, **arguments for a specific event instance are usually mentioned in multiple sentences**. Simply employing all arguments in the knowledge base to label back in sentences will generate few sentences as training samples. As shown in Table 1, only 0.02% of instances can find all argument mentions in one sentence.

Event Type	EI#	A#	S#
education.education	530,538	8	0
film.film_crew_gig	252,948	3	8
people.marriage	152,276	5	0
...	...	...	...
military.military_service	27,933	6	0
olympics.olympic_medal_honor	20,790	5	4
sum of the selected 21 events	3,870,492	100	798

Table 1: Statistics of events in Freebase. EI# denotes number of event instances in Freebase. A# denotes number of arguments for each event types, and S# indicates number of sentences contain all arguments of each event type in Wikipedia.

To solve above problems, we propose an approach to automatically generate labeled data for large scale EE by jointly using world knowledge (Freebase) and linguistic knowledge (FrameNet). At first, we put forward an approach to prioritize

arguments and select key or representative arguments (see details in Section 3.1) for each event type by using Freebase; Secondly, we merely use key arguments to label events and figure out trigger words; Thirdly, an external linguistic knowledge resource, FrameNet, is employed to filter noisy trigger words and expand more triggers; After that, we propose a Soft Distant Supervision (SDS) for EE to automatically label training data, which assumes that any sentence containing all key arguments in Freebase and a corresponding trigger word is likely to express that event in some way, and arguments occurring in that sentence are likely to play the corresponding roles in that event. Finally, we evaluate the quality of the automatically labeled training data by both manual and automatic evaluations. In addition, we employ a CNN-based EE approach with multi-instance learning for the automatically labeled data as a baseline for further research on this data. In summary, the contributions of this paper are as follows:

- To our knowledge, it is the first work to automatically label data for large scale EE via world knowledge and linguistic knowledge. All the labeled data in this paper have been released and can be downloaded freely[2].
- We propose an approach to figure out key arguments of an event by using Freebase, and use them to automatically detect events and corresponding trigger words. Moreover, we employ FrameNet to filter noisy triggers and expand more triggers.
- The experimental results show that the quality of our large scale automatically labeled data is competitive with elaborately human-annotated data. Also, our automatically labeled data can augment traditional human-annotated data, which could significantly improve the extraction performance.

2 Background

In this paper, we respectively use Freebase as our world knowledge containing event instance and FrameNet as the linguistic knowledge containing trigger information. The articles in Wikipedia are used as unstructured texts to be labeled. To understand our method easily, we first introduce them as follows:

Freebase is a semantic knowledge base (Bollacker et al., 2008), which makes use of mediators (also called compound value types, CVTs) to merge multiple values into a single value. As shown in Figure 3, *people.marriage* is one type of CVTs. There are many instances of *people.marriage* and the marriage of *Barack Obama* and *Michelle Obama* is numbered as *m.02nqglv*. *Spouse*, *from*, *to* and *location of ceremony* are roles of the *people.marriage* CVTs. *Barack Obama*, *Michelle Obama*, *10/3/1992* and *Trinity United Church of Christ* are the values of the instances. In this paper, we regard these CVTs as events, type of CVTs as event type, CVT instances as event instances, values in CVTs as arguments in events and roles of CVTs as the roles of arguments play in the event, respectively. According to the statistics of the Freebase released on 23^{th} April, 2015, there are around 1885 CVTs and around 14 million CVTs instances. After filtering out useless and meaningless CVTs, such as CVTs about user profiles and website information, we select 21 types of CVTs with around 3.8 million instances for experiments, which mainly involves events about *education*, *military*, *sports* and so on.

FrameNet[3] is a linguistic resource storing information about lexical and predicate argument semantics (Baker et al., 1998). FrameNet contains more than $1,000$ frames and $10,000$ Lexical Units (LUs). Each frame of FrameNet can be taken as a semantic frame of a type of events (Liu et al., 2016). Each frame has a set of lemmas with part of speech tags that can evoke the frame, which are called LUs. For example, *appoint.v* is a LU of *Appointing* frame in FrameNet, which can be mapped to *people.appointment* events in Freebase. And a LUs of the frame plays a similar role as the trigger of an event. Thus we use FrameNet to detect triggers in our automatically data labeling process.

Wikipedia[4] that we used was released on January, 2016. All 6.3 million articles in it are used in our experiments. We use Wikipedia because it is relatively up-to-date, and much of the information in Freebase is derived from Wikipedia.

3 Method of Generating Training Data

Figure 4 describes the architecture of automatically labeling data, which primarily involves the following four components: (i) Key argument de-

[2]https://github.com/acl2017submission/event-data

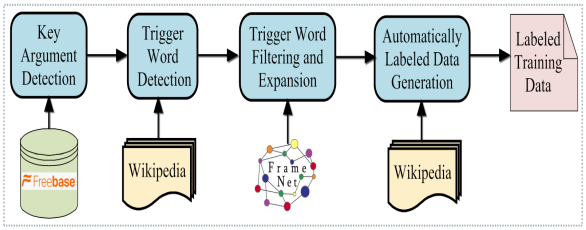

Figure 4: The architecture of automatically labeling training data for large scale event extraction.

tection, which prioritizes arguments of each event type and selects key arguments for each type of event; (ii) Trigger word detection, which uses key arguments to label sentences that may express events preliminarily, and then detect triggers; (iii) Trigger word filtering and expansion, which uses FrameNet to filter noisy triggers and expand triggers; (iv) Automatically labeled data generation, which uses a SDS to label events in sentences.

3.1 Key Argument Detection

This section illustrates how to detect key arguments for each event type via Freebase. Intuitively, arguments of a type of event play different roles. Some arguments play indispensable roles in an event, and serve as vital clues when distinguishing different events. For example, compared with arguments like *time*, *location* and so on, *spouses* are key arguments in a *marriage* event. We call these arguments as key arguments. We propose to use *Key Rate* (KR) to estimate the importance of an argument to a type of event, which is decided by two factors: *Role Saliency* and *Event Relevance*.

Role Saliency (RS) reflects the saliency of an argument to represent a specific event instance of a given event type. If we tend to use an argument to distinguish one event instance form other instances of a given event type, this argument will play a salient role in the given event type. We define RS as follows:

$$RS_{ij} = \frac{Count(A_i, ET_j)}{Count(ET_j)} \quad (1)$$

where RS_{ij} is the role saliency of i-th argument to j-th event type, $Count(A_i\ , ET_j)$ is the number of $Arguemnt_i$ occurring in all instances of $eventType_j$ in Freebase and $Count(ET_j)$ is the number of instances of $eventType_j$ in Freebase.

Event Relevance (ER) reflects the ability in which an argument can be used to discriminate different event types. If an argument occurs in every event type, the argument will have a low event relevance. We propose to compute ER as follows:

$$ER_i = \log \frac{Sum(ET)}{1 + Count(ETCi)} \quad (2)$$

where ER_i is the event relevance of i-th argument, $Sum\ (ET)$ is the number of all event types in knowledge base and $Count(ETC_i)$ is the number of event types containing i-th argument. Finally, KR is computed as follows:

$$KR_{ij} = RS_{ij} * ER_i \quad (3)$$

We compute KR for all arguments of each event type, and sort them according to KR. Then we choose top K arguments as key arguments.

3.2 Trigger Word Detection

After detecting key arguments for every event types, we use these key arguments to label sentences that may express events in Wikipedia. At first, we use Standford CoreNLP tool[5] to converts the raw Wikipedia texts into a sequence of sentences, attaches NLP annotations (POS tag, NER tag). Finally, we select sentences that contains all key arguments of an event instance in Freebase as sentences expressing corresponding events. Then we use these labeled sentences to detect triggers.

In a sentence, a verb tend to express an occurrence of an event. For example, in ACE 2005 English data, there are 60% of events triggered by verbs. As shown in Figure 1, *threw* is a trigger of *Attack* event. Intuitively, if a verb occurs more times than other verbs in the labeled sentences of one event type , the verb tends to trigger this type of event; and if a verb occurs in sentences of every event types, like *is*, the verb will have a low probability to trigger events. Thus we propose *Trigger Candidate Frequency* (TCF) and *Trigger Event Type Frequency* (TETF) to evaluate above two aspects. Finally we employ *Trigger Rate* (TR), which is the product of TCF and TETF to estimate the probability of a verb to be a trigger, which is formulated as follows:

$$TR_{ij} = TCF_{ij} * TETF_i \quad (4)$$

$$TCF_{ij} = \frac{Count(V_i, ETS_j)}{Count(ETS_j)} \quad (5)$$

[5]http://stanfordnlp.github.io/CoreNLP/

$$TETF_i = \log \frac{Sum(ET)}{1 + Count(ETI_i)} \quad (6)$$

where TR_{ij} is the trigger rate of i-th verb to j-th event type, $Count(V_i, ETS_j)$ is the number of sentences, which express j-th type of event and contain i-th verb, $Count(ETS_j)$ is the number of sentences expressing j-th event type, $Count(ETI_i)$ is the number of event types, which have the labeled sentences containing i-th verb. Finally, we choose verbs with high TR values as the trigger words for each event type.

3.3 Trigger Word Filtering and Expansion

We can obtain an initial verbal trigger lexicon by above trigger word detection. However, this initial trigger lexicon is noisy and merely contains verbal triggers. The nominal triggers like *marriage* are missing. Because the number of nouns in one sentence is usually larger than that of verbs, it is hard to use TR to find nominal triggers. Thus, we propose to use linguistic resource FrameNet to filter noisy verbal triggers and expand nominal triggers. As the success of word embedding in capturing semantics of words (Turian et al., 2010), we employ word embedding to map the events in Freebase to frames in FrameNet. Specifically, we use the average word embedding of all words in i-th Freebase event type name e_i and word embedding of k-th lexical units of j-th frame $e_{j,k}$ to compute the semantic similarity. Finally, we select the frame contains max similarity of e_i and $e_{j,k}$ as the mapped frame, which can be formulated as follows:

$$frame(i) = \arg\max_j(similarity(e_i, e_{j,k})) \quad (7)$$

Then, we filter the verb, which is in initial verbal trigger word lexicon and not in the mapping frame. And we use nouns with high confidence in the mapped frame to expand trigger lexicon.

3.4 Automatically labeled data generation

Finally, we propose a Soft Distant Supervision and use it to automatically generate training data, which assumes that any sentence containing all key arguments in Freebase and a corresponding trigger word is likely to express that event in some way, and arguments occurring in that sentence are likely to play the corresponding roles in that event.

4 Method of Event Extraction

In this paper, event extraction is formulated as a two-stage, multi-class classification task. The first stage is called *Event Classification*, which aims to predict whether the key argument candidates participate in a Freebase event. If the key arguments participate a Freebase event, the second stage is conducted, which aims to assign arguments to the event and identify their corresponding roles. We call this stage as *argument classification*. We employ two similar Dynamic Multi-pooling Convolutional Neural Networks with Multi-instance Learning (DMCNNs-MIL) for above two stages. The Dynamic Multi-pooling Convolutional Neural Networks (DMCNNs) is the best reported CNN-based model for event extraction (Chen et al., 2015) by using human-annotated training data. However, our automatically labeled data face a noise problem, which is a intrinsic problem of using DS to construct training data (Hoffmann et al., 2011; Surdeanu et al., 2012). In order to alleviate the wrong label problem, we use Multi-instance Learning (MIL) for two DMCNNs. Because the second stage is more complicated and limited in space, we take the MIL used in arguments classification as an example and describes as follows:

We define all of the parameters for the stage of argument classification to be trained in DMCNNs as θ. Suppose that there are T bags $\{M_1, M_2, ..., M_T\}$ and that the i-th bag contains q_i instances (sentences) $M_i = \{m_i^1, m_i^2, ..., m_i^{q_i}\}$, the objective of multi-instance learning is to predict the labels of the unseen bags. In stage of argument classification, we take sentences containing the same argument candidate and triggers with a same event type as a bag and all instances in a bag are considered independently. Given an input instance m_i^j, the network with the parameter θ outputs a vector O, where the r-th component O_r corresponds to the score associated with argument role r. To obtain the conditional probability $p(r|m_i^j, \theta)$, we apply a softmax operation over all argument role types:

$$p(r|m_i^j, \theta) = \frac{e^{o_r}}{\sum_{k=1}^{n} e^{o_k}} \quad (8)$$

where, n is the number of roles. And the objective of multi-instance learning is to discriminate bags rather than instances. Thus, we define the objective function on the bags. Given all (T) training bags (M_i, y_i), we can define the objective function

Event Type	Freebase Size	Sentences (KA)	Sentences (KA+T)	Examples of argument roles sorted by KR	Examples of triggers
people.marriage	152,276	56,837	26,349	spouse, spouse, from, to, location	marriage, marry, wed, wedding, couple,..., wife
music.group_membership	239,813	90,617	20,742	group, member, start, role, end	musician, singer, sing, sang, sung, concert,..., play
education.education	530,538	26,966	11,849	student, institution, degree,..., minor	educate, education, graduate, learn, study,..., student

...	...	...	...	...	...
sum of 21 selected events	3,870,492	421,602	72,611	argument1, argument2 ,..., argumentN	trigger1, trigger2, trigger3, ... , triggerN

Table 2: The statistics of five largest automatically labeled events in selected 21 Freebase events, with their size of instances in Freebase, sentences labeled with key argument (KA) and KA + Triggers(T), examples of arguments roles sorted by KR and examples of triggers.

using cross-entropy at the bag level as follows:

$$J(\theta) = \sum_{i=1}^{T} \log p(y_i | m_i^j, \theta) \quad (9)$$

where j is constrained as follows:

$$j^* = \arg\max_j p(r | m_i^j, \theta) \quad 1 \leq j \leq q_i \quad (10)$$

To compute the network parameter θ, we maximize the log likelihood $J(\theta)$ through stochastic gradient descent over mini-batches with the Adadelta (Zeiler, 2012) update rule.

5 Experiments

In this section, we first manually evaluate our automatically labeled data. Then, we conduct automatic evaluations for our labeled data based on ACE corpus and analyze effects of different approaches to automatically label training data. Finally, we shows the performance of DMCNNs-MIL on our automatically labeled data.

5.1 Our Automatically Labeled Data

By using the proposed methods, a large set of labeled data could be generated automatically. Table 2 shows the statistics of the five largest automatically labeled events among selected 21 Freebase events. Two hyper parameters, the number of key arguments and the value of TR in our automatically data labeling, are set as 2 and 0.8, by grid search respectively. When we merely use two key arguments to label data, we will obtain $421,602$ labeled sentences. However, these sentences miss labeling triggers. Thus, we leverage these rough labeled data and FrameNet to find triggers and use SDS to generate labeled data. Finally, $72,611$ labeled sentences are generated automatically. Compared with nearly $6,000$ human annotated labeled sentence in ACE, our method can automatically generate large scale labeled training data.

5.2 Manual Evaluations of Labeled Data

##001 He is the uncle of [**Amal Clooney**], [**wife**] of the actor [**George Clooney**].
Trigger: wife **Event Type:** Marriage **MannalAnotate[Y/N]:**
Argument: Amal Clooney **Role:**Spouse **MannalAnotate[Y/N]:**
Argument: George Clooney **Role:**Spouse **MannalAnotate[Y/N]:**

##002 She was [**married**] to the cinematographer [**Theo Nischwitz**] and was sometimes credited as [**Gertrud Hinz-Nischwitz**].
Trigger: married **Event Type:** Marriage **MannalAnotate[Y/N]:**
Argument: Theo Nischwitz **Role:**Spouse **MannalAnotate[Y/N]:**
Argument: Gertrud Hinz-Nischwitz **Role:**Spouse **MannalAnotate[Y/N]:**

Figure 5: Examples of manual evaluations.

We firstly manually evaluate the precision of our automatically generated labeled data. We randomly select 500 samples from our automatically labeled data. Each selected sample is a sentence with a highlighted trigger, labeled arguments and corresponding event type and argument roles. Figure 5 gives some samples. Annotators are asked to assign one of two labels to each sample. "Y": the word highlighted in the given sentence indeed triggers an event of the corresponding type or the word indeed plays the corresponding role in that event. Otherwise "N" is labeled. It is very easy to annotate a sample for annotators, thus the annotated results are expected to be of high quality. Each sample is independently annotated by three annotators[6] (including one of the authors and two of our colleagues who are familiar with event extraction task) and the final decision is made by voting.

Stage	Average Precision
Trigger Labeling	88.9
Argument Labeling	85.4

Table 3: Manual Evaluation Results

We repeat above evaluation process on the final $72,611$ labeled data three times and the average precision is shown in Table 3. Our automatically generated data can achieve a precision of 88.9 and 85.4 for trigger labeling and argument labeling re-

[6]The inter-agreement rate is 87.5%

Methods	Trigger Identification(%)			Trigger Identification + Classification(%)			Argument Identification(%)			Argument Role(%)		
	P	R	F	P	R	F	P	R	F	P	R	F
Li's structure trained with ACE	76.9	65.0	70.4	73.7	62.3	67.5	69.8	47.9	56.8	64.7	44.4	52.7
Chen's DMCNN trained with ACE	80.4	67.7	73.5	75.6	63.6	69.1	68.8	51.9	59.1	62.2	46.9	53.5
Nguyen's JRNN trained with ACE	68.5	75.7	71.9	66.0	73.0	69.3	61.4	64.2	62.8	54.2	56.7	55.4
DMCNN trained with ED Only	77.6	67.7	72.3	72.9	63.7	68.0	64.9	51.7	57.6	58.7	46.7	52.0
DMCNN trained with ACE+ED	79.7	69.6	**74.3**	75.7	66.0	**70.5**	71.4	56.9	**63.3**	62.8	50.1	**55.7**

Table 4: Overall performance on ACE blind test data

spectively, which demonstrates that our automatically labeled data is of high quality.

5.3 Automatic Evaluations of Labeled Data

To prove the effectiveness of the proposed approach automatically, we add automatically generated labeled data into ACE dataset to expand the training sets and see whether the performance of the event extractor trained on such expanded training sets is improved. In our automatically labeled data, there are some event types that can correspond to those in ACE dataset. For example, our *people.marriage* events can be mapped to *life.marry* events in ACE2005 dataset. We mapped these types of events manually and we add them into ACE training corpus in two ways. (1) we delete the human annotated ACE data for these mapped event types in ACE dataset and add our automatically labeled data to remainder ACE training data. We call this Expanded Data (ED) as *ED Only*. (2) We directly add our automatically labeled data of mapped event types to ACE training data and we call this training data as *ACE+ED*. Then we use such data to train the same event extraction model (DMCNN) and evaluate them on the ACE testing data set. Following (Nguyen et al., 2016; Chen et al., 2015; Li et al., 2013), we used the same test set with 40 newswire articles and the same development set with 30 documents and the rest 529 documents are used for ACE training set. And we use the same evaluation metric P, R, F as ACE task defined. We select three baselines trained with ACE data. (1) *Li's structure*, which is the best reported structured-based system (Li et al., 2013). (2) *Chen's DMCNN*, which is the best reported CNN-based system (Chen et al., 2015). (3) *Nguyen's JRNN*, which is the state-of-the-arts system (Nguyen et al., 2016).

The results are shown in Table 4. Compared with all models, *DMCNN trained with ACE+ED* achieves the highest performance. This demonstrates that our automatically generated labeled data could expand human annotated training data effectively. Moreover, compared with *Chen's DMCNN trained with ACE*, *DMCNN trained with ED Only* achieves a competitive performance. This demonstrates that our large scale automatically labeled data is competitive with elaborately human-annotated data.

5.4 Discussion

Impact of Key Rate

In this section, we prove the effectiveness of KR to find key arguments and explore the impact of different numbers of key arguments to automatically generate data. We specifically select two methods as baselines for comparison with our KR method: ER and RS, which use the event relevance and role salience to sort arguments of each type of events respectively. Then we choose the same number of key arguments in all methods and use these key arguments to label data. After that we evaluate these methods by using above automatic evaluations based on ACE data. Results are shown in Table 5. *ACE+KR* achieve the best performance in both stages. This demonstrates the effectiveness of our KR methods.

Feature	**Trigger**	**Argument**
	F_1	F_1
ACE	69.1	53.5
ACE + RS	70.1	55.3
ACE + ER	69.5	54.2
ACE + KR	**70.5**	**55.7**

Table 5: Effects of ER, RS and KR

To explore the impact of different numbers of key arguments, we sort all arguments of each type of events according to KR value and select top k arguments as the key arguments. Examples are shown in Table 2. Then we automatically evaluate the performance by using automatic evaluations proposed above. Figure 6 shows the results, when we set $k = 2$, the method achieves a best

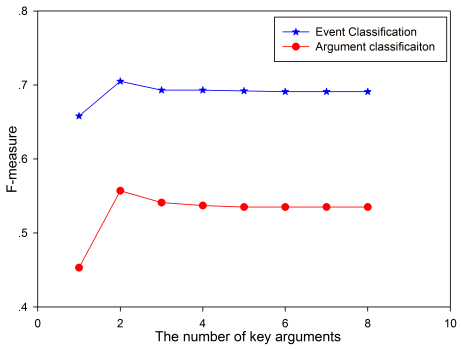

Figure 6: Effects of the number of key arguments

performance in both stages. Then, the F1 value reduces as k grows. The reason is that the heuristics for data labeling are stricter as k grows. As a result, less training data is generated. For example, if $k = 2$, we will get $25,797$ sentences labeled as *people.marriage* events and we will get 534 labeled sentences, if $k = 3$. However, when we set $k = 1$, although more labeled data are generated, the precision could not be guaranteed.

Impact of Trigger Rate and FrameNet

In this section, we prove the effectiveness of TR and FrameNet to find triggers. We specifically select two methods as baselines: TCF and TETF. TCF, TETF and TR respectively use the trigger candidate frequency, trigger event type frequency and trigger rate to sort trigger candidates of each type of events. Then we generate initial trigger lexicon by using all trigger candidates with high TCF value, TETF value or TR value. We set these hyper parameters as $0.8, 0.9$ and 0.8, respectively, which are determined by grid search from $(0.5, 0.6, 0.7, 0.8, 0.9, 1.0)$. FrameNet was used to filter noisy verbal triggers and expand nominal triggers. Trigger examples generated by *TR+Framenet* are shown in Table 2. Then we evaluate the performance of these methods by using above automatic evaluations. Results are shown in Table 6, Compared with *ACE+TCF* and *ACE+TETF*, *ACE+TR* gains a higher performance in both stages. It demonstrates the effectiveness of our TR methods. When we use FrameNet to generate triggers, compared with *ACE+TR*, we get a 1.0 improvement on trigger classification and a 1.7 improvement on argument classification. Such improvements are higher than improvements gained by other methods (TCF, IEF, TR), which demonstrates the effectiveness of the usage of FrameNet.

Feature	Trigger	Argument
	F_1	F_1
ACE	69.1	53.5
ACE + TCF	69.3	53.8
ACE + TETF	69.2	53.7
ACE + TR	69.5	54.0
ACE + TR + FrameNet	**70.5**	**55.7**

Table 6: Effects of TCF, TETF,TR and FrameNet

5.5 Performance of DMCNN-MIL

Following previous work (Mintz et al., 2009) in distant supervised RE, we evaluate our method in two ways: held-out and manual evaluation.

Held-out Evaluation

In the held-out evaluation, we hold out part of the Freebase event data during training, and compare newly discovered event instances against this held-out data. We use the following criteria to judge the correctness of each predicted event automatically: (1) An event is correct if its key arguments and event type match those of an event instance in Freebase; (2) An argument is correctly classified if its event type and argument role match those of any of the argument instance in the corresponding Freebase event. Figure 7 and Figure 8 show the precision-recall (P-R) curves for each method in the two stages of event extraction respectively. We can see that multi-instance learning is effective to alleviate the noise problem in our distant supervised event extraction.

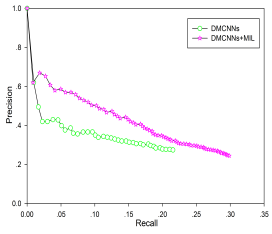

Figure 7: P-R curves for event classification.

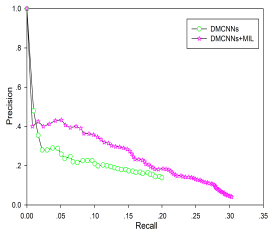

Figure 8: P-R curves for argument classification.

Human Evaluation

Because the incomplete nature of Freebase, held-out evaluation suffers from false negatives problem. We also perform a manual evaluation to eliminate these problems. In the manual evaluation, we manually check the newly discovered event instances that are not in Freebase. Because the number of these event instances in the test data is unknown, we cannot calculate the recall in this case.

Instead, we calculate the precision of the top n extracted event instances. The human evaluation results are presented in Table 7. We can see that DMCNNs-MIL achieves the best performance.

Methods	Event Classificaiton			
	Top 100	Top 300	Top 500	Average
DMCNNs	58.7	54.3	52.9	55.3
DMCNNs+MIL	**70.6**	**67.2**	**64.3**	**67.4**
Methods	Argument Classificaiton			
	Top 100	Top 300	Top 500	Average
DMCNNs	43.5	40.6	36.7	40.3
DMCNNs+MIL	**50.8**	**45.6**	**43.5**	**46.6**

Table 7: Precision for top 100, 300, and 500 events

6 Related Work

Most of previous event extraction work focused on supervised learning paradigm and trained event extractors on human-annotated data which yield relatively high performance. (Ahn, 2006; Ji and Grishman, 2008; Hong et al., 2011; McClosky et al., 2011; Li et al., 2013, 2014; Chen et al., 2015; Nguyen and Grishman, 2015; Nguyen et al., 2016). However, these supervised methods depend on the quality of the training data and labeled training data is expensive to produce. Unsupervised methods can extract large numbers of events without using labeled data (Chambers and Jurafsky, 2011; Cheung et al., 2013; Huang et al., 2016). But extracted events may not be easy to be mapped to events for a particular knowledge base.

Distant supervision have been used in relation extraction for automatically labeling training data (Mintz et al., 2009; Hinton et al., 2012; Krause et al., 2012; Krishnamurthy and Mitchell, 2012; Berant et al., 2013; Surdeanu et al., 2012; Zeng et al., 2015). But DS for RE cannot directly use for EE. For the reasons that an event is more complicated than a relation and the task of EE is more difficult than RE. The best reported supervised RE and EE system got a F1-score of 88.0% (Wang et al., 2016) and 55.4% (Nguyen et al., 2016) respectively. Reschke et al. (2014) extended the distant supervision approach to fill slots in plane crash. However, the method can only extract arguments of one plane crash type and need flight number strings as input. In other words, the approach cannot extract whole event with different types automatically.

7 Conclusion and Future Work

In this paper, we present an approach to automatically label training data for EE. The experimental results show the quality of our large scale automatically labeled data is competitive with elaborately human-annotated data. Also, we provide a DMCNN-MIL model for this data as a baseline for further research. In the future, we will use the proposed automatically data labeling method to more event types and explore more models to extract events by using automatically labeled data.

Time Expression Analysis and Recognition Using Syntactic Token Types and General Heuristic Rules

Xiaoshi Zhong, Aixin Sun, and Erik Cambria
School of Computer Science and Engineering

{xszhong,axsun,cambria}@ntu.edu.sg

Abstract

Extracting time expressions from free text is a fundamental task for many applications. We analyze time expressions from four different datasets and find that only a small group of words are used to express time information and that the words in time expressions demonstrate similar syntactic behaviour. Based on the findings, we propose a type-based approach named SynTime[1] for time expression recognition. Specifically, we define three main syntactic token types, namely *time token*, *modifier*, and *numeral*, to group time-related token regular expressions. On the types we design general heuristic rules to recognize time expressions. In recognition, SynTime first identifies time tokens from raw text, then searches their surroundings for modifiers and numerals to form time segments, and finally merges the time segments to time expressions. As a light-weight rule-based tagger, SynTime runs in real time, and can be easily expanded by simply adding keywords for the text from different domains and different text types. Experiments on benchmark datasets and tweets data show that SynTime outperforms state-of-the-art methods.

1 Introduction

Time expression plays an important role in information retrieval and many applications in natural language processing (Alonso et al., 2011; Campos et al., 2014). Recognizing time expressions from free text has attracted considerable attention since last decade (Verhagen et al., 2007, 2010; UzZaman et al., 2013).

[1] Source: https://github.com/zhongxiaoshi/syntime

We analyze time expressions in four datasets: TimeBank (Pustejovsky et al., 2003b), Gigaword (Parker et al., 2011), WikiWars (Mazur and Dale, 2010), and Tweets. From the analysis we make four findings about time expressions. First, most time expressions are very short, with 80% of time expressions containing no more than three tokens. Second, at least 91.8% of time expressions contain at least one time token. Third, the vocabulary used to express time information is very small, with a small group of keywords. Finally, words in time expressions demonstrate similar syntactic behaviour. All the findings relate to the principle of least effort (Zipf, 1949). That is, people tend to act under the least effort in order to minimize the cost of energy at both individual level and collective level to language usage (Zipf, 1949). Time expression is part of language and acts as an interface of communication. Short expressions, occurrence, small vocabulary, and similar syntactic behaviour all reduce the cost of energy required to communicate.

According to the findings we propose a type-based approach named SynTime ('Syn' stands for syntactic) to recognize time expressions. Specifically, we define three main token types, namely *time token*, *modifier*, and *numeral*, to group time-related token regular expressions. Time tokens are the words that explicitly express time information, such as time units (e.g., 'year'). Modifiers modify time tokens; they appear before or after time tokens, e.g., 'several' and 'ago' in 'several years ago.' Numerals are ordinals and numbers. From free text SynTime first identifies time tokens, then recognizes modifiers and numerals.

Naturally, SynTime is a rule-based tagger. The key difference between SynTime and other rule-based taggers lies in the way of defining token types and the way of designing rules. The definition of token type in SynTime is inspired by part-

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 420–429
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1039

of-speech in which "linguists group some words of language into classes (sets) which show similar syntactic behaviour." (Manning and Schutze, 1999) SynTime defines token types for tokens according to their syntactic behaviour. Other rule-based taggers define types for tokens based on their semantic meaning. For example, SUTime defines 5 semantic modifier types, such as frequency modifiers;[2] while SynTime defines 5 syntactic modifier types, such as modifiers that appear before time tokens. (See Section 4.1 for details.) Accordingly, other rule-based taggers design deterministic rules based on their meanings of tokens themselves. SynTime instead designs general rules on the token types rather than on the tokens themselves. For example, our general rules do not work on tokens 'February' nor '1989' but on their token types 'MONTH' and 'YEAR.' That is why we call SynTime a type-based approach. More importantly, other rule-based taggers design rules in a fixed method, including fixed length and fixed position. In contrast, SynTime designs general rules in a heuristic way, based on the idea of boundary expansion. The general heuristic rules are quite light-weight that it makes SynTime much more flexible and expansible, and leads SynTime to run in real time.

The heuristic rules are designed on token types and are independent of specific tokens, SynTime therefore is independent of specific domains, specific text types, and even specific languages that consist of specific tokens. In this paper, we test SynTime on specific domains and specific text types in English. (The test for other languages needs only to construct a collection of token regular expressions in the target language under our defined token types.) Specifically, we evaluate SynTime against three state-of-the-art methods (i.e., HeidelTime, SUTime, and UWTime) on three datasets: TimeBank, WikiWars, and Tweets.[3] TimeBank and Tweets are comprehensive datasets while WikiWars is a specific domain dataset about war; TimeBank and WikiWars are the datasets in formal text while Tweets dataset is in informal text. Experiments show that SynTime achieves comparable results on WikiWars dataset, and significantly outperforms the three state-of-the-art baselines on TimeBank and Tweets datasets. More importantly, SynTime achieves the best recalls on all three datasets and exceptionally good results on Tweets dataset. To sum up, we make the following contributions.

- We analyze time expressions from four datasets and make four findings. The findings provide evidence in terms of time expression for the principle of least effort (Zipf, 1949).
- We propose a time tagger named SynTime to recognize time expressions using syntactic token types and general heuristic rules. SynTime is independent of specific tokens, and therefore independent of specific domains, specific text types, and specific languages.
- We conduct experiments on three datasets, and the results demonstrate the effectiveness of SynTime against state-of-the-art baselines.

2 Related Work

Many research works on time expression identification are reported in TempEval exercises (Verhagen et al., 2007, 2010; UzZaman et al., 2013). The task is divided into two subtasks: recognition and normalization.

Rule-based Time Expression Recognition. Rule-based time taggers like GUTime, HeidelTime, and SUTime, predefine time-related words and rules (Verhagen et al., 2005; Strötgen and Gertz, 2010; Chang and Manning, 2012). HeidelTime (Strötgen and Gertz, 2010) hand-crafts rules with time resources like weekdays and months, and leverages language clues like part-of-speech to identify time expression. SUTime (Chang and Manning, 2012) designs deterministic rules using a cascade finite automata (Hobbs et al., 1997) on regular expressions over tokens (Chang and Manning, 2014). It first identifies individual words, then expands them to chunks, and finally to time expressions. Rule-based taggers achieve very good results in TempEval exercises.

SynTime is also a rule-based tagger while its key difference from other rule-based taggers is that between the rules and the tokens it introduces a layer of token type; its rules work on token types and are independent of specific tokens. Moreover, SynTime designs rules in a heuristic way.

Machine Learning based Method. Machine learning based methods extract features from the text and apply statistical models on the features for recognizing time expressions. Example features

[2] https://github.com/stanfordnlp/CoreNLP/tree/master/src/edu/stanford/nlp/time/rules

[3] Gigaword dataset is not used in our experiments because the labels in the dataset are not the ground truth labels but instead are automatically generated by other taggers.

include character features, word features, syntactic features, semantic features, and gazetteer features (Llorens et al., 2010; Filannino et al., 2013; Bethard, 2013). The statistical models include Markov logic network, logistic regression, support vector machines, maximum entropy, and conditional random fields (Llorens et al., 2010; UzZaman and Allen, 2010; Filannino et al., 2013; Bethard, 2013). Some models obtain good performance, and even achieve the highest F_1 of 82.71% on strict match in TempEval-3 (Bethard, 2013).

Outside TempEval exercises, Angeli et al. leverage compositional grammar and employ a EM-style approach to learn a latent parser for time expression recognition (Angeli et al., 2012). In the method named UWTime, Lee et al. handcraft a combinatory categorial grammar (CCG) (Steedman, 1996) to define a set of lexicon with rules and use L1-regularization to learn linguistic context (Lee et al., 2014). The two methods explicitly use linguistic information. In (Lee et al., 2014), especially, CCG could capture rich structure information of language, similar to the rule-based methods. Tabassum et al. focus on resolving the dates in tweets, and use distant supervision to recognize time expressions (Tabassum et al., 2016). They use five time types and assign one of them to each word, which is similar to SynTime in the way of defining types over tokens. However, they focus only on the type of date, while SynTime recoginizes all the time expressions and does not involve learning and runs in real time.

Time Expression Normalization. Methods in TempEval exercises design rules for time expression normalization (Verhagen et al., 2005; Strötgen and Gertz, 2010; Llorens et al., 2010; UzZaman and Allen, 2010; Filannino et al., 2013; Bethard, 2013). Because the rule systems have high similarity, Llorens et al. suggest to construct a large knowledge base as a public resource for the task (Llorens et al., 2012). Some researchers treat the normalization process as a learning task and use machine learning methods (Lee et al., 2014; Tabassum et al., 2016). Lee et al. (Lee et al., 2014) use AdaGrad algorithm (Duchi et al., 2011) and Tabassum et al. (Tabassum et al., 2016) use a log-linear algorithm to normalize time expressions.

SynTime focuses only on the recognition task. The normalization could be achieved by using methods similar to the existing rule systems, because they are highly similar (Llorens et al., 2012).

Table 1: Statistics of the datasets (A tweet here is a document.)

Dataset	#Docs	#Words	#TIMEX
TimeBank	183	61,418	1,243
Gigaword	2,452	666,309	12,739
WikiWars	22	119,468	2,671
Tweets	942	18,199	1,127

3 Time Expression Analysis

3.1 Dataset

We conduct an analysis on four datasets: TimeBank, Gigaword, WikiWars, and Tweets. TimeBank (Pustejovsky et al., 2003b) is a benchmark dataset in TempEval series (Verhagen et al., 2007, 2010; UzZaman et al., 2013), consisting of 183 news articles. Gigaword (Parker et al., 2011) is a large *automatically* labelled dataset with 2,452 news articles and used in TempEval-3. WikiWars dataset is derived from Wikipedia articles about wars (Mazur and Dale, 2010). Tweets is our manually annotated dataset with 942 tweets of which each contains at least one time expression. Table 1 summarizes the datasets.

3.2 Finding

From the four datasets, we analyze their time expressions and make four findings. We will see that despite the four datasets vary in corpus sizes, in text types, and in domains, their time expressions demonstrate similar characteristics.

Finding 1 *Time expressions are very short. More than 80% of time expressions contain no more than three words and more than 90% contain no more than four words.*

Figure 1 plots the length distribution of time expressions. Although the texts are collected from different sources (i.e., news articles, Wikipedia articles, and tweets) and vary in sizes, the length

Table 2: The percentage of time expressions that contain at least one time token, and the average length of time expressions

Dataset	Percent	Average Length
TimeBank	94.61	2.00
Gigaword	96.44	1.70
WikiWars	91.81	2.38
Tweets	96.01	1.51

Table 3: Number of distinct words and number of distinct time tokens in time expressions

Dataset	#Words	#Time Tokens
TimeBank	130	64
Gigaword	214	80
WikiWars	224	74
Tweets	107	64

of time expressions follow a similar distribution. In particular, the one-word time expressions range from 36.23% in WikiWars to 62.91% in Tweets. In informal communication people tend to use words in minimum length to express time information. The third column in Table 2 reports the average length of time expressions. On average, time expressions contain about two words.

Finding 2 *More than 91% of time expressions contain at least one time token.*

The second column in Table 2 reports the percentage of time expressions that contain at least one time token. We find that at least 91.81% of time expressions contain time token(s). (Some time expressions have no time token but depend on other time expressions; in '2 to 8 days,' for example, '2' depends on '8 days.') This suggests that time tokens account for time expressions. Therefore, to recognize time expressions, it is essential to recognize their time tokens.

Finding 3 *Only a small group of time-related keywords are used to express time information.*

From the time expressions in all four datasets, we find that the group of keywords used to express time information is small.

Table 3 reports the number of distinct words and of distinct time tokens. The words/tokens are manually normalized before counting and their variants are ignored. For example, 'year' and '5yrs' are counted as one token 'year.' Numerals in the counting are ignored. Despite the four datasets vary in sizes, domains, and text types, the numbers of their distinct time tokens are comparable.

Across the four datasets, the number of distinct words is 350, about half of the simply summing of 675; the number of distinct time tokens is 123, less than half of the simply summing 282. Among the 123 distinct time tokens, 45 appear in all the four datasets, and 101 appear in at least two datasets. This indicates that time tokens, which account for time expressions, are highly overlapped across the four datasets. In other words, time expressions highly overlap at their time tokens.

Finding 4 *POS information could not distinguish time expressions from common words, but within time expressions, POS tags can help distinguish their constituents.*

For each dataset we list the top 10 POS tags that appear in time expressions, and their percentages over the whole text. Among the 40 tags (10 $\times$ 4 datasets), 37 have percentage lower than 20%; other 3 are CD. This indicates that POS could not provide enough information to distinguish time expressions from common words. However, the most common POS tags in time expressions are NN*, JJ, RB, CD, and DT. Within time expressions, the time tokens usually have NN* and RB, the modifiers have JJ and RB, and the numerals have CD. This finding indicates that for the time expressions, their similar constituents behave in similar syntactic way. When seeing this, we realize that this is exactly how linguists define part-of-speech for language.[4] The definition of POS for language inspires us to define a syntactic type system for the time expression, part of language.

The four findings all relate to the principle of least effort (Zipf, 1949). That is, people tend to act with least effort so as to minimize the cost of energy at both individual and collective levels to the language usage (Zipf, 1949). Time expression is part of language and acts as an interface of communication. Short expressions, occurrence, small vocabulary, and similar syntactic behaviour all reduce the cost of energy required to communicate.

To summarize: on average, a time expression contains two tokens of which one is time token and the other is modifier/numeral, and the size of time tokens is small. To recognize a time expression, therefore, we first recognize the time token, then recognize the modifier/numeral.

[4] "linguists group some words of language into classes (sets) which show similar syntactic behaviour." (Manning and Schutze, 1999)

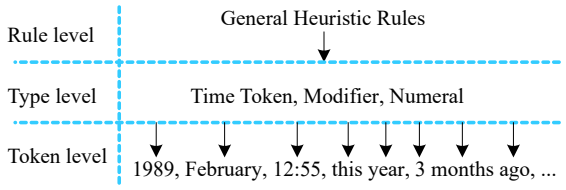

Figure 2: Layout of SynTime. The layout consists of three levels: token level, type level, and rule level. Token types group the constituent tokens of time expressions. Heuristic rules work on token types, and are independent of specific tokens.

4 SynTime: Syntactic Token Types and General Heuristic Rules

SynTime defines a syntactic type system for the tokens of time expressions, and designs heuristic rules working on the token types. Figure 2 shows the layout of SynTime, consisting of three levels: Token level, type level, and rule level. Token types at the type level group the tokens of time expressions. Heuristic rules lie at the rule level, working on token types rather than on tokens themselves. That is why the heuristic rules are general. For example, the heuristic rules do not work on tokens '1989' nor 'February,' but on their token types 'YEAR' and 'MONTH.' The heuristic rules are only relevant to token types, and are independent of specific tokens. For this reason, our token types and heuristic rules are independent of specific domains, specific text types, and even specific languages that consist of specific tokens. In this paper, we test SynTime on specific domain (i.e., war domain) and specific text types (i.e., formal text and informal text) in English. The test for other languages simply needs to construct a set of token regular expressions in the target language under our defined token types.

Figure 3 shows the overview of SynTime in practice. Shown on the left-hand side, SynTime is initialized with regular expressions over tokens. After initialization, SynTime can be directly applied on text. On the other hand, SynTime can be easily expanded by simply adding the time-related token regular expressions from training text under each defined token type. The expansion enables SynTime to recognize time expressions in text from different domains and different text types.

Shown on the right-hand side of Figure 3, SynTime recognizes time expression through three main steps. In the first step, SynTime identifies

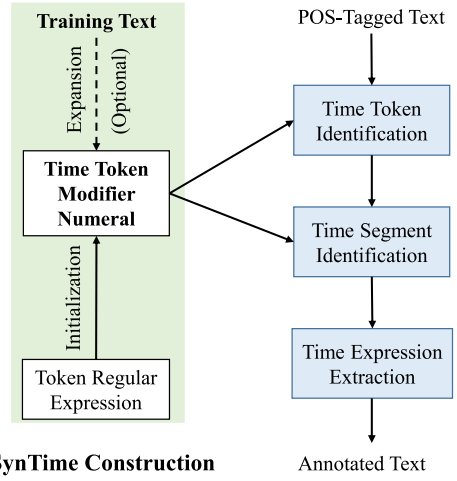

Figure 3: Overview of SynTime. Left-hand side shows the construction of SynTime, with initialization using token regular expressions, and optional expansion using training text. Right-hand side shows the main steps of SynTime recognizing time expressions.

time tokens from the POS-tagged raw text. Then around the time tokens SynTime searches for modifiers and numerals to form time segments. In the last step, SynTime transforms the time segments to time expressions.

4.1 SynTime Construction

We define a syntactic type system for time expression, specifically, 15 token types for time tokens, 5 token types for modifiers, and 1 token type for numeral. Token types to tokens is like POS tags to words; for example, 'February' has a POS tag of NNP and a token type of MONTH.

Time Token. We define 15 token types for the time tokens and use their names similar to Joda-Time classes:[5] DECADE (-), YEAR (-), SEASON (5), MONTH (12), WEEK (7), DATE (-), TIME (-), DAY_TIME (27), TIMELINE (12), HOLIDAY (20), PERIOD (9), DURATION (-), TIME_UNIT (15), TIME_ZONE (6), and ERA (2). Number in '()' indicates the number of distinct tokens in this token type. '-' indicates that this token type involves changing digits and cannot be counted.

Modifier. We define 3 token types for the modifiers according to their possible positions relative to time tokens. Modifiers that appear before time tokens are PREFIX (48); modifiers after time tokens are SUFFIX (2). LINKAGE (4) link two time

[5] http://www.joda.org/joda-time/

tokens. Besides, we define 2 special modifier types, COMMA (1) for comma ',' and IN_ARTICLE (2) for indefinite articles 'a' and 'an.'

TimeML (Pustejovsky et al., 2003a) and TimeBank (Pustejovsky et al., 2003b) do not treat most prepositions like 'on' as a part of time expressions. Thus SynTime does not collect those prepositions.

Numeral. Number in time expressions can be a time token e.g., '10' in 'October 10, 2016,' or a modifier e.g., '10' in '10 days.' We define NUMERAL (-) for the ordinals and numbers.

SynTime Initialization. The token regular expressions for initializing SynTime are collected from SUTime,[6] a state-of-the-art rule-based tagger that achieved the highest recall in TempEval-3 (Chang and Manning, 2012, 2013). Specifically, we collect from SUTime only the tokens and the regular expressions over tokens, and discard its other rules of recognizing full time expressions.

4.2 Time Expression Recognition

On the token types, SynTime designs a small set of heuristic rules to recognize time expressions. The recognition process includes three main steps: (1) time token identification, (2) time segment identification, and (3) time expression extraction.

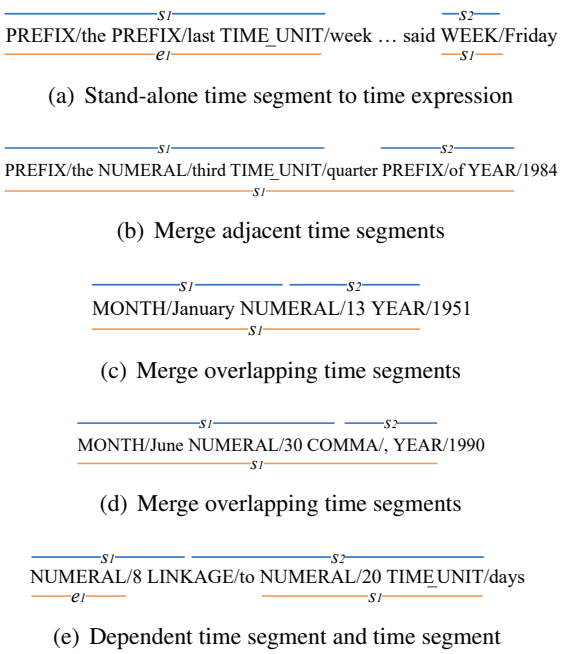
4.2.1 Time Token Identification

Identifying time tokens is simple, through matching of string and regular expressions. Some words might cause ambiguity. For example, 'May' could be a modal verb, or the fifth month of year. To filter out the ambiguous words, we use POS information. In implementation, we use Stanford POS Tagger;[7] and the POS tags for matching the instances of token types in SynTime are based on our Finding 4 in Section 3.2.

Besides time tokens are identified, in this step, individual token is assigned with one token type of either modifier or numeral if it is matched with token regular expressions. In the next two steps, SynTime works on those token types.

4.2.2 Time Segment Identification

The task of time segment identification is to search the surrounding of each time token identified in previous step for modifiers and numerals, then gather the time token with its modifiers and numerals to form a time segment. The searching is



(a) Stand-alone time segment to time expression

(b) Merge adjacent time segments

(c) Merge overlapping time segments

(d) Merge overlapping time segments

(e) Dependent time segment and time segment

Figure 4: Example time segments and time expressions. The above labels are from time segment identification; the below labels are for time expression extraction.

under simple heuristic rules in which the key idea is to expand the time token's boundaries.

At first, each time token is a time segment. If it is either a PERIOD or DURATION, then no need to further search. Otherwise, search its left and its right for modifiers and numerals. For the left searching, if encounter a PREFIX or NUMERAL or IN_ARTICLE, then continue searching. For the right searching, if encounter a SUFFIX or NUMERAL, then continue searching. Both the left and the right searching stop when reaching a COMMA or LINKAGE or a non-modifier/numeral word. The left searching does not exceed the previous time token; the right searching does not exceed the next time token. A time segment consists of exactly one time token, and zero or some modifiers/numerals.

A special kind of time segments do not contain any time token; they depend on other time segments next to them. For example, in '8 to 20 days,' 'to 20 days' is a time segment, and '8 to' forms a dependent time segment. (See Figure 4(e).)

4.2.3 Time Expression Extraction

The task of time expression extraction is to extract time expressions from the identified time segments in which the core step is to determine whether to merge two adjacent or overlapping time segments into a new time segment.

[6] https://github.com/stanfordnlp/CoreNLP/tree/master/src/edu/stanford/nlp/time/rules

[7] http://nlp.stanford.edu/software/tagger.shtml

We scan the time segments in a sentence from beginning to the end. A stand-alone time segment is a time expression. (See Figure 4(a).) The focus is to deal with two or more time segments that are adjacent or overlapping. If two time segments s_1 and s_2 are adjacent, merge them to form a new time segment s_1. (See Figure 4(b).) Consider that s_1 and s_2 overlap at a shared boundary. According to our time segment identification, the shared boundary could be a modifier or a numeral. If the word at the shared boundary is neither a COMMA nor a LINKAGE, then merge s_1 and s_2. (See Figure 4(c).) If the word is a LINKAGE, then extract s_1 as a time expression and continue scanning. When the shared boundary is a COMMA, merge s_1 and s_2 only if the COMMA's previous token and its next token satisfy the three conditions: (1) the previous token is a time token or a NUMERAL; (2) the next token is a time token; and (3) the token types of the previous token and of the next token are not the same. (See Figure 4(d).)

Although Figure 4 shows the examples as token types together with the tokens, we should note that the heuristic rules only work on the token types. After the extraction step, time expressions are exported as a sequence of tokens from the sequence of token types.

4.3 SynTime Expansion

SynTime could be expanded by simply adding new words under each defined token type without changing any rule. The expansion requires the words to be added to be annotated manually. We apply the initial SynTime on the time expressions from training text and list the words that are not covered. Whether the uncovered words are added to SynTime is manually determined. The rule for determination is that the added words can not cause ambiguity and should be generic. WikiWars dataset contains a few examples like this: 'The time Arnold reached Quebec City.' Words in this example are extremely descriptive, and we do not collect them. In tweets, on the other hand, people may use abbreviations and informal variants; for example, '2day' and 'tday' are popular spellings of 'today.' Such kind of abbreviations and informal variants will be collected.

According to our findings, not many words are used to express time information, the manual addition of keywords thus will not cost much. In addition, we find that even in tweets people tend to use formal words. In the Twitter word clusters trained from 56 million English tweets,[8] the most often used words are the formal words, and their frequencies are much greater than the informal words'. The cluster of 'today,'[9] for example, its most often use is the formal one, 'today,' which appears 1,220,829 times; while its second most often use '2day' appears only 34,827 times. The low rate of informal words (e.g., about 3% in 'today' cluster) suggests that even in informal environment the manual keyword addition costs little.

5 Experiments

We evaluate SynTime against three state-of-the-art baselines (i.e., HeidelTime, SUTime, and UWTime) on three datasets (i.e., TimeBank, WikiWars, and Tweets). WikiWars is a specific domain dataset about war; TimeBank and WikiWars are the datasets in formal text while Tweets dataset is in informal text. For SynTime we report the results of its two versions: SynTime-I and SynTime-E. SynTime-I is the initial version, and SynTime-E is the expanded version of SynTime-I.

5.1 Experiment Setting

Datasets. We use three datasets of which TimeBank and WikiWars are benchmark datasets whose details are shown in Section 3.1; Tweets is our manually labeled dataset that are collected from Twitter. For Tweets dataset, we randomly sample 4000 tweets and use SUTime to tag them. 942 tweets of which each contains at least one time expression. From the remaining 3,058 tweets, we randomly sample 500 and manually annotate them, and find that only 15 tweets contain time expressions. We therefore roughly consider that SUTime misses about 3% time expressions in tweets. Two annotators then manually annotate the 942 tweets with discussion to final agreement according to the standards of TimeML and TimeBank. We finally get 1,127 manually labeled time expressions. For the 942 tweets, we randomly sample 200 tweets as test set, and the rest 742 as training set, because a baseline UWTime requires training.

Baseline Methods. We compare SynTime with methods: HeidelTime (Strötgen and Gertz, 2010), SUTime (Chang and Manning, 2012), and UW-

	SynTime-E	**91.49**	**93.48**	**92.47**	93.62	**95.65**	94.62
WikiWars	HeidelTime(Lee et al., 2014)	85.20	79.30	82.10	92.60	86.20	89.30
	SUTime	78.61	76.69	76.64	95.74	89.57	92.55
	UWTime(Lee et al., 2014)	**87.70**	78.80	**83.00**	**97.60**	87.60	92.30
	SynTime-I	80.00	80.22	80.11	92.16	92.41	92.29
	SynTime-E	79.18	**83.47**	81.27	90.49	**95.39**	**92.88**
Tweets	HeidelTime	**89.58**	72.88	80.37	95.83	77.97	85.98
	SUTime	76.03	77.97	76.99	88.43	90.68	89.54
	UWTime	88.54	72.03	79.44	**96.88**	78.81	86.92
	SynTime-I	89.52	94.07	91.74	93.55	98.31	95.87
	SynTime-E	89.20	**94.49**	**91.77**	93.20	**98.78**	**95.88**

Time (Lee et al., 2014). HeidelTime and SUTime both are rule-based methods, and UWTime is a learning method. When training UWTime on Tweets, we try two settings: (1) train with only Tweets training set; (2) train with TimeBank and Tweets training set. The second setting achieves slightly better result and we report that result.

Evaluation Metrics. We follow TempEval-3 and use their evaluation toolkit[10] to report $Precision$, $Recall$, and F_1 in terms of *strict match* and *relaxed match* (UzZaman et al., 2013).

5.2 Experiment Result

Table 4 reports the overall performance. Among the 18 measures, SynTime-I and SynTime-E achieve 12 best results and 13 second best results. Except the strict match on WikiWars dataset, both SynTime-I and SynTime-E achieve F_1 above 91%. For the relaxed match on all three datasets, SynTime-I and SynTime-E achieve recalls above 92%. The high recalls are consistent with our finding that at least 91.81% of time expressions contain time token(s). (See Table 2.) This indicates that SynTime covers most of time tokens. On Tweets dataset, SynTime-I and SynTime-E achieve exceptionally good performance. Their F_1 reach 91.74% with 11.37% improvement in strict match and 95.87% with 6.33% improvement in relaxed match. The reasons are that in informal environment people tend to use time expressions in minimum length, (62.91% of one-word time expressions in Tweets; see Figure 1.) the size of time keywords is small, (only 60 distinct time tokens; see Table 3.) and even in tweets people tend to use formal words. (See Section 4.3 for our finding from Twitter word clusters.) For precision, SynTime achieves comparable results in strict match and performs slightly poorer in relaxed match.

5.2.1 SynTime-I vs. Baseline Methods

On TimeBank dataset, SynTime-I achieves F_1 of 92.09% in strict match and of 94.96% in relaxed match. On Tweets, SynTime-I achieves 91.74% and 95.87%, respectively. It outperforms all the baseline methods. The reason is that for the rule-based time taggers, their rules are designed in a fixed way, lacking flexibility. For example, SUTime could recognize '1 year' but not 'year 1.' For the machine learning based methods, some of the features they used actually hurt the modelling. Time expressions involve quite many changing numbers which in themselves affect the pattern recognition. For example, it is difficult to build connection between 'May 22, 1986' and 'February 01, 1989' at the level of word or of character. One suggestion is to consider a type-based learning method that could use type information. For example, the above two time expressions refer to the same pattern of 'MONTH NUMERAL COMMA

[10] http://www.cs.rochester.edu/~naushad/tempeval3/tools.zip

Table 5: Number of time tokens and modifiers for expansion

Dataset	#Time Tokens	#Modifiers
TimeBank	3	5
WikiWars	16	21
Tweets	3	2

YEAR' at the level of token type. POS is a kind of type information. But according to our analysis, POS could not distinguish time expressions from common words. Features need carefully designing. On WikiWars, SynTime-I achieves competitive results in both matches. Time expressions in WikiWars include lots of prepositions and quite a few descriptive time expressions. SynTime could not fully recognize such kinds of time expressions because it follows TimeML and TimeBank.

5.2.2 SynTime-E vs. SynTime-I

Table 5 lists the number of time tokens and modifiers added to SynTime-I to get SynTime-E.

On TimeBank and Tweets datasets, only a few tokens are added, the corresponding results are affected slightly. This confirms that the size of time words is small, and that SynTime-I covers most of time words. On WikiWars dataset, relatively more tokens are added, SynTime-E performs much better than SynTime-I, especially in recall. It improves the recall by 3.25% in strict match and by 2.98% in relaxed match. This indicates that with more words added from specific domains (e.g., WikiWars dataset about war), SynTime can significantly improve the performance.

5.3 Limitations

SynTime assumes that words are tokenized and POS tagged correctly. In reality, however, the tokenized and tagged words are not that perfect, due to the limitation of used tools. For example, Stanford POS Tagger assigns VBD to the word 'sat' in 'friday or sat' while whose tag should be NNP. The incorrect tokens and POS tags affect the result.

6 Conclusion and future work

We conduct an analysis on time expressions from four datasets, and find that time expressions in general are very short and expressed by a small vocabulary, and words in time expressions demonstrate similar syntactic behavior. Our findings provide evidence in terms of time expression for the principle of least effort (Zipf, 1949). Inspired by part-of-speech, based on the findings, we define a syntactic type system for the time expression, and propose a type-based time expression tagger, named by SynTime. SynTime defines syntactic token types for tokens and on the token types it designs general heuristic rules based on the idea of boundary expansion. Experiments on three datasets show that SynTime outperforms the state-of-the-art baselines, including rule-based time taggers and machine learning based time tagger. Because our heuristic rules are quite simple, SynTime is light-weight and runs in real time.

Our token types and heuristic rules are independent of specific tokens, SynTime therefore is independent of specific domains, specific text types, and even specific languages that consist of specific tokens. In this paper, we test SynTime on specific domains and specific text types in English. The test for other languages needs only to construct a collection of token regular expressions in the target language under our defined token types.

Time expression is part of language and follows the principle of least effort. Since language usage relates to human habits (Zipf, 1949; Chomsky, 1986; Pinker, 1995), we might expect that humans would share some common habits, and therefore expect that other parts of language would more or less follow the same principle. In the future we will try our analytical method on other parts of language.

Abstract

Distant supervision significantly reduces human efforts in building training data for many classification tasks. While promising, this technique often introduces noise to the generated training data, which can severely affect the model performance. In this paper, we take a deep look at the application of distant supervision in relation extraction. We show that the dynamic transition matrix can effectively characterize the noise in the training data built by distant supervision. The transition matrix can be effectively trained using a novel curriculum learning based method without any direct supervision about the noise. We thoroughly evaluate our approach under a wide range of extraction scenarios. Experimental results show that our approach consistently improves the extraction results and outperforms the state-of-the-art in various evaluation scenarios.

1 Introduction

Distant supervision (DS) is rapidly emerging as a viable means for supporting various classification tasks – from relation extraction (Mintz et al., 2009) and sentiment classification (Go et al., 2009) to cross-lingual semantic analysis (Fang and Cohn, 2016). By using knowledge learned from seed examples to label data, DS automatically prepares large scale training data for these tasks.

While promising, DS does not guarantee perfect results and often introduces noise to the generated data. In the context of relation extraction, DS works by considering sentences containing both the subject and object of a <*subj*, rel, *obj*> triple as its supports. However, the generated data are not always perfect. For instance, DS could match the knowledge base (KB) triple, <*Donald Trump*, born-in, *New York*> in *false positive* contexts like *Donald Trump worked in New York City*. Prior works (Takamatsu et al., 2012; Ritter et al., 2013) show that DS often mistakenly labels real positive instances as negative (*false negative*) or versa vice (*false positive*), and there could be confusions among positive labels as well. These noises can severely affect training and lead to poorly-performing models.

Tackling the noisy data problem of DS is non-trivial, since there usually lacks of explicit supervision to capture the noise. Previous works have tried to remove sentences containing unreliable syntactic patterns (Takamatsu et al., 2012), design new models to capture certain types of noise or aggregate multiple predictions under the *at-least-one assumption* that at least one of the aligned sentences supports the triple in KB (Riedel et al., 2010; Surdeanu et al., 2012; Ritter et al., 2013; Min et al., 2013). These approaches represent a substantial leap forward towards making DS more practical. however, are either tightly couple to certain types of noise, or have to rely on manual rules to filter noise, thus unable to scale. Recent breakthrough in neural networks provides a new way to reduce the influence of incorrectly labeled data by aggregating multiple training instances attentively for relation classification, without explicitly characterizing the inherent noise (Lin et al., 2016; Zeng et al., 2015). Although promising, modeling noise within neural network architectures is still in its early stage and much remains to be done.

In this paper, we aim to enhance DS noise modeling by providing the capability to explicitly characterize the noise in the DS-style training data

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 430–439
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1040

within neural networks architectures. We show that while noise is inevitable, it is possible to characterize the noise pattern in a unified framework along with its original classification objective. Our key insight is that the DS-style training data typically contain useful clues about the noise pattern. For example, we can infer that since some people work in their birthplaces, DS could wrongly label a training sentence describing a working place as a born-in relation. Our novel approach to noisy modeling is to use a dynamically-generated transition matrix for each training instance to (1) characterize the possibility that the DS labeled relation is confused and (2) indicate its noise pattern. To tackle the challenge of no direct guidance over the noise pattern, we employ a curriculum learning based training method to gradually model the noise pattern over time, and utilize trace regularization to control the behavior of the transition matrix during training. Our approach is flexible – while it does not make any assumptions about the data quality, the algorithm can make effective use of the data-quality prior knowledge to guide the learning procedure when such clues are available.

We apply our method to the relation extraction task and evaluate under various scenarios on two benchmark datasets. Experimental results show that our approach consistently improves both extraction settings, outperforming the state-of-the-art models in different settings.

Our work offers an effective way for tackling the noisy data problem of DS, making DS more practical at scale. Our main contributions are to (1) design a *dynamic* transition matrix structure to characterize the noise introduced by DS, and (2) design a curriculum learning based framework to adaptively guide the training procedure to learn with noise.

2 Problem Definition

The task of distantly supervised relation extraction is to extract knowledge triples, <*subj*, rel, *obj*>, from free text with the training data constructed by aligning existing KB triples with a large corpus. Specifically, given a triple in KB, DS works by first retrieving all the sentences containing both *subj* and *obj* of the triple, and then constructing the training data by considering these sentences as support to the existence of the triple. This task can be conducted in both the sentence and the bag levels. The former takes a sentence s containing both $subj$ and obj as input, and outputs the relation expressed by the sentence between $subj$ and obj. The latter setting alleviates the noisy data problem by using the ***at-least-one assumption*** that at least one of the retrieved sentences containing both $subj$ and obj supports the <*subj*, rel, *obj*> triple. It takes a bag of sentences S as input where each sentence $s \in S$ contains both $subj$ and obj, and outputs the relation between $subj$ and obj expressed by this bag.

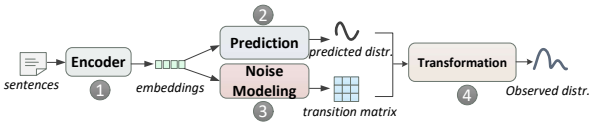

Figure 1: Overview of our approach

3 Our approach

In order to deal with the noisy training data obtained through DS, our approach follows four steps as depicted in Figure 1. First, each input sentence is fed to a sentence encoder to generate an embedding vector. Our model then takes the sentence embeddings as input and produce a predicted relation distribution, $\mathbf{p}$, for the input sentence (or the input sentence bag). At the same time, our model dynamically produces a transition matrix, $\mathbf{T}$, which is used to characterize the noise pattern of sentence (or the bag). Finally, the predicted distribution is multiplied by the transition matrix to produce the observed relation distribution, $\mathbf{o}$, which is used to match the noisy relation labels assigned by DS while the predicted relation distribution $\mathbf{p}$ serves as output of our model during testing. One of the key challenges of our approach is on determining the element values of the transition matrix, which will be described in Section 4.

3.1 Sentence-level Modeling

Sentence Embedding and Prediction In this work, we use a piecewise convolutional neural network (Zeng et al., 2015) for sentence encoding, but other sentence embedding models can also be used. We feed the sentence embedding to a full connection layer, and use *softmax* to generate the predicted relation distribution, $\mathbf{p}$.

Noise Modeling First, each sentence embedding $\mathbf{x}$, generated b sentence encoder, is passed to a full connection layer as a non-linearity to obtain the sentence embedding $\mathbf{x}_n$ used specifically for noise modeling. We then use *softmax* to calculate the

transition matrix $\mathbf{T}$, for each sentence:

$$T_{ij} = \frac{exp(\mathbf{w}_{ij}^T \mathbf{x}_n + b)}{\sum_{j=1}^{|\mathbb{C}|} exp(\mathbf{w}_{ij}^T \mathbf{x}_n + b)} \quad (1)$$

where T_{ij} is the conditional probability for the input sentence to be labeled as relation j by DS, given i as the true relation, b is a scalar bias, $|\mathbb{C}|$ is the number of relations, $\mathbf{w}_{ij}$ is the weight vector characterizing the confusion between i and j.

Here, we dynamically produce a transition matrix, $\mathbf{T}$, specifically for each sentence, but with the parameters ($\mathbf{w}_{ij}$) shared across the dataset. By doing so, we are able to adaptively characterize the noise pattern for each sentence, with a few parameters only. In contrast, one could also produce a global transition matrix for all sentences, with much less computation, where one need not to compute $\mathbf{T}$ on the fly (see Section 6.1).

Observed Distribution When we characterize the noise in a sentence with a transition matrix $\mathbf{T}$, if its true relation is i, we can assume that i might be erroneously labeled as relation j by DS with probability T_{ij}. We can therefore capture the observed relation distribution, $\mathbf{o}$, by multiplying $\mathbf{T}$ and the predicted relation distribution, $\mathbf{p}$:

$$\mathbf{o} = \mathbf{T}^T \cdot \mathbf{p} \quad (2)$$

where $\mathbf{o}$ is then normalized to ensure $\sum_i o_i = 1$.

Rather than using the predicted distribution $\mathbf{p}$ to directly match the relation labeled by DS (Zeng et al., 2015; Lin et al., 2016), here we utilize $\mathbf{o}$ to match the noisy labels during training and still use $\mathbf{p}$ as output during testing, which actually captures the procedure of how the noisy label is produced and thus protects $\mathbf{p}$ from the noise.

3.2 Bag Level Modeling

Bag Embedding and Prediction One of the key challenges for bag level model is how to aggregate the embeddings of individual sentences into the bag level. In this work, we experiment two methods, namely average and attention aggregation (Lin et al., 2016). The former calculates the bag embedding, $\mathbf{s}$, by averaging the embeddings of each sentence, and then feed it to a *softmax* classifier for relation classification.

The attention aggregation calculates an attention value, a_{ij}, for each sentence i in the bag with respect to each relation j, and aggregates to the bag level as $\mathbf{s}_j$, by the following equations[1]:

$$\mathbf{s}_j = \sum_i^n a_{ij}\mathbf{x}_i;\ a_{ij} = \frac{exp(\mathbf{x}_i^T \mathbf{r}_j)}{\sum_{i'}^n exp(\mathbf{x}_{i'}^T \mathbf{r}_j)} \quad (3)$$

where $\mathbf{x}_i$ is the embedding of sentence i, n the number of sentences in the bag, and $\mathbf{r}_j$ is the randomly initialized embedding for relation j. In similar spirit to (Lin et al., 2016), the resulting bag embedding $\mathbf{s}_j$ is fed to a *softmax* classifier to predict the probability of relation j for the given bag.

Noise Modeling Since the transition matrix addresses the transition probability with respect to each true relation, the attention mechanism appears to be a natural fit for calculating the transition matrix in bag level. Similar to attention aggregation above, we calculate the bag embedding with respect to each relation using Equation 3, but with a separate set of relation embeddings $\mathbf{r'}_j$. We then calculate the transition matrix, $\mathbf{T}$, by:

$$T_{ij} = \frac{exp(\mathbf{s}_i^T \mathbf{r'}_j + b_i)}{\sum_{j=1}^{|\mathbb{C}|} exp(\mathbf{s}_i^T \mathbf{r'}_j + b_i)} \quad (4)$$

where $\mathbf{s}_i$ is the bag embedding regarding relation i, and $\mathbf{r'}_j$ is the embedding for relation j.

4 Curriculum Learning based Training

One of the key challenges of this work is on how to train and produce the transition matrix to model the noise in the training data without any direct guidance and human involvement. A straightforward solution is to directly align the observed distribution, $\mathbf{o}$, with respect to the noisy labels by minimizing the sum of the two terms: $CrossEntropy(\mathbf{o}) + Regularization$. However, doing so does not guarantee that the prediction distribution, $\mathbf{p}$, will match the true relation distribution. The problem is at the beginning of the training, we have no prior knowledge about the noise pattern, thus, both $\mathbf{T}$ and $\mathbf{p}$ are less reliable, making the training procedure be likely to trap into some poor local optimum. Therefore, we require a technique to guide our model to gradually adapt to the noisy training data, e.g., learning something simple first, and then trying to deal with noises.

[1] While (Lin et al., 2016) use bilinear function to calculate a_{ij}, we simply use dot product since we find these two functions perform similarly in our experiments.

Fortunately, this is exactly what curriculum learning can do. The idea of curriculum learning (Bengio et al., 2009) is simple: starting with the easiest aspect of a task, and leveling up the difficulty gradually, which fits well to our problem. We thus employ a curriculum learning framework to guide our model to gradually learn how to characterize the noise. Another advantage is to avoid falling into poor local optimum.

With curriculum learning, our approach provides the flexibility to combine prior knowledge of noise, e.g., splitting a dataset into reliable and less reliable subsets, to improve the effectiveness of the transition matrix and better model the noise.

4.1 Trace Regularization

Before proceeding to training details, we first discuss how we characterize the noise level of the data by controlling the trace of its transition matrix. Intuitively, if the noise is small, the transition matrix $\mathbf{T}$ will tend to become an identity matrix, i.e., given a set of annotated training sentences, the observed relations and their true relations are almost identical. Since each row of $\mathbf{T}$ sums to 1, the similarity between the transition matrix and the identity matrix can be represented by its trace, $trace(\mathbf{T})$. The larger the $trace(\mathbf{T})$ is, the larger the diagonal elements are, and the more similar the transition matrix $\mathbf{T}$ is to the identity matrix, indicating a lower level of noise. Therefore, we can characterize the noise pattern by controlling the expected value of $trace(\mathbf{T})$ in the form of regularization. For example, we will expect a larger $trace(\mathbf{T})$ for reliable data, but a smaller $trace(\mathbf{T})$ for less reliable data. Another advantage of employing trace regularization is that it could help reduce the model complexity and avoid overfitting.

4.2 Training

To tackle the challenge of no direct guidance over the noise patterns, we implement a curriculum learning based training method to first train the model without considerations for noise. In other words, we first focus on the loss from the prediction distribution $\mathbf{p}$, and then take the noise modeling into account gradually along the training process, i.e., gradually increasing the importance of the loss from the observed distribution $\mathbf{o}$ while decreasing the importance of $\mathbf{p}$. In this way, the prediction branch is roughly trained before the model managing to characterize the noise, thus avoids being stuck into poor local optimum. We thus design to minimize the following loss function:

$$L = \sum_{i=1}^{N} -((1-\alpha)log(o_{iy_i}) + \alpha log(p_{iy_i})) - \beta trace(\mathbf{T}^i) \quad (5)$$

where $0<\alpha\leq 1$ and $\beta>0$ are two weighting parameters, y_i is the relation assigned by DS for the i-th instance, N the total number of training instances, o_{iy_i} is the probability that the observed relation for the i-th instance is y_i, and p_{iy_i} is the probability to predict relation y_i for the i-th instance.

Initially, we set α=1, and train our model completely by minimizing the loss from the prediction distribution $\mathbf{p}$. That is, we do not expect to model the noise, but focus on the prediction branch at this time. As the training progresses, the prediction branch gradually learns the basic prediction ability. We then decrease α and β by $0<\rho<1$ ($\alpha^*=\rho\alpha$ and $\beta^*=\rho\beta$) every τ epochs, i.e., learning more about the noise from the observed distribution $\mathbf{o}$ and allowing a relatively smaller $trace(\mathbf{T})$ to accommodate more noise. The motivation behind is to put more and more effort on learning the noise pattern as the training proceeds, with the essence of curriculum learning. This gradually learning paradigm significantly distinguishes from prior work on noise modeling for DS seen to date. Moreover, as such a method does not rely on any extra assumptions, it can serve as our default training method for $\mathbf{T}$.

With Prior Knowledge of Data Quality On the other hand, if we happen to have prior knowledge about which part of the training data is more reliable and which is less reliable, we can utilize this knowledge as guidance to design the curriculum. Specifically, we can build a curriculum by first training the prediction branch on the reliable data for several epochs, and then adding the less reliable data to train the full model. In this way, the prediction branch is roughly trained before exposed to more noisy data, thus is less likely to fall into poor local optimum.

Furthermore, we can take better control of the training procedure with trace regularization, e.g., encouraging larger $trace(\mathbf{T})$ for reliable subset and smaller $trace(\mathbf{T})$ for less relaibale ones. Specifically, we propose to minimize:

$$L = \sum_{m=1}^{M}\sum_{i=1}^{N_m} -log(o_{mi,y_{mi}}) - \beta_m trace(\mathbf{T}^{mi}) \quad (6)$$

where β_m is the regularization weight for the m-th data subset, M is the total number of subsets, N_m the number of instances in m-th subset, and $\mathbf{T}^{mi}$, y_{mi} and $o_{mi,y_{mi}}$ are the transition matrix, the relation labeled by DS and the observed probability of this relation for the i-th training instance in the m-th subset, respectively. Note that different from Equation 5, this loss function does not need to initiate training by minimizing the loss regarding the prediction distribution $\mathbf{p}$, since one can easily start by learning from the most reliable split first.

We also use trace regularization for the most reliable subset, since there are still some noise annotations inevitably appearing in this split. Specifically, we expect its $trace(\mathbf{T})$ to be large (using a positive β) so that the elements of $\mathbf{T}$ will be centralized to the diagonal and $\mathbf{T}$ will be more similar to the identity matrix. As for the less reliable subset, we expect the $trace(\mathbf{T})$ to be small (using a negative β) so that the elements of the transition matrix will be diffusive and $\mathbf{T}$ will be less similar to the identity matrix. In other words, the transition matrix is encouraged to characterize the noise.

Note that this loss function only works for sentence level models. For bag level models, since reliable and less reliable sentences are all aggregated into a sentence bag, we can not determine which bag is reliable and which is not. However, bag level models can still build a curriculum by changing the content of a bag, e.g., keeping reliable sentences in the bag first, then gradually adding less reliable ones, and training with Equation 5, which could benefit from the prior knowledge of data quality as well.

5 Evaluation Methodology

Our experiments aim to answer two main questions: (1) is it possible to model the noise in the training data generated through DS, even when there is no prior knowledge to guide us? and (2) whether the prior knowledge of data quality can help our approach better handle the noise.

We apply our approach to both sentence level and bag level extraction models, and evaluate in the situations where we do not have prior knowledge of the data quality as well as where such prior knowledge is available.

5.1 Datasets

We evaluate our approach on two datasets.

TIMERE We build TIMERE by using DS to align time-related Wikidata (Vrandečić and Krötzsch, 2014) KB triples to Wikipedia text. It contains 278,141 sentences with 12 types of relations between an entity mention and a time expression. We choose to use time-related relations because time expressions speak for themselves in terms of reliability. That is, given a KB triple $<e$, rel, $t>$ and its aligned sentences, the finer-grained the time expression t appears in the sentence, the more likely the sentence supports the existence of this triple. For example, a sentence containing both *Alphabet* and *October-2-2015* is very likely to express the inception-time of *Alphabet*, while a sentence containing both *Alphabet* and *2015* could instead talk about many events, e.g., releasing financial report of 2015, hiring a new CEO, etc. Using this heuristics, we can split the dataset into 3 subsets according to different granularities of the time expressions involved, indicating different levels of reliability. Our criteria for determining the reliability are as follows. Instances with full date expressions, i.e., Year-Month-Day, can be seen as the most reliable data, while those with partial date expressions, e.g., Month-Year and Year-Only, are considered as less reliable. Negative data are constructed heuristically that any *entity-time* pairs in a sentence without corresponding triples in Wikidata are treated as negative data. During training, we can access 184,579 negative and 77,777 positive sentences, including 22,214 reliable, 2,094 and 53,469 less reliable ones. The validation set and test set are randomly sampled from the reliable (full-date) data for relatively fair evaluations and contains 2,776, 2,771 positive sentences and 5,143, 5,095 negative sentences, respectively.

ENTITYRE is a widely-used entity relation extraction dataset, built by aligning triples in Freebase to the New York Times (NYT) corpus (Riedel et al., 2010). It contains 52 relations, 136,947 positive and 385,664 negative sentences for training, and 6,444 positive and 166,004 negative sentences for testing. Unlike TIMERE, this dataset does not contain any prior knowledge about the data quality. Since the sentence level annotations in ENTITYRE are too noisy to serve as gold standard, we only evaluate bag-level models on ENTITYRE, a standard practice in previous works (Surdeanu et al., 2012; Zeng et al., 2015; Lin et al., 2016).

5.2 Experimental Setup

Hyper-parameters We use 200 convolution kernels with widow size 3. During training, we use stochastic gradient descend (SGD) with batch size 20. The learning rates for sentence-level and bag-level models are 0.1 and 0.01, respectively.

Sentence level experiments are performed on TIMERE, using 100-d word embeddings pre-trained using GloVe (Pennington et al., 2014) on Wikipedia and Gigaword (Parker et al., 2011), and 20-d vectors for distance embeddings. Each of the three subsets of TIMERE is added after the previous phase has run for 15 epochs. The trace regularization weights are $\beta_1 = 0.01$, $\beta_2 = -0.01$ and $\beta_3 = -0.1$, respectively, from the reliable to the most unreliable, with the ratio of β_3 and β_2 fixed to 10 or 5 when tuning.

Bag level experiments are performed on both TIMERE and ENTITYRE. For TIMERE, we use the same parameters as above. For ENTITYRE, we use 50-d word embeddings pre-trained on the NYT corpus using word2vec (Mikolov et al., 2013), and 5-d vectors for distance embedding. For both datasets, α and β in Eq. 5 are initialized to 1 and 0.1, respectively. We tried various decay rates, {0.95, 0.9, 0.8}, and steps, {3, 5, 8}. We found that using a decay rate of 0.9 with step of 5 gives best performance in most cases.

Evaluation Metric The performance is reported using the precision-recall (PR) curve, which is a standard evaluation metric in relation extraction. Specifically, the extraction results are first ranked decreasingly by their confidence scores, then the precision and recall are calculated by setting the threshold to be the score of each extraction result one by one.

Naming Conventions We evaluate our approach under a wide range of settings for sentence level (sent_) and bag level (bag_) models: (1) _mix: trained on all three subsets of TIMERE mixed together; (2) _reliable: trained using the reliable subset of TIMERE only; (3) _PR: trained with prior knowledge of annotation quality, i.e., starting from the reliable data and then adding the unreliable data; (4) _TM: trained with dynamic transition matrix; (5) _GTM: trained with a global transition matrix. In bag level, we also investigate the performance of average aggregation (_avg) and attention aggregation (_att).

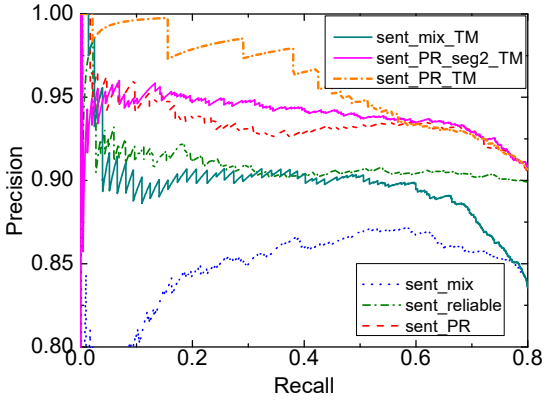

Figure 2: Sentence Level Results on TIMERE

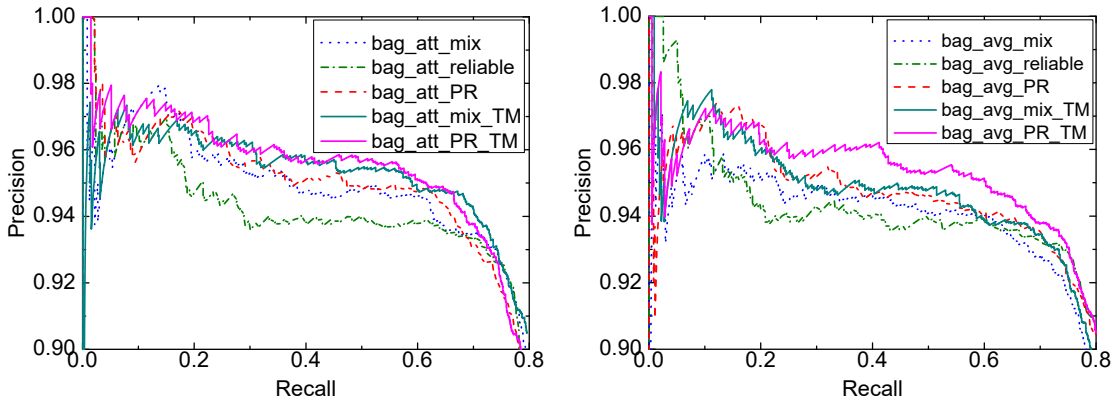
6 Experimental Results

6.1 Performance on TIMERE

Sentence Level Models The results of sentence level models on TIMERE are shown in Figure 2. We can see that mixing all subsets together (sent_mix) gives the worst performance, significantly worse than using the reliable subset only (sent_reliable). This suggests the noisy nature of the training data obtained through DS and properly dealing with the noise is the key for DS for a wider range of applications. When getting help from our dynamic transition matrix, the model (sent_mix_TM) significantly improves sent_mix, delivering the same level of performance as sent_reliable in most cases. This suggests that our transition matrix can help to mitigate the bad influence of noisy training instances.

Now let us consider the PR scenario where one can build a curriculum by first training on the reliable subset, then gradually moving to both reliable and less reliable data. We can see that, this simple curriculum learning based model (sent_PR) further outperforms sent_reliable significantly, indicating that the curriculum learning framework not only reduces the effect of noise, but also helps the model learn from noisy data. When applying the transition matrix approach into this curriculum learning framework using one reliable subset and one unreliable subset generated by mixing our two less reliable subsets, our model (sent_PR_seg2_TM) further improves sent_PR by utilizing the dynamic transition matrix to model the noise. It is not surprising that when we use all three subsets separately, our model (sent_PR_TM) significantly outperforms all other models by a large margin.



(a) Attention Aggregation

(b) Average Aggregation

Figure 3: Bag Level Results on TIMERE

Bag Level Models In this setting, we first look at the performance of the bag level models with attention aggregation. The results are shown in Figure 3(a). Consider the comparison between the model trained on the reliable subset only (`bag_att_reliable`) and the one trained on the mixed dataset (`bag_att_mix`). In contrast to the sentence level, `bag_att_mix` outperforms `bag_att_reliable` by a large margin, because `bag_att_mix` has taken the *at-least-one assumption* into consideration through the attention aggregation mechanism (Eq. 3), which can be seen as a denoising step within the bag. This may also be the reason that when we introduce either our dynamic transition matrix (`bag_att_mix_TM`) or the curriculum of using prior knowledge of data quality (`bag_att_PR`) into the bag level models, the improvement regarding `bag_att_mix` is not as significant as in the sentence level.

However, when we apply our dynamic transition matrix into the curriculum built upon prior knowledge of data quality (`bag_att_PR_TM`), the performance gets further improved. This happens especially in the high precision part compared to `bag_att_PR`. We also note that the bag level's *at-least-one assumption* does not always hold, and there are still false negative and false positive problems. Therefore, using our transition matrix approach with or without prior knowledge of data quality, i.e., `bag_att_mix_TM` and `bag_att_PR_TM`, both improve the performance, and `bag_att_PR_TM` performs slightly better.

The results of bag level models with average aggregation are shown in Figure 3(b), where the relative ranking of various settings is similar to those with attention aggregation. A notable difference is that both `bag_avg_PR` and `bag_avg_mix_TM` improve `bag_avg_mix` by a larger margin compared to that in the attention aggregation setting. The reason may be that the average aggregation mechanism is not as good as the attention aggregation in denoising within the bag, which leaves more space for our transition matrix approach or curriculum learning with prior knowledge to improve. Also note that `bag_avg_reliable` performs best in the very-low-recall region but worst in general. This is because that it ranks higher the sentences expressing either `birth-date` or `death-date`, the simplest but the most common relations in the dataset, but fails to learn other relations with limited or noisy training instances, given its relatively simple aggregation strategy.

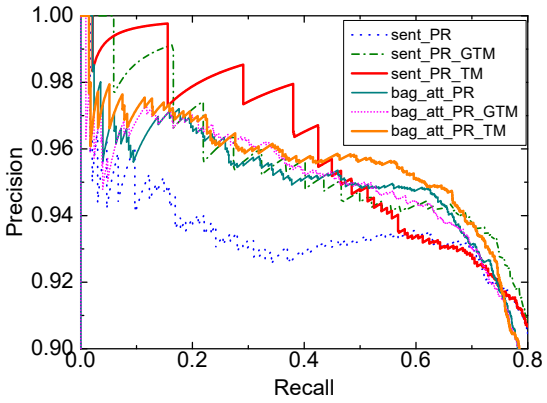


Figure 4: Global TM v.s. Dynamic TM

Global v.s. Dynamic Transition Matrix We also compare our dynamic transition matrix method with the global transition matrix method, which maintains only one transition matrix for all training instances. Specifically, instead of dynam-

ically generating a transition matrix for each datum, we first initialize an identity matrix $\mathbf{T}' \in \mathbb{R}^{|\mathbb{C}|\times|\mathbb{C}|}$, where $|\mathbb{C}|$ is the number of relations (including `no-relation`). Then the global transition matrix $\mathbf{T}$ is built by applying *softmax* to each row of $\mathbf{T}'$ so that $\sum_j \mathbf{T}_{ij} = 1$:

$$T_{ij} = \frac{e^{T'_{ij}}}{\sum_{j=1}^{|\mathbb{C}|} e^{T'_{ij}}} \quad (7)$$

where T_{ij} and T'_{ij} are the elements in the i^{th} row and j^{th} column of $\mathbf{T}$ and $\mathbf{T}'$. The element values of matrix $\mathbf{T}'$ are also updated via backpropagation during training. As shown in Figure 4, using one global transition matrix (`_GTM`) is also beneficial and improves both the sentence level (`sent_PR`) and bag level (`bag_att_PR`) models. However, since the global transition matrix only captures the global noise pattern, it fails to characterize individuals with subtle differences, resulting in a performance drop compared to the dynamic one (`_TM`).

Case Study We find our transition matrix method tends to obtain more significant improvement on noisier relations. For example, *time_of_spacecraft_landing* is noisier than *time_of_spacecraft_launch* since compared to the launching of a spacecraft, there are fewer sentences containing the landing time of a spacecraft that talks directly about the landing. Instead, many of these sentences tend to talk about the activities of the crew. Our `sent_PR_TM` model improves the F1 of *time_of_spacecraft_landing* and *time_of_spacecraft_launch* over `sent_PR` by 9.09% and 2.78%, respectively. The transition matrix makes more significant improvement on *time_of_spacecraft_landing* since there are more noisy sentences for our method to handle, which results in more significant improvement on the quality of the training data.

6.2 Performance on ENTITYRE

We evaluate our bag level models on ENTITYRE. As shown in Figure 5, it is not surprising that the basic model with attention aggregation (`att`) significantly outperforms the average one (`avg`), where `att` in our bag embedding is similar in spirit to (Lin et al., 2016), which has reported the-state-of-the-art performance on ENTITYRE. When injected with our transition matrix approach, both `att_TM` and `avg_TM` clearly outperform their basic versions.

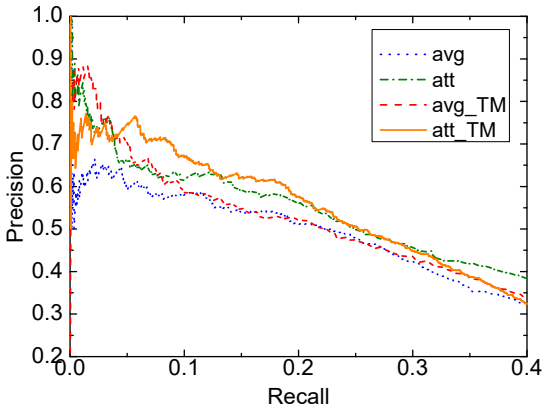

Figure 5: Results on ENTITYRE

Method	P@R_10	P@R_20	P@R_30
Mintz	39.88	28.55	16.81
MultiR	60.94	36.41	-
MIML	60.75	33.82	-
avg	58.04	51.25	42.45
avg_TM	58.56	52.35	43.59
att	61.51	56.36	**45.63**
att_TM	**67.24**	**57.61**	44.90

Table 1: Comparison with feature-based methods. P@R_10/20/30 refers to the precision when recall equals 10%, 20% and 30%.

Similar to the situations in TIMERE, since `att` has taken the *at-least-one assumption* into account through its attention-based bag embedding mechanism, thus the improvement made by `att_TM` is not as large as by `avg_TM`.

We also include the comparison with three feature-based methods: `Mintz` (Mintz et al., 2009) is a multiclass logistic regression model; `MultiR` (Hoffmann et al., 2011) is a probabilistic graphical model that can handle overlapping relations; `MIML` (Surdeanu et al., 2012) is also a probabilistic graphical model but operates in the multi-instance multi-label paradigm. As shown in Table 1, although traditional feature-based methods have reasonable results in the low recall region, their performances drop quickly as the recall goes up, and `MultiR` and `MIML` did not even reach the 30% recall. This indicates that, while human-designed featurs can effectively capture certain relation patterns, their coverage is relatively low. On the other hand, neural network models have more stable performance across different recalls, and `att_TM` performs generally better than other models, indicating again the effectiveness of our transition matrix method.

7 Related Work

In addition to relation extraction, distant supervision (DS) is shown to be effective in generating training data for various NLP tasks, e.g., tweet sentiment classification (Go et al., 2009), tweet named entity classifying (Ritter et al., 2011), etc. However, these early applications of DS do not well address the issue of data noise.

In relation extraction (RE), recent works have been proposed to reduce the influence of wrongly labeled data. The work presented by (Takamatsu et al., 2012) removes potential noisy sentences by identifying bad syntactic patterns at the preprocessing stage. (Xu et al., 2013) use pseudo-relevance feedback to find possible false negative data. (Riedel et al., 2010) make the *at-least-one assumption* and propose to alleviate the noise problem by considering RE as a multi-instance classification problem. Following this assumption, people further improves the original paradigm using probabilistic graphic models (Hoffmann et al., 2011; Surdeanu et al., 2012), and neural network methods (Zeng et al., 2015). Recently, (Lin et al., 2016) propose to use attention mechanism to reduce the noise within a sentence bag. Instead of characterizing the noise, these approaches only aim to alleviate the effect of noise.

The *at-least-one assumption* is often too strong in practice, and there are still chances that the sentence bag may be false positive or false negative. Thus it is important to model the noise pattern to guide the learning procedure. (Ritter et al., 2013) and (Min et al., 2013) try to employ a set of latent variables to represent the true relation. Our approach differs from them in two aspects. We target noise modeling in neutral networks while they target probabilistic graphic models. We further advance their models by providing the capability to model the fine-grained transition from the true relation to the observed, and the flexibility to combine indirect guidance.

Outside of NLP, various methods have been proposed in computer vision to model the data noise using neural networks. (Sukhbaatar et al., 2015) utilize a global transition matrix with weight decay to transform the true label distribution to the observed. (Reed et al., 2014) use a hidden layer to represent the true label distribution but try to force it to predict both the noisy label and the input. (Chen and Gupta, 2015; Xiao et al., 2015) first estimate the transition matrix on a clean dataset and apply to the noisy data. Our model shares similar spirit with (Misra et al., 2016) in that we all dynamically generate a transition matrix for each training instance, but, instead of using vanilla SGD, we train our model with a novel curriculum learning training framework with trace regularization to control the behavior of transition matrix. In NLP, the only work in neural-network-based noise modeling is to use one single global transition matrix to model the noise introduced by cross-lingual projection of training data (Fang and Cohn, 2016). Our work advances them through generating a transition matrix dynamically for each instance, to avoid using one single component to characterize both reliable and unreliable data.

8 Conclusions

In this paper, we investigate the noise problem inherent in the DS-style training data. We argue that the data speak for themselves by providing useful clues to reveal their noise patterns. We thus propose a novel transition matrix based method to dynamically characterize the noise underlying such training data in a unified framework along the original prediction objective. One of our key innovations is to exploit a curriculum learning based training method to gradually learn to model the underlying noise pattern without direct guidance, and to provide the flexibility to exploit any prior knowledge of the data quality to further improve the effectiveness of the transition matrix. We evaluate our approach in two learning settings of the distantly supervised relation extraction. The experimental results show that the proposed method can better characterize the underlying noise and consistently outperform start-of-the-art extraction models under various scenarios.

Abstract

We consider the problem of parsing natural language descriptions into source code written in a general-purpose programming language like Python. Existing data-driven methods treat this problem as a language generation task without considering the underlying syntax of the target programming language. Informed by previous work in semantic parsing, in this paper we propose a novel neural architecture powered by a grammar model to explicitly capture the target syntax as prior knowledge. Experiments find this an effective way to scale up to generation of complex programs from natural language descriptions, achieving state-of-the-art results that well outperform previous code generation and semantic parsing approaches.

1 Introduction

Every programmer has experienced the situation where they know what they want to do, but do not have the ability to turn it into a concrete implementation. For example, a Python programmer may want to "*sort my_list in descending order*," but not be able to come up with the proper syntax `sorted(my_list, reverse=True)` to realize his intention. To resolve this impasse, it is common for programmers to search the web in natural language (NL), find an answer, and modify it into the desired form (Brandt et al., 2009, 2010). However, this is time-consuming, and thus the software engineering literature is ripe with methods to directly generate code from NL descriptions, mostly with hand-engineered methods highly tailored to specific programming languages (Balzer, 1985; Little and Miller, 2009; Gvero and Kuncak, 2015).

In parallel, the NLP community has developed methods for data-driven semantic parsing, which attempt to map NL to structured logical forms executable by computers. These logical forms can be general-purpose meaning representations (Clark and Curran, 2007; Banarescu et al., 2013), formalisms for querying knowledge bases (Tang and Mooney, 2001; Zettlemoyer and Collins, 2005; Berant et al., 2013) and instructions for robots or personal assistants (Artzi and Zettlemoyer, 2013; Quirk et al., 2015; Misra et al., 2015), among others. While these methods have the advantage of being learnable from data, compared to the programming languages (PLs) in use by programmers, the *domain-specific* languages targeted by these works have a schema and syntax that is relatively simple.

Recently, Ling et al. (2016) have proposed a data-driven code generation method for high-level, *general-purpose* PLs like Python and Java. This work treats code generation as a sequence-to-sequence modeling problem, and introduce methods to generate words from character-level models, and copy variable names from input descriptions. However, unlike most work in semantic parsing, it does not consider the fact that code has to be well-defined programs in the target syntax.

In this work, we propose a data-driven syntax-based neural network model tailored for generation of general-purpose PLs like Python. In order to capture the strong underlying syntax of the PL, we define a model that transduces an NL statement into an Abstract Syntax Tree (AST; Fig. 1(a), § 2) for the target PL. ASTs can be deterministically generated for all well-formed programs using standard parsers provided by the PL, and thus give us a way to obtain syntax information with minimal engineering. Once we generate an AST, we can use deterministic generation tools to convert the AST into surface code. We hypothesize

Table 1: Example production rules for common Python statements (Python Software Foundation, 2016)

that such a structured approach has two benefits.

First, we hypothesize that structure can be used to constrain our search space, ensuring generation of well-formed code. To this end, we propose a syntax-driven neural code generation model. The backbone of our approach is a *grammar model* (§ 3) which formalizes the generation story of a derivation AST into sequential application of *actions* that either apply production rules (§ 3.1), or emit terminal tokens (§ 3.2). The underlying syntax of the PL is therefore encoded in the grammar model *a priori* as the set of possible actions. Our approach frees the model from recovering the underlying grammar from limited training data, and instead enables the system to focus on learning the compositionality among existing grammar rules. Xiao et al. (2016) have noted that this imposition of structure on neural models is useful for semantic parsing, and we expect this to be even more important for general-purpose PLs where the syntax trees are larger and more complex.

Second, we hypothesize that structural information helps to model information flow within the neural network, which naturally reflects the recursive structure of PLs. To test this, we extend a standard recurrent neural network (RNN) decoder to allow for additional neural connections which reflect the recursive structure of an AST (§ 4.2). As an example, when expanding the node ⋆ in Fig. 1(a), we make use of the information from both its parent and left sibling (the dashed rectangle). This enables us to locally pass information of relevant code segments via neural network connections, resulting in more confident predictions.

Experiments (§ 5) on two Python code generation tasks show 11.7% and 9.3% absolute improvements in accuracy against the state-of-the-art system (Ling et al., 2016). Our model also gives competitive performance on a standard semantic parsing benchmark[1].

2 The Code Generation Problem

Given an NL description x, our task is to generate the code snippet c in a modern PL based on the intent of x. We attack this problem by first generating the underlying AST. We define a probabilistic grammar model of generating an AST y given x: $p(y|x)$. The best-possible AST $\hat{y}$ is then given by

$$\hat{y} = \arg\max_y p(y|x). \quad (1)$$

$\hat{y}$ is then deterministically converted to the corresponding surface code c.[2] While this paper uses examples from Python code, our method is PL-agnostic.

Before detailing our approach, we first present a brief introduction of the Python AST and its underlying grammar. The Python abstract grammar contains a set of production rules, and an AST is generated by applying several production rules composed of a head node and multiple child nodes. For instance, the first rule in Tab. 1 is used to generate the function call `sorted(·)` in Fig. 1(a). It consists of a head node of type `Call`, and three child nodes of type `expr`, `expr*` and `keyword*`, respectively. Labels of each node are noted within brackets. In an AST, non-terminal nodes sketch the general structure of the target code, while terminal nodes can be categorized into two types: *operation terminals* and *variable terminals*. Operation terminals correspond to basic arithmetic operations like `AddOp`.Variable terminal nodes store values for variables and constants of built-in data types[3]. For instance, all terminal nodes in Fig. 1(a) are variable terminal nodes.

3 Grammar Model

Before detailing our neural code generation method, we first introduce the grammar model at its core. Our probabilistic grammar model defines the generative story of a derivation AST. We fac-

[1] Implementation available at https://github.com/neulab/NL2code

[2] We use `astor` library to convert ASTs into Python code.

[3] `bool`, `float`, `int`, `str`.

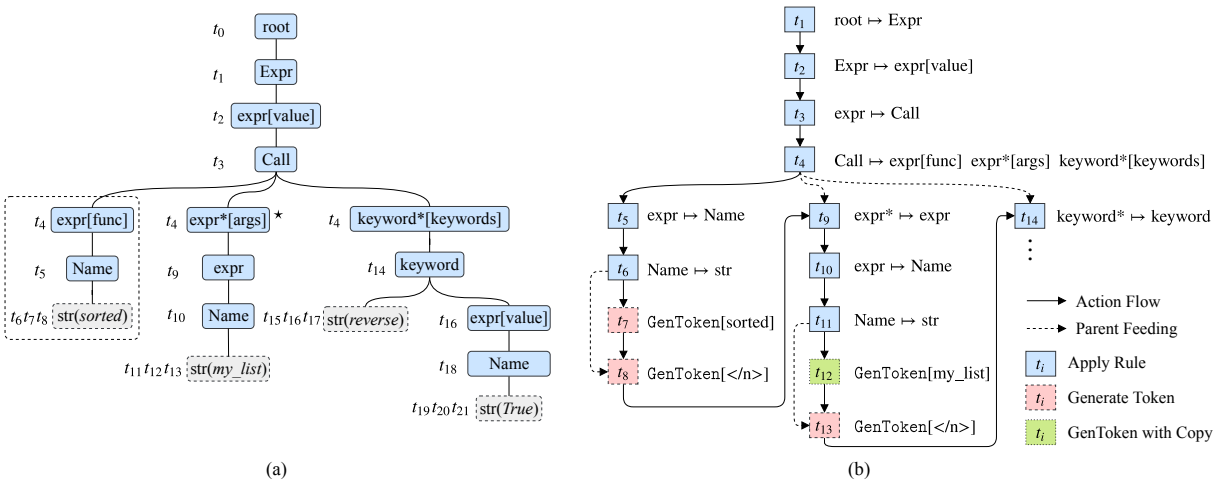

Figure 1: (a) the Abstract Syntax Tree (AST) for the given example code. Dashed nodes denote terminals. Nodes are labeled with time steps during which they are generated. (b) the action sequence (up to t_{14}) used to generate the AST in (a)

torize the generation process of an AST into sequential application of *actions* of two types:

- APPLYRULE$[r]$ applies a production rule r to the current derivation tree;
- GENTOKEN$[v]$ populates a variable terminal node by appending a terminal token v.

Fig. 1(b) shows the generation process of the target AST in Fig. 1(a). Each node in Fig. 1(b) indicates an action. Action nodes are connected by solid arrows which depict the chronological order of the action flow. The generation proceeds in depth-first, left-to-right order (dotted arrows represent parent feeding, explained in § 4.2.1).

Formally, under our grammar model, the probability of generating an AST y is factorized as:

$$p(y|x) = \prod_{t=1}^{T} p(a_t|x, a_{<t}), \qquad (2)$$

where a_t is the action taken at time step t, and $a_{<t}$ is the sequence of actions before t. We will explain how to compute the action probabilities $p(a_t|\cdot)$ in Eq. (2) in § 4. Put simply, the generation process begins from a `root` node at t_0, and proceeds by the model choosing APPLYRULE actions to generate the overall program structure from a closed set of grammar rules, then at leaves of the tree corresponding to variable terminals, the model switches to GENTOKEN actions to generate variables or constants from the open set. We describe this process in detail below.

3.1 APPLYRULE Actions

APPLYRULE actions generate program structure, expanding the current node (the *frontier node* at time step t: n_{f_t}) in a depth-first, left-to-right traversal of the tree. Given a fixed set of production rules, APPLYRULE chooses a rule r from the subset that has a head matching the type of n_{f_t}, and uses r to expand n_{f_t} by appending all child nodes specified by the selected production. As an example, in Fig. 1(b), the rule `Call` $\mapsto$ `expr...` expands the frontier node `Call` at time step t_4, and its three child nodes `expr`, `expr*` and `keyword*` are added to the derivation.

APPLYRULE actions grow the derivation AST by appending nodes. When a variable terminal node (e.g., `str`) is added to the derivation and becomes the frontier node, the grammar model then switches to GENTOKEN actions to populate the variable terminal with tokens.

Unary Closure Sometimes, generating an AST requires applying a chain of unary productions. For instance, it takes three time steps ($t_9 - t_{11}$) to generate the sub-structure `expr*` $\mapsto$ `expr` $\mapsto$ `Name` $\mapsto$ `str` in Fig. 1(a). This can be effectively reduced to one step of APPLYRULE action by taking the closure of the chain of unary productions and merging them into a single rule: `expr*` $\mapsto^*$ `str`. Unary closures reduce the number of actions needed, but would potentially increase the size of the grammar. In our experiments we tested our model both with and without unary closures (§ 5).

3.2 GENTOKEN Actions

Once we reach a frontier node n_{f_t} that corresponds to a variable type (e.g., `str`), GENTOKEN actions are used to fill this node with values. For general-purpose PLs like Python, variables and constants have values with one or multiple tokens. For in-

stance, a node that stores the name of a function (e.g., `sorted`) has a single token, while a node that denotes a string constant (e.g., `a='hello world'`) could have multiple tokens. Our model copes with both scenarios by firing GENTOKEN actions at one or more time steps. At each time step, GENTOKEN appends one terminal token to the current frontier variable node. A special `</n>` token is used to "close" the node. The grammar model then proceeds to the new frontier node.

Terminal tokens can be generated from a predefined vocabulary, or be directly copied from the input NL. This is motivated by the observation that the input description often contains out-of-vocabulary (OOV) variable names or literal values that are directly used in the target code. For instance, in our running example the variable name `my_list` can be directly copied from the the input at t_{12}. We give implementation details in § 4.2.2.

4 Estimating Action Probabilities

We estimate action probabilities in Eq. (2) using attentional neural encoder-decoder models with an information flow structured by the syntax trees.

4.1 Encoder

For an NL description x consisting of n words $\{w_i\}_{i=1}^{n}$, the encoder computes a context sensitive embedding $\mathbf{h_i}$ for each w_i using a bidirectional Long Short-Term Memory (LSTM) network (Hochreiter and Schmidhuber, 1997), similar to the setting in (Bahdanau et al., 2014). See supplementary materials for detailed equations.

4.2 Decoder

The decoder uses an RNN to model the sequential generation process of an AST defined as Eq. (2). Each action step in the grammar model naturally grounds to a time step in the decoder RNN. Therefore, the action sequence in Fig. 1(b) can be interpreted as unrolling RNN time steps, with solid arrows indicating RNN connections. The RNN maintains an internal state to track the generation process (§ 4.2.1), which will then be used to compute action probabilities $p(a_t|x, a_{<t})$ (§ 4.2.2).

4.2.1 Tracking Generation States

Our implementation of the decoder resembles a vanilla LSTM, with additional neural connections (parent feeding, Fig. 1(b)) to reflect the topological structure of an AST. The decoder's internal hidden state at time step t, $\mathbf{s}_t$, is given by:

$$\mathbf{s}_t = f_{\text{LSTM}}([\mathbf{a}_{t-1} : \mathbf{c}_t : \mathbf{p}_t : \mathbf{n}_{f_t}], \mathbf{s}_{t-1}), \quad (3)$$

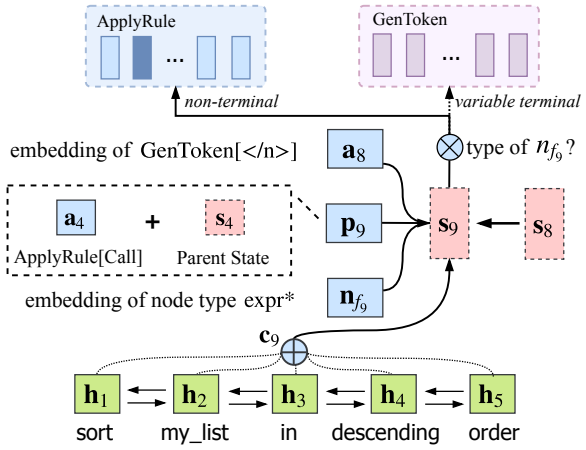

Figure 2: Illustration of a decoder time step ($t = 9$)

where $f_{\text{LSTM}}(\cdot)$ is the LSTM update function. $[:]$ denotes vector concatenation. $\mathbf{s}_t$ will then be used to compute action probabilities $p(a_t|x, a_{<t})$ in Eq. (2). Here, $\mathbf{a}_{t-1}$ is the embedding of the previous action. $\mathbf{c}_t$ is a context vector retrieved from input encodings $\{\mathbf{h}_i\}$ via soft attention. $\mathbf{p}_t$ is a vector that encodes the information of the parent action. $\mathbf{n}_{f_t}$ denotes the node type embedding of the current frontier node n_{f_t}[4]. Intuitively, feeding the decoder the information of n_{f_t} helps the model to keep track of the frontier node to expand.

Action Embedding $\mathbf{a}_t$ We maintain two action embedding matrices, $\mathbf{W}_R$ and $\mathbf{W}_G$. Each row in $\mathbf{W}_R$ ($\mathbf{W}_G$) corresponds to an embedding vector for an action APPLYRULE$[r]$ (GENTOKEN$[v]$).

Context Vector $\mathbf{c}_t$ The decoder RNN uses soft attention to retrieve a context vector $\mathbf{c}_t$ from the input encodings $\{\mathbf{h}_i\}$ pertain to the prediction of the current action. We follow Bahdanau et al. (2014) and use a Deep Neural Network (DNN) with a single hidden layer to compute attention weights.

Parent Feeding $\mathbf{p}_t$ Our decoder RNN uses additional neural connections to directly pass information from parent actions. For instance, when computing $\mathbf{s}_9$, the information from its parent action step t_4 will be used. Formally, we define the *parent action step* p_t as the time step at which the frontier node n_{f_t} is generated. As an example, for t_9, its parent action step p_9 is t_4, since n_{f_9} is the node $\star$, which is generated at t_4 by the APPLYRULE[`Call`$\mapsto \ldots$] action.

We model parent information $\mathbf{p}_t$ from two sources: (1) the hidden state of parent action $\mathbf{s}_{p_t}$, and (2) the embedding of parent action $\mathbf{a}_{p_t}$. $\mathbf{p}_t$ is the concatenation. The parent feeding schema en-

[4]We maintain an embedding for each node type.

ables the model to utilize the information of parent code segments to make more confident predictions. Similar approaches of injecting parent information were also explored in the SEQ2TREE model in Dong and Lapata (2016)[5].

4.2.2 Calculating Action Probabilities

In this section we explain how action probabilities $p(a_t|x, a_{<t})$ are computed based on $\mathbf{s}_t$.

APPLYRULE The probability of applying rule r as the current action a_t is given by a softmax[6]:

$$p(a_t = \text{APPLYRULE}[r]|x, a_{<t}) = \text{softmax}(\mathbf{W}_R \cdot g(\mathbf{s}_t))^\intercal \cdot \mathbf{e}(r) \quad (4)$$

where $g(\cdot)$ is a non-linearity $\tanh(\mathbf{W} \cdot \mathbf{s}_t + \mathbf{b})$, and $\mathbf{e}(r)$ the one-hot vector for rule r.

GENTOKEN As in § 3.2, a token v can be generated from a predefined vocabulary or copied from the input, defined as the marginal probability:

$$p(a_t = \text{GENTOKEN}[v]|x, a_{<t}) = p(\text{gen}|x, a_{<t})p(v|\text{gen}, x, a_{<t}) + p(\text{copy}|x, a_{<t})p(v|\text{copy}, x, a_{<t}).$$

The selection probabilities $p(\text{gen}|\cdot)$ and $p(\text{copy}|\cdot)$ are given by $\text{softmax}(\mathbf{W}_S \cdot \mathbf{s}_t)$. The probability of generating v from the vocabulary, $p(v|\text{gen}, x, a_{<t})$, is defined similarly as Eq. (4), except that we use the GENTOKEN embedding matrix $\mathbf{W}_G$, and we concatenate the context vector $\mathbf{c}_t$ with $\mathbf{s}_t$ as input. To model the copy probability, we follow recent advances in modeling copying mechanism in neural networks (Gu et al., 2016; Jia and Liang, 2016; Ling et al., 2016), and use a pointer network (Vinyals et al., 2015) to compute the probability of copying the i-th word from the input by attending to input representations $\{\mathbf{h}_i\}$:

$$p(w_i|\text{copy}, x, a_{<t}) = \frac{\exp(\omega(\mathbf{h}_i, \mathbf{s}_t, \mathbf{c}_t))}{\sum_{i'=1}^{n} \exp(\omega(\mathbf{h}_{i'}, \mathbf{s}_t, \mathbf{c}_t))},$$

where $\omega(\cdot)$ is a DNN with a single hidden layer. Specifically, if w_i is an OOV word (e.g., the variable name `my_list`), which is represented by a special `<unk>` token during encoding, we then directly copy the actual word w_i from the input description to the derivation.

4.3 Training and Inference

Given a dataset of pairs of NL descriptions x_i and code snippets c_i, we parse c_i into its AST y_i and decompose y_i into a sequence of oracle actions, which explains the generation story of y_i under the grammar model. The model is then optimized by maximizing the log-likelihood of the oracle action sequence. At inference time, given an NL description, we use beam search to approximate the best AST $\hat{y}$ in Eq. (1). See supplementary materials for the pseudo-code of the inference algorithm.

[5] SEQ2TREE generates tree-structured outputs by conditioning on the hidden states of parent non-terminals, while our parent feeding uses the states of parent actions.

[6] We do not show bias terms for all softmax equations.

Dataset	HS	DJANGO	IFTTT

Table 2: Statistics of datasets and associated grammars

5 Experimental Evaluation

5.1 Datasets and Metrics

HEARTHSTONE (HS) dataset (Ling et al., 2016) is a collection of Python classes that implement cards for the card game HearthStone. Each card comes with a set of fields (e.g., name, cost, and description), which we concatenate to create the input sequence. This dataset is relatively difficult: input descriptions are short, while the target code is in complex class structures, with each AST having 137 nodes on average.

DJANGO dataset (Oda et al., 2015) is a collection of lines of code from the Django web framework, each with a manually annotated NL description. Compared with the HS dataset where card implementations are somewhat homogenous, examples in DJANGO are more diverse, spanning a wide variety of real-world use cases like string manipulation, IO operations, and exception handling.

IFTTT dataset (Quirk et al., 2015) is a domain-specific benchmark that provides an interesting side comparison. Different from HS and DJANGO which are in a general-purpose PL, programs in IFTTT are written in a domain-specific language used by the IFTTT task automation

App. Users of the App write simple instructions (e.g., `If Instagram.AnyNewPhotoByYou Then Dropbox.AddFileFromURL`) with NL descriptions (e.g., "*Autosave your Instagram photos to Dropbox*"). Each statement inside the `If` or `Then` clause consists of a channel (e.g., `Dropbox`) and a function (e.g., `AddFileFromURL`)[7]. This simple structure results in much more concise ASTs (7 nodes on average). Because all examples are created by ordinary Apps users, the dataset is highly noisy, with input NL very loosely connected to target ASTs. The authors thus provide a high-quality filtered test set, where each example is verified by at least three annotators. We use this set for evaluation. Also note IFTTT's grammar has more productions (Tab. 2), but this does not imply that its grammar is more complex. This is because for HS and DJANGO terminal tokens are generated by GENTOKEN actions, but for IFTTT, all the code is generated directly by APPLYRULE actions.

Metrics As is standard in semantic parsing, we measure **accuracy**, the fraction of correctly generated examples. However, because generating an exact match for complex code structures is non-trivial, we follow Ling et al. (2016), and use token-level **BLEU-4** with as a secondary metric, defined as the averaged BLEU scores over all examples.[8]

5.2 Setup

Preprocessing All input descriptions are tokenized using NLTK. We perform simple canonicalization for DJANGO, such as replacing quoted strings in the inputs with place holders. See supplementary materials for details. We extract unary closures whose frequency is larger than a threshold k ($k = 30$ for HS and 50 for DJANGO).

Configuration The size of all embeddings is 128, except for node type embeddings, which is 64. The dimensions of RNN states and hidden layers are 256 and 50, respectively. Since our datasets are relatively small for a data-hungry neural model, we impose strong regularization using recurrent dropouts (Gal and Ghahramani, 2016) for all recurrent networks, together with standard dropout layers added to the inputs and outputs of the decoder RNN. We validate the dropout probability from $\{0, 0.2, 0.3, 0.4\}$. For decoding, we use a beam size of 15.

Table 3: Results on two Python code generation tasks. †Results previously reported in Ling et al. (2016).

5.3 Results

Evaluation results for Python code generation tasks are listed in Tab. 3. Numbers for our systems are averaged over three runs. We compare primarily with two approaches: (1) Latent Predictor Network (LPN), a state-of-the-art sequence-to-sequence code generation model (Ling et al., 2016), and (2) SEQ2TREE, a neural semantic parsing model (Dong and Lapata, 2016). SEQ2TREE generates trees one node at a time, and the target grammar is not explicitly modeled a priori, but *implicitly* learned from data. We test both the original SEQ2TREE model released by the authors and our revised one (SEQ2TREE–UNK) that uses unknown word replacement to handle rare words (Luong et al., 2015). For completeness, we also compare with a strong neural machine translation (NMT) system (Neubig, 2015) using a standard encoder-decoder architecture with attention and unknown word replacement[9], and include numbers from other baselines used in Ling et al. (2016). On the HS dataset, which has relatively large ASTs, we use unary closure for our model and SEQ2TREE, and for DJANGO we do not.

[7] Like Beltagy and Quirk (2016), we strip function parameters since they are mostly specific to users.

[8] These two metrics are not ideal: accuracy only measures exact match and thus lacks the ability to give credit to semantically correct code that is different from the reference, while it is not clear whether BLEU provides an appropriate proxy for measuring semantics in the code generation task. A more intriguing metric would be directly measuring semantic/functional code equivalence, for which we present a pilot study at the end of this section (cf. Error Analysis). We leave exploring more sophisticated metrics (e.g. based on static code analysis) as future work.

[9] For NMT, we also attempted to find the best-scoring syntactically correct predictions in the size-5 beam, but this did not yield a significant improvement over the NMT results in Tab. 3.

– frontier embed.	**90.1**	78.7

Table 4: Results on the noise-filtered IFTTT test set of ">3 agree with gold annotations" (averaged over three runs), our model performs competitively among neural models.

System Comparison As in Tab. 3, our model registers 11.7% and 9.3% absolute improvements over LPN in accuracy on HS and DJANGO. This boost in performance strongly indicates the importance of modeling grammar in code generation. For the baselines, we find LPN outperforms NMT and SEQ2TREE in most cases. We also note that SEQ2TREE achieves a decent accuracy of 13.6% on HS, which is due to the effect of unknown word replacement, since we only achieved 1.5% without it. A closer comparison with SEQ2TREE is insightful for understanding the advantage of our syntax-driven approach, since both SEQ2TREE and our system output ASTs: (1) SEQ2TREE predicts one node each time step, and requires additional "dummy" nodes to mark the boundary of a subtree. The sheer number of nodes in target ASTs makes the prediction process error-prone. In contrast, the APPLYRULE actions of our grammar model allows for generating multiple nodes at a single time step. Empirically, we found that in HS, SEQ2TREE takes more than 300 time steps on average to generate a target AST, while our model takes only 170 steps. (2) SEQ2TREE does not directly use productions in the grammar, which possibly leads to grammatically incorrect ASTs and thus empty code outputs. We observe that the ratio of grammatically incorrect ASTs predicted by SEQ2TREE on HS and DJANGO are 21.2% and 10.9%, respectively, while our system guarantees grammaticality.

Ablation Study We also ablated our best-performing models to analyze the contribution of each component. "–frontier embed." removes the frontier node embedding $\mathbf{n}_{f_t}$ from the decoder RNN inputs (Eq. (3)). This yields worse results on DJANGO while gives slight improvements in accuracy on HS. This is probably because that the grammar of HS has fewer node types, and thus the RNN is able to keep track of n_{f_t} without depending on its embedding. Next, "–parent feed." removes the parent feeding mechanism. The accuracy drops significantly on HS, with a marginal deterioration on DJANGO. This result is interesting because it suggests that parent feeding is more important when the ASTs are larger, which will be the case when handling more complicated code generation tasks like HS. Finally, removing the pointer network ("–copy terminals") in GENTOKEN actions gives poor results, indicating that it is important to directly copy variable names and values from the input.

The results with and without unary closure demonstrate that, interestingly, it is effective on HS but not on DJANGO. We conjecture that this is because on HS it significantly reduces the number of actions from 173 to 142 (c.f., Tab. 2), with the number of productions in the grammar remaining unchanged. In contrast, DJANGO has a broader domain, and thus unary closure results in more productions in the grammar (237 for DJANGO vs. 100 for HS), increasing sparsity.

Performance by the size of AST We further investigate our model's performance w.r.t. the size of the gold-standard ASTs in Figs. 3 and 4. Not surprisingly, the performance drops when the size of the reference ASTs increases. Additionally, on the HS dataset, the BLEU score still remains at around 50 even when the size of ASTs grows to 200, indicating that our proposed syntax-driven approach is robust for long code segments.

Domain Specific Code Generation Although this is not the focus of our work, evaluation on IFTTT brings us closer to a standard semantic parsing set-

input *<name> Brawl </name> <cost> 5 </cost> <desc> Destroy all minions except one (chosen randomly) </desc> <rarity> Epic </rarity> ...*

pred.
```
class Brawl(SpellCard):
  def __init__(self):
    super().__init__('Brawl', 5, CHARACTER_CLASS.
        WARRIOR, CARD_RARITY.EPIC)
  def use(self, player, game):
    super().use(player, game)
    targets = copy.copy(game.other_player.minions)
    targets.extend(player.minions)
    for minion in targets:
      minion.die(self)

input *self.plural is an lambda function with an argument n, which returns result of boolean expression n not equal to integer 1*

pred. `self.plural = lambda n: len(n)` ✗

ref. `self.plural = lambda n: int(n!=1)`

Table 5: Predicted examples from HS (1st) and DJANGO. Copied contents (copy probability > 0.9) are highlighted.

ting, which helps to investigate similarities and differences between generation of more complicated general-purpose code and and more limited-domain simpler code. Tab. 4 shows the results, following the evaluation protocol in (Beltagy and Quirk, 2016) for accuracies at both channel and full parse tree (channel + function) levels. Our full model performs on par with existing neural network-based methods, while outperforming other neural models in full tree accuracy (82.0%). This score is close to the best classical method (LR), which is based on a logistic regression model with rich hand-engineered features (e.g., brown clusters and paraphrase). Also note that the performance between NMT and other neural models is much closer compared with the results in Tab. 3. This suggests that general-purpose code generation is more challenging than the simpler IFTTT setting, and therefore modeling structural information is more helpful.

Case Studies We present output examples in Tab. 5. On HS, we observe that most of the time our model gives correct predictions by filling learned code templates from training data with arguments (e.g., cost) copied from input. This is in line with the findings in Ling et al. (2016). However, we do find interesting examples indicating that the model learns to generalize beyond trivial copying. For instance, the first example is one that our model predicted wrong — it generated code block A instead of the gold B (it also missed a function definition not shown here). However, we find that the block A actually conveys part of the input intent by destroying all, not some, of the minions. Since we are unable to find code block A in the training data, it is clear that the model has learned to generalize to some extent from multiple training card examples with similar semantics or structure.

The next two examples are from DJANGO. The first one shows that the model learns the usage of common API calls (e.g., `os.path.join`), and how to populate the arguments by copying from inputs. The second example illustrates the difficulty of generating code with complex nested structures like lambda functions, a scenario worth further investigation in future studies. More examples are attached in supplementary materials.

Error Analysis To understand the sources of errors and how good our evaluation metric (exact match) is, we randomly sampled and labeled 100 and 50 failed examples (with accuracy=0) from DJANGO and HS, respectively. We found that around 2% of these examples in the two datasets are actually semantically equivalent. These examples include: (1) using different parameter names when defining a function; (2) omitting (or adding) default values of parameters in function calls. While the rarity of such examples suggests that our exact match metric is reasonable, more advanced evaluation metrics based on statistical code analysis are definitely intriguing future work.

For DJANGO, we found that 30% of failed cases were due to errors where the pointer network failed to appropriately copy a variable name into the correct position. 25% were because the generated code only partially implemented the required functionality. 10% and 5% of errors were due to malformed English inputs and pre-processing errors, respectively. The remaining 30% of examples were errors stemming from multiple sources, or errors that could not be easily categorized into the above. For HS, we found that all failed card examples were due to partial implementation errors, such as the one shown in Table 5.

6 Related Work

Code Generation and Analysis Most works on code generation focus on generating code for domain specific languages (DSLs) (Kushman and

Barzilay, 2013; Raza et al., 2015; Manshadi et al., 2013), with neural network-based approaches recently explored (Liu et al., 2016; Parisotto et al., 2016; Balog et al., 2016). For general-purpose code generation, besides the general framework of Ling et al. (2016), existing methods often use language and task-specific rules and strategies (Lei et al., 2013; Raghothaman et al., 2016). A similar line is to use NL queries for code retrieval (Wei et al., 2015; Allamanis et al., 2015). The reverse task of generating NL summaries from source code has also been explored (Oda et al., 2015; Iyer et al., 2016). Finally, our work falls into the broad field of probabilistic modeling of source code (Maddison and Tarlow, 2014; Nguyen et al., 2013). Our approach of factoring an AST using probabilistic models is closely related to Allamanis et al. (2015), which uses a factorized model to measure the semantic relatedness between NL and ASTs for code retrieval, while our model tackles the more challenging generation task.

Semantic Parsing Our work is related to the general topic of semantic parsing, which aims to transform NL descriptions into executable logical forms. The target logical forms can be viewed as DSLs. The parsing process is often guided by grammatical formalisms like combinatory categorical grammars (Kwiatkowski et al., 2013; Artzi et al., 2015), dependency-based syntax (Liang et al., 2011; Pasupat and Liang, 2015) or task-specific formalisms (Clarke et al., 2010; Yih et al., 2015; Krishnamurthy et al., 2016; Mei et al., 2016). Recently, there are efforts in designing neural network-based semantic parsers (Misra and Artzi, 2016; Dong and Lapata, 2016; Neelakantan et al., 2016; Yin et al., 2016). Several approaches have be proposed to utilize grammar knowledge in a neural parser, such as augmenting the training data by generating examples guided by the grammar (Kociský et al., 2016; Jia and Liang, 2016). Liang et al. (2016) used a neural decoder which constrains the space of next valid tokens in the query language for question answering. Finally, the structured prediction approach proposed by Xiao et al. (2016) is closely related to our model in using the underlying grammar as prior knowledge to constrain the generation process of derivation trees, while our method is based on a unified grammar model which jointly captures production rule application and terminal symbol generation, and scales to general purpose code generation tasks.

7 Conclusion

This paper proposes a syntax-driven neural code generation approach that generates an abstract syntax tree by sequentially applying actions from a grammar model. Experiments on both code generation and semantic parsing tasks demonstrate the effectiveness of our proposed approach.

Acknowledgment

We are grateful to Wang Ling for his generous help with LPN and setting up the benchmark. We thank I. Beltagy for providing the IFTTT dataset. We also thank Li Dong for helping with SEQ2TREE and insightful discussions.

Abstract

Most methods to learn bilingual word embeddings rely on large parallel corpora, which is difficult to obtain for most language pairs. This has motivated an active research line to relax this requirement, with methods that use document-aligned corpora or bilingual dictionaries of a few thousand words instead. In this work, we further reduce the need of bilingual resources using a very simple self-learning approach that can be combined with any dictionary-based mapping technique. Our method exploits the structural similarity of embedding spaces, and works with as little bilingual evidence as a 25 word dictionary or even an automatically generated list of numerals, obtaining results comparable to those of systems that use richer resources.

1 Introduction

Multilingual word embeddings have attracted a lot of attention in recent times. In addition to having a direct application in inherently crosslingual tasks like machine translation (Zou et al., 2013) and crosslingual entity linking (Tsai and Roth, 2016), they provide an excellent mechanism for transfer learning, where a model trained in a resource-rich language is transferred to a less-resourced one, as shown with part-of-speech tagging (Zhang et al., 2016), parsing (Xiao and Guo, 2014) and document classification (Klementiev et al., 2012).

Most methods to learn these multilingual word embeddings make use of large parallel corpora (Gouws et al., 2015; Luong et al., 2015), but there have been several proposals to relax this requirement, given its scarcity in most language pairs. A possible relaxation is to use document-aligned or label-aligned comparable corpora (Søgaard et al., 2015; Vulić and Moens, 2016; Mogadala and Rettinger, 2016), but large amounts of such corpora are not always available for some language pairs.

An alternative approach that we follow here is to independently train the embeddings for each language on monolingual corpora, and then learn a linear transformation to map the embeddings from one space into the other by minimizing the distances in a bilingual dictionary, usually in the range of a few thousand entries (Mikolov et al., 2013a; Artetxe et al., 2016). However, dictionaries of that size are not readily available for many language pairs, specially those involving less-resourced languages.

In this work, we reduce the need of large bilingual dictionaries to much smaller seed dictionaries. Our method can work with as little as 25 word pairs, which are straightforward to obtain assuming some basic knowledge of the languages involved. The method can also work with trivially generated seed dictionaries of numerals (i.e. 1-1, 2-2, 3-3, 4-4...) making it possible to learn bilingual word embeddings without any real bilingual data. In either case, we obtain very competitive results, comparable to other state-of-the-art methods that make use of much richer bilingual resources.

The proposed method is an extension of existing mapping techniques, where the dictionary is used to learn the embedding mapping and the embedding mapping is used to induce a new dictionary iteratively in a self-learning fashion (see Figure 1). In spite of its simplicity, our analysis of the implicit optimization objective reveals that the method is exploiting the structural similarity of independently trained embeddings.

We analyze previous work in Section 2. Section 3 describes the self-learning framework, while Section 4 presents the experiments. Section 5 analyzes the underlying optimization objective, and Section 6 presents an error analysis.

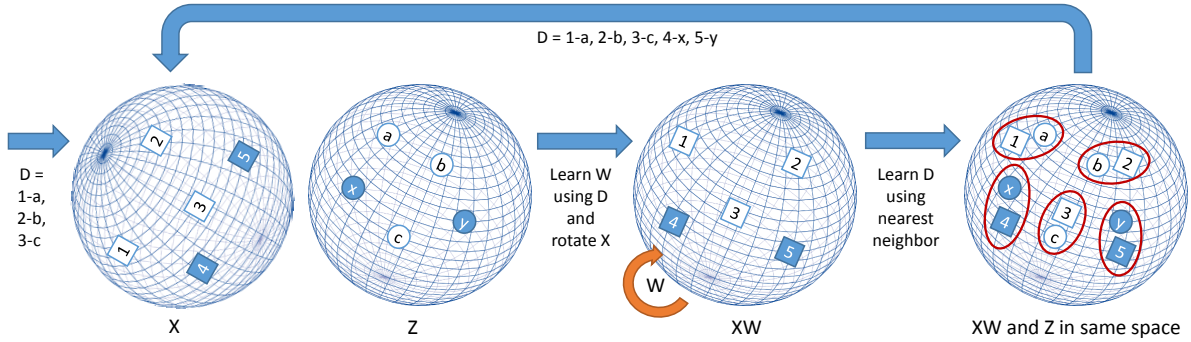

Figure 1: A general schema of the proposed self-learning framework. Previous works learn a mapping W based on the seed dictionary D, which is then used to learn the full dictionary. In our proposal we use the new dictionary to learn a new mapping, iterating until convergence.

2 Related work

We will first focus on bilingual embedding mappings, which are the basis of our proposals, and then on other unsupervised and weakly supervised methods to learn bilingual word embeddings.

2.1 Bilingual embedding mappings

Methods to induce bilingual mappings work by independently learning the embeddings in each language using monolingual corpora, and then learning a transformation from one embedding space into the other based on a bilingual dictionary.

The first of such methods is due to Mikolov et al. (2013a), who learn the linear transformation that minimizes the sum of squared Euclidean distances for the dictionary entries. The same optimization objective is used by Zhang et al. (2016), who constrain the transformation matrix to be orthogonal. Xing et al. (2015) incorporate length normalization in the training of word embeddings and maximize the cosine similarity instead, enforcing the orthogonality constraint to preserve the length normalization after the mapping. Finally, Lazaridou et al. (2015) use max-margin optimization with intruder negative sampling.

Instead of learning a single linear transformation from the source language into the target language, Faruqui and Dyer (2014) use canonical correlation analysis to map both languages to a shared vector space. Lu et al. (2015) extend this work and apply deep canonical correlation analysis to learn non-linear transformations.

Artetxe et al. (2016) propose a general framework that clarifies the relation between Mikolov et al. (2013a), Xing et al. (2015), Faruqui and Dyer (2014) and Zhang et al. (2016) as variants of the same core optimization objective, and show that a new variant is able to surpass them all. While most of the previous methods use gradient descent, Artetxe et al. (2016) propose an efficient analytical implementation for those same methods, recently extended by Smith et al. (2017) to incorporate dimensionality reduction.

A prominent application of bilingual embedding mappings, with a direct application in machine translation (Zhao et al., 2015), is bilingual lexicon extraction, which is also the main evaluation method. More specifically, the learned mapping is used to induce the translation of source language words that were missing in the original dictionary, usually by taking their nearest neighbor word in the target language according to cosine similarity, although Dinu et al. (2015) and Smith et al. (2017) propose alternative retrieval methods to address the hubness problem.

2.2 Unsupervised and weakly supervised bilingual embeddings

As mentioned before, our method works with as little as 25 word pairs, while the methods discussed previously use thousands of pairs. The only exception in this regard is the work by Zhang et al. (2016), who only use 10 word pairs with good results on transfer learning for part-of-speech tagging. Our experiments will show that, although their method captures coarse-grained relations, it fails on finer-grained tasks like bilingual lexicon induction.

Bootstrapping methods similar to ours have been previously proposed for traditional count-based vector space models (Peirsman and Padó, 2010; Vulić and Moens, 2013). However, while previous techniques incrementally build a high-

Algorithm 1 Traditional framework

3: EVALUATE_DICTIONARY(D)

dimensional model where each axis encodes the co-occurrences with a specific word and its equivalent in the other language, our method works with low-dimensional pre-trained word embeddings, which are more widely used nowadays.

A practical aspect for reducing the need of bilingual supervision is on the design of the seed dictionary. This is analyzed in depth by Vulić and Korhonen (2016), who propose using document-aligned corpora to extract the training dictionary. A more common approach is to rely on shared words and cognates (Peirsman and Padó, 2010; Smith et al., 2017), eliminating the need of bilingual data in practice. Our use of shared numerals exploits the same underlying idea, but relies on even less bilingual evidence and should thus generalize better to distant language pairs.

Miceli Barone (2016) and Cao et al. (2016) go one step further and attempt to learn bilingual embeddings without any bilingual evidence. The former uses adversarial autoencoders (Makhzani et al., 2016), combining an encoder that maps the source language embeddings into the target language, a decoder that reconstructs the original embeddings, and a discriminator that distinguishes mapped embeddings from real target language embeddings, whereas the latter adds a regularization term to the training of word embeddings that pushes the mean and variance of each dimension in different languages close to each other. Although promising, the reported performance in both cases is poor in comparison to other methods.

Finally, the induction of bilingual knowledge from monolingual corpora is closely related to the decipherment scenario, for which models that incorporate word embeddings have also been proposed (Dou et al., 2015). However, decipherment is only concerned with translating text from one language to another and relies on complex statistical models that are designed specifically for that purpose, while our approach is more general and learns task-independent multilingual embeddings.

3 Proposed self-learning framework

As discussed in Section 2.1, a common evaluation task (and practical application) of bilingual embedding mappings is to induce bilingual lexicons, that is, to obtain the translation of source words that were missing in the training dictionary, which are then compared to a gold standard test dictionary for evaluation. This way, one can say that the seed (train) dictionary is used to learn a mapping, which is then used to induce a better dictionary (at least in the sense that it is larger). Algorithm 1 summarizes this framework.

Following this observation, we propose to use the output dictionary in Algorithm 1 as the input of the same system in a self-learning fashion which, assuming that the output dictionary was indeed better than the original one, should serve to learn a better mapping and, consequently, an even better dictionary the second time. The process can then be repeated iteratively to obtain a hopefully better mapping and dictionary each time until some convergence criterion is met. Algorithm 2 summarizes this alternative framework that we propose.

Our method can be combined with any embedding mapping and dictionary induction technique (see Section 2.1). However, efficiency turns out to be critical for a variety of reasons. First of all, by enclosing the learning logic in a loop, the total training time is increased by the number of iterations. Even more importantly, our framework requires to explicitly build the entire dictionary at each iteration, whereas previous work tends to induce the translation of individual words on-demand later at runtime. Moreover, from the second iteration onwards, it is this induced, full dictionary that has to be used to learn the embedding mapping, and not the considerably smaller seed dictionary as it is typically done. In the following two subsections, we respectively describe the embedding mapping method and the dictionary in-

duction method that we adopt in our work with these efficiency requirements in mind.

3.1 Embedding mapping

As discussed in Section 2.1, most previous methods to learn embedding mappings use variants of gradient descent. Among the more efficient exact alternatives, we decide to adopt the one by Artetxe et al. (2016) for its simplicity and good results as reported in their paper. We next present their method, adapting the formalization to explicitly incorporate the dictionary as required by our self-learning algorithm.

Let X and Z denote the word embedding matrices in two languages so that X_{i*} corresponds to the ith source language word embedding and Z_{j*} corresponds to the jth target language embedding. While Artetxe et al. (2016) assume these two matrices are aligned according to the dictionary, we drop this assumption and represent the dictionary explicitly as a binary matrix D, so that $D_{ij} = 1$ if the ith source language word is aligned with the jth target language word. The goal is then to find the optimal mapping matrix W^* so that the sum of squared Euclidean distances between the mapped source embeddings $X_{i*}W$ and target embeddings Z_{j*} for the dictionary entries D_{ij} is minimized:

$$W^* = \arg\min_W \sum_i \sum_j D_{ij} ||X_{i*}W - Z_{j*}||^2$$

Following Artetxe et al. (2016), we length normalize and mean center the embedding matrices X and Z in a preprocessing step, and constrain W to be an orthogonal matrix (i.e. $WW^T = W^TW = I$), which serves to enforce monolingual invariance, preventing a degradation in monolingual performance while yielding to better bilingual mappings. Under such orthogonality constraint, minimizing the squared Euclidean distance becomes equivalent to maximizing the dot product, so the above optimization objective can be reformulated as follows:

$$W^* = \arg\max_W \operatorname{Tr}\left(XWZ^TD^T\right)$$

where $\operatorname{Tr}(\cdot)$ denotes the trace operator (the sum of all the elements in the main diagonal). The optimal orthogonal solution for this problem is given by $W^* = UV^T$, where $X^TDZ = U\Sigma V^T$ is the singular value decomposition of X^TDZ. Since the dictionary matrix D is sparse, this can be efficiently computed in linear time with respect to the number of dictionary entries.

3.2 Dictionary induction

As discussed in Section 2.1, practically all previous work uses nearest neighbor retrieval for word translation induction based on embedding mappings. In nearest neighbor retrieval, each source language word is assigned the closest word in the target language. In our work, we use the dot product between the mapped source language embeddings and the target language embeddings as the similarity measure, which is roughly equivalent to cosine similarity given that we apply length normalization followed by mean centering as a preprocessing step (see Section 3.1). This way, following the notation in Section 3.1, we set $D_{ij} = 1$ if $j = \text{argmax}_k\,(X_{i*}W) \cdot Z_{k*}$ and $D_{ij} = 0$ otherwise[1].

While we find that independently computing the similarity measure between all word pairs is prohibitively slow, the computation of the entire similarity matrix XWZ^T can be easily vectorized using popular linear algebra libraries, obtaining big performance gains. However, the resulting similarity matrix is often too large to fit in memory when using large vocabularies. For that reason, instead of computing the entire similarity matrix XWZ^T in a single step, we iteratively compute submatrices of it using vectorized matrix multiplication, find their corresponding maxima each time, and then combine the results.

4 Experiments and results

In this section, we experimentally test the proposed method in bilingual lexicon induction and crosslingual word similarity. Subsection 4.1 describes the experimental settings, while Subsections 4.2 and 4.3 present the results obtained in each of the tasks. The code and resources necessary to reproduce our experiments are available at `https://github.com/artetxem/vecmap`.

4.1 Experimental settings

For easier comparison with related work, we evaluated our mappings on **bilingual lexicon induction** using the public **English-Italian** dataset by Dinu et al. (2015), which includes monolingual word embeddings in both languages together with a bilingual dictionary split in a training set and a

[1] Note that we induce the dictionary entries starting from the source language words. We experimented with other alternatives in development, with minor differences.

test set[2]. The embeddings were trained with the word2vec toolkit with CBOW and negative sampling (Mikolov et al., 2013b)[3], using a 2.8 billion word corpus for English (ukWaC + Wikipedia + BNC) and a 1.6 billion word corpus for Italian (itWaC). The training and test sets were derived from a dictionary built form Europarl word alignments and available at OPUS (Tiedemann, 2012), taking 1,500 random entries uniformly distributed in 5 frequency bins as the test set and the 5,000 most frequent of the remaining word pairs as the training set.

In addition to English-Italian, we selected two other languages from different language families with publicly available resources. We thus created analogous datasets for **English-German** and **English-Finnish**. In the case of German, the embeddings were trained on the 0.9 billion word corpus SdeWaC, which is part of the WaCky collection (Baroni et al., 2009) that was also used for English and Italian. Given that Finnish is not included in this collection, we used the 2.8 billion word Common Crawl corpus provided at WMT 2016[4] instead, which we tokenized using the Stanford Tokenizer (Manning et al., 2014). In addition to that, we created training and test sets for both pairs from their respective Europarl dictionaries from OPUS following the exact same procedure used for English-Italian, and the word embeddings were also trained using the same configuration as Dinu et al. (2015).

Given that the main focus of our work is on **small seed dictionaries**, we created random subsets of 2,500, 1,000, 500, 250, 100, 75, 50 and 25 entries from the original training dictionaries of 5,000 entries. This was done by shuffling once the training dictionaries and taking their first k entries, so it is guaranteed that each dictionary is a strict subset of the bigger dictionaries.

In addition to that, we explored using automatically generated dictionaries as a shortcut to practical unsupervised learning. For that purpose, we created **numeral dictionaries**, consisting of words matching the `[0-9]+` regular expression in both vocabularies (e.g. 1-1, 2-2, 3-3, 1992-1992 etc.). The resulting dictionary had 2772 entries for English-Italian, 2148 for English-German, and 2345 for English-Finnish. While more sophisticated approaches are possible (e.g. involving the edit distance of all words), we believe that this method is general enough that should work with practically any language pair, as Arabic numerals are often used even in languages with a different writing system (e.g. Chinese and Russian).

While bilingual lexicon induction is a standard evaluation task for seed dictionary based methods like ours, it is unsuitable for bilingual corpus based methods, as statistical word alignment already provides a reliable way to derive dictionaries from bilingual corpora and, in fact, this is how the test dictionary itself is built in our case. For that reason, we carried out some experiments in **crosslingual word similarity** as a way to test our method in a different task and allowing to compare it to systems that use richer bilingual data. There are no many crosslingual word similarity datasets, and we used the RG-65 and WordSim-353 crosslingual datasets for English-German and the WordSim-353 crosslingual dataset for English-Italian as published by Camacho-Collados et al. (2015) [5].

As for the **convergence criterion**, we decide to stop training when the improvement on the average dot product for the induced dictionary falls below a given threshold from one iteration to the next. After length normalization, the dot product ranges from -1 to 1, so we decide to set this threshold at 1e-6, which we find to be a very conservative value yet enough that training takes a reasonable amount of time. The curves in the next section confirm that this was a reasonable choice.

This convergence criterion is usually met in less than 100 iterations, each of them taking 5 minutes on a modest desktop computer (Intel Core i5-4670 CPU with 8GiB of RAM), including the induction of a dictionary of 200,000 words at each iteration.

4.2 Bilingual lexicon induction

For the experiments on bilingual lexicon induction, we compared our method with those proposed by Mikolov et al. (2013a), Xing et al. (2015), Zhang et al. (2016) and Artetxe et al. (2016), all of them implemented as part of the framework proposed by the latter. The results ob-

Table 1: Accuracy (%) on bilingual lexicon induction for different seed dictionaries

tained with the 5,000 entry, 25 entry and the numerals dictionaries for all the 3 language pairs are given in Table 1.

The results for the 5,000 entry dictionaries show that our method is comparable or even better than the other systems. As another reference, the best published results using nearest-neighbor retrieval are due to Lazaridou et al. (2015), who report an accuracy of 40.20% for the full English-Italian dictionary, almost at pair with our system (39.67%).

In any case, the main focus of our work is on smaller dictionaries, and it is under this setting that our method really stands out. The 25 entry and numerals columns in Table 1 show the results for this setting, where all previous methods drop dramatically, falling below 1% accuracy in all cases. The method by Zhang et al. (2016) also obtains poor results with small dictionaries, which reinforces our hypothesis in Section 2.2 that their method can only capture coarse-grain bilingual relations for small dictionaries. In contrast, our proposed method obtains very competitive results for all dictionaries, with a difference of only 1-2 points between the full dictionary and both the 25 entry dictionary and the numerals dictionary in all three languages. Figure 2 shows the curve of the English-Italian accuracy for different seed dictionary sizes, confirming this trend.

Finally, it is worth mentioning that, even if all the three language pairs show the same general behavior, there are clear differences in their absolute accuracy numbers, which can be attributed to the linguistic proximity of the languages involved. In particular, the results for English-Finnish are about 10 points below the rest, which is explained by the fact that Finnish is a non-indoeuropean agglutinative language, making the task considerably more difficult for this language pair. In this regard, we believe that the good results with small dictionaries are a strong indication of the robustness of our method, showing that it is able to learn good bilingual mappings from very little bilingual evidence even for distant language pairs where the structural similarity of the embedding spaces is presumably weaker.

4.3 Crosslingual word similarity

In addition to the baseline systems in Section 4.2, in the crosslingual similarity experiments we also tested the method by Luong et al. (2015), which is the state-of-the-art for bilingual word embeddings based on parallel corpora (Upadhyay et al., 2016)[6]. As this method is an extension of word2vec, we used the same hyperparameters as for the monolingual embeddings when possible (see Section 4.1), and leave the default ones otherwise. We used Europarl as our parallel corpus to train this method as done by the authors, which consists of nearly 2 million parallel sentences.

As shown in the results in Table 2, our method obtains the best results in all cases, surpassing the rest of the dictionary-based methods by 1-3 points depending on the dataset. But, most importantly, it does not suffer from any significant degradation for using smaller dictionaries and, in fact, our method gets better results using the 25 entry dictionary or the numeral list as the only bilingual evidence than any of the baseline systems using much richer resources.

The relatively poor results of Luong et al. (2015) can be attributed to the fact that the dictionary based methods make use of much bigger monolingual corpora, while methods based on parallel corpora are restricted to smaller corpora. However, it is not clear how to introduce monolingual corpora on those methods. We did run some experiments with BilBOWA (Gouws et al., 2015), which supports training in monolingual corpora in addition to bilingual corpora, but obtained very poor results[7]. All in all, our experiments show

[6]We also tested English-German pre-trained embeddings from Klementiev et al. (2012) and Chandar A P et al. (2014). They both had coverage problems that made the results hard to compare, and, when considering the correlations for the word pairs in their vocabulary, their performance was poor.

[7]Upadhyay et al. (2016) report similar problems using

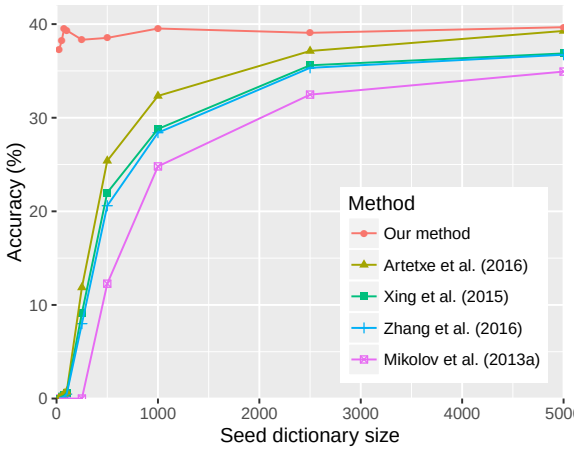

Figure 2: Accuracy on English-Italian bilingual lexicon induction for different seed dictionaries

that it is better to use large monolingual corpora in combination with very little bilingual data rather than a bilingual corpus of a standard size alone.

5 Global optimization objective

It might seem somehow surprising at first that, as seen in the previous section, our simple self-learning approach is able to learn high quality bilingual embeddings from small seed dictionaries instead of falling in degenerated solutions. In this section, we try to shed light on our approach, and give empirical evidence supporting our claim.

More concretely, we argue that, for the embedding mapping and dictionary induction methods described in Section 3, the proposed self-learning framework is implicitly solving the following global optimization problem[8]:

$$W^* = \arg\max_W \sum_i \max_j (X_{i*}W) \cdot Z_{j*}$$
$$\text{s.t.} \quad WW^T = W^TW = I$$

Contrary to the optimization objective for W in Section 3.1, the global optimization objective does not refer to any dictionary, and maximizes the similarity between each source language word and its closest target language word. Intuitively, a random solution would map source language embeddings to seemingly random locations in the target language space, and it would thus be unlikely that they have any target language word nearby, making the optimization value small. In contrast, a good solution would map source language words close to their translation equivalents in the target language space, and they would thus have their corresponding embeddings nearby, making the optimization value large. While it is certainly possible to build degenerated solutions that take high optimization values for small subsets of the vocabulary, we think that the structural similarity between independently trained embedding spaces in different languages is strong enough that optimizing this function yields to meaningful bilingual mappings when the size of the vocabulary is much larger than the dimensionality of the embeddings.

The reasoning for how the self-learning framework is optimizing this objective is as follows. At the end of each iteration, the dictionary D is updated to assign, for the current mapping W, each source language word to its closest target language word. This way, when we update W to maximize the average similarity of these dictionary entries at the beginning of the next iteration, it is guaranteed that the value of the optimization objective will improve (or at least remain the same). The reason is that the average similarity between each word and what were previously the closest words will be improved if possible, as this is what the updated W directly optimizes (see Section 3.1). In addition to that, it is also possible that, for some source words, some other target words get closer after the update. Thanks to this, our self-learning algorithm is guaranteed to converge to a local optimum of the above global objective, behaving like an alternating optimization algorithm for it.

It is interesting to note that the above reasoning is valid no matter what the the initial solution is, and, in fact, the global optimization objective does not depend on the seed dictionary nor any other

BilBOWA.

[8]While we restrict our formal analysis to the embedding mapping and dictionary induction method that we use, the general reasoning should be valid for other choices as well.

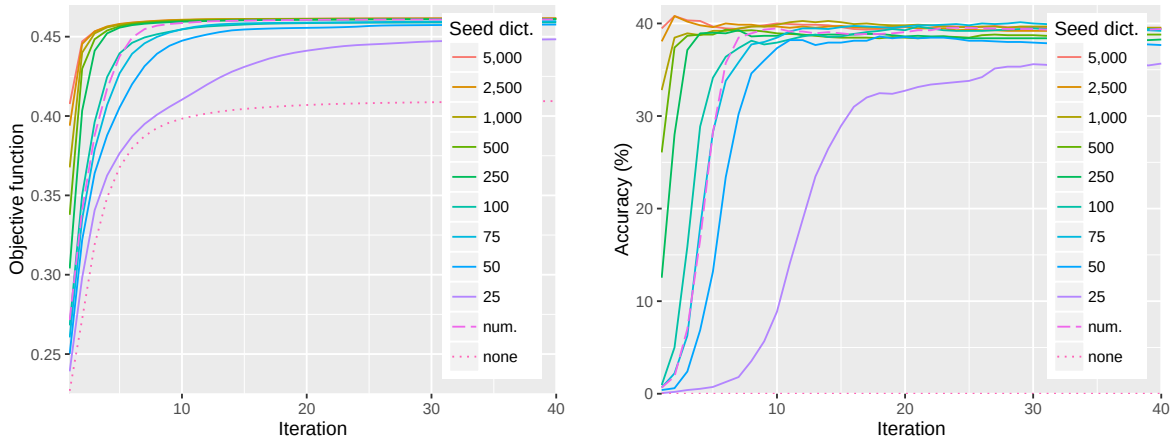

Figure 3: Learning curve on English-Italian according to the global objective function (left) and the accuracy on bilingual lexicon induction (right)

bilingual resource. For that reason, it should be possible to use a random initialization instead of a small seed dictionary. However, we empirically observe that this works poorly in practice, as our algorithm tends to get stuck in poor local optima when the initial solution is not good enough.

The general behavior of our method is reflected in Figure 3, which shows the learning curve for different seed dictionaries according to both the objective function and the accuracy on bilingual lexicon induction. As it can be seen, the objective function is improved from iteration to iteration and converges to a local optimum just as expected. At the same time, the learning curves show a strong correlation between the optimization objective and the accuracy, as it can be clearly observed that improving the former leads to an improvement of the latter, confirming our explanations. Regarding random initialization, the figure shows that the algorithm gets stuck in a poor local optimum of the objective function, which is the reason of the bad performance (0% accuracy) on bilingual lexicon induction, but the proposed optimization objective itself seems to be adequate.

Finally, we empirically observe that our algorithm learns similar mappings no matter what the seed dictionary was. We first repeated our experiments on English-Italian bilingual lexicon induction for 5 different dictionaries of 25 entries, obtaining an average accuracy of 38.15% and a standard deviation of only 0.75%. In addition to that, we observe that the overlap between the predictions made when starting with the full dictionary and the numerals dictionary is 76.00% (60.00% for the 25 entry dictionary). At the same time, 37.00% of the test cases are correctly solved by both instances, and it is only 5.07% of the test cases that one of them gets right and the other wrong (34.00% and 8.94% for the 25 entry dictionary). This suggests that our algorithm tends to converge to similar solutions even for disjoint seed dictionaries, which is in line with our view that we are implicitly optimizing an objective that is independent from the seed dictionary, yet a seed dictionary is necessary to build a good enough initial solution to avoid getting stuck in poor local optima. For that reason, it is likely that better methods to tackle this optimization problem would allow learning bilingual word embeddings without any bilingual evidence at all and, in this regard, we believe that our work opens exciting opportunities for future research.

6 Error analysis

So as to better understand the behavior of our system, we performed an error analysis of its output in English-Italian bilingual lexicon induction when starting with the 5,000 entry, the 25 entry and the numeral dictionaries in comparison with the baseline method of Artetxe et al. (2016) with the 5,000 entry dictionary. For that purpose, we took 100 random examples from the test set in the [1-5K] frequency bin, another 100 from the [5K-20K] frequency bin and 30 from the [100K-200K] frequency bin, and manually analyzed each of the errors made by all the 4 different variants.

Our analysis first reveals that, in all the cases, about a third of the translations taken as erroneous according to the gold standard are not so in real-

ity. This corresponds to both different morphological variants of the gold standard translations (e.g. *dichiarato/dichiarò*) and other valid translations that were missing in the gold standard (e.g. *climb* → *salita* instead of the gold standard *scalato*). This phenomenon is considerably more pronounced in the first frequency bins, which already have a much higher accuracy according to the gold standard.

As for the actual errors, we observe that nearly a third of them correspond to named entities for all the different variants. Interestingly, the vast majority of the proposed translations in these cases are also named entities (e.g. *Ryan* → *Jason*, *John* → *Paolo*), which are often highly related to the original ones (e.g. *Volvo* → *BMW*, *Olympus* → *Nikon*). While these are clear errors, it is understandable that these methods are unable to discriminate between named entities to this degree based solely on the distributional hypothesis, in particular when it comes to common proper names (e.g. *John*, *Andy*), and one could design alternative strategies to address this issue like taking the edit distance as an additional signal.

For the remaining errors, all systems tend to propose translations that have some degree of relationship with the correct ones, including near-synonyms (e.g. *guidelines* → *raccomandazioni*), antonyms (e.g. *sender* → *destinatario*) and words in the same semantic field (e.g. *nominalism* → *intuizionismo* / *innatismo*, which are all philosophical doctrines). However, there are also a few instances where the relationship is weak or unclear (e.g. *loch* → *giardini*, *sweep* → *serrare*). We also observe a few errors that are related to multiwords or collocations (e.g. *carrier* → *aereo*, presumably related to the multiword *air carrier* / *linea aerea*), as well as some rare word that is repeated across many translations (*Ferruzzi*), which could be attributed to the hubness problem (Dinu et al., 2015; Lazaridou et al., 2015).

All in all, our error analysis reveals that the baseline method of Artetxe et al. (2016) and the proposed algorithm tend to make the same kind of errors regardless of the seed dictionary used by the latter, which reinforces our interpretation in the previous section regarding an underlying optimization objective that is independent from any training dictionary. Moreover, it shows that the quality of the learned mappings is much better than what the raw accuracy numbers might suggest, encouraging the incorporation of these techniques in other applications.

7 Conclusions and future work

In this work, we propose a simple self-learning framework to learn bilingual word embedding mappings in combination with any embedding mapping and dictionary induction technique. Our experiments on bilingual lexicon induction and crosslingual word similarity show that our method is able to learn high quality bilingual embeddings from as little bilingual evidence as a 25 word dictionary or an automatically generated list of numerals, obtaining results that are competitive with state-of-the-art systems using much richer bilingual resources like larger dictionaries or parallel corpora. In spite of its simplicity, a more detailed analysis shows that our method is implicitly optimizing a meaningful objective function that is independent from any bilingual data which, with a better optimization method, might allow to learn bilingual word embeddings in a completely unsupervised manner.

In the future, we would like to delve deeper into this direction and fine-tune our method so it can reliably learn high quality bilingual word embeddings without any bilingual evidence at all. In addition to that, we would like to explore non-linear transformations (Lu et al., 2015) and alternative dictionary induction methods (Dinu et al., 2015; Smith et al., 2017). Finally, we would like to apply our model in the decipherment scenario (Dou et al., 2015).

Acknowledgements

We thank the anonymous reviewers for their insightful comments and Flavio Merenda for his help with the error analysis.

Abstract

We present a system which parses sentences into Abstract Meaning Representations, improving state-of-the-art results for this task by more than 5%. AMR graphs represent semantic content using linguistic properties such as semantic roles, coreference, negation, and more. The AMR parser does not rely on a syntactic preparse, or heavily engineered features, and uses five recurrent neural networks as the key architectural components for inferring AMR graphs.

1 Introduction

Semantic analysis is the process of extracting meaning from text, revealing key ideas such as "who did what to whom, when, how, and where?", and is considered to be one of the most complex tasks in natural language processing. Historically, an important consideration has been the definition of the output of the task - how can the concepts in a sentence be captured in a general, consistent and expressive manner that facilitates downstream semantic processing? Over the years many formalisms have been proposed as suitable target representations including variants of first order logic, semantic networks, and frame-based slot-filler notations. Such representations have found a place in many semantic applications but there is no clear consensus as to the best representation. However, with the rise of supervised machine learning techniques, a new requirement has come to the fore: the ability of human annotators to quickly and reliably generate semantic representations as training data.

Abstract Meaning Representation (AMR) (Banarescu et al., 2012)[1] was developed to provide a computationally useful and expressive representation that could be reliably generated by human annotators. Sentence meanings in AMR are represented in the form of graphs consisting of concepts (nodes) connected by labeled relations (edges). AMR graphs include a number of traditional NLP representations including named entities (Nadeau and Sekine, 2007), word senses (Banerjee and Pedersen, 2002), coreference relations, and predicate-argument structures (Kingsbury and Palmer, 2002; Palmer et al., 2005). More recent innovations include wikification of named entities and normalization of temporal expressions (Verhagen et al., 2010; Strötgen and Gertz, 2010). (2016) provides an insightful discussion of the relationship between AMR and other formal representations including first order logic.

The process of creating AMR's for sentences is called AMR Parsing and was first introduced in (Flanigan et al., 2014). A key factor driving the development of AMR systems has been the increasing availability of training resources in the form of corpora where each sentence is paired with a corresponding AMR representation [2]. A consistent framework for evaluating AMR parsers was defined by the Semeval-2016 Meaning Representation Parsing Task[3]. Standard training, development and test splits for the AMR Annotation Release 1 corpus are provided, as well as an additional out-of-domain test dataset, for system comparisons. [4]

Viewed as a structured prediction task, AMR parsing poses some difficult challenges not faced by other related language processing tasks including part of speech tagging, syntactic parsing or se-

(a) An AMR graphical depiction of the meaning of the sentence ***France plans further nuclear cooperation with numerous countries .*** Concepts are represented as ovals, and relations are the directed connections between them. Predicate concepts are labelled with their PropBank sense, and semantic roles are indicated by "Arg" relations. Non-Arg relations like name or mod are called "Nargs" in this paper. Note the shaded section, which shows an example of a *subgraph*, containing related concepts and relations. In the example, the subgraph represents "France" which includes the category *country* and a shortened link to the France wiki page.
