(b) General Architecture for the AMR Parser, which creates an AMR based on the words in a sentence. The 5 B-LSTM networks infer structures of the AMR. For example, the SG network infers subgraphs, which are mostly single concept, like "plan-01" or "further", but can also be like the more complex shaded "France" subgraph in the example. Other B-LSTM networks are used to infer predicate argument relations (Args), other relations (Nargs), attributes like "TOP" (Attr) and name categories like "country" for France (Ncat).

Figure 1: An example Abstract Meaning Representation and the architecture of the AMR parser, which produces an AMR from a sentence.

mantic role labeling. The prediction task in these settings can be cast as per-token labeling tasks (i.e. IOB tags) or as a sequence of discrete parser actions, as in transition-based (shift-reduce) approaches to dependency parsing.

The first challenge is that AMR representations are by design abstracted away from their associated surface forms. AMR corpora pair sentences with their corresponding representations, without providing an explicit annotation, or alignment, that links the parts of the representation to their corresponding elements of the sentence. Not surprisingly, this complicates training, decoding and evaluation.

The second challenge is the fact that, as noted earlier, the AMR parsing task is an amalgam of predicate identification and classification, entity recognition, co-reference, word sense disambiguation and semantic role labeling — each of which relies on the others for successful analysis. The architecture and system presented in the following sections is largely motivated by these two challenges.

2 Related Work

2.1 AMR Parsers

Most current AMR parsers are constructed using some form of supervised machine learning that exploits existing AMR corpora. In general, these systems make use of features derived from various forms of syntactic analysis, ranging from part-of-speech tagging to more complex dependency or phrase-structure analysis. Currently, most systems fall into two classes: (1) systems that incrementally transform a dependency parse into an AMR

graph using transition-based systems (Wang et al., 2015, 2016), and (2) graph-oriented approaches that use syntactic features to score edges between all concept pairs, and then use a maximum spanning connected subgraph (MSCG) algorithm to select edges that will constitute the graph (Flanigan et al., 2014; Werling et al., 2015).

As expected, there are exceptions to these general approaches. The largely rule-based approach of (2015) converts logical forms from an existing semantic analyzer into AMR graphs. They demonstrate the ability to use their existing system to generate AMRs in German, French, Spanish and Japanese without the need for a native AMR corpus.

(2015) proposes a synchronous hyperedge replacement grammar solution, (2015) uses syntax-based machine translation techniques to create tree structures similar to AMR, while (2015) creates logical form representations of sentences and then converts these to AMR.

An exception to the use of heavily engineered features is the deep learning approach of (2016), which, following (Collobert et al., 2011), relies on word embeddings and recurrent neural networks to generate AMR graphs.

2.2 Bidirectional LSTM Neural Networks

Unlike relatively simple sequence processing tasks like part-of-speech tagging and NER, semantic analysis requires the ability to keep track of relevant information that may be arbitrarily far away from the words currently under consideration. Recurrent neural networks (RNNs) are a class of neural architecture that use a form of short-term memory in order to solve this semantic distance problem. Basic RNN systems have been enhanced with the use of special memory cell units, referred to as Long Short-Term Memory neural networks, or LSTM's (Hochreiter and Schmidhuber, 1997). Such systems can effectively process information dispersed over hundreds of words (Schmidhuber et al., 2002; Gers et al., 2001).

Bidirectional LSTMs (B-LSTM) networks are LSTMs that are connected so that both future and past sequence context can be examined. (2015), successfully used a bidirectional LSTM network for semantic role labelling. We use the LSTM cell as described in (Graves et al., 2013), configured in a B-LSTM shown in Figure 2, as the core network architecture in the system. Five B-LSTM Neural Networks comprise the parser.

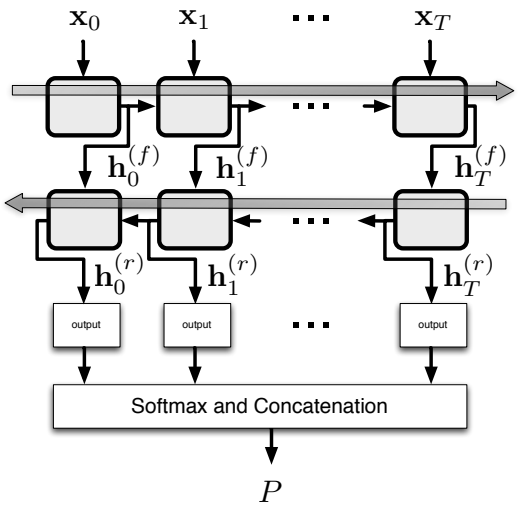

Figure 2: A general diagram of a B-LSTM network, showing the feature input vectors x_i, the forward layer (f) and the reverse layer (r). The network generates vectors of log likelihoods which are converted to probability vectors and then joined together to form an array of probabilities.

3 Parser Overview

Our parser[5] will be explained using this example sentence: ***France plans further nuclear cooperation with numerous countries .***

A graphical depiction of an AMR for this sentence is shown in Figure 1a.

Given an input sentence, the approach taken in our AMR parser is similar to (Flanigan et al., 2014) in that it consists of two subtasks: (1) discover the concepts (nodes and sub-graphs) present in the sentence, and (2) determine the relations (arcs) that connect the concepts (relations capture both traditional predicate-argument structures (ARGs), as well as additional modifier relations that capture notions including quantification, polarity, and cardinality.) Neither of these tasks is straightforward in the AMR context. Among the complications are the fact that individual words may contribute to more than one node (as in the case of France), parts of the graph may be "reentrant", participating in relations with multiple concepts, and predicate-argument and modifier relations can be introduced by arbitrary parts of the input.

At a high level, our system takes an input sentence in form of a vector of word embeddings

[5] source at https://github.com/BillFoland/daisyluAMR

and uses a series of recurrent neural networks to (1) discover the basic set of nodes and subgraphs that comprise the AMR, (2) discover the set of predicate-argument relations among those concepts, and (3) identifying any relevant modifier relations that are present.

A high level block diagram of the parser is shown in Figure 1b. The parser extracts features from the sentence which are processed by a bidirectional LSTM network (B-LSTM) to create a set of AMR subgraphs, which contain one or two concepts as well as their internal relations to each other. Features based on the sentence and these subgraphs are then processed by a pair of B-LSTM networks to compute the probabilities of relations between all subgraphs. All subgraphs are then connected using an iterative, greedy algorithm to compute a single component graph, with all subgraphs connected by relations. Separately, another two B-LSTM networks compute attribute and name categories, which are then appended to the graph. Finally, the subgraphs are expanded into the most probable AMR concept and relation primitives to create the final AMR.

4 Detailed Parser Architecture

4.1 AMR Spans, Subgraphs, and Subgraph Decoding

Mapping the words in a sentence to AMR concepts is a critical first step in the parsing process, and can influence the performance of all subsequent processing. Although the most common mapping is one word to one concept, a series of consecutive words, or **span**, can also be associated with an AMR concept. Likewise, a span of words can be mapped to a small connected **subgraph**, such as the single word span *France* which is mapped to a subgraph composed of two concepts connected by a *name* relation. (see the shaded section of Figure 1a).

Training corpora provide sentences which are annotated by humans with AMR graphs, not necessarily including a reference span to subgraph mapping. An automatic AMR **aligner** can be used to predict relationships between words and gold AMR's. We use the alignments produced by the aligner of (2014), along with the words and reference AMR graphs, to identify a **subgraph type** to associate with each span. Each word in the sentence is then associated with an IOBES subgraph type tag. We call the algorithm which defines span to subgraph mapping the **Expert Span Identifier**, and use it to train the SG Network.

A convenient development detail stems from the fact that during the AMR creation process, the identified subgraphs must be expanded into individual concepts and relations. For example, the subgraph type "Named", along with the span *France*, must be expanded to create the concepts, relations, and attributes shown in Figure 1a. A **Subgraph Expander** algorithm implements this task, which is essentially the inverse of the Expert Span Identifier. The Expert Span Identifier and Subgraph Expander were developed by cascading the two in a test configuration as shown in Figure 3a.

4.2 Features

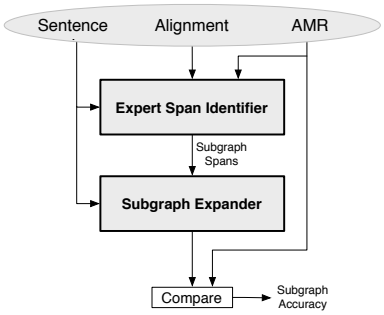
All input features for the five networks correspond to the sequence of words in the input sentence, and are presented to the networks as indices into lookup tables. With the exception of pre-trained word embeddings, these lookup tables are randomly initialized prior to training and representations are created during the training process.

4.2.1 Word Embeddings

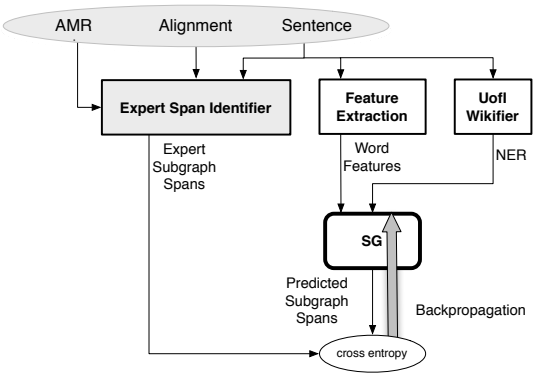
The use of distributed word representations generated from large text corpora is pervasive in modern NLP. We start with 300 dimension GloVe representations (Pennington et al., 2014) trained on the 840 billion word common crawl (Smith et al., 2013). We added two binary dimensions: one for out of vocabulary words, and one for padding, resulting in vectors with a width of 302. These embeddings are mapped from the words in the sentence, and are then trained using back propagation just like other parameters in the network.

4.2.2 Wikifier

The AMR standard was expanded to include the annotation of named entities with a canonical form, using Wikipedia as the standard (see *France* in Figure 1a). The wiki link associated with this "wikification" is expressed using the :wiki attribute, which requires some kind of global external knowledge of the Wikipedia ontology. We use the University of Illinois Wikifier (Ratinov et al., 2011; Cheng and Roth, 2013) to identify the :link directly, and use the possible categories output from the wikifier as feature inputs to the NCat Network.



(a) Expert System and Subgraph Expander Development. The alignment between the words in the sentence and elements of the AMR is provided by an automatic aligner. The expert system uses the sentence, reference AMR, and alignment to identify spans of words which are related to concepts within the AMR. These spans are also labelled with a subgraph type. A "subgraph expander" uses the words and subgraph type to expand into AMR subgraphs.



(b) SG Network Training. The SG Network uses just the words in the sentence as input, and is trained to imitate the output of the Expert System. This output defines spans of words and their subgraph types, which are the nodes of the AMR graph. Later stages of the system use this information to infer other aspects of the AMR, like relations (edges).

Figure 3: SG Model Development Details.

Named Entity Recognition can be valuable input to a parser, and state-of-the-art NER systems can be created using convolutional neural networks (Collobert et al., 2011) or LSTM (Chiu and Nichols, 2015) aided by information from gazetteers. These gazetteers are large dictionaries containing well known named entities (e.g., (Florian et al., 2003)).

Rather than add gazetteer features to our system, we make use of the NER information already calculated and provided by the Univ. of Illinois Wikifier. We then encode the classified named entities output from the wikifier as feature embeddings, which are used by the SG Network.

4.2.3 AMR Subgraph (SG) Network

The features used as input to the SG network are:

- word: 45Kx302, the word embeddings
- suffix: 430x5, embeddings based on the final two letters of each word.
- caps: 5x5, embeddings based on the capitalization pattern of the word.
- NER: 5x5, embeddings indexed by NER from the Wikifier, 'O', 'LOC', 'ORG', 'PER' or 'MISC'.

The SG Network produces probabilities for 46 BIOES tagged subgraph types, and the highest probability tag is chosen for each word, as shown for the example sentence in Table 1.

4.2.4 Predicate Argument Relations (Args) Network

The AMR concepts (nodes) are connected by relations (arcs). We found it convenient to distinguish predicate argument relations, or "Args" from other relations, which we call "Nargs". For example, see ARG0 and ARG1 relations in Figure 1a are "Args", compared with the name, degree, mod, or quant relations which are "Nargs".

The Args Network is run once for each predicate subgraph, and produces a matrix P_{args} which defines the probability (prior to the identification of any relations[6]) of a type of predicate argument relation from a predicate subgraph to any other SG identified subgraph. (For example, see ARG0 and ARG1 relations in Figure 1a.) The matrix has dimensions 5 by s, where 5 is the number of predicate arg relations identified by the network, and s is the total number of subgraphs identified by the SG Network for the sentence.

The Args features, calculated for each source predicate subgraph, are:

- Word, Suffix and Caps as in the SG network.
- SG: 46x5, indexed by the SG network identified subgraph.
- PredWords[5], 45Kx302: The word embeddings of the word and surrounding 2 words associated with the source predicate subgraph.

[6]relation probabilities change as hard decisions are made, see section 4.3

words	BIOES	Prob	kind
France	S_Named	0.995	Named subgraph
plans	S_Pred-01	0.997	plan-01
further	S_NonPred	0.931	further
nuclear	S_NonPred	0.990	nucleus

SG[S_NonPred]	10
SG[S_NonPred]	10
SG[S_Pred-01]	10
SG[O]	10
SG[S_NonPred]	10
Distance[4]	5

Table 2: Args Network Features for the word *France* while evaluating outgoing args for the word *cooperation*, associated with predicate **cooperate-01**

- PredSG[5], 46x10: The SG embedding of the word and surrounding 2 words associated with the source predicate subgraph.
- regionMark: 21x5, indexed by the distance in words between the word and the word associated with the source predicate subgraph.

Table 2 shows an example feature set for one subgraph while evaluating a predicate subgraph.

4.2.5 Non-Predicate Relations (Nargs) Network

The Nargs Network uses features similar to the Args network. It is run once for each subgraph, and produces a matrix P_{nargs} which defines the probability of a type of relation from a subgraph to any other subgraph, prior to the identification of any relations.[7] The matrix has dimensions 43 by s, where 43 is the number of non-arg relations identified by the network, and s is the total number of subgraphs identified by the SG Network for the sentence.

4.2.6 Attributes (Attr) Network

The Attr Network determines a primary attribute for each subgraph, if any.[8] This network is simplified to detect only one attribute (there could be many) per subgraph, and only computes probabilities for the two most common attributes: TOP and polarity. Note that subgraph expansion also identifies many attributes, for example the words associated with named entities, or the normalized quantity and date representations. A known shortcoming of this network is that the TOP and polarity attributes are not mutually exclusive, but noting that the cooccurrence of the two does not occur in the training data, we chose to avoid adding a separate network to allow the prediction of both attributes for a single subgraph.

4.2.7 Named Category (NCat) Network

The NCat Network uses features similar to the SG Network, along with the suggested categories (up to eight) from the Wikifier, and produces probabilities for each of 68 :instance roles, or categories, for named entities identified in the training set AMR's.

- Word, Suffix and Caps as in the SG network.
- WikiCat[8]: 108 x 5, indexed by suggested categories from the Wikifier.

4.3 Relation Resolution

The generated P_{args} and P_{nargs} for each SG identified subgraph are processed to determine the most likely relation connections, using the constraints:

[7] Degree, mod, or quant are examples of Narg relations in Figure 1a.

[8] (TOP: plan-01) and (op1: france) are attribute examples shown in Figure 1a.

1. AMR's are single component graphs without cycles.
2. AMR's are simple directed graphs, a max of one relation between any two subgraphs is allowed.
3. Outgoing predicate relations are limited to one of each kind (i.e. can't have two ARG0's)

We initialize a graph description with all the subgraphs identified by the SG network. Probabilities for all possible edges are represented in the P_{args} and P_{nargs} matrices. The Subgraphs are connected to one another by applying a greedy algorithm, which repeatedly selects the most probable edge from the P_{args} and P_{nargs} matrices and adds the edge to the graph description. After an edge is selected to be added to the graph, we adjust P_{args} and P_{nargs} based on the constraints (hard decisions change the probabilities), and repeat adding edges until all remaining edge probabilities are below a threshold. (The optimum value of this threshold, 0.55, was found by experimenting with the development data set). From then on, only the most probable edges which span graph components are chosen, until the graph contains a single component.

Expressed as a step by step procedure, we first define $p_{connect}$ as the probability threshold at which to require graph component spanning, and we repeat the following, until any two subgraphs in the graph are connected by at least one path.

1. Select the most probable outgoing relation from any of the identified subgraph probability matrices. Denote this probability as p_r.
2. If $p_r < p_{connect}$, keep selecting most probable relations until a component spanning connection is found.
3. Add the selected relation to the graph. If a cycle is created, reverse the relation direction and label.
4. Eliminate impossible relations based on the constraints and re-normalize the affected P_{args} and P_{nargs} matrices.

4.4 AMR Construction

AMR Construction converts the connected subgraph AMR into the final AMR graph form, with proper concepts, relations, and root, as follows:

1. The TOP attribute occurs exactly once in each AMR, so the subgraph with highest TOP probability produced by the Attr network is identified. The AMR graph is adjusted so that it is rooted with the most probable TOP subgraph. After graph adjustment, new cycles are sometimes created, which are removed by using *-of* relation reversal.
2. The subgraphs identified by the SG network, which were considered to be single nodes during relation resolution, are expanded to basic AMR concepts and relations to form a concept/relation AMR graph representation, using the Subgraph Expander component developed as shown in Figure 3b. When a subgraph contains two concepts, the choice of connecting to parent or child within the subgraph is made based on training data statistics of each relation type (Arg or Narg) for each subgraph type.
3. Nationalities are normalized (e.g. French to France).
4. A very basic coreference resolution is performed by merging all concepts representing "I" into a single concept. Coreference resolution was otherwise ignored due to development time constraints.

5 Experimental Setup

Semantic graph comparison can be tricky because direct graph alignment fails in the presence of just a few miscompares. A practical graph comparison program called Smatch (Cai and Knight, 2013) is used to consistently evaluate AMR parsers. The smatch python script provides an F1 evaluation metric for whole-sentence semantic graph analysis by comparing sets of triples which describe portions of the graphs, and uses a hill climbing algorithm for efficiency.

All networks, including SG, were trained using stochastic gradient descent (SGD) with a fixed learning rate. We tried sentence level log-likelihood, which trains a viterbi decoder, as a training objective, but found no improvement over word-level likelihood (cross entropy). After all LSTM and linear layers, we added dropout to minimize overfitting (Hinton et al., 2012) and batch normalization to reduce sensitivity to learning rates and initialization (Ioffe and Szegedy, 2015).

For each of the five networks, we used the LDC2015E86 training split to train parameters, and periodically interrupted training to run the dev split (forward) in order to monitor performance.

The model parameters which resulted in best dev performance were saved as the final model. The test split was used as the "in domain" data set to assess the fully assembled parser. The inferred AMR's were then evaluated using the smatch program to produce an F1 score.

An evaluation dataset was provided for Semeval 2016 task 8, which is significantly different from the LDC2015E86 split dataset. ((2016) describes the eval dataset as "quite difficult to parse, particularly due to creative approaches to word representation in the web forum portion").

6 Results

We report the statistics for smatch results of the "test" and "eval" datasets for 12 trained systems in Table 3. The top five scores for Semeval 2016 task 8, representing the previous state-of-the-art, are shown for context. With a smatch score of between 0.651 and 0.654, and a mean of 0.652, our system improves the state-of-the-art AMR parser performance by between 5.07% and 5.55%, and by a mean of 5.22%. The best performing systems for in-domain (dev and test) data correlated well with the best ones for the out-of-domain (eval) data, although the scores for the eval dataset were lower overall.

6.1 Individual Network Results

The word spans tagged by the SG network are used to determine the features for the other networks. In particular, every span identified as a predicate will trigger the system to evaluate the Args network in order to determine the probabilities of outgoing predicate ARG relations. Likewise, all spans identified as subgraphs (other than named subgraphs) will lead to a Nargs network evaluation to determine outgoing non-Arg relations. The SG network identifies predicates with 0.93 F1, named subgraphs with 0.91 F1, and all other subgraphs with 0.94 F1.

The Args network identifies ARG0 and ARG1 relations with 0.73 F1, but identification of ARG2, ARG3, and ARG4 drops down to (0.53, 0.20, and 0.43). It is difficult for the system to generalize among these relation tags because they differ significantly between predicates.

7 Conclusion and Future Work

We have shown that B-LSTM neural networks can be used as the basis for a graph based semantic parser. Our AMR parser effectively exploits the ability of B-LSTM networks to learn to selectively extract information from words separated by long distances in a sentence, and to build up higher level representations by rejecting or remembering important information during sequence processing. There are changes which could be made to eliminate all pre-processing and to further improve parser performance.

Eliminating the need for syntactic pre-parsing is valuable since a syntactic parser takes up significant time and computational resources, and errors in the generated syntax will propagate into an AMR parser. Our approach avoids both of these problems, while generating high quality results.

Wikification tasks are generally independent from parsing, but wiki links are a requirement for the latest AMR specification. Since our preferred wikifier application generates NER information, we used the generated NER tags as input to the SG network. But it would also be fairly easy to add gazetteer information to the network features in order to remove the need for NER preprocessing. Therefore, the wikification subtask is the only portion of the parser which requires any pre-processing at all. Incorporating wikification gazetteers as B-LSTM features might allow a performant, fully self contained parser to be created.

Sense disambiguation is not a very generalizable task, senses other than 01 and 02 for different predicates may differ from each other in ways which are very difficult to discern. A better approach to disambiguation is to consider predicates separately, solving for a set of coefficients for each verb found in the training set. A general set of model parameters could then be used to handle unseen examples. Likewise, high level ARGs like ARG2 and ARG3 don't generalize very well among different predicates, and ARG inference accuracy could be improved with predicate-specific network parameters for the most common cases.

The alignment between concepts and words is not a reliable, direct mapping: some concepts cannot be grounded to words, some are ambiguous, and automatic aligners tend to have high error rates relative to human aligning judgements. Improvements in the quality of the alignment in training data would improve parsing results.

System	Description	Test F1	Eval (OOD) F1
Our Parser (summary of 12 trained systems)	**mean**	**0.707**	**0.652**
	min	**0.706**	**0.651**
	max	**0.709**	**0.654**

Abstract

We introduce a new deep learning model for semantic role labeling (SRL) that significantly improves the state of the art, along with detailed analyses to reveal its strengths and limitations. We use a deep highway BiLSTM architecture with constrained decoding, while observing a number of recent best practices for initialization and regularization. Our 8-layer ensemble model achieves 83.2 F1 on the CoNLL 2005 test set and 83.4 F1 on CoNLL 2012, roughly a 10% relative error reduction over the previous state of the art. Extensive empirical analysis of these gains show that (1) deep models excel at recovering long-distance dependencies but can still make surprisingly obvious errors, and (2) that there is still room for syntactic parsers to improve these results.

1 Introduction

Semantic role labeling (SRL) systems aim to recover the predicate-argument structure of a sentence, to determine essentially "who did what to whom", "when", and "where." Recently breakthroughs involving end-to-end deep models for SRL without syntactic input (Zhou and Xu, 2015; Marcheggiani et al., 2017) seem to overturn the long-held belief that syntactic parsing is a prerequisite for this task (Punyakanok et al., 2008). In this paper, we show that this result can be pushed further using deep highway bidirectional LSTMs with constrained decoding, again significantly moving the state of the art (another 2 points on CoNLL 2005). We also present a careful empirical analysis to determine what works well and what might be done to progress even further.

Our model combines a number of best practices in the recent deep learning literature. Following Zhou and Xu (2015), we treat SRL as a BIO tagging problem and use deep bidirectional LSTMs. However, we differ by (1) simplifying the input and output layers, (2) introducing highway connections (Srivastava et al., 2015; Zhang et al., 2016), (3) using recurrent dropout (Gal and Ghahramani, 2016), (4) decoding with BIO-constraints, and (5) ensembling with a product of experts. Our model gives a 10% relative error reduction over previous state of the art on the test sets of CoNLL 2005 and 2012. We also report performance with predicted predicates to encourage future exploration of end-to-end SRL systems.

We present detailed error analyses to better understand the performance gains, including (1) design choices on architecture, initialization, and regularization that have a surprisingly large impact on model performance; (2) different types of prediction errors showing, e.g., that deep models excel at predicting long-distance dependencies but still struggle with known challenges such as PP-attachment errors and adjunct-argument distinctions; (3) the role of syntax, showing that there is significant room for improvement given oracle syntax but errors from existing automatic parsers prevent effective use in SRL.

In summary, our main contributions incluede:

- A new state-of-the-art deep network for end-to-end SRL, supported by publicly available code and models.[1]
- An in-depth error analysis indicating where the model works well and where it still struggles, including discussion of structural consistency and long-distance dependencies.
- Experiments that point toward directions for future improvements, including a detailed discussion of how and when syntactic parsers could be used to improve these results.

2 Model

Two major factors contribute to the success of our deep SRL model: (1) applying recent advances in training deep recurrent neural networks such as highway connections (Srivastava et al., 2015) and RNN-dropouts (Gal and Ghahramani, 2016),[2] and (2) using an A* decoding algorithm (Lewis and Steedman, 2014; Lee et al., 2016) to enforce structural consistency at prediction time without adding more complexity to the training process.

Formally, our task is to predict a sequence $\boldsymbol{y}$ given a sentence-predicate pair $(\boldsymbol{w}, v)$ as input. Each $y_i \in \boldsymbol{y}$ belongs to a discrete set of BIO tags $\boldsymbol{T}$. Words outside argument spans have the tag O, and words at the beginning and inside of argument spans with role r have the tags B_r and I_r respectively. Let $n = |\boldsymbol{w}| = |\boldsymbol{y}|$ be the length of the sequence.

Predicting an SRL structure under our model involves finding the highest-scoring tag sequence over the space of all possibilities $\mathcal{Y}$:

$$\hat{\boldsymbol{y}} = \operatorname*{argmax}_{\boldsymbol{y} \in \mathcal{Y}} f(\boldsymbol{w}, \boldsymbol{y}) \tag{1}$$

We use a deep bidirectional LSTM (BiLSTM) to learn a locally decomposed scoring function conditioned on the input: $\sum_{t=1}^{n} \log p(y_t \mid \boldsymbol{w})$.

To incorporate additional information (e.g., structural consistency, syntactic input), we augment the scoring function with penalization terms:

$$f(\boldsymbol{w}, \boldsymbol{y}) = \sum_{t=1}^{n} \log p(y_t \mid \boldsymbol{w}) - \sum_{c \in \mathcal{C}} c(\boldsymbol{w}, y_{1:t}) \tag{2}$$

Each constraint function c applies a *non-negative* penalty given the input $\boldsymbol{w}$ and a length-t prefix $y_{1:t}$. These constraints can be hard or soft depending on whether the penalties are finite.

2.1 Deep BiLSTM Model

Our model computes the distribution over tags using stacked BiLSTMs, which we define as follows:

$$\boldsymbol{i}_{l,t} = \sigma(\mathbf{W}^l_{\mathrm{i}}[\boldsymbol{h}_{l,t+\delta_l}, \boldsymbol{x}_{l,t}] + \boldsymbol{b}^l_{\mathrm{i}}) \tag{3}$$
$$\boldsymbol{o}_{l,t} = \sigma(\mathbf{W}^l_{\mathrm{o}}[\boldsymbol{h}_{l,t+\delta_l}, \boldsymbol{x}_{l,t}] + \boldsymbol{b}^l_{\mathrm{o}}) \tag{4}$$
$$\boldsymbol{f}_{l,t} = \sigma(\mathbf{W}^l_{\mathrm{f}}[\boldsymbol{h}_{l,t+\delta_l}, \boldsymbol{x}_{l,t}] + \boldsymbol{b}^l_{\mathrm{f}} + 1) \tag{5}$$
$$\tilde{\boldsymbol{c}}_{l,t} = \tanh(\mathbf{W}^l_{\mathrm{c}}[\boldsymbol{h}_{l,t+\delta_l}, \boldsymbol{x}_{l,t}] + \boldsymbol{b}^l_{\mathrm{c}}) \tag{6}$$
$$\boldsymbol{c}_{l,t} = \boldsymbol{i}_{l,t} \circ \tilde{\boldsymbol{c}}_{l,t} + \boldsymbol{f}_{l,t} \circ \boldsymbol{c}_{t+\delta_l} \tag{7}$$
$$\boldsymbol{h}_{l,t} = \boldsymbol{o}_{l,t} \circ \tanh(\boldsymbol{c}_{l,t}) \tag{8}$$

[2] We thank Mingxuan Wang for suggesting highway connections with simplified inputs and outputs. Part of our model is extended from his unpublished implementation.

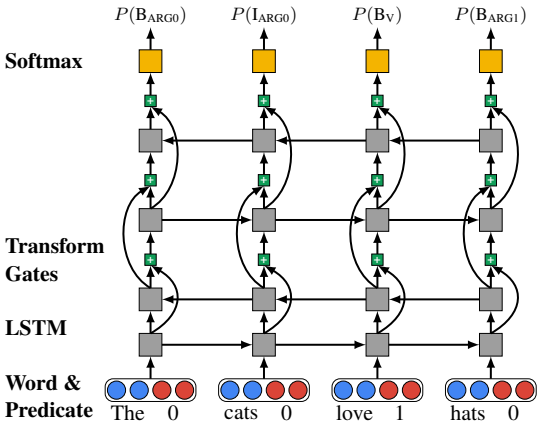

Figure 1: Highway LSTM with four layers. The curved connections represent highway connections, and the plus symbols represent transform gates that control inter-layer information flow.

where $x_{l,t}$ is the input to the LSTM at layer l and timestep t. δ_l is either 1 or -1, indicating the directionality of the LSTM at layer l.

To stack the LSTMs in an interleaving pattern, as proposed by Zhou and Xu (2015), the layer-specific inputs $x_{l,t}$ and directionality δ_l are arranged in the following manner:

$$\boldsymbol{x}_{l,t} = \begin{cases} [\mathbf{W}_{\text{emb}}(w_t), \mathbf{W}_{\text{mask}}(t = v)] & l = 1 \\ \boldsymbol{h}_{l-1,t} & l > 1 \end{cases} \tag{9}$$

$$\delta_l = \begin{cases} 1 & \text{if } l \text{ is even} \\ -1 & \text{otherwise} \end{cases} \tag{10}$$

The input vector $\boldsymbol{x}_{1,t}$ is the concatenation of token w_t's word embedding and an embedding of the binary feature $(t = v)$ indicating whether w_t word is the given predicate.

Finally, the locally normalized distribution over output tags is computed via a softmax layer:

$$p(y_t \mid \boldsymbol{x}) \propto \exp(\mathbf{W}^y_{\text{tag}} \boldsymbol{h}_{L,t} + \boldsymbol{b}_{\text{tag}}) \tag{11}$$

Highway Connections To alleviate the vanishing gradient problem when training deep BiLSTMs, we use gated highway connections (Zhang et al., 2016; Srivastava et al., 2015). We include *transform gates* $\boldsymbol{r}_t$ to control the weight of linear and non-linear transformations between layers (See Figure 1). The output $\boldsymbol{h}_{l,t}$ is changed to:

$$\boldsymbol{r}_{l,t} = \sigma(\mathbf{W}^l_{\mathrm{r}}[\boldsymbol{h}_{l,t-1}, \boldsymbol{x}_t] + \boldsymbol{b}^l_{\mathrm{r}}) \tag{12}$$
$$\boldsymbol{h}'_{l,t} = \boldsymbol{o}_{l,t} \circ \tanh(\boldsymbol{c}_{l,t}) \tag{13}$$
$$\boldsymbol{h}_{l,t} = \boldsymbol{r}_{l,t} \circ \boldsymbol{h}'_{l,t} + (1 - \boldsymbol{r}_{l,t}) \circ \mathbf{W}^l_{\mathrm{h}} \boldsymbol{x}_{l,t} \tag{14}$$

Recurrent Dropout To reduce over-fitting, we use dropout as described in Gal and Ghahramani (2016). A shared dropout mask $\boldsymbol{z}_l$ is applied to the hidden state:

$$\widetilde{\boldsymbol{h}}_{l,t} = \boldsymbol{r}_{l,t} \circ \boldsymbol{h}'_{l,t} + (1 - \boldsymbol{r}_{l,t}) \circ \mathbf{W}^l_{\mathrm{h}} \boldsymbol{x}_{l,t} \quad (15)$$

$$\boldsymbol{h}_{l,t} = \boldsymbol{z}_l \circ \widetilde{\boldsymbol{h}}_{l,t} \quad (16)$$

$\boldsymbol{z}_l$ is shared across timesteps at layer l to avoid amplifying the dropout noise along the sequence.

2.2 Constrained A* Decoding

The approach described so far does not model any dependencies between the output tags. To incorporate constraints on the output structure at decoding time, we use A* search over tag prefixes for decoding. Starting with an empty sequence, the tag sequence is built from left to right. The score for a partial sequence with length t is defined as:

$$f(\boldsymbol{w}, y_{1:t}) = \sum_{i=1}^{t} \log p(y_i \mid \boldsymbol{w}) - \sum_{c \in \mathcal{C}} c(\boldsymbol{w}, y_{1:i}) \quad (17)$$

An admissible A* heuristic can be computed efficiently by summing over the best possible tags for all timesteps after t:

$$g(\boldsymbol{w}, y_{1:t}) = \sum_{i=t+1}^{n} \max_{y_i \in \boldsymbol{T}} \log p(y_i \mid \boldsymbol{w}) \quad (18)$$

Exploration of the prefixes is determined by an agenda $\mathcal{A}$ which is sorted by $f(\boldsymbol{w}, y_{1:t}) + g(\boldsymbol{w}, y_{1:t})$. In the worst case, A* explores exponentially many prefixes, but because the distribution $p(y_t \mid \boldsymbol{w})$ learned by the BiLSTM models is very peaked, the algorithm is efficient in practice. We list some example constraints as follows:

BIO Constraints These constraints reject any sequence that does not produce valid BIO transitions, such as $\mathrm{B}_{\mathrm{ARG0}}$ followed by $\mathrm{I}_{\mathrm{ARG1}}$.

SRL Constraints Punyakanok et al. (2008); Täckström et al. (2015) described a list of SRL-specific global constraints:

- Unique core roles (U): Each core role (ARG0-ARG5, ARGA) should appear at most once for each predicate.
- Continuation roles (C): A continuation role C-X can exist only when its base role X is realized before it.
- Reference roles (R): A reference role R-X can exist only when its base role X is realized (not necessarily before R-X).

We only enforce U and C constraints, since the R constraints are more commonly violated in gold data and enforcing them results in worse performance (see discussions in Section 4.3).

Syntactic Constraints We can enforce consistency with a given parse tree by rejecting or penalizing arguments that are not constituents. In Section 4.4, we will discuss the motivation behind using syntactic constraints and experimental results using both predicted and gold syntax.

2.3 Predicate Detection

While the CoNLL 2005 shared task assumes gold predicates as input (Carreras and Màrquez, 2005), this information is not available in many downstream applications. We propose a simple model for end-to-end SRL, where the system first predicts a set of predicate words $\boldsymbol{v}$ from the input sentence $\boldsymbol{w}$. Then each predicate in $\boldsymbol{v}$ is used as an input to argument prediction. We independently predict whether each word in the sentence is a predicate, using a binary softmax over the outputs of a bidirectional LSTM trained to maximize the likelihood of the gold labels.

3 Experiments

3.1 Datasets

We measure the performance of our SRL system on two PropBank-style, span-based SRL datasets: CoNLL-2005 (Carreras and Màrquez, 2005) and CoNLL-2012 (Pradhan et al., 2013)[3]. Both datasets provide gold predicates (their index in the sentence) as part of the input. Therefore, each provided predicate corresponds to one training/test tag sequence. We follow the train-development-test split for both datasets and use the official evaluation script from the CoNLL 2005 shared task for evaluation on both datasets.

3.2 Model Setup

Our network consists of 8 BiLSTM layers (4 forward LSTMs and 4 reversed LSTMs) with 300-dimensional hidden units, and a softmax layer for predicting the output distribution.

Initialization All the weight matrices in BiLSTMs are initialized with random orthonormal matrices as described in Saxe et al. (2013).

Table 2: Experimental results on CoNLL 2012 in the same metrics as above. We compare our best single and ensemble (PoE) models against Zhou and Xu (2015), FitzGerald et al. (2015), Täckström et al. (2015) and Pradhan et al. (2013).

All tokens are lower-cased and initialized with 100-dimensional GloVe embeddings pre-trained on 6B tokens (Pennington et al., 2014) and updated during training. Tokens that are not covered by GloVe are replaced with a randomly initialized UNK embedding.

Training We use Adadelta (Zeiler, 2012) with $\epsilon = 1e^{-6}$ and $\rho = 0.95$ and mini-batches of size 80. We set RNN-dropout probability to 0.1 and clip gradients with norm larger than 1. All the models are trained for 500 epochs with early stopping based on development results. [4]

Ensembling We use a product of experts (Hinton, 2002) to combine predictions of 5 models, each trained on 80% of the training corpus and validated on the remaining 20%. For the CoNLL 2012 corpus, we split the training data from each sub-genre into 5 folds, such that the training data will have similar genre distributions.

Constrained Decoding We experimented with different types of constraints on the CoNLL 2005 and CoNLL 2012 development sets. Only the BIO hard constraints significantly improve over the ensemble model. Therefore, in our final results, we only use BIO hard constraints during decoding. [5]

3.3 Results

In Table 1 and 2, we compare our best single and ensemble model with previous work. Our ensemble (PoE) has an absolute improvement of 2.1 F1 on both CoNLL 2005 and CoNLL 2012 over the previous state of the art. Our single model also achieves more than a 0.4 improvement on both datasets. In comparison with the best reported results, our percentage of completely correct predicates improves by 5.9 points. While the continuing trend of improving SRL without syntax seems to suggest that neural end-to-end systems no longer needs parsers, our analysis in Section 4.4 will show that accurate syntactic information can improve these deep models.

[4] Training the full model on CoNLL 2005 takes about 5 days on a single Titan X Pascal GPU.

[5] A* search in this setting finds the optimal sequence for all sentences and is therefore equivalent to Viterbi decoding.

	Predicate Detection			End-to-end SRL (Single)			End-to-end SRL (PoE)

Table 3: Predicate detection performance and end-to-end SRL results using predicted predicates. Δ F1 shows the absolute performance drop compared to our best ensemble model with gold predicates.

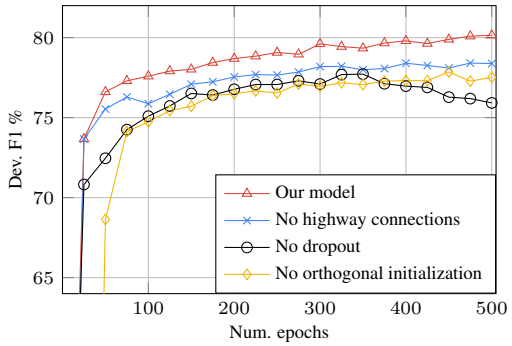

Figure 2: Smoothed learning curve of various ablations. The combination of highway layers, orthonormal parameter initialization and recurrent dropout is crucial to achieving strong performance. The numbers shown here are without constrained decoding.

3.4 Ablations

Figure 2 shows learning curves of our model ablations on the CoNLL 2005 development set. We ablate our full model by removing highway connections, RNN-dropout, and orthonormal initialization independently. Without dropout, the model overfits at around 300 epochs at 78 F1. Orthonormal parameter initialization is surprisingly important—without this, the model achieves only 65 F1 within the first 50 epochs. All 8 layer ablations suffer a loss of more than 1.7 in absolute F1 compared to the full model.

3.5 End-to-end SRL

The network for predicate detection (Section 2.3) contains 2 BiLSTM layers with 100-dimensional hidden units, and is trained for 30 epochs. For end-to-end evaluation, all arguments predicted for the false positive predicates are counted as precision loss, and all arguments for the false negative predicates are considered as recall loss.

Table 3 shows the predicate detection F1 as well as end-to-end SRL results with predicted predicates.[6] On CoNLL 2005, the predicate detector achieved over 96 F1, and the final SRL results only drop 1.2-3.5 F1 compared to using the gold predicates. However, on CoNLL 2012, the predicate detector has only about 90 F1, and the final SRL results decrease by up to 6.2 F1. This is at least in part due to the fact that CoNLL 2012 contains some nominal and copula predicates (Weischedel et al., 2013), making predicate identification a more challenging problem.

4 Analysis

To better understand our deep SRL model and its relation to previous work, we address the following questions with a suite of empirical analyses:

- What is the model good at and what kinds of mistakes does it make?
- How well do LSTMs model global structural consistency, despite conditionally independent tagging decisions?
- Is our model implicitly learning syntax, and could explicitly modeling syntax still help?

All the analysis in this section is done on the CoNLL 2005 development set with gold predicates, unless otherwise stated. We are also able to compare to previous systems whose model predictions are available online (Punyakanok et al., 2005; Pradhan et al., 2005).[7]

4.1 Error Types Breakdown

Inspired by Kummerfeld et al. (2012), we define a set of oracle transformations that fix various prediction errors *sequentially* and observe the relative improvement after each operation (see Table 4). Figure 3 shows how our work compares to the pre-

[6]The frame identification numbers reported in Pradhan et al. (2013) are not comparable, due to errors in the original release of the data, as mentioned in Täckström et al. (2015).

[7]Model predictions of CoNLL 2005 systems: http://www.cs.upc.edu/~srlconll/st05/st05.html

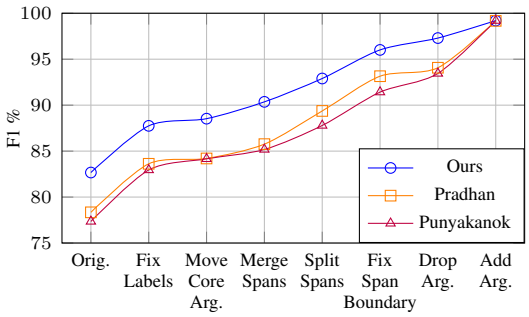

Figure 3: Performance after doing each type of oracle transformation in sequence, compared to two strong non-neural baselines. The gap is closed after the *Add Arg.* transformation, showing how our approach is gaining from predicting more arguments than traditional systems.

vious systems in terms of different types of mistakes. While our model makes a similar number of labeling errors to traditional syntax-based systems, it has far fewer missing arguments (perhaps due to parser errors making some arguments difficult to recover for syntax-based systems).

Label Confusion As shown in Table 4, our system most commonly makes labeling errors, where the predicted span is an argument but the role was incorrectly labeled. Table 5 shows a confusion matrix for the most frequent labels. The model often confuses ARG2 with AM-DIR, AM-LOC and AM-MNR. These confusions can arise due to the use of ARG2 in many verb frames to represent semantic relations such as direction or location. For example, ARG2 in the frame *move.01* is defined as *Arg2-GOL: destination*. [8] This type of argument-adjunct distinction is known to be difficult (Kingsbury et al., 2002), and it is not surprising that our neural model has many such failure cases.

Attachment Mistakes A second common source of error is reflected by the *Merge Spans* transformation (10.6%) and the *Split Spans* transformation (14.7%). These errors are closely tied to prepositional phrase (PP) attachment errors, which are also known to be some of the biggest challenges for linguistic analysis (Kummerfeld et al., 2012). Figure 4 shows the distribution of syntactic span labels involved in an attachment mistake, where 62% of the syntactic spans are prepositional phrases. For example, in *Sumitomo*

[8] Source: Unified verb index: `http://verbs.colorado.edu`.

Operation	Description	%
Fix Labels	Correct the span label if its boundary matches gold.	29.3
Move Arg.	Move a unique core argument to its correct position.	4.5
Merge Spans	Combine two predicted spans into a gold span if they are separated by at most one word.	10.6
Split Spans	Split a predicted span into two gold spans that are separated by at most one word.	14.7
Fix Boundary	Correct the boundary of a span if its label matches an overlapping gold span.	18.0
Drop Arg.	Drop a predicted argument that does not overlap with any gold span.	7.4
Add Arg.	Add a gold argument that does not overlap with any predicted span.	11.0

Table 4: Oracle transformations paired with the relative error reduction after each operation. All the operations are permitted only if they do not cause any overlapping arguments.

financed the acquisition from Sears, our model mistakenly labels the prepositional phrase *from Sears* as the ARG2 of *financed*, whereas it should instead attach to *acquisition*.

4.2 Long-range Dependencies

To analyze the model's ability to capture long-range dependencies, we compute the F1 of our model on arguments with various distances to the predicate. Figure 5 shows that performance tends to degrade, for all models, for arguments further from the predicate. Interestingly, the gap between shallow and deep models becomes much larger for the long-distance predicate-argument structures. The absolute gap between our 2 layer and 8 layer models is 3-4 F1 for arguments that are within 2 words to the predicate, and 5-6 F1 for arguments that are farther away from the predicate. Surpris-

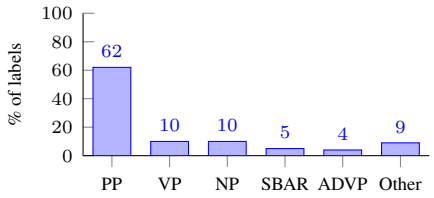

Figure 4: For cases where our model either splits a gold span into two ($Z \rightarrow XY$) or merges two gold constituents ($XY \rightarrow Z$), we show the distribution of syntactic labels for the Y span. Results show the major cause of these errors is inaccurate prepositional phrase attachment.

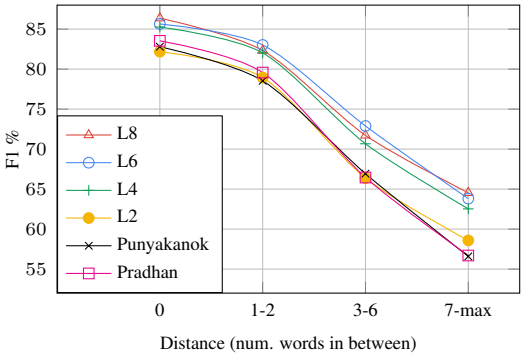

Figure 5: F1 by surface distance between predicates and arguments. Performance degrades least rapidly on long-range arguments for the deeper neural models.

ingly, the neural model performance deteriorates less severely on long-range dependencies than traditional syntax-based models.

4.3 Structural Consistency

We can quantify two types of structural consistencies: the BIO constraints and the SRL-specific constraints. Via our ablation study, we show that deeper BiLSTMs are better at enforcing these structural consistencies, although not perfectly.

BIO Violations The BIO format requires argument spans to begin with a B tag. Any I tag directly following an O tag or a tag with different label is considered a violation. Table 6 shows the number of BIO violations per token for BiLSTMs with different depths. The number of BIO violations decreases when we use a deeper model. The gap is biggest between 2-layer and 4-layer models, and diminishes after that.

It is surprising that although the deeper models generate impressively accurate token-level predictions, they still make enough BIO errors to significantly hurt performance—when these constraints are simple enough to be enforced by trivial rules. We compare the average entropy between tokens involved in BIO violations with the averaged entropy of all tokens. For the 8-layer model, the average entropy on these tokens is 30 times higher than the averaged entropy on all tokens. This suggests that BIO inconsistencies occur when there is some ambiguity. For example, if the model is unsure whether two consecutive words should belong to an ARG0 or ARG1, it might generate inconsistent BIO sequences such as B_{ARG0}, I_{ARG1} when decoding at the token level. Using BIO-constrained decoding can resolve this ambiguity and result in a structurally consistent solution.

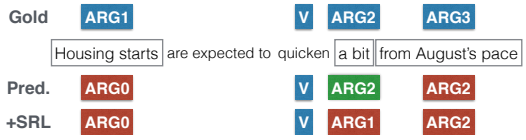

Figure 6: Example where performance is hurt by enforcing the constraint that core roles may only occur once (+SRL).

SRL Structure Violations The model predictions can also violate the SRL-specific constraints commonly used in prior work (Punyakanok et al., 2008; Täckström et al., 2015). As shown in Table 7, the model occasionally violates these SRL constraints. With our constrained decoding algorithm, it is straightforward to enforce the unique core roles (U) and continuation roles (C) constraints during decoding. The constrained decoding results are shown with the model named *L8+PoE+SRL* in Table 7.

Although the violations are eliminated, the performance does not significantly improve. This is mainly due to two factors: (1) the model often already satisfies these constraints on its own, so the number of violations to be fixed are relatively small, and (2) the gold SRL structure sometimes violates the constraints and enforcing hard constraints can hurt performance. Figure 6 shows a sentence in the CoNLL 2005 development set. Our original model produces two ARG2s for the predicate *quicken*, and this violates the SRL constraints. When the A* decoder fixes this violation, it changes the first ARG1 into ARG2 because ARG0, ARG1, ARG2 is a more frequent pattern in the training data and has higher overall score.

	Accuracy		Violations	Avg. Entropy	
Model (no BIO)	F1	Token	BIO	All	BIO
L8+PoE	81.5	91.5	0.07	0.02	0.72
L8	80.5	90.9	0.07	0.02	0.73
L6	80.1	90.3	0.06	0.02	0.72
L4	79.1	90.2	0.08	0.02	0.70
L2	74.6	88.4	0.18	0.03	0.66

Table 6: Comparison of BiLSTM models without BIO decoding. We compare F1 and token-level accuracy (Token), averaged BIO violations per token (BIO), overall model entropy (All) model entropy at tokens involved in BIO violations (BIO). Increasing the depth of the model beyond 4 does not produce more structurally consistent output, emphasizing the need for constrained decoding.

4.4 Can Syntax Still Help SRL?

The Propbank-style SRL formalism is closely tied to syntax (Bonial et al., 2010; Weischedel et al., 2013). In Table 7, we show that 98.7% of the gold SRL arguments match an unlabeled constituent in the gold syntax tree. Similar to some recent work (Zhou and Xu, 2015), our model achieves strong performance without directly modeling syntax. A natural question follows: are neural SRL models implicitly learning syntax? Table 7 shows the trend of deeper models making predictions that are more consistent with the gold syntax in terms of span boundaries. With our best model (*L8+PoE*), 94.3% of the predicted arguments spans are part of the gold parse tree. This consistency is on par with previous CoNLL 2005 systems that directly model constituency and use predicted parse trees as features (Punyakanok, 95.3% and Pradhan, 93.0%).

Constrained Decoding with Syntax The above analysis raises a further question: would improving consistency with syntax provide improvements for SRL? Our constrained decoding algorithm described in Section 2.2 enables us to inject syntax as a decoding constraint without having to retrain the model. Specifically, if the decoded sequence contains k arguments that do not match any unlabeled syntactic constituent, it will receive a penalty of kC, where C is a single parameter dictating how much the model should trust the provided syntax. In Figure 7, we compare the SRL accuracy with syntactic constraints specified by gold parse or automatic parses. When using gold syntax, the predictions improve up to 2 F1 as the penalty increases. A state-of-the-art parser (Choe and Charniak, 2016) provides smaller gains, while using the Charniak parser (Charniak, 2000) hurts performance if the model places too much trust in it. These results suggest that high-quality syntax can still make a large impact on SRL.

			SRL-Violations		
Model or Oracle	F1	Syn %	U	C	R
Gold	100.0	98.7	24	0	61
L8+PoE	82.7	94.3	37	3	68
L8	81.6	94.0	48	4	73
L6	81.4	93.7	39	3	85
L4	80.5	93.2	51	3	84
L2	77.2	91.3	96	5	72
L8+PoE+SRL	82.8	94.2	5	1	68
L8+PoE+AutoSyn	83.2	96.1	113	3	68
L8+PoE+GoldSyn	85.0	97.6	102	3	68
Punyakanok	77.4	95.3	0	0	0
Pradhan	78.3	93.0	84	3	58

Table 7: Comparison of models with different depths and decoding constraints (in addition to BIO) as well as two previous systems. We compare F1, unlabeled agreement with gold constituency (Syn%) and each type of SRL-constraint violations (**U**nique core roles, **C**ontinuation roles and **R**eference roles). Our best model produces a similar number of constraint violations to the gold annotation, explaining why deterministically enforcing these constraints is not helpful.

A known challenge for syntactic parsers is robustness on out-of-domain data. Therefore we provide experimental results in Table 8 for both CoNLL 2005 and CoNLL 2012, which consists of 8 different genres. The penalties are tuned on the two development sets separately ($C = 10000$ on CoNLL 2005 and $C = 20$ on CoNLL 2012). On the CoNLL 2005 development set, the predicted syntax gives a 0.5 F1 improvement over our best model, while on in-domain test and out-of-domain development sets, the improvement is much smaller. As expected, on CoNLL 2012, syntax improves most on the newswire (NW) domain. These improvements suggest that while decoding with hard constraints is beneficial, joint training or multi-task learning could be even more effective by leveraging full, labeled syntactic structures.

5 Related Work

Traditional approaches to semantic role labeling have used syntactic parsers to identify constituents and model long-range dependencies, and enforced

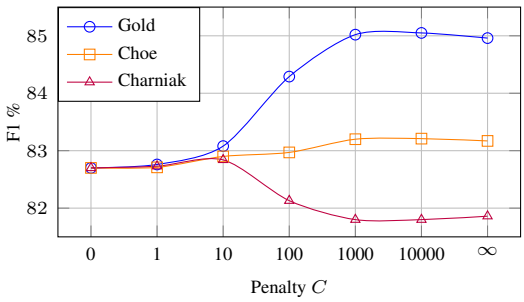

Figure 7: Performance of syntax-constrained decoding as the non-constituent penalty increases for syntax from two parsers (from Choe and Charniak (2016) and Charniak (2000)) and gold syntax. The best existing parser gives a small improvement, but the improvement from gold syntax shows that there is still potential for syntax to help SRL.

	CoNLL-05		CoNLL-2012 Dev.						
	Dev.	Test	BC	BN	NW	MZ	PT	TC	WB
L8+PoE	82.7	84.6	81.4	82.8	82.8	80.4	93.6	84.8	81.0
+AutoSyn	83.2	84.8	81.5	82.8	83.2	80.6	93.7	84.9	81.1

Table 8: F1 on CoNLL 2005, and the development set of CoNLL 2012, broken down by genres. Syntax-constrained decoding (+AutoSyn) shows bigger improvement on in-domain data (CoNLL 05 and CoNLL 2012 NW).

global consistency using integer linear programming (Punyakanok et al., 2008) or dynamic programs (Täckström et al., 2015). More recently, neural methods have been employed on top of syntactic features (FitzGerald et al., 2015; Roth and Lapata, 2016). Our experiments show that off-the-shelf neural methods have a remarkable ability to learn long-range dependencies, syntactic constituency structure, and global constraints without coding task-specific mechanisms for doing so.

An alternative line of work has attempted to reduce the dependency on syntactic input for semantic role labeling models. Collobert et al. (2011) first introduced an end-to-end neural-based approach with sequence-level training and uses a convolutional neural network to model the context window. However, their best system fell short of traditional feature-based systems. Neural methods have also been used as classifiers in transition-based SRL systems (Henderson et al., 2013; Swayamdipta et al., 2016). Most recently, several successful LSTM-based architectures have achieved state-of-the-art results in English span-based SRL (Zhou and Xu, 2015), Chinese SRL (Wang et al., 2015), and dependency-based SRL (Marcheggiani et al., 2017) with little to no syntactic input. Our techniques push results to more than 3 F1 over the best syntax-based models. However, we also show that there is potential for syntax to further improve performance.

6 Conclusion and Future Work

We presented a new deep learning model for span-based semantic role labeling with a 10% relative error reduction over the previous state of the art. Our ensemble of 8 layer BiLSTMs incorporated some of the recent best practices such as orthonormal initialization, RNN-dropout, and highway connections, and we have shown that they are crucial for getting good results with deep models.

Extensive error analysis sheds light on the strengths and limitations of our deep SRL model, with detailed comparison against shallower models and two strong non-neural systems. While our deep model is better at recovering long-distance predicate-argument relations, we still observe structural inconsistencies, which can be alleviated by constrained decoding.

Finally, we posed the question of whether deep SRL still needs syntactic supervision. Despite recent success without syntactic input, we found that our best neural model can still benefit from accurate syntactic parser output via straightforward constrained decoding. In our oracle experiment, we observed a 3 F1 improvement by leveraging gold syntax, showing the potential for high quality parsers to further improve deep SRL models.

Abstract

This paper proposes *KB-InfoBot*[1] — a multi-turn dialogue agent which helps users search Knowledge Bases (KBs) without composing complicated queries. Such goal-oriented dialogue agents typically need to interact with an external database to access real-world knowledge. Previous systems achieved this by issuing a symbolic query to the KB to retrieve entries based on their attributes. However, such symbolic operations break the differentiability of the system and prevent end-to-end training of neural dialogue agents. In this paper, we address this limitation by replacing symbolic queries with an induced "soft" posterior distribution over the KB that indicates which entities the user is interested in. Integrating the soft retrieval process with a reinforcement learner leads to higher task success rate and reward in both simulations and against real users. We also present a fully neural end-to-end agent, trained entirely from user feedback, and discuss its application towards personalized dialogue agents.

1 Introduction

The design of intelligent assistants which interact with users in natural language ranks high on the agenda of current NLP research. With an increasing focus on the use of statistical and machine learning based approaches (Young et al., 2013), the last few years have seen some truly remarkable conversational agents appear on the market (e.g. Apple Siri, Microsoft Cortana, Google Allo). These agents can perform simple tasks, answer factual questions, and sometimes also aimlessly chit-chat with the user, but they still lag far behind a human assistant in terms of both the variety and complexity of tasks they can perform. In particular, they lack the ability to learn from interactions with a user in order to improve and adapt with time. Recently, Reinforcement Learning (RL) has been explored to leverage user interactions to adapt various dialogue agents designed, respectively, for task completion (Gašić et al., 2013), information access (Wen et al., 2016b), and chitchat (Li et al., 2016a).

We focus on KB-InfoBots, a particular type of dialogue agent that helps users navigate a Knowledge Base (KB) in search of an entity, as illustrated by the example in Figure 1. Such agents must necessarily query databases in order to retrieve the requested information. This is usually done by performing semantic parsing on the input to construct a symbolic query representing the beliefs of the agent about the user goal, such as Wen et al. (2016b), Williams and Zweig (2016), and Li et al. (2017)'s work. We call such an operation a *Hard-KB* lookup. While natural, this approach has two drawbacks: (1) the retrieved results do not carry any information about uncertainty in semantic parsing, and (2) the retrieval operation is non differentiable, and hence the parser and dialog policy are trained separately. This makes online end-to-end learning from user feedback difficult once the system is deployed.

In this work, we propose a probabilistic framework for computing the posterior distribution of the user target over a knowledge base, which we term a *Soft-KB* lookup. This distribution is constructed from the agent's belief about the attributes of the entity being searched for. The dialogue policy network, which decides the next system action, receives as input this full distribution instead of a handful of retrieved results. We show in our ex-

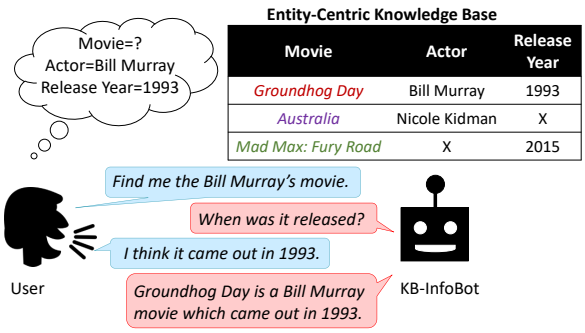

Figure 1: An interaction between a user looking for a movie and the KB-InfoBot. An entity-centric knowledge base is shown above the KB-InfoBot (missing values denoted by **X**).

periments that this framework allows the agent to achieve a higher task success rate in fewer dialogue turns. Further, the retrieval process is differentiable, allowing us to construct an end-to-end trainable KB-InfoBot, all of whose components are updated online using RL.

Reinforcement learners typically require an environment to interact with, and hence static dialogue corpora cannot be used for their training. Running experiments on human subjects, on the other hand, is unfortunately too expensive. A common workaround in the dialogue community (Young et al., 2013; Schatzmann et al., 2007b; Scheffler and Young, 2002) is to instead use *user simulators* which mimic the behavior of real users in a consistent manner. For training KB-InfoBot, we adapt the publicly available[2] simulator described in Li et al. (2016b).

Evaluation of dialogue agents has been the subject of much research (Walker et al., 1997; Möller et al., 2006). While the metrics for evaluating an InfoBot are relatively clear — the agent should return the correct entity in a minimum number of turns — the environment for testing it not so much. Unlike previous KB-based QA systems, our focus is on multi-turn interactions, and as such there are no publicly available benchmarks for this problem. We evaluate several versions of KB-InfoBot with the simulator and on real users, and show that the proposed Soft-KB lookup helps the reinforcement learner discover better dialogue policies. Initial experiments on the end-to-end agent also demonstrate its strong learning capability.

2 Related Work

Our work is motivated by the neural GenQA (Yin et al., 2016a) and neural enquirer (Yin et al., 2016b) models for querying KBs via natural language in a fully "neuralized" way. However, the key difference is that these systems assume that users can compose a complicated, compositional natural language query that can uniquely identify the element/answer in the KB. The research task is to parse the query, i.e., turning the natural language query into a sequence of SQL-like operations. Instead we focus on how to query a KB interactively without composing such complicated queries in the first place. Our work is motivated by the observations that (1) users are more used to issuing simple queries of length less than 5 words (Spink et al., 2001); (2) in many cases, it is unreasonable to assume that users can construct compositional queries without prior knowledge of the structure of the KB to be queried.

Also related is the growing body of literature focused on building end-to-end dialogue systems, which combine feature extraction and policy optimization using deep neural networks. Wen et al. (2016b) introduced a modular neural dialogue agent, which uses a Hard-KB lookup, thus breaking the differentiability of the whole system. As a result, training of various components of the dialogue system is performed separately. The intent network and belief trackers are trained using supervised labels specifically collected for them; while the policy network and generation network are trained separately on the system utterances. We retain modularity of the network by keeping the belief trackers separate, but replace the hard lookup with a differentiable one.

Dialogue agents can also interface with the database by augmenting their output action space with predefined API calls (Williams and Zweig, 2016; Zhao and Eskenazi, 2016; Bordes and Weston, 2016; Li et al., 2017). The API calls modify a query hypothesis maintained outside the end-to-end system which is used to retrieve results from this KB. This framework does not deal with uncertainty in language understanding since the query hypothesis can only hold one slot-value at a time. Our approach, on the other hand, directly models the uncertainty to construct the posterior over the KB.

Wu et al. (2015) presented an entropy minimization dialogue management strategy for In-

foBots. The agent always asks for the value of the slot with maximum entropy over the remaining entries in the database, which is optimal in the absence of language understanding errors, and serves as a baseline against our approach. Reinforcement learning neural turing machines (RL-NTM) (Zaremba and Sutskever, 2015) also allow neural controllers to interact with discrete external interfaces. The interface considered in that work is a one-dimensional memory tape, while in our work it is an entity-centric KB.

3 Probabilistic KB Lookup

This section describes a probabilistic framework for querying a KB given the agent's beliefs over the fields in the KB.

3.1 Entity-Centric Knowledge Base (EC-KB)

A Knowledge Base consists of triples of the form (h, r, t), which denotes that *relation* r holds between the *head* h and *tail* t. We assume that the KB-InfoBot has access to a domain-specific entity-centric knowledge base (EC-KB) (Zwicklbauer et al., 2013) where all head entities are of a particular type (such as movies or persons), and the relations correspond to attributes of these head entities. Such a KB can be converted to a table format whose rows correspond to the unique head entities, columns correspond to the unique relation types (*slots* henceforth), and some entries may be missing. An example is shown in Figure 1.

3.2 Notations and Assumptions

Let $\mathcal{T}$ denote the KB table described above and $\mathcal{T}_{i,j}$ denote the jth slot-value of the ith entity. $1 \leq i \leq N$ and $1 \leq j \leq M$. We let V^j denote the vocabulary of each slot, i.e. the set of all distinct values in the j-th column. We denote missing values from the table with a special token and write $\mathcal{T}_{i,j} = \Psi$. $M_j = \{i : \mathcal{T}_{i,j} = \Psi\}$ denotes the set of entities for which the value of slot j is missing. Note that the user may still know the actual value of $\mathcal{T}_{i,j}$, and we assume this lies in V^j. We do not deal with new entities or relations at test time.

We assume a uniform prior $G \sim \mathcal{U}[\{1, ...N\}]$ over the rows in the table $\mathcal{T}$, and let binary random variables $\Phi_j \in \{0, 1\}$ indicate whether the user knows the value of slot j or not. The agent maintains M multinomial distributions $p_j^t(v)$ for $v \in V^j$ denoting the probability at turn t that the user constraint for slot j is v, given their utterances U_1^t till that turn. The agent also maintains M binomials $q_j^t = \Pr(\Phi_j = 1)$ which denote the probability that the user knows the value of slot j.

We assume that column values are independently distributed to each other. This is a strong assumption but it allows us to model the user goal for each slot independently, as opposed to modeling the user goal over KB entities directly. Typically $\max_j |V^j| < N$ and hence this assumption reduces the number of parameters in the model.

3.3 Soft-KB Lookup

Let $p_{\mathcal{T}}^t(i) = \Pr(G = i|U_1^t)$ be the posterior probability that the user is interested in row i of the table, given the utterances up to turn t. We assume all probabilities are conditioned on user inputs U_1^t and drop it from the notation below. From our assumption of independence of slot values, we can write $p_{\mathcal{T}}^t(i) \propto \prod_{j=1}^{M} \Pr(G_j = i)$, where $\Pr(G_j = i)$ denotes the posterior probability of user goal for slot j pointing to $\mathcal{T}_{i,j}$. Marginalizing this over Φ_j gives:

$$\begin{aligned}\Pr(G_j = i) &= \sum_{\phi=0}^{1} \Pr(G_j = i, \Phi_j = \phi) \qquad (1)\\ &= q_j^t \Pr(G_j = i|\Phi_j = 1) + \\ &\quad (1 - q_j^t) \Pr(G_j = i|\Phi_j = 0).\end{aligned}$$

For $\Phi_j = 0$, the user does not know the value of the slot, and from the prior:

$$\Pr(G_j = i|\Phi_j = 0) = \frac{1}{N}, \quad 1 \leq i \leq N \qquad (2)$$

For $\Phi_j = 1$, the user knows the value of slot j, but this may be missing from $\mathcal{T}$, and we again have two cases:

$$\Pr(G_j = i|\Phi_j = 1) = \begin{cases} \frac{1}{N}, & i \in M_j \\ \frac{p_j^t(v)}{N_j(v)}\left(1 - \frac{|M_j|}{N}\right), & i \notin M_j \end{cases} \qquad (3)$$

Here, $N_j(v)$ is the count of value v in slot j. Detailed derivation for (3) is provided in Appendix A. Combining (1), (2), and (3) gives us the procedure for computing the posterior over KB entities.

4 Towards an End-to-End-KB-InfoBot

We claim that the Soft-KB lookup method has two benefits over the Hard-KB method – (1) it helps the agent discover better dialogue policies by providing it more information from the language understanding unit, (2) it allows end-to-end training of both dialogue policy and language understanding in an online setting. In this section we describe several agents to test these claims.

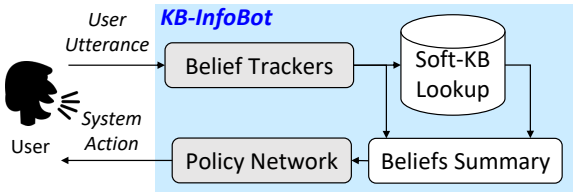

Figure 2: High-level overview of the end-to-end KB-InfoBot. Components with trainable parameters are highlighted in gray.

4.1 Overview

Figure 2 shows an overview of the components of the KB-InfoBot. At each turn, the agent receives a natural language utterance u^t as input, and selects an action a^t as output. The action space, denoted by $\mathcal{A}$, consists of $M+1$ actions — *request(slot=i)* for $1 \leq i \leq M$ will ask the user for the value of slot i, and *inform(I)* will inform the user with an ordered list of results I from the KB. The dialogue ends once the agent chooses *inform*.

We adopt a modular approach, typical to goal-oriented dialogue systems (Wen et al., 2016b), consisting of: a *belief tracker* module for identifying user intents, extracting associated slots, and tracking the dialogue state (Yao et al., 2014; Hakkani-Tür et al., 2016; Chen et al., 2016b; Henderson et al., 2014; Henderson, 2015); an interface with the database to query for relevant results (*Soft-KB* lookup); a *summary* module to summarize the state into a vector; a *dialogue policy* which selects the next system action based on current state (Young et al., 2013). We assume the agent only responds with dialogue acts. A template-based *Natural Language Generator* (NLG) can be easily constructed for converting dialogue acts into natural language.

4.2 Belief Trackers

The InfoBot consists of M belief trackers, one for each slot, which get the user input x^t and produce two outputs, p_j^t and q_j^t, which we shall collectively call the *belief state*: p_j^t is a multinomial distribution over the slot values v, and q_j^t is a scalar probability of the user knowing the value of slot j. We describe two versions of the belief tracker.

Hand-Crafted Tracker: We first identify mentions of slot-names (such as "actor") or slot-values (such as "Bill Murray") from the user input u^t, using token-level keyword search. Let $\{w \in x\}$ denote the set of tokens in a string x[3], then for each slot in $1 \leq j \leq M$ and each value $v \in V^j$, we compute its *matching score* as follows:

$$s_j^t[v] = \frac{|\{w \in u^t\} \cap \{w \in v\}|}{|\{w \in v\}|} \quad (4)$$

A similar score b_j^t is computed for the slot-names. A one-hot vector $req^t \in \{0,1\}^M$ denotes the previously requested slot from the agent, if any. q_j^t is set to 0 if $req^t[j]$ is 1 but $s_j^t[v] = 0\ \forall v \in V^j$, i.e. the agent requested for a slot but did not receive a valid value in return, else it is set to 1.

Starting from an prior distribution p_j^0 (based on the counts of the values in the KB), $p_j^t[v]$ is updated as:

$$p_j^t[v] \propto p_j^{t-1}[v] + C\left(s_j^t[v] + b_j^t + \mathbb{1}(req^t[j] = 1)\right) \quad (5)$$

Here C is a tuning parameter, and the normalization is given by setting the sum over v to 1.

Neural Belief Tracker: For the neural tracker the user input u^t is converted to a vector representation x^t, using a bag of n-grams (with $n = 2$) representation. Each element of x^t is an integer indicating the count of a particular n-gram in u^t. We let V^n denote the number of unique n-grams, hence $x^t \in \mathbb{N}_0^{V^n}$.

Recurrent neural networks have been used for belief tracking (Henderson et al., 2014; Wen et al., 2016b) since the output distribution at turn t depends on all user inputs till that turn. We use a Gated Recurrent Unit (GRU) (Cho et al., 2014) for each tracker, which, starting from $h_j^0 = \mathbf{0}$ computes $h_j^t = \text{GRU}(x^1, \ldots, x^t)$ (see Appendix B for details). $h_j^t \in \mathbb{R}^d$ can be interpreted as a summary of what the user has said about slot j till turn t. The belief states are computed from this vector as follows:

$$p_j^t = \text{softmax}(W_j^p h_j^t + b_j^p) \quad (6)$$

$$q_j^t = \sigma(W_j^\Phi h_j^t + b_j^\Phi) \quad (7)$$

Here $W_j^p \in \mathbb{R}^{V^j \times d}$, $b_j^p \in \mathbb{R}^{V^j}$, $W_j^\Phi \in \mathbb{R}^d$ and $b_j^\Phi \in \mathbb{R}$, are trainable parameters.

4.3 Soft-KB Lookup + Summary

This module uses the Soft-KB lookup described in section 3.3 to compute the posterior $p_\mathcal{T}^t \in \mathbb{R}^N$ over the EC-KB from the belief states $(p_j^t,\ q_j^t)$.

[3] We use the NLTK tokenizer available at http://www.nltk.org/api/nltk.tokenize.html

Collectively, outputs of the belief trackers and the soft-KB lookup can be viewed as the current dialogue state internal to the KB-InfoBot. Let $s^t = [p_1^t, p_2^t, ..., p_M^t, q_1^t, q_2^t, ..., q_M^t, p_\mathcal{T}^t]$ be the vector of size $\sum_j V^j + M + N$ denoting this state. It is possible for the agent to directly use this state vector to select its next action a^t. However, the large size of the state vector would lead to a large number of parameters in the policy network. To improve efficiency we extract summary statistics from the belief states, similar to (Williams and Young, 2005).

Each slot is summarized into an entropy statistic over a distribution w_j^t computed from elements of the KB posterior $p_\mathcal{T}^t$ as follows:

$$w_j^t(v) \propto \sum_{i:\mathcal{T}_{i,j}=v} p_\mathcal{T}^t(i) + p_j^0(v) \sum_{i:\mathcal{T}_{i,j}=\Psi} p_\mathcal{T}^t(i)\,. \tag{8}$$

Here, p_j^0 is a prior distribution over the values of slot j, estimated using counts of each value in the KB. The probability mass of v in this distribution is the agent's confidence that the user goal has value v in slot j. This two terms in (8) correspond to rows in KB which have value v, and rows whose value is unknown (weighted by the prior probability that an unknown might be v). Then the summary statistic for slot j is the entropy $H(w_j^t)$. The KB posterior $p_\mathcal{T}^t$ is also summarized into an entropy statistic $H(p_\mathcal{T}^t)$.

The scalar probabilities q_j^t are passed as is to the dialogue policy, and the final summary vector is $\tilde{s}^t = [H(\tilde{p}_1^t), ..., H(\tilde{p}_M^t), q_1^t, ..., q_M^t, H(p_\mathcal{T}^t)]$. Note that this vector has size $2M + 1$.

4.4 Dialogue Policy

The dialogue policy's job is to select the next action based on the current summary state $\tilde{s}^t$ and the dialogue history. We present a hand-crafted baseline and a neural policy network.

Hand-Crafted Policy: The rule based policy is adapted from (Wu et al., 2015). It asks for the slot $\hat{j} = \arg\min H(\tilde{p}_j^t)$ with the minimum entropy, except if – (i) the KB posterior entropy $H(p_\mathcal{T}^t) < \alpha_R$, (ii) $H(\tilde{p}_j^t) < \min(\alpha_T, \beta H(\tilde{p}_j^0)$, (iii) slot j has already been requested Q times. α_R, α_T, β, Q are tuned to maximize reward against the simulator.

Neural Policy Network: For the neural approach, similar to (Williams and Zweig, 2016; Zhao and Eskenazi, 2016), we use an RNN to allow the network to maintain an internal state of dialogue history. Specifically, we use a GRU unit followed by a fully-connected layer and softmax nonlinearity to model the policy π over actions in $\mathcal{A}$ ($W^\pi \in \mathrm{R}^{|\mathcal{A}|\times d}$, $b^\pi \in \mathrm{R}^{|\mathcal{A}|}$):

$$h_\pi^t = \text{GRU}(\tilde{s}^1, ..., \tilde{s}^t) \tag{9}$$

$$\pi = \text{softmax}(W^\pi h_\pi^t + b^\pi)\,. \tag{10}$$

During training, the agent samples its actions from the policy to encourage exploration. If this action is *inform()*, it must also provide an ordered set of entities indexed by $I = (i_1, i_2, \ldots, i_R)$ in the KB to the user. This is done by sampling R items from the KB-posterior $p_\mathcal{T}^t$. This mimics a search engine type setting, where R may be the number of results on the first page.

5 Training

Parameters of the neural components (denoted by θ) are trained using the REINFORCE algorithm (Williams, 1992). We assume that the learner has access to a reward signal r_t throughout the course of the dialogue, details of which are in the next section. We can write the expected discounted return of the agent under policy π as $J(\theta) = \mathbf{E}_\pi\left[\sum_{t=0}^H \gamma^t r_t\right]$ (γ is the discounting factor). We also use a baseline reward signal b, which is the average of all rewards in a batch, to reduce the variance in the updates (Greensmith et al., 2004). When only training the dialogue policy π using this signal, updates are given by (details in Appendix C):

$$\nabla_\theta J(\theta) = \mathbf{E}_\pi\Big[\sum_{k=0}^H \nabla_\theta \log \pi_\theta(a^k) \sum_{t=0}^H \gamma^t (r_t - b)\Big]\,, \tag{11}$$

For end-to-end training we need to update both the dialogue policy and the belief trackers using the reinforcement signal, and we can view the retrieval as another policy μ_θ (see Appendix C). The updates are given by:

$$\nabla_\theta J(\theta) = \mathbf{E}_{a\sim\pi, I\sim\mu}\Big[\big(\nabla_\theta \log \mu_\theta(I) + \sum_{h=0}^H \nabla_\theta \log \pi_\theta(a_h)\big) \sum_{k=0}^H \gamma^k (r_k - b)\Big]\,, \tag{12}$$

In the case of end-to-end learning, we found that for a moderately sized KB, the agent almost always fails if starting from random initialization.

In this case, credit assignment is difficult for the agent, since it does not know whether the failure is due to an incorrect sequence of actions or incorrect set of results from the KB. Hence, at the beginning of training we have an *Imitation Learning* (IL) phase where the belief trackers and policy network are trained to mimic the hand-crafted agents. Assume that $\hat{p}_j^t$ and $\hat{q}_j^t$ are the belief states from a rule-based agent, and $\hat{a}^t$ its action at turn t. Then the loss function for imitation learning is:

$$\mathcal{L}(\theta) = \mathbf{E}\big[D(\hat{p}_j^t||p_j^t(\theta)) + H(\hat{q}_j^t, q_j^t(\theta)) - \log \pi_\theta(\hat{a}^t)\big]$$

$D(p||q)$ and $H(p,q)$ denote the KL divergence and cross-entropy between p and q respectively.

The expectations are estimated using a mini-batch of dialogues of size B. For RL we use RMSProp (Hinton et al., 2012) and for IL we use vanilla SGD updates to train the parameters θ.

6 Experiments and Results

Previous work in KB-based QA has focused on single-turn interactions and is not directly comparable to the present study. Instead we compare different versions of the KB-InfoBot described above to test our claims.

6.1 KB-InfoBot versions

We have described two belief trackers – (A) Hand-Crafted and (B) Neural, and two dialogue policies – (C) Hand-Crafted and (D) Neural.

Rule agents use the hand-crafted belief trackers and hand-crafted policy (A+C). **RL** agents use the hand-crafted belief trackers and the neural policy (A+D). We compare three variants of both sets of agents, which differ only in the inputs to the dialogue policy. The *No-KB* version only takes entropy $H(\hat{p}_j^t)$ of each of the slot distributions. The *Hard-KB* version performs a hard-KB lookup and selects the next action based on the entropy of the slots over retrieved results. This is the same approach as in Wen et al. (2016b), except that we take entropy instead of summing probabilities. The *Soft-KB* version takes summary statistics of the slots and KB posterior described in Section 4. At the end of the dialogue, all versions inform the user with the top results from the KB posterior $p_\mathcal{T}^t$, hence the difference only lies in the policy for action selection. Lastly, the **E2E** agent uses the neural belief tracker and the neural policy (B+D), with a Soft-KB lookup. For the RL agents, we also append $\hat{q}_j^t$ and a one-hot encoding of the previous agent action to the policy network input. Hyperparameter details for the agents are provided in Appendix D.

KB-split	N	M	$\max_j \lvert V^j \rvert$	$\lvert M_j \rvert$
Small	277	6	17	20%
Medium	428	6	68	20%
Large	857	6	101	20%
X-Large	3523	6	251	20%

Table 1: Movies-KB statistics for four splits. Refer to Section 3.2 for description of columns.

6.2 User Simulator

Training reinforcement learners is challenging because they need an environment to operate in. In the dialogue community it is common to use simulated users for this purpose (Schatzmann et al., 2007a,b; Cuayáhuitl et al., 2005; Asri et al., 2016). In this work we adapt the publicly-available user simulator presented in Li et al. (2016b) to follow a simple agenda while interacting with the KB-InfoBot, as well as produce natural language utterances . Details about the simulator are included in Appendix E. During training, the simulated user also provides a reward signal at the end of each dialogue. The dialogue is a success if the user target is in top $R = 5$ results returned by the agent; and the reward is computed as $\max(0, 2(1-(r-1)/R))$, where r is the actual rank of the target. For a failed dialogue the agent receives a reward of -1, and at each turn it receives a reward of -0.1 to encourage short sessions[4]. The maximum length of a dialogue is 10 turns beyond which it is deemed a failure.

6.3 Movies-KB

We use a movie-centric KB constructed using the IMDBPy[5] package. We constructed four different splits of the dataset, with increasing number of entities, whose statistics are given in Table 1. The original KB was modified to reduce the number of actors and directors in order to make the task more challenging[6]. We randomly remove 20% of the values from the agent's copy of the KB to simulate a scenario where the KB may be incomplete. The user, however, may still know these values.

[4] A turn consists of one user action and one agent action.

[5] http://imdbpy.sourceforge.net/

[6] We restricted the vocabulary to the first few unique values of these slots and replaced all other values with a random value from this set.

	Agent	Small KB			Medium KB			Large KB			X-Large KB

Table 2: Performance comparison. Average (±std error) for 5000 runs after choosing the best model during training. **T:** Average number of turns. **S:** Success rate. **R:** Average reward.

6.4 Simulated User Evaluation

We compare each of the discussed versions along three metrics: the average rewards obtained (R), success rate (S) (where success is defined as providing the user target among top R results), and the average number of turns per dialogue (T). For the RL and E2E agents, during training we fix the model every 100 updates and run 2000 simulations with greedy action selection to evaluate its performance. Then after training we select the model with the highest average reward and run a further 5000 simulations and report the performance in Table 2. For reference we also show the performance of an agent which receives perfect information about the user target without any errors, and selects actions based on the entropy of the slots (*Max*). This can be considered as an upper bound on the performance of any agent (Wu et al., 2015).

In each case the Soft-KB versions achieve the highest average reward, which is the metric all agents optimize. In general, the trade-off between minimizing average turns and maximizing success rate can be controlled by changing the reward signal. Note that, except the E2E version, all versions share the same belief trackers, but by re-asking values of some slots they can have different posteriors p_T^t to inform the results. This shows that having full information about the current state of beliefs over the KB helps the Soft-KB agent discover better policies. Further, reinforcement learning helps discover better policies than the hand-crafted rule-based agents, and we see a higher reward for RL agents compared to Rule ones. This is due to the noisy natural language inputs; with perfect information the rule-based strategy is optimal. Interestingly, the RL-Hard agent has the minimum number of turns in 2 out of the 4 settings, at the cost of a lower success rate and average reward. This agent does not receive any information about the uncertainty in semantic parsing, and it tends to inform as soon as the number of retrieved results becomes small, even if they are incorrect.

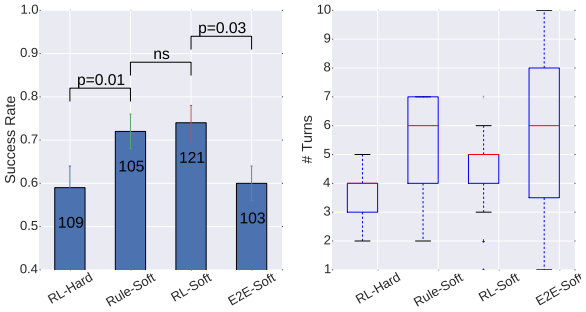

Figure 3: Performance of KB-InfoBot versions when tested against real users. **Left:** Success rate, with the number of test dialogues indicated on each bar, and the p-values from a two-sided permutation test. **Right:** Distribution of the number of turns in each dialogue (differences in mean are significant with $p < 0.01$).

Among the Soft-KB agents, we see that E2E>RL>Rule, except for the X-Large KB. For E2E, the action space grows exponentially with the size of the KB, and hence credit assignment gets more difficult. Future work should focus on improving the E2E agent in this setting. The difficulty of a KB-split depends on number of entities it has, as well as the number of unique values for each slot (more unique values make the problem easier). Hence we see that both the "Small" and "X-Large" settings lead to lower reward for the agents, since $\frac{\max_j |V^j|}{N}$ is small for them.

6.5 Human Evaluation

We further evaluate the KB-InfoBot versions trained using the simulator against real subjects, recruited from the author's affiliations. In each session, in a typed interaction, the subject was first presented with a target movie from the "Medium" KB-split along with a subset of its associated slot-

Turn	Dialogue	Rank	Dialogue	Rank	Dialogue	Rank
1	can i get a movie directed by maiellaro *request actor*	75	find a movie directed by hemecker *request actor*	7	peter greene acted in a family comedy - what was it? *request actor*	35
2	neal *request mpaa_rating*	2	i dont know *request mpaa_rating*	7	peter *request mpaa_rating*	28

Figure 4: Sample dialogues between users and the KB-InfoBot (RL-Soft version). Each turn begins with a user utterance followed by the *agent response*. **Rank** denotes the rank of the target movie in the KB-posterior after each turn.

values from the KB. To simulate the scenario where end-users may not know slot values correctly, the subjects in our evaluation were presented multiple values for the slots from which they could choose any one while interacting with the agent. Subjects were asked to initiate the conversation by specifying some of these values, and respond to the agent's subsequent requests, all in natural language. We test RL-Hard and the three Soft-KB agents in this study, and in each session one of the agents was picked at random for testing. In total, we collected 433 dialogues, around 20 per subject. Figure 3 shows a comparison of these agents in terms of success rate and number of turns, and Figure 4 shows some sample dialogues from the user interactions with RL-Soft.

In comparing Hard-KB versus Soft-KB lookup methods we see that both Rule-Soft and RL-Soft agents achieve a higher success rate than RL-Hard, while E2E-Soft does comparably. They do so in an increased number of average turns, but achieve a higher average reward as well. Between RL-Soft and Rule-Soft agents, the success rate is similar, however the RL agent achieves that rate in a lower number of turns on average. RL-Soft achieves a success rate of 74% on the human evaluation and 80% against the simulated user, indicating minimal overfitting. However, all agents take a higher number of turns against real users as compared to the simulator, due to the noisier inputs.

The E2E gets the highest success rate against the simulator, however, when tested against real users it performs poorly with a lower success rate and a higher number of turns. Since it has more trainable components, this agent is also most prone to overfitting. In particular, the vocabulary of the simulator it is trained against is quite limited ($V^n = 3078$), and hence when real users

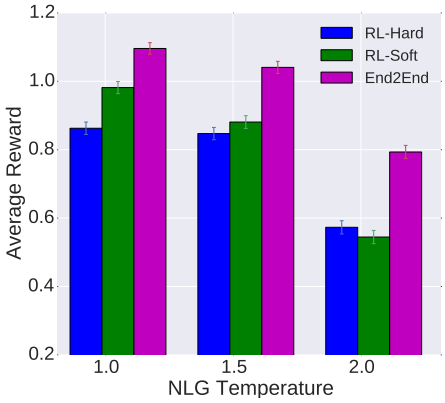

Figure 5: Average rewards against simulator as temperature of softmax in NLG output is increased. Higher temperature leads to more noise in output. Average over 5000 simulations after selecting the best model during training.

provided inputs outside this vocabulary, it performed poorly. In the future we plan to fix this issue by employing a better architecture for the language understanding and belief tracker components Hakkani-Tür et al. (2016); Liu and Lane (2016); Chen et al. (2016b,a), as well as by pretraining on separate data.

While its generalization performance is poor, the E2E system also exhibits the strongest learning capability. In Figure 5, we compare how different agents perform against the simulator as the temperature of the output softmax in its NLG is increased. A higher temperature means a more uniform output distribution, which leads to generic simulator responses irrelevant to the agent questions. This is a simple way of introducing noise in the utterances. The performance of all agents drops as the temperature is increased, but less so for the E2E agent, which can adapt its belief tracker to the inputs it receives. Such adaptation

is key to the personalization of dialogue agents, which motivates us to introduce the E2E agent.

7 Conclusions and Discussion

This work is aimed at facilitating the move towards end-to-end trainable dialogue agents for information access. We propose a differentiable probabilistic framework for querying a database given the agent's beliefs over its fields (or slots). We show that such a framework allows the downstream reinforcement learner to discover better dialogue policies by providing it more information. We also present an E2E agent for the task, which demonstrates a strong learning capacity in simulations but suffers from overfitting when tested on real users. Given these results, we propose the following deployment strategy that allows a dialogue system to be tailored to specific users via learning from agent-user interactions. The system could start off with an RL-Soft agent (which gives good performance out-of-the-box). As the user interacts with this agent, the collected data can be used to train the E2E agent, which has a strong learning capability. Gradually, as more experience is collected, the system can switch from RL-Soft to the personalized E2E agent. Effective implementation of this, however, requires the E2E agent to learn quickly and this is the research direction we plan to focus on in the future.

A Posterior Derivation

Here, we present a derivation for equation 3, i.e., the posterior over the KB slot when the user knows the value of that slot. For brevity, we drop $\Phi_j = 0$ from the condition in all probabilities below. For the case when $i \in M_j$, we can write:

$$\begin{aligned}
&\Pr(G_j = i) \\
&= \Pr(G_j \in M_j) \Pr(G_j = i | G_j \in M_j) \\
&= \frac{|M_j|}{N} \frac{1}{|M_j|} = \frac{1}{N}\,,
\end{aligned} \tag{13}$$

where we assume all missing values to be equally likely, and estimate the prior probability of the goal being missing from the count of missing values in that slot. For the case when $i = v \notin M_j$:

$$\begin{aligned}
&\Pr(G_j = i) \\
&= \Pr(G_j \notin M_j) \Pr(G_j = i | G_j \notin M_j) \\
&= \left(1 - \frac{|M_j|}{N}\right) \times \frac{p_j^t(v)}{N_j(v)}\,,
\end{aligned} \tag{14}$$

where the second term comes from taking the probability mass associated with v in the belief tracker and dividing it equally among all rows with value v.

We can also verify that the above distribution is valid: i.e., it sums to 1:

$$\begin{aligned}
&\sum_i \Pr(G_j = i) \\
&= \sum_{i \in M_j} \Pr(G_j = i) + \sum_{i \notin M_j} \Pr(G_j = i) \\
&= \sum_{i \in M_j} \frac{1}{N} + \sum_{i \notin M_j} \left(1 - \frac{|M_j|}{N}\right) \frac{p_j^t(v)}{\#_j v} \\
&= \frac{|M_j|}{N} + \left(1 - \frac{|M_j|}{N}\right) \sum_{i \notin M_j} \frac{p_j^t(v)}{\#_j v} \\
&= \frac{|M_j|}{N} + \left(1 - \frac{|M_j|}{N}\right) \sum_{i \in V^j} \#_j v \frac{p_j^t(v)}{\#_j v} \\
&= \frac{|M_j|}{N} + \left(1 - \frac{|M_j|}{N}\right) \times 1 \\
&= 1\,.
\end{aligned}$$

B Gated Recurrent Units

A Gated Recurrent Unit (GRU) (Cho et al., 2014) is a recurrent neural network which operates on an input sequence $x_1, \ldots, x_t$. Starting from an initial state h_0 (usually set to $\mathbf{0}$ it iteratively computes the final output h_t as follows:

$$\begin{aligned}
r_t &= \sigma(W_r x_t + U_r h_{t-1} + b_r) \\
z_t &= \sigma(W_z x_t + U_z h_{t-1} + b_z) \\
\tilde{h}_t &= \tanh(W_h x_t + U_h(r_t \odot h_{t-1}) + b_h) \\
h_t &= (1 - z_t) \odot h_{t-1} + z_t \odot \tilde{h}_t\,.
\end{aligned} \tag{15}$$

Here σ denotes the sigmoid nonlinearity, and $\odot$ an element-wise product.

C REINFORCE updates

We assume that the learner has access to a reward signal r_t throughout the course of the dialogue, details of which are in the next section. We can write the expected discounted return of the agent under policy π as follows:

$$J(\theta) = \mathbf{E}\left[\sum_{t=0}^{H} \gamma^t r_t\right] \tag{16}$$

Here, the expectation is over all possible trajectories τ of the dialogue, θ denotes the trainable parameters of the learner, H is the maximum length of an episode, and γ is the discounting factor. We can use the likelihood ratio trick (Glynn, 1990) to write the gradient of the objective as follows:

$$\nabla_\theta J(\theta) = \mathbf{E}\left[\nabla_\theta \log p_\theta(\tau) \sum_{t=0}^{H} \gamma^t r_t\right]\,, \tag{17}$$

where $p_\theta(\tau)$ is the probability of observing a particular trajectory under the current policy. With a Markovian assumption, we can write

$$p_\theta(\tau) = p(s_0) \prod_{k=0}^{H} p(s_{k+1}|s_k, a_k) \pi_\theta(a_k|s_k), \tag{18}$$

where θ denotes dependence on the neural network parameters. From 17,18 we obtain

$$\nabla_\theta J(\theta) = \mathbf{E}_{a \sim \pi}\Big[\sum_{k=0}^{H} \nabla_\theta \log \pi_\theta(a_k) \sum_{t=0}^{H} \gamma^t r_t\Big]\,, \tag{19}$$

If we need to train both the policy network and the belief trackers using the reinforcement signal, we can view the KB posterior $p_\mathcal{T}^t$ as another policy. During training then, to encourage exploration, when the agent selects the *inform* action we

sample R results from the following distribution to return to the user:

$$\mu(I) = p_{\mathcal{T}}^t(i_1) \times \frac{p_{\mathcal{T}}^t(i_2)}{1 - p_{\mathcal{T}}^t(i_1)} \times \cdots . \quad (20)$$

This formulation also leads to a modified version of the episodic REINFORCE update rule (Williams, 1992). Specifically, eq. 18 now becomes,

$$p_\theta(\tau) = \left[p(s_0) \prod_{k=0}^{H} p(s_{k+1}|s_k, a_k) \pi_\theta(a_k|s_k) \right] \mu_\theta(I), \quad (21)$$

Notice the last term μ_θ above which is the posterior of a set of results from the KB. From 17,21 we obtain

$$\nabla_\theta J(\theta) = \mathbf{E}_{a\sim\pi, I\sim\mu} \Big[\big(\nabla_\theta \log \mu_\theta(I) + \sum_{h=0}^{H} \nabla_\theta \log \pi_\theta(a_h) \big) \sum_{k=0}^{H} \gamma^k r_k \Big] , \quad (22)$$

D Hyperparameters

We use GRU hidden state size of $d = 50$ for the RL agents and $d = 100$ for the E2E, a learning rate of 0.05 for the imitation learning phase and 0.005 for the reinforcement learning phase, and minibatch size 128. For the rule agents, hyperparameters were tuned to maximize the average reward of each agent in simulations. For the E2E agent, imitation learning was performed for 500 updates, after which the agent switched to reinforcement learning. The input vocabulary is constructed from the NLG vocabulary and bigrams in the KB, and its size is 3078.

E User Simulator

At the beginning of each dialogue, the simulated user randomly samples a target entity from the EC-KB and a random combination of *informable slots* for which it knows the value of the target. The remaining slot-values are unknown to the user. The user initiates the dialogue by providing a subset of its informable slots to the agent and requesting for an entity which matches them. In subsequent turns, if the agent requests for the value of a slot, the user complies by providing it or informs the agent that it does not know that value. If the agent informs results from the KB, the simulator checks whether the target is among them and provides the reward.

We convert dialogue acts from the user into natural language utterances using a separately trained natural language generator (NLG). The NLG is trained in a sequence-to-sequence fashion, using conversations between humans collected by crowd-sourcing. It takes the dialogue actions (DAs) as input, and generates template-like sentences with slot placeholders via an LSTM decoder. Then, a post-processing scan is performed to replace the slot placeholders with their actual values, which is similar to the decoder module in (Wen et al., 2015, 2016a). In the LSTM decoder, we apply beam search, which iteratively considers the top k best sentences up to time step t when generating the token of the time step $t + 1$. For the sake of the trade-off between the speed and performance, we use the beam size of 3 in the following experiments.

There are several sources of error in user utterances. Any value provided by the user may be corrupted by noise, or substituted completely with an incorrect value of the same type (e.g., "Bill Murray" might become just "Bill" or "Tom Cruise"). The NLG described above is inherently stochastic, and may sometimes generate utterances irrelevant to the agent request. By increasing the temperature of the output softmax in the NLG we can increase the noise in user utterances.

Sequential Matching Network: A New Architecture for Multi-turn Response Selection in Retrieval-Based Chatbots

Abstract

We study response selection for multi-turn conversation in retrieval-based chatbots. Existing work either concatenates utterances in context or matches a response with a highly abstract context vector finally, which may lose relationships among utterances or important contextual information. We propose a sequential matching network (SMN) to address both problems. SMN first matches a response with each utterance in the context on multiple levels of granularity, and distills important matching information from each pair as a vector with convolution and pooling operations. The vectors are then accumulated in a chronological order through a recurrent neural network (RNN) which models relationships among utterances. The final matching score is calculated with the hidden states of the RNN. An empirical study on two public data sets shows that SMN can significantly outperform state-of-the-art methods for response selection in multi-turn conversation.

1 Introduction

Conversational agents include task-oriented dialog systems and non-task-oriented chatbots. Dialog systems focus on helping people complete specific tasks in vertical domains (Young et al., 2010), while chatbots aim to naturally and meaningfully converse with humans on open domain topics (Ritter et al., 2011). Existing work on building chatbots includes generation -based methods and retrieval-based methods. Retrieval based chatbots enjoy the advantage of informative and fluent responses, because they select a proper response for the current conversation from a repository with response selection algorithms. While most existing work on retrieval-based chatbots studies response selection for single-turn conversation (Wang et al., 2013) which only considers the last input message, we consider the problem in a multi-turn scenario. In a chatbot, multi-turn response selection takes a message and utterances in its previous turns as input and selects a response that is natural and relevant to the whole context.

	Context
utterance 1	*Human*: How are you doing?
utterance 2	*ChatBot*: I am going to **hold a drum class** in Shanghai. Anyone wants to join? The location is near Lujiazui.
utterance 3	*Human*: Interesting! Do you have coaches who can help me practice **drum**?
utterance 4	*ChatBot*: Of course.
utterance 5	*Human*: Can I have a free first lesson?
	Response Candidates
response 1	Sure. Have you ever played drum before? ✓
response 2	What lessons do you want? ✗

Table 1: An example of multi-turn conversation

The key to response selection lies in input-response matching. Different from single-turn conversation, multi-turn conversation requires matching between a response and a conversation context in which one needs to consider not only the matching between the response and the input message but also matching between responses and utterances in previous turns. The challenges of the task include (1) how to identify important information (words, phrases, and sentences) in context, which is crucial to selecting a proper response and leveraging relevant information in matching; and (2) how to model relationships among the utterances in the context. Table 1 illustrates the challenges with an example. First, "hold a drum class" and "drum" in context are very important. Without them, one may find responses relevant to the message (i.e., the fifth utterance of the context) but nonsense in the context (e.g., "what lessons do you want?"). Second, the message highly depends on the second utterance in the context, and

the order of the utterances matters in response selection: exchanging the third utterance and the fifth utterance may lead to different responses. Existing work, however, either ignores relationships among utterances when concatenating them together (Lowe et al., 2015), or loses important information in context in the process of converting the whole context to a vector without enough supervision from responses (e.g., by a hierarchical RNN (Zhou et al., 2016)).

We propose a sequential matching network (SMN), a new context based matching model that can tackle both challenges in an end-to-end way. The reason that existing models lose important information in the context is that they first represent the whole context as a vector and then match the context vector with a response vector. Thus, responses in these models connect with the context until the final step in matching. To avoid information loss, SMN matches a response with each utterance in the context at the beginning and encodes important information in each pair into a matching vector. The matching vectors are then accumulated in the utterances' temporal order to model their relationships. The final matching degree is computed with the accumulation of the matching vectors. Specifically, for each utterance-response pair, the model constructs a word-word similarity matrix and a sequence-sequence similarity matrix by the word embeddings and the hidden states of a recurrent neural network with gated recurrent units (GRU) (Chung et al., 2014) respectively. The two matrices capture important matching information in the pair on a word level and a segment (word subsequence) level respectively, and the information is distilled and fused as a matching vector through an alternation of convolution and pooling operations on the matrices. By this means, important information from multiple levels of granularity in context is recognized under sufficient supervision from the response and carried into matching with minimal loss. The matching vectors are then uploaded to another GRU to form a matching score for the context and the response. The GRU accumulates the pair matching in its hidden states in the chronological order of the utterances in context. It models relationships and dependencies among the utterances in a matching fashion and has the utterance order supervise the accumulation of pair matching. The matching degree of the context and the response is computed by a logit model with the hidden states of the GRU. SMN extends the powerful "2D" matching paradigm in text pair matching for single-turn conversation to context based matching for multi-turn conversation, and enjoys the advantage of both important information in utterance-response pairs and relationships among utterances being sufficiently preserved and leveraged in matching.

We test our model on the Ubuntu dialogue corpus (Lowe et al., 2015) which is a large scale publicly available English data set for research in multi-turn conversation. The results show that our model can significantly outperform state-of-the-art methods, and improvement to the best baseline model on $R_{10}@1$ is over 6%. In addition to the Ubuntu corpus, we create a human-labeled Chinese data set, namely the Douban Conversation Corpus, and test our model on it. In contrast to the Ubuntu corpus in which data is collected from a specific domain and negative candidates are randomly sampled, conversations in this data come from the open domain, and response candidates in this data set are collected from a retrieval engine and labeled by three human judges. On this data, our model improves the best baseline model by 3% on $R_{10}@1$ and 4% on $P@1$. As far as we know, Douban Conversation Corpus is the first human-labeled data set for multi-turn response selection and could be a good complement to the Ubuntu corpus. We have released Douban Conversation Corups and our source code at `https://github.com/MarkWuNLP/MultiTurnResponseSelection`

Our contributions in this paper are three-folds: (1) the proposal of a new context based matching model for multi-turn response selection in retrieval-based chatbots; (2) the publication of a large human-labeled data set to research communities; (3) empirical verification of the effectiveness of the model on public data sets.

2 Related Work

Recently, building a chatbot with data driven approaches (Ritter et al., 2011; Ji et al., 2014) has drawn significant attention. Existing work along this line includes retrieval-based methods (Hu et al., 2014; Ji et al., 2014; Wang et al., 2015; Yan et al., 2016; Wu et al., 2016b; Zhou et al., 2016; Wu et al., 2016a) and generation-based methods (Shang et al., 2015; Serban et al., 2015; Vinyals and Le, 2015; Li et al., 2015, 2016; Xing et al.,

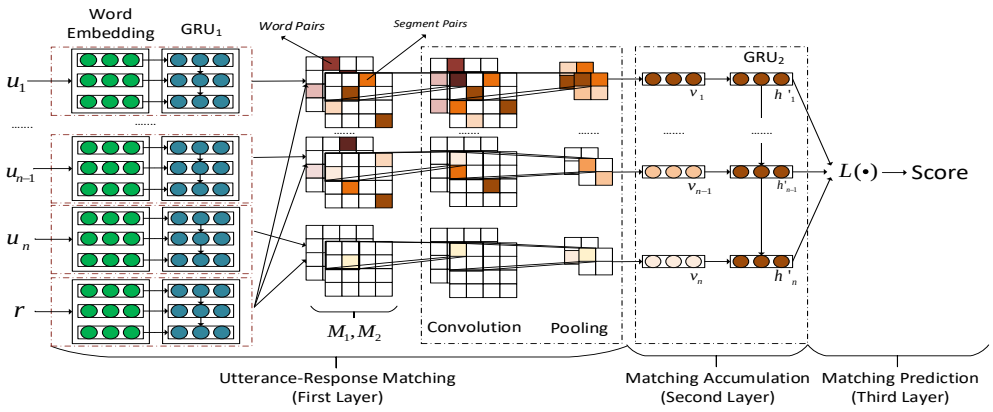

Figure 1: Architecture of SMN

2016; Serban et al., 2016). Our work is a retrieval-based method, in which we study context-based response selection.

Early studies of retrieval-based chatbots focus on response selection for single-turn conversation (Wang et al., 2013; Ji et al., 2014; Wang et al., 2015; Wu et al., 2016b). Recently, researchers have begun to pay attention to multi-turn conversation. For example, Lowe et al. (2015) match a response with the literal concatenation of context utterances. Yan et al. (2016) concatenate context utterances with the input message as reformulated queries and perform matching with a deep neural network architecture. Zhou et al. (2016) improve multi-turn response selection with a multi-view model including an utterance view and a word view. Our model is different in that it matches a response with each utterance at first and accumulates matching information instead of sentences by a GRU, thus useful information for matching can be sufficiently retained.

3 Sequential Matching Network

3.1 Problem Formalization

Suppose that we have a data set $\mathcal{D} = \{(y_i, s_i, r_i)\}_{i=1}^{N}$, where $s_i = \{u_{i,1}, \ldots, u_{i,n_i}\}$ represents a conversation context with $\{u_{i,k}\}_{k=1}^{n_i}$ as utterances. r_i is a response candidate and $y_i \in \{0, 1\}$ denotes a label. $y_i = 1$ means r_i is a proper response for s_i, otherwise $y_i = 0$. Our goal is to learn a matching model $g(\cdot, \cdot)$ with $\mathcal{D}$. For any context-response pair (s, r), $g(s, r)$ measures the matching degree between s and r.

3.2 Model Overview

We propose a sequential matching network (SMN) to model $g(\cdot, \cdot)$. Figure 1 gives the architecture. SMN first decomposes context-response matching into several utterance-response pair matching and then all pairs matching are accumulated as a context based matching through a recurrent neural network. SMN consists of three layers. The first layer matches a response candidate with each utterance in the context on a word level and a segment level, and important matching information from the two levels is distilled by convolution, pooling and encoded in a matching vector. The matching vectors are then fed into the second layer where they are accumulated in the hidden states of a recurrent neural network with GRU following the chronological order of the utterances in the context. The third layer calculates the final matching score with the hidden states of the second layer.

SMN enjoys several advantages over existing models. First, a response candidate can match each utterance in the context at the very beginning, thus matching information in every utterance-response pair can be sufficiently extracted and carried to the final matching score with minimal loss. Second, information extraction from each utterance is conducted on different levels of granularity and under sufficient supervision from the response, thus semantic structures that are useful for response selection in each utterance can be well identified and extracted. Third, matching and utterance relationships are coupled rather than separately modeled, thus utterance relationships (e.g., order), as a kind of knowledge, can supervise the formation of the matching score.

By taking utterance relationships into account, SMN extends the "2D" matching that has proven effective in text pair matching for single-turn response selection to sequential "2D" matching for

context based matching in response selection for multi-turn conversation. In the following sections, we will describe details of the three layers.

3.3 Utterance-Response Matching

Given an utterance u in a context s and a response candidate r, the model looks up an embedding table and represents u and r as $\mathbf{U} = [e_{u,1}, \ldots, e_{u,n_u}]$ and $\mathbf{R} = [e_{r,1}, \ldots, e_{r,n_r}]$ respectively, where $e_{u,i}, e_{r,i} \in \mathbb{R}^d$ are the embeddings of the i-th word of u and r respectively. $\mathbf{U} \in \mathbb{R}^{d \times n_u}$ and $\mathbf{R} \in \mathbb{R}^{d \times n_r}$ are then used to construct a word-word similarity matrix $\mathbf{M}_1 \in \mathbb{R}^{n_u \times n_r}$ and a sequence-sequence similarity matrix $\mathbf{M}_2 \in \mathbb{R}^{n_u \times n_r}$ which are two input channels of a convolutional neural network (CNN). The CNN distills important matching information from the matrices and encodes the information into a matching vector v.

Specifically, $\forall i, j$, the (i, j)-th element of $\mathbf{M}_1$ is defined by

$$e_{1,i,j} = e_{u,i}^{\top} \cdot e_{r,j}. \tag{1}$$

$\mathbf{M}_1$ models the matching between u and r on a word level.

To construct $\mathbf{M}_2$, we first employ a GRU to transform $\mathbf{U}$ and $\mathbf{R}$ to hidden vectors. Suppose that $\mathbf{H}_u = [h_{u,1}, \ldots, h_{u,n_u}]$ are the hidden vectors of $\mathbf{U}$, then $\forall i$, $h_{u,i} \in \mathbb{R}^m$ is defined by

$$\begin{aligned} z_i &= \sigma(\mathbf{W_z} e_{u,i} + \mathbf{U_z} h_{u,i-1}) \\ r_i &= \sigma(\mathbf{W_r} e_{u,i} + \mathbf{U_r} h_{u,i-1}) \\ \widetilde{h}_{u,i} &= tanh(\mathbf{W_h} e_{u,i} + \mathbf{U_h}(r_i \odot h_{u,i-1})) \\ h_{u,i} &= z_i \odot \widetilde{h}_{u,i} + (1 - z_i) \odot h_{u,i-1}, \end{aligned} \tag{2}$$

where $h_{u,0} = 0$, z_i and r_i are an update gate and a reset gate respectively, $\sigma(\cdot)$ is a sigmoid function, and $\mathbf{W_z}$, $\mathbf{W_h}$, $\mathbf{W_r}$, $\mathbf{U_z}$, $\mathbf{U_r}$,$\mathbf{U_h}$ are parameters. Similarly, we have $\mathbf{H}_r = [h_{r,1}, \ldots, h_{r,n_r}]$ as the hidden vectors of $\mathbf{R}$. Then, $\forall i, j$, the (i, j)-th element of $\mathbf{M}_2$ is defined by

$$e_{2,i,j} = h_{u,i}^{\top} \mathbf{A} h_{r,j}, \tag{3}$$

where $\mathbf{A} \in \mathbb{R}^{m \times m}$ is a linear transformation. $\forall i$, GRU models the sequential relationship and the dependency among words up to position i and encodes the text segment until the i-th word to a hidden vector. Therefore, $\mathbf{M}_2$ models the matching between u and r on a segment level.

$\mathbf{M}_1$ and $\mathbf{M}_2$ are then processed by a CNN to form v. $\forall f = 1, 2$, CNN regards $\mathbf{M}_f$ as an input channel, and alternates convolution and max-pooling operations. Suppose that $z^{(l,f)} = \left[z_{i,j}^{(l,f)}\right]_{I^{(l,f)} \times J^{(l,f)}}$ denotes the output of feature maps of type-f on layer-l, where $z^{(0,f)} = \mathbf{M}_f$, $\forall f = 1, 2$. On the convolution layer, we employ a 2D convolution operation with a window size $r_w^{(l,f)} \times r_h^{(l,f)}$, and define $z_{i,j}^{(l,f)}$ as

$$z_{i,j}^{(l,f)} = \sigma\Big(\sum_{f'=0}^{F_{l-1}} \sum_{s=0}^{r_w^{(l,f)}} \sum_{t=0}^{r_h^{(l,f)}} \mathbf{W}_{s,t}^{(l,f)} \cdot z_{i+s,j+t}^{(l-1,f')} + \mathbf{b}^{l,k}\Big), \tag{4}$$

where $\sigma(\cdot)$ is a ReLU, $\mathbf{W}^{(l,f)} \in \mathbb{R}^{r_w^{(l,f)} \times r_h^{(l,f)}}$ and $\mathbf{b}^{l,k}$ are parameters, and F_{l-1} is the number of feature maps on the $(l-1)$-th layer. A max pooling operation follows a convolution operation and can be formulated as

$$z_{i,j}^{(l,f)} = \max_{p_w^{(l,f)} > s \geq 0} \max_{p_h^{(l,f)} > t \geq 0} z_{i+s,j+t}, \tag{5}$$

where $p_w^{(l,f)}$ and $p_h^{(l,f)}$ are the width and the height of the 2D pooling respectively. The output of the final feature maps are concatenated and mapped to a low dimensional space with a linear transformation as the matching vector $v \in \mathbb{R}^q$.

According to Equation (1), (3), (4), and (5), we can see that by learning word embedding and parameters of GRU from training data, words or segments in an utterance that are useful for recognizing the appropriateness of a response may have high similarity with some words or segments in the response and result in high value areas in the similarity matrices. These areas will be transformed and selected by convolution and pooling operations and carry important information in the utterance to the matching vector. This is how our model identifies important information in context and leverage it in matching under the supervision of the response. We consider multiple channels because we want to capture important matching information on multiple levels of granularity of text.

3.4 Matching Accumulation

Suppose that $[v_1, \ldots, v_n]$ is the output of the first layer (corresponding to n pairs), at the second layer, a GRU takes $[v_1, \ldots, v_n]$ as an input and encodes the matching sequence into its hidden states $H_m = [h'_1, \ldots, h'_n] \in \mathbb{R}^{q \times n}$ with a detailed parameterization similar to Equation (2). This layer has two functions: (1) it models the dependency and the temporal relationship of utterances in the

context; (2) it leverages the temporal relationship to supervise the accumulation of the pair matching as a context based matching. Moreover, from Equation (2), we can see that the reset gate (i.e., r_i) and the update gate (i.e., z_i) control how much information from the previous hidden state and the current input flows to the current hidden state, thus important matching vectors (corresponding to important utterances) can be accumulated while noise in the vectors can be filtered out.

3.5 Matching Prediction and Learning

With $[h'_1, \ldots, h'_n]$, we define $g(s, r)$ as

$$g(s, r) = softmax(\mathbf{W_2} L[h'_1, \ldots, h'_n] + \mathbf{b_2}), \quad (6)$$

where $\mathbf{W_2}$ and $\mathbf{b_2}$ are parameters. We consider three parameterizations for $L[h'_1, \ldots, h'_n]$: (1) only the last hidden state is used. Then $L[h'_1, \ldots, h'_n] = h'_n$. (2) the hidden states are linearly combined. Then, $L[h'_1, \ldots, h'_n] = \sum_{i=1}^{n} w_i h'_i$, where $w_i \in \mathbb{R}$. (3) we follow (Yang et al., 2016) and employ an attention mechanism to combine the hidden states. Then, $L[h'_1, \ldots, h'_n]$ is defined as

$$\begin{aligned} t_i &= tanh(\mathbf{W_{1,1}} h_{u_i,n_u} + \mathbf{W_{1,2}} h'_i + \mathbf{b_1}), \\ \alpha_i &= \frac{exp(t_i^\top t_s)}{\sum_i (exp(t_i^\top t_s))}, \\ L[h'_1, \ldots, h'_n] &= \sum_{i=1}^{n} \alpha_i h'_i, \end{aligned} \quad (7)$$

where $\mathbf{W_{1,1}} \in \mathbb{R}^{q \times m}$, $\mathbf{W_{1,2}} \in \mathbb{R}^{q \times q}$ and $\mathbf{b_1} \in \mathbb{R}^q$ are parameters. h'_i and h_{u_i,n_u} are the i-th matching vector and the final hidden state of the i-th utterance respectively. $t_s \in \mathbb{R}^q$ is a virtual context vector which is randomly initialized and jointly learned in training.

Both (2) and (3) aim to learn weights for $\{h'_1, \ldots, h'_n\}$ from training data and highlight the effect of important matching vectors in the final matching. The difference is that weights in (2) are static, because the weights are totally determined by the positions of utterances, while weights in (3) are dynamically computed by the matching vectors and utterance vectors. We denote our model with the three parameterizations of $L[h'_1, \ldots, h'_n]$ as SMN$_{last}$, SMN$_{static}$, and SMN$_{dynamic}$, and empirically compare them in experiments.

We learn $g(\cdot, \cdot)$ by minimizing cross entropy with $\mathcal{D}$. Let Θ denote the parameters of SMN, then the objective function $\mathcal{L}(\mathcal{D}, \Theta)$ of learning can be formulated as

$$-\sum_{i=1}^{N} [y_i log(g(s_i, r_i)) + (1 - y_i) log(1 - g(s_i, r_i))]\,. \quad (8)$$

4 Response Candidate Retrieval

In practice, a retrieval-based chatbot, to apply the matching approach to the response selection, one needs to retrieve a number of response candidates from an index beforehand. While candidate retrieval is not the focus of the paper, it is an important step in a real system. In this work, we exploit a heuristic method to obtain response candidates from the index. Given a message u_n with $\{u_1, \ldots, u_{n-1}\}$ utterances in its previous turns, we extract the top 5 keywords from $\{u_1, \ldots, u_{n-1}\}$ based on their tf-idf scores[1] and expand u_n with the keywords. Then we send the expanded message to the index and retrieve response candidates using the inline retrieval algorithm of the index. Finally, we use $g(s, r)$ to rerank the candidates and return the top one as a response to the context.

5 Experiments

We tested our model on a publicly available English data set and a Chinese data set published with this paper.

5.1 Ubuntu Corpus

The English data set is the Ubuntu Corpus (Lowe et al., 2015) which contains multi-turn dialogues collected from chat logs of the Ubuntu Forum. The data set consists of 1 million context-response pairs for training, 0.5 million pairs for validation, and 0.5 million pairs for testing. Positive responses are true responses from humans, and negative ones are randomly sampled. The ratio of the positive and the negative is 1:1 in training, and 1:9 in validation and testing. We used the copy shared by Xu et al. (2016) [2] in which numbers, urls, and paths are replaced by special placeholders. We followed (Lowe et al., 2015) and employed recall at position k in n candidates ($R_n@k$) as evaluation metrics.

[1] Tf is word frequency in the context, while idf is calculated using the entire index.

[2] https://www.dropbox.com/s/2fdn26rj6h9bpvl/ubuntudata.zip?dl=0

5.2 Douban Conversation Corpus

The Ubuntu Corpus is a domain specific data set, and response candidates are obtained from negative sampling without human judgment. To further verify the efficacy of our model, we created a new data set with open domain conversations, called the Douban Conversation Corpus. Response candidates in the test set of the Douban Conversation Corpus are collected following the procedure of a retrieval-based chatbot and are labeled by human judges. It simulates the real scenario of a retrieval-based chatbot. We publish it to research communities to facilitate the research of multi-turn response selection.

Specifically, we crawled 1.1 million dyadic dialogues (conversation between two persons) longer than 2 turns from Douban group[3] which is a popular social networking service in China. We randomly sampled 0.5 million dialogues for creating a training set, 25 thousand dialouges for creating a validation set, and $1,000$ dialogues for creating a test set, and made sure that there is no overlap between the three sets. For each dialogue in training and validation, we took the last turn as a positive response for the previous turns as a context and randomly sampled another response from the 1.1 million data as a negative response. There are 1 million context-response pairs in the training set and 50 thousand pairs in the validation set.

To create the test set, we first crawled 15 million post-reply pairs from Sina Weibo[4] which is the largest microblogging service in China and indexed the pairs with Lucene[5]. We took the last turn of each Douban dyadic dialogue in the test set as a message, retrieved 10 response candidates from the index following the method in Section 4, and finally formed a test set with $10,000$ context-response pairs. We recruited three labelers to judge if a candidate is a proper response to the context. A proper response means the response can naturally reply to the message given the whole context. Each pair received three labels and the majority of the labels were taken as the final decision. Table 2 gives the statistics of the three sets. Note that the Fleiss' kappa (Fleiss, 1971) of the labeling is 0.41, which indicates that the three labelers reached a relatively high agreement.

Besides $R_n@k$s, we also followed the convention of information retrieval and employed mean average precision (MAP) (Baeza-Yates et al., 1999), mean reciprocal rank (MRR) (Voorhees et al., 1999), and precision at position 1 (P@1) as evaluation metrics. We did not calculate $R_2@1$ because in Douban corpus one context could have more than one correct responses, and we have to randomly sample one for $R_2@1$, which may bring bias to evaluation. When using the labeled set, we removed conversations with all negative responses or all positive responses, as models make no difference with them. There are $6,670$ context-response pairs left in the test set.

	train	val	test
# context-response pairs	1M	50k	10k
# candidates per context	2	2	10
# positive candidates per context	1	1	1.18
Min. # turns per context	3	3	3
Max. # turns per context	98	91	45
Avg. # turns per context	6.69	6.75	6.45
Avg. # words per utterance	18.56	18.50	20.74

Table 2: Statistics of Douban Conversation Corpus

5.3 Baseline

We considered the following baselines:

Basic models: models in (Lowe et al., 2015) and (Kadlec et al., 2015) including TF-IDF, RNN, CNN, LSTM and BiLSTM.

Multi-view: the model proposed by Zhou et al. (2016) that utilizes a hierarchical recurrent neural network to model utterance relationships.

Deep learning to respond (DL2R): the model proposed by Yan et al. (2016) that reformulates the message with other utterances in the context.

Advanced single-turn matching models: since BiLSTM does not represent the state-of-the-art matching model, we concatenated the utterances in a context and matched the long text with a response candidate using more powerful models including MV-LSTM (Wan et al., 2016) (2D matching), Match-LSTM (Wang and Jiang, 2015), Attentive-LSTM (Tan et al., 2015) (two attention based models), and Multi-Channel which is described in Section 3.3. Multi-Channel is a simple version of our model without considering utterance relationships. We also appended the top 5 tf-idf words in context to the input message, and computed the score between the expanded message and a response with Multi-Channel, denoted as Multi-Channel$_{exp}$.

Table 3: Evaluation results on the two data sets. Numbers in bold mean that the improvement is statistically significant compared with the best baseline.

5.4 Parameter Tuning

For baseline models, if their results are available in existing literature (e.g., those on the Ubuntu corpus), we just copied the numbers, otherwise we implemented the models following the settings in the literatures. All models were implemented using Theano (Theano Development Team, 2016). Word embeddings were initialized by the results of word2vec (Mikolov et al., 2013) which ran on the training data, and the dimensionality of word vectors is 200. For Multi-Channel and layer one of our model, we set the dimensionality of the hidden states of GRU as 200. We tuned the window size of convolution and pooling in $\{(2,2),(3,3)(4,4)\}$ and chose $(3,3)$ finally. The number of feature maps is 8. In layer two, we set the dimensionality of matching vectors and the hidden states of GRU as 50. The parameters were updated by stochastic gradient descent with Adam algorithm (Kingma and Ba, 2014) on a single Tesla K80 GPU. The initial learning rate is 0.001, and the parameters of Adam, β_1 and β_2 are 0.9 and 0.999 respectively. We employed early-stopping as a regularization strategy. Models were trained in mini-batches with a batch size of 200, and the maximum utterance length is 50. We set the maximum context length (i.e., number of utterances) as 10, because the performance of models does not improve on contexts longer than 10 (details are shown in the Section 5.6). We padded zeros if the number of utterances in a context is less than 10, otherwise we kept the last 10 utterances.

5.5 Evaluation Results

Table 3 shows the evaluation results on the two data sets. Our models outperform baselines greatly in terms of all metrics on both data sets, with the improvements being statistically significant (t-test with p-value ≤ 0.01, except R_{10}@5 on Douban Corpus). Even the state-of-the-art single-turn matching models perform much worse than our models. The results demonstrate that one cannot neglect utterance relationships and simply perform multi-turn response selection by concatenating utterances together. Our models achieve significant improvements over Multi-View, which justified our "matching first" strategy. DL2R is worse than our models, indicating that utterance reformulation with heuristic rules is not a good method for utilizing context information. R_n@ks are low on the Douban Corpus as there are multiple correct candidates for a context (e.g., if there are 3 correct responses, then the maximum R_{10}@1 is 0.33). SMN$_{dynamic}$ is only slightly better than SMN$_{static}$ and SMN$_{last}$. The reason might be that the GRU can select useful signals from the matching sequence and accumulate them in the final state with its gate mechanism, thus the efficacy of an attention mechanism is not obvious for the task at hand.

5.6 Further Analysis

Visualization: we visualize the similarity matrices and the gates of GRU in layer two using an example from the Ubuntu corpus to further clarify how our model identifies important information in the context and how it selects important matching vectors with the gate mechanism of GRU as described in Section 3.3 and Section 3.4. The example is $\{u_1$*: how can unzip many rar (* $\_number\_$ *for example) files at once;* u_2*: sure you can do that in bash;* u_3*: okay how?* u_4*: are the files all*

Figure 2: Model visualization. Darker areas mean larger value.

in the same directory? u_5: yes they all are; r: then the command glebihan should extract them all from/to that directory}. It is from the test set and our model successfully ranked the correct response to the top position. Due to space limitation, we only visualized $\mathbf{M}_1$, $\mathbf{M}_2$ and the update gate (i.e. z) in Figure 2. We can see that in u_1 important words including "unzip", "rar", "files" are recognized and carried to matching by "command", "extract", and "directory" in r, while u_3 is almost useless and thus little information is extracted from it. u_1 is crucial to response selection and nearly all information from u_1 and r flows to the hidden state of GRU, while other utterances are less informative and the corresponding gates are almost "closed" to keep the information from u_1 and r until the final state.

Model ablation: we investigate the effect of different parts of SMN by removing them one by one from SMN$_{last}$, shown in Table 4. First, replacing the multi-channel "2D" matching with a neural tensor network (NTN) (Socher et al., 2013) (denoted as Replace$_M$) makes the performance drop dramatically. This is because NTN only matches a pair by an utterance vector and a response vector and loses important information in the pair. Together with the visualization, we can conclude that "2D" matching plays a key role in the "matching first" strategy as it captures the important matching information in each pair with minimal loss. Second, the performance drops slightly when replacing the GRU for matching accumulation with a multi-layer perceptron (denoted as Replace$_A$). This indicates that utterance relationships are useful. Finally, we left only one channel in matching and found that $\mathbf{M}_2$ is a little more powerful than $\mathbf{M}_1$ and we achieve the best results with both of them (except on $R_{10}@5$ on the Douban Corpus).

Performance across context length: we study how our model (SMN$_{last}$) performs across the length of contexts. Figure 3 shows the comparison on MAP in different length intervals on the Douban corpus. Our model consistently performs better than the baselines, and when contexts become longer, the gap becomes larger. The results demonstrate that our model can well capture the dependencies, especially long dependencies, among utterances in contexts.

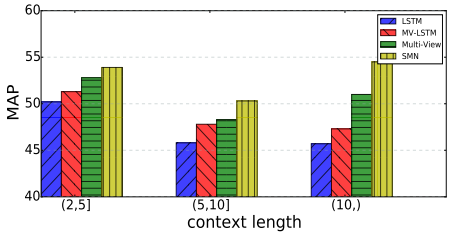

Figure 3: Comparison across context length

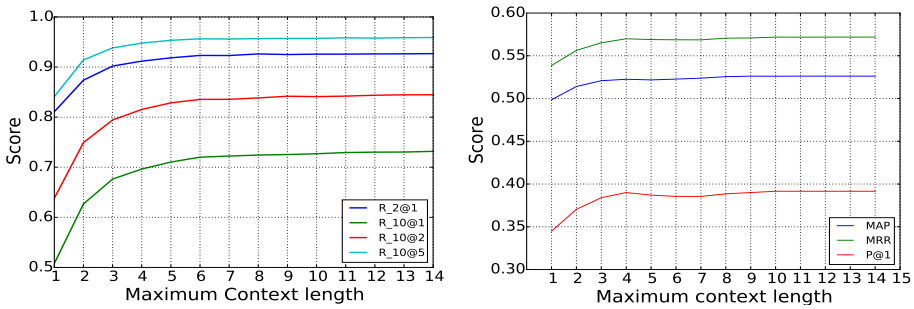
Maximum context length: we investigate the influence of maximum context length for SMN. Figure 4 shows the performance of SMN on Ubuntu Corpus and Douban Corpus with respect to maximum context length. From Figure 4, we find that performance improves significantly when the maximum context length is lower than 5, and becomes stable after the context length reaches 10. This indicates that context information is important for multi-turn response selection, and we can set the maximum context length as 10 to balance effectiveness and efficiency.

Error analysis: although SMN outperforms baseline methods on the two data sets, there are



(a) Ubuntu Corpus (b) Douban Conversation Corpus

Figure 4: Performance of SMN across maximum context length

still several problems that cannot be handled perfectly.

(1) Logical consistency. SMN models the context and response on the semantic level, but pays little attention to logical consistency. This leads to several DSATs in the Douban Corpus. For example, given a context {*a: Does anyone know Newton jogging shoes? b: 100 RMB on Taobao. a: I know that. I do not want to buy it because that is a fake which is made in Qingdao ,b: Is it the only reason you do not want to buy it?* }, SMN gives a large score to the response { *It is not a fake. I just worry about the date of manufacture*}. The response is inconsistent with the context on logic, as it claims that the jogging shoes are not fake. In the future, we shall explore the logic consistency problem in retrieval-based chatbots.

(2) No correct candidates after retrieval. In the experiment, we prepared 1000 contexts for testing, but only 667 contexts have correct candidates after candidate response retrieval. This indicates that there is still room for candidate retrieval components to improve, and only expanding the input message with several keywords in context may not be a perfect approach for candidate retrieval. In the future, we will consider advanced methods for retrieving candidates.

6 Conclusion and Future Work

We present a new context based model for multi-turn response selection in retrieval-based chatbots. Experiment results on open data sets show that the model can significantly outperform the state-of-the-art methods. Besides, we publish the first human-labeled multi-turn response selection data set to research communities. In the future, we shall study how to model logical consistency of responses and improve candidate retrieval.

Learning word-like units from joint audio-visual analysis

David Harwath and James Glass
Computer Science and Artificial Intelligence Laboratory

Abstract

Given a collection of images and spoken audio captions, we present a method for discovering word-like acoustic units in the continuous speech signal and grounding them to semantically relevant image regions. For example, our model is able to detect spoken instances of the words "lighthouse" within an utterance and associate them with image regions containing lighthouses. We do not use any form of conventional automatic speech recognition, nor do we use any text transcriptions or conventional linguistic annotations. Our model effectively implements a form of spoken language acquisition, in which the computer learns not only to recognize word categories by sound, but also to enrich the words it learns with semantics by grounding them in images.

1 Introduction

1.1 Problem Statement and Motivation

Automatically discovering words and other elements of linguistic structure from continuous speech has been a longstanding goal in computational linguists, cognitive science, and other speech processing fields. Practically all humans acquire language at a very early age, but this task has proven to be an incredibly difficult problem for computers. While conventional automatic speech recognition (ASR) systems have a long history and have recently made great strides thanks to the revival of deep neural networks (DNNs), their reliance on highly supervised training paradigms has essentially restricted their application to the major languages of the world, accounting for a small fraction of the more than 7,000 human languages spoken worldwide (Lewis et al., 2016). The main reason for this limitation is the fact that these supervised approaches require enormous amounts of very expensive human transcripts. Moreover, the use of the written word is a convenient but limiting convention, since there are many oral languages which do not even employ a writing system. In constrast, infants learn to communicate verbally before they are capable of reading and writing - so there is no inherent reason why spoken language systems need to be inseparably tied to text.

The key contribution of this paper has two facets. First, we introduce a methodology capable of not only discovering word-like units from continuous speech at the waveform level with no additional text transcriptions or conventional speech recognition apparatus. Instead, we jointly learn the semantics of those units via visual associations. Although we evaluate our algorithm on an English corpus, it could conceivably run on any language without requiring any text or associated ASR capability. Second, from a computational perspective, our method of speech pattern discovery runs in linear time. Previous work has presented algorithms for performing acoustic pattern discovery in continuous speech (Park and Glass, 2008; Jansen et al., 2010; Jansen and Van Durme, 2011) without the use of transcriptions or another modality, but those algorithms are limited in their ability to scale by their inherent $O(n^2)$ complexity, since they do an exhaustive comparison of the data against itself. Our method leverages correlated information from a second modality - the visual domain - to guide the discovery of words and phrases. This enables our method to run in $O(n)$ time, and we demonstrate it scalability by discovering acoustic patterns in over 522 hours of audio.

1.2 Previous Work

A sub-field within speech processing that has garnered much attention recently is unsupervised

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 506–517
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1047

speech pattern discovery. Segmental Dynamic Time Warping (S-DTW) was introduced by Park and Glass (2008), which discovers repetitions of the same words and phrases in a collection of untranscribed acoustic data. Many subsequent efforts extended these ideas (Jansen et al., 2010; Jansen and Van Durme, 2011; Dredze et al., 2010; Harwath et al., 2012; Zhang and Glass, 2009). Alternative approaches based on Bayesian nonparametric modeling (Lee and Glass, 2012; Ondel et al., 2016) employed a generative model to cluster acoustic segments into phoneme-like categories, and related works aimed to segment and cluster either reference or learned phoneme-like tokens into higher-level units (Johnson, 2008; Goldwater et al., 2009; Lee et al., 2015).

While supervised object detection is a standard problem in the vision community, several recent works have tackled the problem of weakly-supervised or unsupervised object localization (Bergamo et al., 2014; Cho et al., 2015; Zhou et al., 2015; Cinbis et al., 2016). Although the focus of this work is discovering acoustic patterns, in the process we jointly associate the acoustic patterns with clusters of image crops, which we demonstrate capture visual patterns as well.

The computer vision and NLP communities have begun to leverage deep learning to create multimodal models of images and text. Many works have focused on generating annotations or text captions for images (Socher and Li, 2010; Frome et al., 2013; Socher et al., 2014; Karpathy et al., 2014; Karpathy and Li, 2015; Vinyals et al., 2015; Fang et al., 2015; Johnson et al., 2016). One interesting intersection between word induction from phoneme strings and multimodal modeling of images and text is that of Gelderloos and Chrupaa (2016), who uses images to segment words within captions at the phoneme string level. Other work has taken these ideas beyond text, and attempted to relate images to spoken audio captions directly at the waveform level (Roy, 2003; Harwath and Glass, 2015; Harwath et al., 2016). The work of (Harwath et al., 2016) is the most similar to ours, in which the authors learned embeddings at the entire image and entire spoken caption level and then used the embeddings to perform bidirectional retrieval. In this work, we go further by automatically segmenting and clustering the spoken captions into individual word-like units, as well as the images into object-like categories.

2 Experimental Data

We employ a corpus of over 200,000 spoken captions for images taken from the Places205 dataset (Zhou et al., 2014), corresponding to over 522 hours of speech data. The captions were collected using Amazon's Mechanical Turk service, in which workers were shown images and asked to describe them verbally in a free-form manner. The data collection scheme is described in detail in Harwath et al. (2016), but the experiments in this paper leverage nearly twice the amount of data. For training our multimodal neural network as well as the pattern discovery experiments, we use a subset of 214,585 image/caption pairs, and we hold out a set of 1,000 pairs for evaluating the multimodal network's retrieval ability. Because we lack ground truth text transcripts for the data, we used Google's Speech Recognition public API to generate proxy transcripts which we use when analyzing our system. Note that the ASR was only used for analysis of the results, and was not involved in any of the learning.

3 Audio-Visual Embedding Neural Networks

We first train a deep multimodal embedding network similar in spirit to the one described in Harwath et al. (2016), but with a more sophisticated architecture. The model is trained to map entire image frames and entire spoken captions into a shared embedding space; however, as we will show, the trained network can then be used to localize patterns corresponding to words and phrases within the spectrogram, as well as visual objects within the image by applying it to small sub-regions of the image and spectrogram. The model is comprised of two branches, one which takes as input images, and the other which takes as input spectrograms. The image network is formed by taking the off-the-shelf VGG 16 layer network (Simonyan and Zisserman, 2014) and replacing the softmax classification layer with a linear transform which maps the 4096-dimensional activations of the second fully connected layer into our 1024-dimensional multimodal embedding space. In our experiments, the weights of this projection layer are trained, but the layers taken from the VGG network below it are kept fixed. The second branch of our network analyzes speech spectrograms as if they were black and white images. Our spectrograms are computed using 40 log Mel

filterbanks with a 25ms Hamming window and a 10ms shift. The input to this branch always has 1 color channel and is always 40 pixels high (corresponding to the 40 Mel filterbanks), but the width of the spectrogram varies depending upon the duration of the spoken caption, with each pixel corresponding to approximately 10 milliseconds worth of audio. The architecture we use is entirely convolutional and shown below, where C denotes the number of convolutional channels, W is filter width, H is filter height, and S is pooling stride.

1. Convolution: C=128, W=1, H=40, ReLU
2. Convolution: C=256, W=11, H=1, ReLU
3. Maxpool: W=3, H=1, S=2
4. Convolution: C=512, W=17, H=1, ReLU
5. Maxpool: W=3, H=1, S=2
6. Convolution: C=512, W=17, H=1, ReLU
7. Maxpool: W=3, H=1, S=2
8. Convolution: C=1024, W=17, H=1, ReLU
9. Meanpool over entire caption
10. L2 normalization

In practice during training, we restrict the caption spectrograms to all be 1024 frames wide (i.e., 10sec of speech) by applying truncation or zero padding. Additionally, both the images and spectrograms are mean normalized before training. The overall multimodal network is formed by tying together the image and audio branches with a layer which takes both of their output vectors and computes an inner product between them, representing the similarity score between a given image/caption pair. We train the network to assign high scores to matching image/caption pairs, and lower scores to mismatched pairs.

Within a minibatch of B image/caption pairs, let $S_j^p, j = 1, \ldots, B$ denote the similarity score of the j^{th} image/caption pair as output by the neural network. Next, for each pair we randomly sample one impostor caption and one impostor image from the same minibatch. Let S_j^i denote the similarity score between the j^{th} caption and its impostor image, and S_j^c be the similarity score between the j^{th} image and its impostor caption. The total loss for the entire minibatch is then computed as

$$\mathcal{L}(\theta) = \sum_{j=1}^{B} [\max(0, S_j^c - S_j^p + 1) + \max(0, S_j^i - S_j^p + 1)] \quad (1)$$

We train the neural network with 50 epochs of stochastic gradient descent using a batch size $B = 128$, a momentum of 0.9, and a learning rate of 1e-5 which is set to geometrically decay by a factor between 2 and 5 every 5 to 10 epochs.

4 Finding and Clustering Audio-Visual Caption Groundings

Although we have trained our multimodal network to compute embeddings at the granularity of entire images and entire caption spectrograms, we can easily apply it in a more localized fashion. In the case of images, we can simply take any arbitrary crop of an original image and resize it to 224x224 pixels. The audio network is even more trivial to apply locally, because it is entirely convolutional and the final mean pooling layer ensures that the output will be a 1024-dim vector no matter the extent of the input. The bigger question is *where* to locally apply the networks in order to discover meaningful acoustic and visual patterns.

Given an image and its corresponding spoken audio caption, we use the term grounding to refer to extracting meaningful segments from the caption and associating them with an appropriate subregion of the image. For example, if an image depicted a person eating ice cream and its caption contained the spoken words "A person is enjoying some ice cream," an ideal set of groundings would entail the acoustic segment containing the word "person" linked to a bounding box around the person, and the segment containing the word "ice cream" linked to a box around the ice cream. We use a constrained brute force ranking scheme to evaluate all possible groundings (with a restricted granularity) between an image and its caption. Specifically, we divide the image into a grid, and extract all of the image crops whose boundaries sit on the grid lines. Because we are mainly interested in extracting regions of interest and not high precision object detection boxes, to keep the number of proposal regions under control we impose several restrictions. First, we use a 10x10 grid on each image regardless of its original size. Second, we define minimum and maximum aspect ratios as 2:3 and 3:2 so as not to introduce too much distortion and also to reduce the number of proposal boxes. Third, we define a minimum bounding width as 30% of the original image width, and similarly a minimum height as 30% of the original image height. In practice, this results in a few thousand proposal regions per image.

To extract proposal segments from the audio

caption spectrogram, we similarly define a 1-dim grid along the time axis, and consider all possible start/end points at 10 frame (pixel) intervals. We impose minimum and maximum segment length constraints at 50 and 100 frames (pixels), implying that our discovered acoustic patterns are restricted to fall between 0.5 and 1 second in duration. The number of proposal segments will vary depending on the caption length, and typically number in the several thousands. Note that when learning groundings we consider the entire audio sequence, and do not incorporate the 10sec duration constraint imposed during training.

Once we have extracted a set of proposed visual bounding boxes and acoustic segments for a given image/caption pair, we use our multimodal network to compute a similarity score between each unique image crop/acoustic segment pair. Each triplet of an image crop, acoustic segment, and similarity score constitutes a proposed grounding. A naive approach would be to simply keep the top N groundings from this list, but in practice we ran into two problems with this strategy. First, many proposed acoustic segments capture mostly silence due to pauses present in natural speech. We solve this issue by using a simple voice activity detector (VAD) which was trained on the TIMIT corpus(Garofolo et al., 1993). If the VAD estimates that 40% or more of any proposed acoustic segment is silence, we discard that entire grounding. The second problem we ran into is the fact that the top of the sorted grounding list is dominated by highly overlapping acoustic segments. This makes sense, because highly informative content words will show up in many different groundings with slightly perturbed start or end times. To alleviate this issue, when evaluating a grounding from the top of the proposal list we compare the interval intersection over union (IOU) of its acoustic segment against all acoustic segments already accepted for further consideration. If the IOU exceeds a threshold of 0.1, we discard the new grounding and continue moving down the list. We stop accumulating groundings once the scores fall to below 50% of the top score in the "keep" list, or when 10 groundings have been added to the "keep" list. Figure 1 displays a pictorial example of our grounding procedure.

Once we have completed the grounding procedure, we are left with a small set of regions of interest in each image and caption spectrogram. We use the respective branches of our multimodal network to compute embedding vectors for each grounding's image crop and acoustic segment. We then employ k-means clustering separately on the collection of image embedding vectors as well as the collection of acoustic embedding vectors. The last step is to establish an affinity score between each image cluster $\mathcal{I}$ and each acoustic cluster $\mathcal{A}$; we do so using the equation

$$\text{Affinity}(\mathcal{I}, \mathcal{A}) = \sum_{\mathbf{i} \in \mathcal{I}} \sum_{\mathbf{a} \in \mathcal{A}} \mathbf{i}^\top \mathbf{a} \cdot \text{Pair}(\mathbf{i}, \mathbf{a}) \quad (2)$$

where $\mathbf{i}$ is an image crop embedding vector, $\mathbf{a}$ is an acoustic segment embedding vector, and $\text{Pair}(\mathbf{i}, \mathbf{a})$ is equal to 1 when $\mathbf{i}$ and $\mathbf{a}$ belong to the same grounding pair, and 0 otherwise. After clustering, we are left with a set of acoustic pattern clusters, a set of visual pattern clusters, and a set of linkages describing which acoustic clusters are associated with which image clusters. In the next section, we investigate these clusters in more detail.

5 Experiments and Analysis

Table 1: Results for image search and annotation on the Places audio caption data (214k training pairs, 1k testing pairs). Recall is shown for the top 1, 5, and 10 hits. The model we use in this paper is compared against the meanpool variant of the model architecture presented in Harwath et al. (2016). For both training and testing, the captions were truncated/zero-padded to 10 seconds.

	Search

This work (text)	0.111	0.383	0.525
	Annotation		
Model	R@1	R@5	R@10
(Harwath et al., 2016)	0.098	0.266	0.352
This work (audio)	0.120	0.307	0.438
This work (text)	0.113	0.341	0.493

We trained our multimodal network on a set of 214,585 image/caption pairs, and vetted it with an image search (given caption, find image) and annotation (given image, find caption) task similar to the one used in Harwath et al. (2016); Karpathy et al. (2014); Karpathy and Li (2015). The image annotation and search recall scores on a 1,000 image/caption pair held-out test set are shown in Table 1. Also shown in this table are the scores

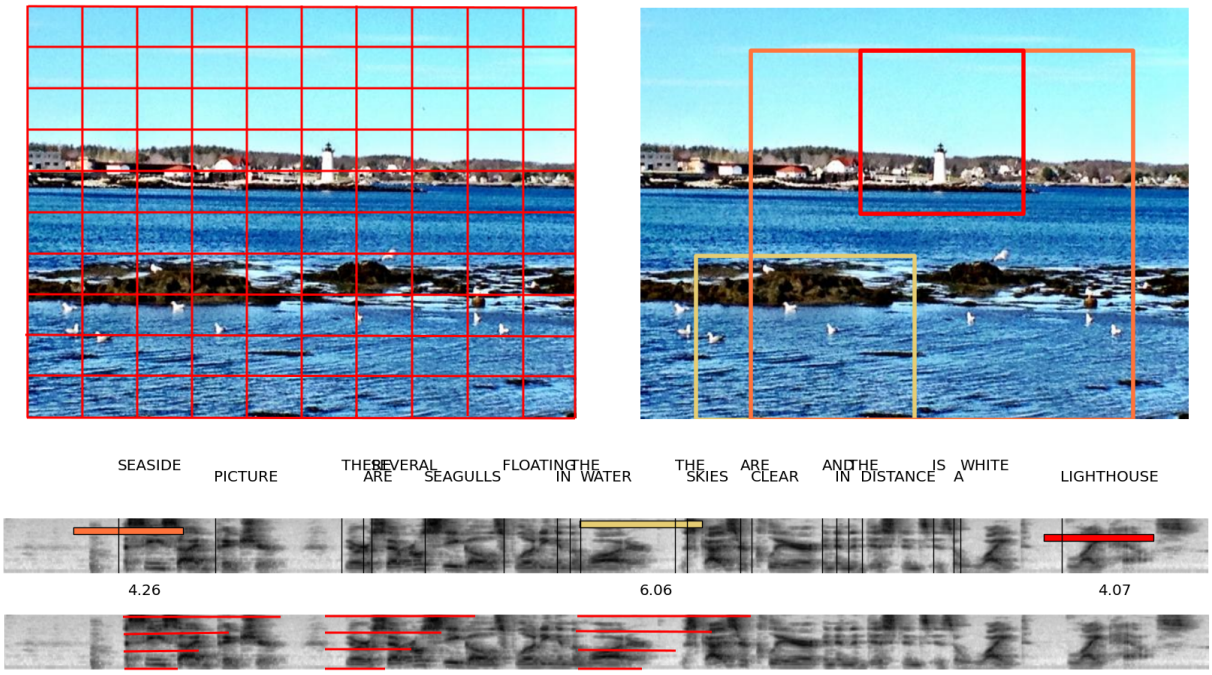

Figure 1: An example of our grounding method. The left image displays a grid defining the allowed start and end coordinates for the bounding box proposals. The bottom spectrogram displays several audio region proposals drawn as the families of stacked red line segments. The image on the right and spectrogram on the top display the final output of the grounding algorithm. The top spectrogram also displays the time-aligned text transcript of the caption, so as to demonstrate which words were captured by the groundings. In this example, the top 3 groundings have been kept, with the colors indicating the audio segment which is grounded to each bounding box.

Word	Count	Word	Count
ocean	2150	castle	766

oceans	16	(noise)	21
ocean water	16	council	13
(noise)	15	stone castle	12
of ocean	14	capitol	10
oceanside	14	old castle	10

Table 2: Examples of the breakdown of word/phrase identities of several acoustic clusters

achieved by a model which uses the ASR text transcriptions for each caption instead of the speech audio. The text captions were truncated/padded to 20 words, and the audio branch of the network was replaced with a branch with the following architecture:

1. Word embedding layer of dimension 200
2. Temporal Convolution: C=512, W=3, ReLU
3. Temporal Convolution: C=1024, W=3
4. Meanpool over entire caption
5. L2 normalization

One would expect that access to ASR hypotheses should improve the recall scores, but the performance gap is not enormous. Access to the ASR hypotheses provides a relative improvement of approximately 21.8% for image search R@10 and 12.5% for annotation R@10 compared to using no transcriptions or ASR whatsoever.

We performed the grounding and pattern clustering steps on the entire training dataset, which resulted in a total of 1,161,305 unique grounding pairs. For evaluation, we wish to assign a label to each cluster and cluster member, but this is not completely straightforward since each acoustic segment may capture part of a word, a whole word, multiple words, etc. Our strategy is to force-align the Google recognition hypothesis text to the audio, and then assign a label string to each acoustic segment based upon which words it overlaps in time. The alignments are created with the help of a Kaldi (Povey et al., 2011) speech recognizer

Table 3: Top 50 clusters with $k = 500$ sorted by increasing variance. Legend: $|C_c|$ is acoustic cluster size, $|C_i|$ is associated image cluster size, Pur. is acoustic cluster purity, σ^2 is acoustic cluster variance, and Cov. is acoustic cluster coverage. A dash (-) indicates a cluster whose majority label is silence.

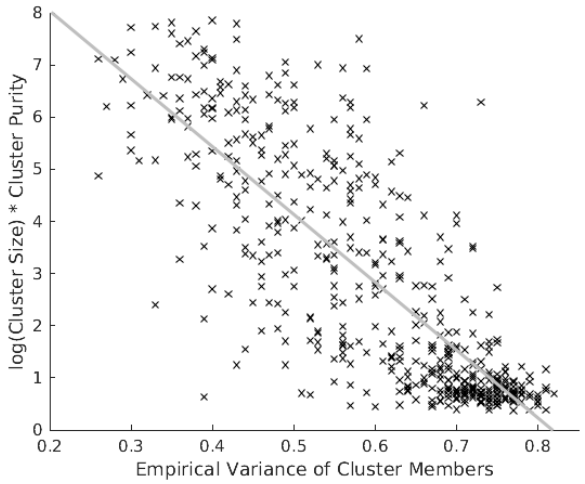

Figure 2: Scatter plot of audio cluster purity weighted by log cluster size vs variance for $k = 500$ (least-squares line superimposed).

based on the standard WSJ recipe and trained using the Google ASR hypothesis as a proxy for the transcriptions. Any word whose duration is overlapped 30% or more by the acoustic segment is included in the label string for the segment. We then employ a majority vote scheme to derive the overall cluster labels. When computing the purity of a cluster, we count a cluster member as matching the cluster label as long as the overall cluster label appears in the member's label string. In other words, an acoustic segment overlapping the words "the lighthouse" would receive credit for matching the overall cluster label "lighthouse". A breakdown of the segments captured by two clusters is shown in Table 2. We investigated some simple schemes for predicting highly pure clusters, and found that the empirical variance of the cluster members (average squared distance to the cluster centroid) was a good indicator. Figure 2 displays a scatter plot of cluster purity weighted by the natural log of the cluster size against the empirical variance. Large, pure clusters are easily predicted by their low empirical variance, while a high variance is indicative of a garbage cluster.

Ranking a set of $k = 500$ acoustic clusters by their variance, Table 3 displays some statistics for the 50 lowest-variance clusters. We see that most of the clusters are very large and highly pure, and their labels reflect interesting object categories being identified by the neural network. We additionally compute the coverage of each cluster by counting the total number of instances of the clus-

2000	1992	1106418	.431	540	.237	1354	790492	.546	484	.271

ter label anywhere in the training data, and then compute what fraction of those instances were captured by the cluster. There are many examples of high coverage clusters, e.g. the "skyscraper" cluster captures 84% of all occurrences of the word "skyscraper", while the "baseball" cluster captures 86% of all occurrences of the word "baseball". This is quite impressive given the fact that no conventional speech recognition was employed, and neither the multimodal neural network nor the grounding algorithm had access to the text transcripts of the captions.

To get an idea of the impact of the k parameter as well as a variance-based cluster pruning threshold based on Figure 2, we swept k from 250 to 2000 and computed a set of statistics shown in Table 4. We compute the standard overall cluster purity evaluation metric in addition to the average coverage across clusters. The table shows the natural tradeoff between cluster purity and redundancy (indicated by the average cluster coverage) as k is increased. In all cases, the variance-based cluster pruning greatly increases both the overall purity and average cluster coverage metrics. We also notice that more unique cluster labels are discovered with a larger k.

Next, we examine the image clusters. Figure 3 displays the 9 most central image crops for a set of 10 different image clusters, along with the majority-vote label of each image cluster's associated audio cluster. In all cases, we see that the image crops are highly relevant to their audio cluster label. We include many more example image clusters in Appendix A.

In order to examine the semantic embedding space in more depth, we took the top 150 clusters from the same $k = 500$ clustering run described in Table 3 and performed t-SNE (van der Maaten and Hinton, 2008) analysis on the cluster centroid vectors. We projected each centroid down to 2 di-

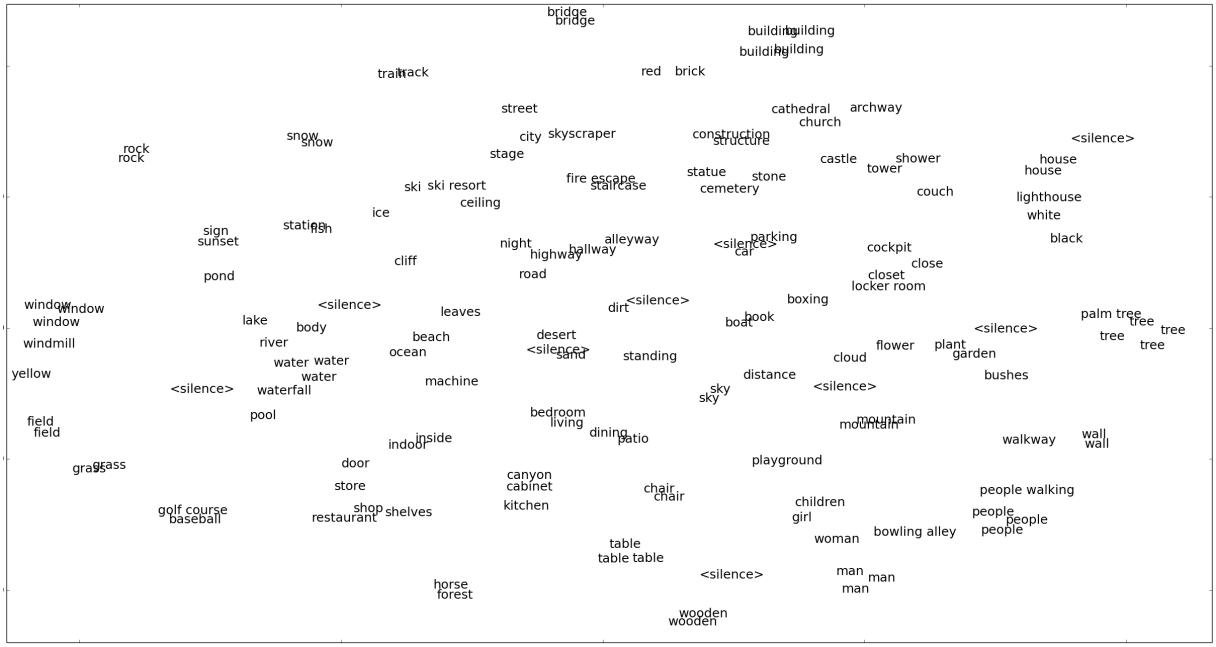

Figure 4: t-SNE analysis of the 150 lowest-variance audio pattern cluster centroids for $k = 500$. Displayed is the majority-vote transcription of the each audio cluster. All clusters shown contained a minimum of 583 members and an average of 2482, with an average purity of .668.

mensions and plotted their majority-vote labels in Figure 4. Immediately we see that different clusters which capture the same label closely neighbor one another, indicating that distances in the embedding space do indeed carry information discriminative across word types (and suggesting that a more sophisticated clustering algorithm than k-means would perform better). More interestingly, we see that semantic information is also reflected in these distances. The cluster centroids for "lake," "river," "body," "water," "waterfall," "pond," and "pool" all form a tight meta-cluster, as do "restaurant," "store," "shop," and "shelves," as well as "children," "girl," "woman," and "man." Many other semantic meta-clusters can be seen in Figure 4, suggesting that the embedding space is capturing information that is highly discriminative both acoustically *and* semantically.

Because our experiments revolve around the discovery of word and object categories, a key question to address is the extent to which the supervision used to train the VGG network constrains or influences the kinds of objects learned. Because the 1,000 object classes from the ILSVRC2012 task (Russakovsky et al., 2015) used to train the VGG network were derived from WordNet synsets (Fellbaum, 1998), we can measure the semantic similarity between the words learned by our network and the ILSVRC2012 class labels by using synset similarity measures within WordNet. We do this by first building a list of the 1,000 WordNet synsets associated with the ILSVRC2012 classes. We then take the set of unique majority-vote labels associated with the discovered word clusters for $k = 500$, filtered by setting a threshold on their variance ($\sigma^2 \leq 0.65$) so as to get rid of garbage clusters, leaving us with 197 unique acoustic cluster labels. We then look up each cluster label in WordNet, and compare all noun senses of the label to every ILSVRC2012 class synset according to the path similarity measure. This measure describes the distance between two synsets in a hyponym/hypernym hierarchy, where a score of 1 represents identity and lower scores indicate less similarity. We retain the highest score between any sense of the cluster label and any ILSVRC2012 synset. Of the 197 unique cluster labels, only 16 had a distance of 1 from any ILSVRC12 class, which would indicate an exact match. A path similarity of 0.5 indicates one degree of separation in the hyponym/hypernym hierarchy - for example, the similarity between "desk" and "table" is 0.5. 47 cluster labels were found to have a similarity of 0.5 to some ILSVRC12 class, leaving 134 cluster labels whose highest similarity to any ILSVRC12 class was less than 0.5. In

other words, more than two thirds of the highly pure pattern clusters learned by our network were dissimilar to all of the 1,000 ILSVRC12 classes used to pretrain the VGG network, indicating that our model is able to generalize far beyond the set of classes found in the ILSVRC12 data. We display the labels of the 40 lowest variance acoustic clusters labels along with the name and similarity score of their closest ILSVRC12 synset in Table 5.

6 Conclusions and Future Work

In this paper, we have demonstrated that a neural network trained to associate images with the waveforms representing their spoken audio captions can successfully be applied to discover and cluster acoustic patterns representing words or short phrases in untranscribed audio data. An analogous procedure can be applied to visual images to discover visual patterns, and then the two modalities can be linked, allowing the network to learn, for example, that spoken instances of the word "train" are associated with image regions containing trains. This is done without the use of a conventional automatic speech recognition system and zero text transcriptions, and therefore is completely agnostic to the language in which the captions are spoken. Further, this is done in $O(n)$ time with respect to the number of image/caption pairs, whereas previous state-of-the-art acoustic pattern discovery algorithms which leveraged acoustic data alone run in $O(n^2)$ time. We demonstrate the success of our methodology on a large-scale dataset of over 214,000 image/caption pairs comprising over 522 hours of spoken audio data, which is to our knowledge the largest scale acoustic pattern discovery experiment ever performed. We have shown that the shared multimodal embedding space learned by our model is discriminative not only across visual object categories, but also acoustically *and* semantically across spoken words.

The future directions in which this research could be taken are incredibly fertile. Because our method creates a segmentation as well as an alignment between images and their spoken captions, a generative model could be trained using these alignments. The model could provide a spoken caption for an arbitrary image, or even synthesize an image given a spoken description. Modeling improvements are also possible, aimed at the goal of incorporating both visual and acoustic localization into the neural network itself. The same framework we use here could be extended to video, enabling the learning of actions, verbs, environmental sounds, and the like. Additionally, by collecting a second dataset of captions for our images in a different language, such as Spanish, our model could be extended to learn the acoustic correspondences for a given object category in both languages. This paves the way for creating a speech-to-speech translation model not only with absolutely zero need for any sort of text transcriptions, but also with zero need for directly parallel linguistic data or manual human translations.

A Additional Cluster Visualizations

Joint CTC/attention decoding for end-to-end speech recognition

Takaaki Hori, Shinji Watanabe, John R. Hershey
Mitsubishi Electric Research Laboratories (MERL)
{thori,watanabe,hershey}@merl.com

Abstract

End-to-end automatic speech recognition (ASR) has become a popular alternative to conventional DNN/HMM systems because it avoids the need for linguistic resources such as pronunciation dictionary, tokenization, and context-dependency trees, leading to a greatly simplified model-building process. There are two major types of end-to-end architectures for ASR: attention-based methods use an attention mechanism to perform alignment between acoustic frames and recognized symbols, and connectionist temporal classification (CTC), uses Markov assumptions to efficiently solve sequential problems by dynamic programming. This paper proposes a joint decoding algorithm for end-to-end ASR with a hybrid CTC/attention architecture, which effectively utilizes both advantages in decoding. We have applied the proposed method to two ASR benchmarks (spontaneous Japanese and Mandarin Chinese), and showing the comparable performance to conventional state-of-the-art DNN/HMM ASR systems without linguistic resources.

1 Introduction

Automatic speech recognition (ASR) is currently a mature set of technologies that have been widely deployed, resulting in great success in interface applications such as voice search. A typical ASR system is factorized into several modules including acoustic, lexicon, and language models based on a probabilistic noisy channel model (Jelinek, 1976). Over the last decade, dramatic improvements in acoustic and language models have been driven by machine learning techniques known as deep learning (Hinton et al., 2012).

However, current systems lean heavily on the scaffolding of complicated legacy architectures that grew up around traditional techniques. For example, when we build an acoustic model from scratch, we have to first build hidden Markov model (HMM) and Gaussian mixture model (GMM) followed by deep neural networks (DNN). In addition, the factorization of acoustic, lexicon, and language models is derived by conditional independence assumptions (especially Markov assumptions), although the data do not necessarily follow such assumptions leading to model misspecification. This factorization form also yields a local optimum since the above modules are optimized separately. Further, to well factorize acoustic and language models, the system requires linguistic knowledge based on a lexicon model, which is usually based on a hand-crafted pronunciation dictionary to map word to phoneme sequence. In addition to the pronunciation dictionary issue, some languages, which do not explicitly have a word boundary, need language-specific tokenization modules (Kudo et al., 2004; Bird, 2006) for language modeling. Finally, inference/decoding has to be performed by integrating all modules resulting in complex decoding. Consequently, it is quite difficult for non-experts to use/develop ASR systems for new applications, especially for new languages.

End-to-end ASR has the goal of simplifying the above module-based architecture into a single-network architecture within a deep learning framework, in order to address the above issues. There are two major types of end-to-end architectures for ASR: attention-based methods use an attention mechanism to perform alignment between acoustic frames and recognized symbols, and connectionist temporal classification (CTC), uses Markov

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 518–529
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1048

assumptions to efficiently solve sequential problems by dynamic programming (Chorowski et al., 2014; Graves and Jaitly, 2014).

The attention-based end-to-end method solves the ASR problem as a sequence mapping from speech feature sequences to text by using encoder-decoder architecture. The decoder network uses an attention mechanism to find an alignment between each element of the output sequence and the hidden states generated by the acoustic encoder network for each frame of acoustic input (Chorowski et al., 2014, 2015; Chan et al., 2015; Lu et al., 2016). This basic temporal attention mechanism is too flexible in the sense that it allows extremely non-sequential alignments. This may be fine for applications such as machine translation where input and output word order are different (Bahdanau et al., 2014; Wu et al., 2016). However, in speech recognition, the feature inputs and corresponding letter outputs generally proceed in the same order. Another problem is that the input and output sequences in ASR can have very different lengths, and these vary greatly from case to case, depending on the speaking rate and writing system, making it more difficult to track the alignment.

However, an advantage is that the attention mechanism does not require any conditional independence assumptions, and could address all the problems cited above. Although the alignment problems of attention-based mechanisms have been partially addressed in (Chorowski et al., 2014; Chorowski and Jaitly, 2016) using various mechanisms, here we propose more rigorous constraints by using CTC-based alignment to guide the decoding.

CTC permits an efficient computation of a strictly monotonic alignment using dynamic programming (Graves et al., 2006; Graves and Jaitly, 2014) although it requires language models and graph-based decoding (Miao et al., 2015) except in the case of huge training data (Amodei et al., 2015; Soltau et al., 2016). We propose to take advantage of the constrained CTC alignment in a hybrid CTC/attention based system during *decoding*. The proposed method adopts a CTC/attention hybrid architecture, which was originally designed to regularize an attention-based encoder network by additionally using a CTC during *training* (Kim et al., 2017). The proposed method extends the architecture to perform one-pass/rescoring joint decoding, where hypotheses of attention-based ASR are boosted by scores obtained by using CTC outputs. This greatly reduces irregular alignments without any heuristic search techniques.

The proposed method is applied to Japanese and Mandarin ASR tasks, which require extra linguistic resources including morphological analyzer (Kudo et al., 2004) or word segmentation (Xue et al., 2003) in addition to pronunciation dictionary to provide accurate lexicon and language models in conventional DNN/HMM ASR. Surprisingly, the method achieved performance comparable to, and in some cases superior to, several state-of-the-art DNN/HMM ASR systems, without using the above linguistic resources.

2 From DNN/HMM to end-to-end ASR

This section briefly provides a formulation of conventional DNN/HMM ASR and CTC or attention based end-to-end ASR.

2.1 Conventional DNN/HMM ASR

ASR deals with a sequence mapping from T-length speech feature sequence $X = \{\mathbf{x}_t \in \mathbb{R}^D | t = 1, \cdots, T\}$ to N-length word sequence $W = \{w_n \in \mathcal{V} | n = 1, \cdots, N\}$. $\mathbf{x}_t$ is a D dimensional speech feature vector (e.g., log Mel filterbanks) at frame t and w_n is a word at position n in vocabulary $\mathcal{V}$. ASR is mathematically formulated with the Bayes decision theory, where the most probable word sequence $\hat{W}$ is estimated among all possible word sequences $\mathcal{V}*$ as follows:

$$\hat{W} = \arg\max_{W \in \mathcal{V}*} p(W|X). \quad (1)$$

The posterior distribution $p(W|X)$ is factorized into the following three distributions by using the Bayes theorem and introducing HMM state sequence $S = \{s_t \in \{1, \cdots, J\} | t = 1, \cdots, T\}$:

$$\text{Eq. (1)} \approx \arg\max_{W} \sum_{S} p(X|S)p(S|W)p(W).$$

The three factors, $p(X|S)$, $p(S|W)$, and $p(W)$, are acoustic, lexicon, and language models, respectively. These are further factorized by using a probabilistic chain rule and conditional independence assumption as follows:

$$\begin{cases} p(X|S) \approx \prod_t \frac{p(s_t|\mathbf{x}_t)}{p(s_t)}, \\ p(S|W) \approx \prod_t p(s_t|s_{t-1}, W), \\ p(W) \quad \approx \prod_n p(w_n|w_{n-1}, \ldots, w_{n-m-1}), \end{cases}$$

where the acoustic model is replaced with the product of framewise posterior distributions $p(s_t|\mathbf{x}_t)$ computed by powerful DNN classifiers by using so-called pseudo likelihood trick (Bourlard and Morgan, 1994). $p(s_t|s_{t-1}, W)$ is represented by an HMM state transition given W, and the conversion from W to HMM states is deterministically performed by using a pronunciation dictionary through a phoneme representation. $p(w_n|w_{n-1}, \ldots, w_{n-m-1})$ is obtained based on an $(m-1)$th-order Markov assumption as a m-gram model.

These conditional independence assumptions are often regarded as too strong assumption, leading to model mis-specification. Also, to train the framewise posterior $p(s_t|\mathbf{x}_t)$, we have to provide a framewise state alignment s_t as a target, which is often provided by a GMM/HMM system. Thus, conventional DNN/HMM systems make the ASR problem formulated with Eq. (1) feasible by using factorization and conditional independence assumptions, at the cost of the problems discussed in Section 1.

2.2 Connectionist Temporal Classification (CTC)

The CTC formulation also follows from Bayes decision theory (Eq. (1)). Note that the CTC formulation uses L-length letter sequence $C = \{c_l \in \mathcal{U} | l = 1, \cdots, L\}$ with a set of distinct letters $\mathcal{U}$. Similarly to Section 2.1, by introducing framewise letter sequence with an additional "blank" ($<\mathtt{b}>$) symbol $Z = \{z_t \in \mathcal{U} \cup <\mathtt{b}> | t = 1, \cdots, T\}$, and by using the probabilistic chain rule and conditional independence assumption, the posterior distribution $p(C|X)$ is factorized as follows:

$$p(C|X) \approx \underbrace{\sum_{Z} \prod_{t} p(z_t|z_{t-1}, C) p(z_t|X)}_{\triangleq p_{\text{ctc}}(C|X)} \frac{p(C)}{p(Z)} \tag{2}$$

As a result, CTC has three distribution components similar to the DNN/HMM case, i.e., framewise posterior distribution $p(z_t|X)$, transition probability $p(z_t|z_{t-1}, C)$[1], and prior distributions of letter and hidden-state sequences, $p(C)$ and $p(Z)$, respectively. We also define the CTC objective function $p_{\text{ctc}}(C|X)$ used in the later formulation. The framewise posterior distribution $p(z_t|X)$ is conditioned on all inputs X, and it is quite natural to be modeled by using bidirectional long short-term memory (BLSTM): $p(z_t|X) = \text{Softmax}(\text{Lin}(\mathbf{h}_t))$ and $\mathbf{h}_t = \text{BLSTM}(X)$. $\text{Softmax}(\cdot)$ is a sofmax activation function, and $\text{Lin}(\cdot)$ is a linear layer to convert hidden vector $\mathbf{h}_t$ to a $(|\mathcal{U}|+1)$ dimensional vector ($+1$ means a blank symbol introduced in CTC).

Although Eq. (2) has to deal with a summation over all possible Z, it is efficiently computed by using dynamic programming (Viterbi/forward-backward algorithm) thanks to the Markov property. In summary, although CTC and DNN/HMM systems are similar to each other due to conditional independence assumptions, CTC does not require pronunciation dictionaries and omits an GMM/HMM construction step.

2.3 Attention mechanism

Compared with hybrid and CTC approaches, the attention-based approach does not make any conditional independence assumptions, and directly estimates the posterior $p(C|X)$ based on a probabilistic chain rule, as follows:

$$p(C|X) = \underbrace{\prod_{l} p(c_l|c_1, \cdots, c_{l-1}, X)}_{\triangleq p_{\text{att}}(C|X)}, \tag{3}$$

where $p_{\text{att}}(C|X)$ is an attention-based objective function. $p(c_l|c_1, \cdots, c_{l-1}, X)$ is obtained by

$$p(c_l|c_1, \cdots, c_{l-1}, X) = \text{Decoder}(\mathbf{r}_l, \mathbf{q}_{l-1}, c_{l-1})$$
$$\mathbf{h}_t = \text{Encoder}(X) \tag{4}$$
$$a_{lt} = \text{Attention}(\{a_{l-1}\}_t, \mathbf{q}_{l-1}, \mathbf{h}_t) \tag{5}$$
$$\mathbf{r}_l = \sum_t a_{lt} \mathbf{h}_t. \tag{6}$$

Eq. (4) converts input feature vectors X into a framewise hidden vector $\mathbf{h}_t$ in an encoder network based on BLSTM, i.e., $\text{Encoder}(X) \triangleq \text{BLSTM}(X)$. $\text{Attention}(\cdot)$ in Eq. (5) is based on a content-based attention mechanism with convolutional features, as described in (Chorowski et al., 2015) (see Appendix A). a_{lt} is an attention weight, and represents a soft alignment of hidden vector $\mathbf{h}_t$ for each output c_l based on the weighted summation of hidden vectors to form letter-wise hidden vector $\mathbf{r}_l$ in Eq. (6). A decoder network is another

[1] Note that in the implementation, the transition value is not normalized (i.e., not a probabilistic value) (Graves and Jaitly, 2014; Miao et al., 2015), similar to the HMM state transition implementation (Povey et al., 2011)

recurrent network conditioned on previous output c_{l-1} and hidden vector $\mathbf{q}_{l-1}$, similar to RNNLM, in addition to letter-wise hidden vector $\mathbf{r}_l$. We use $\text{Decoder}(\cdot) \triangleq \text{Softmax}(\text{Lin}(\text{LSTM}(\cdot)))$.

Attention-based ASR does not explicitly separate each module, and potentially handles the all issues pointed out in Section 1. It implicitly combines acoustic models, lexicon, and language models as encoder, attention, and decoder networks, which can be jointly trained as a single deep neural network.

Compared with DNN/HMM and CTC, which are based on a transition form from $t-1$ to t due to the Markov assumption, the attention mechanism does not maintain this constraint, and often provides irregular alignments. A major focus of this paper is to address this problem by using joint CTC/attention decoding.

3 Joint CTC/attention decoding

This section explains a hybrid CTC/attention network, which potentially utilizes both benefits of CTC and attention in ASR.

3.1 Hybrid CTC/attention architecture

Kim et al. (2017) uses a CTC objective function as an auxiliary task to train the attention model encoder within the multitask learning (MTL) framework, and this paper also uses the same architecture. Figure 1 illustrates the overall architecture of the framework, where the same BLSTM is shared with CTC and attention encoder networks, respectively). Unlike the sole attention model, the forward-backward algorithm of CTC can enforce monotonic alignment between speech and label sequences during training. That is, rather than solely depending on data-driven attention methods to estimate the desired alignments in long sequences, the forward-backward algorithm in CTC helps to speed up the process of estimating the desired alignment. The objective to be maximized is a logarithmic linear combination of the CTC and attention objectives, i.e., $p_{\text{ctc}}(C|X)$ in Eq. (2) and $p_{\text{att}}(C|X)$ in Eq. (3):

$$\mathcal{L}_{\text{MTL}} = \lambda \log p_{\text{ctc}}(C|X) + (1-\lambda) \log p_{\text{att}}(C|X), \tag{7}$$

with a tunable parameter $\lambda : 0 \leq \lambda \leq 1$.

3.2 Decoding strategies

The inference step of our joint CTC/attention-based end-to-end speech recognition is performed

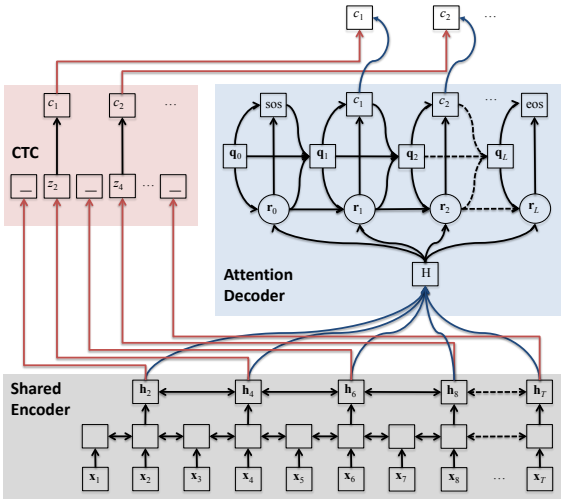

Figure 1: Joint CTC/attention based end-to-end framework: the shared encoder is trained by both CTC and attention model objectives simultaneously. The shared encoder transforms our input sequence $\{\mathbf{x}_t \cdots \mathbf{x}_T\}$ into high level features $H = \{\mathbf{h}_t \cdots \mathbf{h}_T\}$, and the attention decoder generates the letter sequence $\{c_1 \cdots c_L\}$.

by label synchronous decoding with a beam search similar to conventional attention-based ASR. However, we take the CTC probabilities into account to find a hypothesis that is better aligned to the input speech, as shown in Figure 1. Hereafter, we describe the general attention-based decoding and conventional techniques to mitigate the alignment problem. Then, we propose joint decoding methods with a hybrid CTC/attention architecture.

3.2.1 Attention-based decoding in general

End-to-end speech recognition inference is generally defined as a problem to find the most probable letter sequence $\hat{C}$ given the speech input X, i.e.

$$\hat{C} = \arg\max_{C \in \mathcal{U}^*} \log p(C|X). \tag{8}$$

In attention-based ASR, $p(C|X)$ is computed by Eq. (3), and $\hat{C}$ is found by a beam search technique.

Let Ω_l be a set of partial hypotheses of the length l. At the beginning of the beam search, Ω_0 contains only one hypothesis with the starting symbol <sos> and the hypothesis score $\alpha(\texttt{<sos>}, X)$ is set to 0. For $l = 1$ to L_{max}, each partial hypothesis in Ω_{l-1} is expanded by appending possible single letters, and the new hypotheses are stored in Ω_l, where L_{max} is the maximum

length of the hypotheses to be searched. The score of each new hypothesis is computed in the log domain as

$$\alpha(h, X) = \alpha(g, X) + \log p(c|g, X), \quad (9)$$

where g is a partial hypothesis in Ω_{l-1}, c is a letter appended to g, and h is the new hypothesis such that $h = g \cdot c$. If c is a special symbol that represents the end of a sequence, <eos>, h is added to $\hat{\Omega}$ but not Ω_l, where $\hat{\Omega}$ denotes a set of complete hypotheses. Finally, $\hat{C}$ is obtained by

$$\hat{C} = \arg\max_{h \in \hat{\Omega}} \alpha(h, X). \quad (10)$$

In the beam search process, Ω_l is allowed to hold only a limited number of hypotheses with higher scores to improve the search efficiency.

Attention-based ASR, however, may be prone to include deletion and insertion errors because of its flexible alignment property, which can attend to any portion of the encoder state sequence to predict the next label, as discussed in Section 2.3. Since attention is generated by the decoder network, it may prematurely predict the end-of-sequence label, even when it has not attended to all of the encoder frames, making the hypothesis too short. On the other hand, it may predict the next label with a high probability by attending to the same portions as those attended to before. In this case, the hypothesis becomes very long and includes repetitions of the same letter sequence.

3.2.2 Conventional decoding techniques

To alleviate the alignment problem, a length penalty term is commonly used to control the hypothesis length to be selected (Chorowski et al., 2015; Bahdanau et al., 2016). With the length penalty, the decoding objective in Eq. (8) is changed to

$$\hat{C} = \arg\max_{C \in \mathcal{U}^*} \{\log p(C|X) + \gamma|C|\}, \quad (11)$$

where $|C|$ is the length of the sequence C, and γ is a tunable parameter. However, it is actually difficult to completely exclude hypotheses that are too long or too short even if γ is carefully tuned. It is also effective to control the hypothesis length by the minimum and maximum lengths to some extent, where the minimum and maximum are selected as fixed ratios to the length of the input speech. However, since there are exceptionally long or short transcripts compared to the input speech, it is difficult to balance saving such exceptional transcripts and preventing hypotheses with irrelevant lengths.

Another approach is the *coverage* term recently proposed in (Chorowski and Jaitly, 2016), which is incorporated in the decoding objective in Eq. (11) as

$$\hat{C} = \arg\max_{C \in \mathcal{U}^*} \{\log p(C|X) + \gamma|C| + \eta \cdot \text{coverage}(C|X)\}, \quad (12)$$

where the coverage term is computed by

$$\text{coverage}(C|X) = \sum_{t=1}^{T} \left[\sum_{l=1}^{L} a_{lt} > \tau \right]. \quad (13)$$

η and τ are tunable parameters. The coverage term represents the number of frames that have received a cumulative attention greater than τ. Accordingly, it increases when paying close attention to some frames for the first time, but does not increase when paying attention again to the same frames. This property is effective for avoiding looping of the same label sequence within a hypothesis. However, it is still difficult to obtain a common parameter setting for γ, η, τ, and the optional min/max lengths so that they are appropriate for any speech data from different tasks.

3.2.3 Joint decoding

Our joint CTC/attention approach combines the CTC and attention-based sequence probabilities in the inference step, as well as the training step. Suppose $p_{\text{ctc}}(C|X)$ in Eq. (2) and $p_{\text{att}}(C|X)$ in Eq. (3) are the sequence probabilities given by CTC and the attention model. The decoding objective is defined similarly to Eq. (7) as

$$\hat{C} = \arg\max_{C \in \mathcal{U}^*} \{\lambda \log p_{\text{ctc}}(C|X) + (1-\lambda) \log p_{\text{att}}(C|X)\}. \quad (14)$$

The CTC probability enforces a monotonic alignment that does not allow large jumps or looping of the same frames. Accordingly, it is possible to choose a hypothesis with a better alignment and exclude irrelevant hypotheses without relying on the coverage term, length penalty, or min/max lengths.

In the beam search process, the decoder needs to compute a score for each partial hypothesis using Eq. (9). However, it is nontrivial to combine the CTC and attention-based scores in the beam

search, because the attention decoder performs it output-label-synchronously while CTC performs it frame-synchronously. To incorporate the CTC probabilities in the hypothesis score, we propose two methods.

Rescoring

The first method is a two-pass approach, in which the first pass obtains a set of complete hypotheses using the beam search, where only the attention-based sequence probabilities are considered. The second pass rescores the complete hypotheses using the CTC and attention probabilities, where the CTC probabilities are obtained by the forward algorithm for CTC (Graves et al., 2006). The rescoring pass obtains the final result according to

$$\hat{C} = \arg\max_{h \in \hat{\Omega}} \{\lambda \alpha_{\text{ctc}}(h, X) + (1 - \lambda)\alpha_{\text{att}}(h, X)\}, \tag{15}$$

where

$$\begin{cases} \alpha_{\text{ctc}}(h, X) & \triangleq \log p_{\text{ctc}}(h|X) \\ \alpha_{\text{att}}(h, X) & \triangleq \log p_{\text{att}}(h|X) \end{cases}. \tag{16}$$

One-pass decoding

The second method is one-pass decoding, in which we compute the probability of each partial hypothesis using CTC and an attention model. Here, we utilize the CTC prefix probability (Graves, 2008) defined as the cumulative probability of all label sequences that have the partial hypothesis h as their prefix:

$$p_{\text{ctc}}(h, \ldots|X) = \sum_{\nu \in (\mathcal{U} \cup \{\texttt{<eos>}\})^+} p_{\text{ctc}}(h \cdot \nu|X),$$

and we define the CTC score as

$$\alpha_{\text{ctc}}(h, X) \triangleq \log p_{\text{ctc}}(h, \ldots|X), \tag{17}$$

where ν represents all possible label sequences except the empty string. The CTC score cannot be obtained recursively as in Eq. (9), but it can be computed efficiently by keeping the forward probabilities over the input frames for each partial hypothesis. Then it is combined with $\alpha_{\text{att}}(h, X)$.

The beam search algorithm for one-pass decoding is shown in Algorithm 1. Ω_l and $\hat{\Omega}$ are initialized in lines 2 and 3 of the algorithm, which are implemented as queues that accept partial hypotheses of the length l and complete hypotheses, respectively. In lines 4–25, each partial hypothesis g in Ω_{l-1} is extended by each label c in the label set $\mathcal{U}$. Each extended hypothesis h is scored in line 11, where CTC and attention-based scores are obtained by $\alpha_{\text{ctc}}()$ and $\alpha_{\text{att}}()$. After that, if $c =$ <eos>, the hypothesis h is assumed to be complete and stored in $\hat{\Omega}$ in line 13. If $c \neq$ <eos>, h is stored in Ω_l in line 15, where the number of hypotheses in Ω_l is checked in line 16. If the number exceeds the beam width, the hypothesis with the worst score in Ω_l is removed by REMOVEWORST() in line 17.

Algorithm 1 Joint CTC/attention one-pass decoding

```
1: procedure ONEPASSBEAMSEARCH(X, L_max)
2:     Ω_0 ← {<sos>}
3:     Ω̂ ← ∅
4:     for l = 1 ... L_max do
5:         Ω_l ← ∅
6:         while Ω_{l-1} ≠ ∅ do
7:             g ← HEAD(Ω_{l-1})
8:             DEQUEUE(Ω_{l-1})
9:             for each c ∈ U ∪ {<eos>} do
10:                h ← g · c
11:                α(h,X) ← λα_ctc(h,X) + (1−λ)α_att(h,X)
12:                if c = <eos> then
13:                    ENQUEUE(Ω̂, h)
14:                else
15:                    ENQUEUE(Ω_l, h)
16:                    if |Ω_l| > beamWidth then
17:                        REMOVEWORST(Ω_l)
18:                    end if
19:                end if
20:            end for
21:        end while
22:        if ENDDETECT(Ω̂, l) = true then
23:            break                          ▷ exit for loop
24:        end if
25:    end for
26:    return arg max_{h∈Ω̂} α(h, X)
27: end procedure
```

In line 11, the CTC and attention model scores are computed for each partial hypothesis. The attention score is easily obtained in the same manner as Eq. (9), whereas the CTC score requires a modified forward algorithm that computes it label-synchronously. The algorithm to compute the CTC score is summarized in Appendix B. By considering the attention and CTC scores during the beam search, partial hypotheses with irregular alignments can be excluded, and the number of search errors is reduced.

We can optionally apply an end detection technique to reduce the computation by stopping the beam search before l reaches L_{max}. Function ENDDETECT($\hat{\Omega}, l$) in line 22 returns `true` if there is little chance of finding complete hypotheses with higher scores as l increases in the future.

In our implementation, the function returns `true` if

$$\sum_{m=0}^{M-1}\left[\max_{h\in\hat{\Omega}:|h|=l-m}\alpha(h,X)-\max_{h'\in\hat{\Omega}}\alpha(h',X)<D_{\text{end}}\right]=M, \quad (18)$$

where D_{end} and M are predetermined thresholds. This equation becomes true if complete hypotheses with smaller scores are generated M times consecutively. This technique is also available in attention-based decoding and rescoring methods described in Sections 3.2.1–3.2.3.

4 Experiments

We used Japanese and Mandarin Chinese ASR benchmarks to show the effectiveness of the proposed joint CTC/attention decoding approach. The main reason for choosing these two languages is that those ideogram languages have relatively shorter lengths for letter sequences than those in alphabet languages, which reduces computational complexities greatly, and makes it easy to handle context information in a decoder network. Our preliminary investigation shows that Japanese and Mandarin Chinese end-to-end ASR can be easily scaled up, and shows state-of-the-art performance without using various tricks developed in English tasks. Also, we would like to emphasize that the system did not use language-specific processing (e.g., morphological analyzer, Pinyin dictionary), and simply used all appeared characters in their transcriptions including Japanese syllable and Kanji, Chinese, Arabic number, and alphabet characters, as they are.

4.1 Corpus of Spontaneous Japanese (CSJ)

We demonstrated ASR experiments by using the Corpus of Spontaneous Japanese (CSJ) (Maekawa et al., 2000). CSJ is a standard Japanese ASR task based on a collection of monologue speech data including academic lectures and simulated presentations. It has a total of 581 hours of training data and three types of evaluation data, where each evaluation task consists of 10 lectures (totally 5 hours). As input features, we used 40 mel-scale filterbank coefficients, with their first and second order temporal derivatives to obtain a total of 120-dimensional feature vector per frame. The encoder was a 4-layer BLSTM with 320 cells in each layer and direction, and linear projection layer is followed by each BLSTM layer. The 2nd and 3rd bottom layers of the encoder read every second hidden state in the network below, reducing the utterance length by the factor of 4. We used the content-based attention mechanism (Chorowski et al., 2015), where the 10 centered convolution filters of width 100 were used to extract the convolutional features. The decoder network was a 1-layer LSTM with 320 cells. The AdaDelta algorithm (Zeiler, 2012) with gradient clipping (Pascanu et al., 2012) was used for the optimization. D_{end} and M in Eq (18) were set as $\log 1e^{-10}$ and 3, respectively. The hybrid CTC/attention ASR was implemented by using the Chainer deep learning toolkit (Tokui et al., 2015).

Table 1 first compares the character error rate (CER) for conventional attention and MTL based end-to-end ASR without the joint decoding. λ in Eq. (7) was set to 0.1. When decoding, we manually set the minimum and maximum lengths of output sequences by 0.025 and 0.15 times input sequence lengths, respectively. The length penalty γ in Eq. (11) was set to 0.1. Multitask learning (MTL) significantly outperformed attention-based ASR in the all evaluation tasks, which confirms the effectiveness of a hybrid CTC/attention architecture. Table 1 also shows that joint decoding, described in Section 3.2, further improved the performance without setting any search parameters (maximum and minimum lengths, length penalty), but only setting a weight parameter $\lambda = 0.1$ in Eq. (15) similar to the MTL case. Figure 2 also compares the dependency of λ on the CER for the CSJ evaluation tasks, and showing that λ was not so sensitive to the performance if we set λ around the value we used at MTL (i.e., 0.1).

We also compare the performance of the proposed MTL-large, which has a larger network (5-layer encoder network), with the conventional state-of-the-art techniques obtained by using linguistic resources. The state-of-the-art CERs of GMM discriminative training and DNN-sMBR/HMM systems are obtained from the Kaldi recipe (Moriya et al., 2015) and a system based on syllable-based CTC with MAP decoding (Kanda et al., 2016). The Kaldi recipe systems use academic lectures (236h) for AM training and all training-data transcriptions for LM training. Unlike the proposed method, these methods use linguistic resources including a morphological analyzer, pronunciation dictionary, and language model. Note that since the amount of training

Table 1: Character error rate (CER) for conventional attention and hybrid CTC/attention end-to-end ASR. Corpus of Spontaneous Japanese speech recognition (CSJ) task.

Model	Hour	Task1	Task2	Task3
Attention	581	11.4	7.9	9.0
MTL	581	10.5	7.6	8.3
MTL + joint decoding (rescoring)	581	10.1	7.1	7.8
MTL + joint decoding (one pass)	581	10.0	7.1	7.6
MTL-large + joint decoding (rescoring)	581	**8.4**	6.2	**6.9**
MTL-large + joint decoding (one pass)	581	**8.4**	**6.1**	**6.9**
GMM-discr. (Moriya et al., 2015)	236 for AM, 581 for LM	11.2	9.2	12.1
DNN/HMM (Moriya et al., 2015)	236 for AM, 581 for LM	9.0	7.2	9.6
CTC-syllable (Kanda et al., 2016)	581	9.4	7.3	7.5

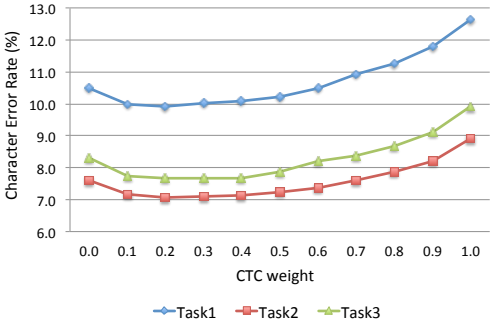

Figure 2: The effect of weight parameter λ in Eq. (14) on the CSJ evaluation tasks (The CERs were obtained by one-pass decoding).

data and experimental configurations of the proposed and reference methods are different, it is difficult to compare the performance listed in the table directly. However, since the CERs of the proposed method are superior to those of the best reference results, we can state that the proposed method achieves the state-of-the-art performance.

4.2 Mandarin telephone speech

We demonstrated ASR experiments on HKUST Mandarin Chinese conversational telephone speech recognition (MTS) (Liu et al., 2006). It has 5 hours recording for evaluation, and we extracted 5 hours from training data as a development set, and used the rest (167 hours) as a training set. All experimental conditions were same as those in Section 4.1 except that we used the $\lambda = 0.5$ in training and decoding instead of 0.1 based on our preliminary investigation and 80 mel-scale filterbank coefficients with pitch features as suggested in (Miao et al., 2016). In decoding, we also added a result of the coverage-term based decoding (Chorowski and Jaitly, 2016), as discussed in Section 3.2 ($\eta = 1.5, \tau = 0.5, \gamma = -0.6$ for attention model and $\eta = 1.0, \tau = 0.5, \gamma = -0.1$ for MTL), since it was difficult to eliminate the irregular alignments during decoding by only tuning the maximum and minimum lengths and length penalty (we set the minimum and maximum lengths of output sequences by 0.0 and 0.1 times input sequence lengths, respectively and set $\gamma = 0.6$ in Table 2).

Table 2 shows the effectiveness of MTL and joint decoding over the attention-based approach, especially showing the significant improvement of the joint CTC/attention decoding. Similar to the CSJ experiments in Section 4.1, we did not use the length-penalty term or the coverage term in joint decoding. This is an advantage of joint decoding over conventional approaches that require many tuning parameters. We also generated more training data by linearly scaling the audio lengths by factors of 0.9 and 1.1 (speed perturb.). The final model achieved **29.9**% without using linguistic resources, which defeats moderate state-of-the-art systems including CTC-based methods[2].

4.3 Decoding speed

We evaluated the speed of the joint decoding methods described in Section 3.2.3. ASR decoding was performed with different beam widths of 1, 3, 5, 10, and 20, and the processing time and CER were measured using a computer with Intel(R) Xeon(R) processors, E5-2690 v3, 2.6 GHz. Although the processors were multicore CPUs and the computer had GPUs, we ran the decoding program as a

[2] Although the proposed method did not reach the performance obtained by a time delayed neural network (TDNN) with lattice-free sequence discriminative training (Povey et al., 2016), our recent work scored **28.0**%, and outperformed the lattice-free MMI result with advanced network architectures.

Table 2: Character error rate (CER) for conventional attention and hybrid CTC/attention end-to-end ASR. HKUST Mandarin Chinese conversational telephone speech recognition (MTS) task.

Model	dev	eval
Attention	40.3	37.8
MTL	38.7	36.6
Attention + coverage	39.4	37.6
MTL + coverage	36.9	35.3
MTL + joint decoding (rescoring)	35.9	34.2
MTL + joint decoding (one pass)	35.5	33.9
MTL-large (speed perturb.) + joint decoding (rescoring)	31.1	30.1
MTL-large (speed perturb.) + joint decoding (one pass)	**31.0**	**29.9**
DNN/HMM	–	35.9
LSTM/HMM (speed perturb.)	–	33.5
CTC with language model (Miao et al., 2016)	–	34.8
TDNN/HMM, lattice-free MMI (speed perturb.) (Povey et al., 2016)	–	28.2

single-threaded process on a CPU to investigate its basic computational cost.

Table 3: RTF versus CER for the one-pass and rescoring methods.

Task	Beam width	Rescoring		One pass	
		RTF	CER	RTF	CER
CSJ Task1	1	0.66	10.9	0.66	10.7
	3	1.11	10.3	1.02	10.1
	5	1.50	10.2	1.31	10.0
	10	2.46	10.1	2.07	10.0
	20	5.02	10.1	3.76	10.0
HKUST Eval set	1	0.68	37.1	0.65	35.9
	3	0.89	34.9	0.86	34.4
	5	1.04	34.6	1.03	34.2
	10	1.55	34.4	1.50	34.0
	20	2.66	34.2	2.55	33.9

Table 3 shows the relationships between the real-time factor (RTF) and the CER for the CSJ and HKUST tasks. We evaluated the rescoring and one-pass decoding methods when using the end detection in Eq. (18). In every beam width, we can see that the one-pass method runs faster with an equal or lower CER than the rescoring method. This result demonstrates that the one-pass decoding is effective for reducing search errors. Finally, we achieved 1xRT with one-pass decoding when using a beam width around 3 to 5, even though it was a single-threaded process on a CPU. However, the decoding process has not yet achieved real-time ASR since CTC and the attention mechanism need to access all of the frames of the input utterance even when predicting the first label. This is an essential problem of most end-to-end ASR approaches and will be solved in future work.

5 Summary and discussion

This paper proposes end-to-end ASR by using joint CTC/attention decoding, which outperformed ordinary attention-based end-to-end ASR by solving the misalignment issues. The joint decoding methods actually reduced most of the irregular alignments, which can be confirmed from the examples of recognition errors and alignment plots shown in Appendix C.

The proposed end-to-end ASR does not require linguistic resources, such as morphological analyzer, pronunciation dictionary, and language model, which are essential components of conventional Japanese and Mandarin Chinese ASR systems. Nevertheless, the method achieved comparable/superior performance to the state-of-the-art conventional systems for the CSJ and MTS tasks. In addition, the proposed method does not require GMM/HMM construction for initial alignments, DNN pre-training, lattice generation for sequence discriminative training, complex search in decoding (e.g., FST decoder or lexical tree search based decoder). Thus, the method greatly simplifies the ASR building process, reducing code size and complexity.

Future work will apply this technique to the other languages including English, where we have to solve an issue of long sequence lengths, which requires heavy computation cost and makes it difficult to train a decoder network. Actually, neural machine translation handles this issue by using a sub word unit (concatenating several letters to form a new sub word unit) (Wu et al., 2016), which would be a promising direction for end-to-end ASR.

A Location-based attention mechanism

This section provides the equations of a location-based attention mechanism Attention$(\cdot)$ in Eq. (5).

$$a_{lt} = \text{Attention}(\{a_{l-1}\}_t, \mathbf{q}_{l-1}, \mathbf{h}_t),$$

where $\{a_{l-1}\}_t = [a_{l-1,1}, \cdots, a_{l-1,T}]^\top$. To obtain a_{lt}, we use the following equations:

$$\{\mathbf{f}_t\}_t = \mathbf{K} * \mathbf{a}_{l-1} \tag{19}$$

$$e_{lt} = \mathbf{g}^\top \tanh(\mathbf{G}^{\text{q}}\mathbf{q}_{l-1} + \mathbf{G}^{\text{h}}\mathbf{h}_t + \mathbf{G}^{\text{f}}\mathbf{f}_t + \mathbf{b}) \tag{20}$$

$$a_{lt} = \frac{\exp(e_{tl})}{\sum_t \exp(e_{tl})} \tag{21}$$

$\mathbf{K}$, $\mathbf{G}^{\text{q}}$, $\mathbf{G}^{\text{h}}$, $\mathbf{G}^{\text{f}}$ are matrix parameters. $\mathbf{b}$ and $\mathbf{g}$ are vector parameters. $*$ denotes convolution along input feature axis t with matrix $\mathbf{K}$ to produce feature $\{\mathbf{f}_t\}_t$.

Algorithm 2 CTC hypothesis score

1: **function** $\alpha_{\text{ctc}}(h, X)$
2: $g, c \leftarrow h$ ▷ split h into the last label c and the rest g
3: **if** $c =$ <eos> **then**
4: **return** $\log\{\gamma_T^{(n)}(g) + \gamma_T^{(b)}(g)\}$
5: **else**
6: $\gamma_1^{(n)}(h) \leftarrow \begin{cases} p(z_1 = c|X) & \text{if } g = \text{<sos>} \\ 0 & \text{otherwise} \end{cases}$
7: $\gamma_1^{(b)}(h) \leftarrow 0$
8: $\Psi \leftarrow \gamma_1^{(n)}(h)$
9: **for** $t = 2 \dots T$ **do**
10: $\Phi \leftarrow \gamma_{t-1}^{(b)}(g) + \begin{cases} 0 & \text{if last}(g) = c \\ \gamma_{t-1}^{(n)}(g) & \text{otherwise} \end{cases}$
11: $\gamma_t^{(n)}(h) \leftarrow \left(\gamma_{t-1}^{(n)}(h) + \Phi\right) p(z_t = c|X)$
12: $\gamma_t^{(b)}(h) \leftarrow \left(\gamma_{t-1}^{(b)}(h) + \gamma_{t-1}^{(n)}(h)\right) p(z_t =$ <b>$|X)$
13: $\Psi \leftarrow \Psi + \Phi \cdot p(z_t = c|X)$
14: **end for**
15: **return** $\log(\Psi)$
16: **end if**
17: **end function**

B CTC-based hypothesis score

The CTC score $\alpha_{\text{ctc}}(h, X)$ in Eq. (17) is computed as shown in Algorithm 2. Let $\gamma_t^{(n)}(h)$ and $\gamma_t^{(b)}(h)$ be the forward probabilities of the hypothesis h over the time frames $1 \dots t$, where the superscripts (n) and (b) denote different cases in which all CTC paths end with a nonblank or blank symbol, respectively. Before starting the beam search, $\gamma_t^{(n)}()$ and $\gamma_t^{(b)}()$ are initialized for $t = 1, \dots, T$ as

$$\gamma_t^{(n)}(\text{<sos>}) = 0, \tag{22}$$

$$\gamma_t^{(b)}(\text{<sos>}) = \prod_{\tau=1}^{t} \gamma_{\tau-1}^{(b)}(\text{<sos>}) p(z_\tau = \text{<b>}|X), \tag{23}$$

where we assume that $\gamma_0^{(b)}(\text{<sos>}) = 1$ and <b> is a blank symbol. Note that the time index t and input length T may differ from those of the input utterance X owing to the subsampling technique for the encoder (Povey et al., 2016; Chan et al., 2015).

In Algorithm 2, the hypothesis h is first split into the last label c and the rest g in line 2. If c is <eos>, it returns the logarithm of the forward probability assuming that h is a complete hypothesis in line 4. The forward probability of h is given by

$$p_{\text{ctc}}(h|X) = \gamma_T^{(n)}(g) + \gamma_T^{(b)}(g) \tag{24}$$

according to the definition of $\gamma_t^{(n)}()$ and $\gamma_t^{(b)}()$. If c is not <eos>, it computes the forward proba-

bilities $\gamma_t^{(n)}(h)$ and $\gamma_t^{(b)}(h)$, and the prefix probability $\Psi = p_{\text{ctc}}(h, \ldots | X)$ assuming that h is not a complete hypothesis. The initialization and recursion steps for those probabilities are described in lines 6–14. In this function, we assume that whenever we compute the probabilities $\gamma_t^{(n)}(h)$, $\gamma_t^{(b)}(h)$ and Ψ, the forward probabilities $\gamma_t^{(n)}(g)$ and $\gamma_t^{(b)}(g)$ have already been obtained through the beam search process because g is a prefix of h such that $|g| < |h|$.

C Examples of irregular alignments

We list examples of irregular alignments caused by attention-based ASR. Figure 3 shows an example of repetitions of word chunks. The first chunk of blue characters in attention-based ASR (MTL) is appeared again, and the whole second chunk part becomes insertion errors. Figure 4 shows an example of deletion errors. The latter half of the sentence in attention-based ASR (MTL) is broken, which causes deletion errors. The hybrid CTC/attention with both multitask learning and joint decoding avoids these issues. Figures 5 and 6 show alignment plots corresponding to Figs. 3 and 4, respectively, where X-axis shows time frames and Y-axis shows the character sequence hypothesis. These visual plots also demonstrate that the proposed joint decoding approach can suppress irregular alignments.

Found in Translation: Reconstructing Phylogenetic Language Trees from Translations

Abstract

Translation has played an important role in trade, law, commerce, politics, and literature for thousands of years. Translators have always tried to be invisible; ideal translations should look as if they were written originally in the target language. We show that traces of the source language remain in the translation product to the extent that it is possible to uncover the history of the source language by looking only at the translation. Specifically, we automatically reconstruct phylogenetic language trees from *monolingual* texts (translated from several source languages). The signal of the source language is so powerful that it is retained even after two phases of translation. This strongly indicates that source language interference is the most dominant characteristic of translated texts, overshadowing the more subtle signals of universal properties of translation.

1 Introduction

Translation has played a major role in human civilization since the rise of law, religion, and trade in multilingual societies. Evidence of scribe translations goes as far back as four millennia ago, to the time of Hammurabi; this practice is also mentioned in the Bible (Esther 1:22; 8:9). For thousands of years, translators have tried to remain invisible, setting a standard according to which the act of translation should be seamless, and its product should look as if it were written originally in the target language. Cicero (106-43 BC) commented on his translation ethics, "I did not hold it necessary to render word for word, but I preserved the general style and force of the language." These words were echoed 500 years later by St. Jerome (347-420 CE), also known as the patron saint of translators, who wrote, "I render, not word for word, but sense for sense." Translator tendency for invisibility has peaked in the past 150 years in the English speaking world (Venuti, 2008), in spite of some calls for "foreignization" in translations, e.g., the German Romanticists, especially the translations from Greek by Friedrich Hölderlin (Steiner, 1975) and Nabokov's translation of Eugene Onegin. These, however, as both Steiner (1975) and Venuti (2008) argue, are the exception to the rule. In fact, in recent years, the quality of translations has been standardized (ISO 17100). Importantly, the translations we studied in our work conform to this standard.

Despite the continuous efforts of translators, translations are known to feature unique characteristics that set them apart from non-translated texts, referred to as *originals* here (Toury, 1980, 1995; Frawley, 1984; Baker, 1993). This is not the result of poor translation, but rather a statistical phenomenon: various features distribute differently in originals than in translations (Gellerstam, 1986).

Several factors may account for the differences between originals and translations; many are classified as *universal* features of translation. Cognitively speaking, all translations, regardless of the source and target language, are susceptible to the same constraints. Therefore, translation products are expected to share similar artifacts. Such universals include *simplification*: the tendency to make complex source structures simpler in the target (Blum-Kulka and Levenston, 1983; Vanderauwerea, 1985); *standardization*: the tendency to over-conform to target language standards (Toury, 1995); and *explicitation*: the tendency to render implicit source structures more explicit in the target language (Blum-Kulka, 1986; Øverås, 1998).

In contrast to translation universals, *interference* reflects the "fingerprints" of the source lan-

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 530–540
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1049

guage on the translation product. Toury (1995) defines interference as "phenomena pertaining to the make-up of the source text tend to be transferred to the target text". Interference, by definition, is a language-pair specific phenomenon; isomorphic structures shared by the source and target languages can easily replace one another, thereby manifesting the underlying process of cross-linguistic influence of the source language on the translation outcome. Pym (2008) points out that interference is a set of both *segmentational and macrostructural features*.

Our main hypothesis is that, due to interference, languages with shared isomorphic structures are likely to share more features in the target language of a translation. Consequently, the distance between two languages, when assessed using such features, can be retained to some extent in translations from these two languages to a third one. Furthermore, we hypothesize that by extracting structures from translated texts, we can generate a phylogenetic tree that reflects the "true" distances among the source languages. Finally, we conjecture that the quality of such trees will improve when constructed using features that better correspond to interference phenomena, and will deteriorate using more universal features of translation.

The main contribution of this paper is thus the demonstration that interference phenomena in translation are powerful to an extent that facilitates clustering source languages into families and (partially) reconstructing intra-families ties; so much so, that these results hold even after two rounds of translation. Moreover, we perform analysis of various linguistic phenomena in the source languages, laying out quantitative grounds for the language typology reconstruction results.

2 Related work

A number of works in historical linguistics have applied methods from the field of bioinformatics, in particular algorithms for generating phylogenetic trees (Ringe et al., 2002; Nakhleh et al., 2005a,b; Ellison and Kirby, 2006; Boc et al., 2010). Most of them rely on lists of *cognates*, words in multiple languages with a common origin that share a similar meaning and a similar pronunciation (Dyen et al., 1992; Rexová et al., 2003). These works all rely on multilingual data, whereas we construct phylogenetic trees from texts in a single language.

The claim that translations exhibit unique properties is well established in translation studies literature (Toury, 1980; Frawley, 1984; Baker, 1993; Toury, 1995). Based on this assumption, several works use text classification techniques employing supervised, and recently also unsupervised, machine learning approaches, to distinguish between originals and translations (Baroni and Bernardini, 2006; Ilisei et al., 2010; Koppel and Ordan, 2011; Volansky et al., 2015; Rabinovich and Wintner, 2015; Avner et al., 2016). The features used in these studies reflect both universal and interference-related traits. Along the way, interference was proven to be a robust phenomenon, operating in every single sentence, even on the morpheme level (Avner et al., 2016). Interference can also be studied on pairs of source- and target languages and focus, for example, on word order (Eetemadi and Toutanova, 2014).

The powerful signal of interference is evident, e.g., by the finding that a classifier trained to distinguish between originals and translations from one language, exhibits lower accuracy when tested on translations from another language, and this accuracy deteriorates proportionally to the distance between the source and target languages (Koppel and Ordan, 2011). Consequently, it is possible to accurately distinguish among translations from various source languages (van Halteren, 2008).

A related task, identifying the native tongue of English language students based only on their writing in English, has been the subject of recent interest (Tetreault et al., 2013). The relations between this task and identification of the source language of translation has been emphazied, e.g., by Tsvetkov et al. (2013). English texts produced by native speakers of a variety of languages have been used to reconstruct phylogenetic trees, with varying degrees of success (Nagata and Whittaker, 2013; Berzak et al., 2014). In contrast to language learners, however, translators translate into their mother tongue, so the texts we studied were written by highly competent native speakers. Our work is the first to construct phylogenetic trees from translations.

3 Methodology

3.1 Dataset

This corpus-based study uses Europarl (Koehn, 2005), the proceedings of the European Parliament and their translations into all the official Eu-

ropean Union (EU) languages. Europarl is one of the most popular parallel resources in natural language processing, and has been used extensively in machine translation. We use a version of Europarl spanning the years 1999 through 2011, in which the direction of translation has been established through a comprehensive cross-lingual validation of the speakers' original language (Rabinovich et al., 2015).

All parliament speeches were translated[1] from the original language into all other EU languages (21 at the time) using English as an intermediate, *pivot* language. We thus refer to translations into English as *direct*, while translations into all other languages, via English as a third language, are *indirect*. We hypothesize that indirect translation will obscure the markers of the original language in the final translation. Nevertheless, we expect (weakened) fingerprints of the source language to be identifiable in the target despite the pivot, presumably resulting in somewhat poorer phylogenetic trees.

We focus on 17 source languages, grouped into 3 language families: Germanic, Romance, and Balto-Slavic.[2] These include translations to English and to French from Bulgarian (BG), Czech (CS), Danish (DA), Dutch (NL), English (EN), French (FR), German (DE), Italian (IT), Latvian (LV), Lithuanian (LT), Polish (PL), Portuguese (PT), Romanian (RO), Slovak (SK), Slovenian (SL), Spanish (ES), and Swedish (SV). We also included texts written originally in English and French.

All datasets were split on sentence boundary, cleaned (empty lines removed), tokenized, and annotated for part-of-speech (POS) using the Stanford tools (Manning et al., 2014). In all the tree reconstruction experiments, we sampled equal-sized chunks from each source language, using as much data as available for all languages. This yielded $27,000$ tokens from translations to English, and $30,000$ tokens from translations into French.

[1]The common practice is that one translates into one's native language; in particular, this practice is strictly imposed in the EU parliament where a translator must have perfect proficiency in the target language, meeting very high standards of accuracy.

[2]We excluded source languages with insufficient amounts of data, along with Greek, which is the only representative of the Hellenic family.

3.2 Features

Following standard practice (Volansky et al., 2015; Rabinovich and Wintner, 2015), we represented both original and translated texts as feature vectors, where the choice of features determines the extent to which we expect source-language interference to be present in the translation product. Crucially, the features abstract away from the contents of the texts and focus on their structure, reflecting, among other things, morphological and syntactic patterns. We use the following feature sets: 1. The top-1,000 most frequent POS trigrams, reflecting shallow syntactic structure. 2. Function words (FW), words known to reflect grammar of texts in numerous classification tasks, as they include non-content words such as articles, prepositions, etc. (Koppel and Ordan, 2011).[3] 3. Cohesive markers (Hinkel, 2001); these words and phrases are assumed to be over-represented in translated texts, where, for example, an implicit contrast in the original is made explicit in the target text with words such as *'but'* or *'however'*.[4] Note that the first two feature sets are strongly associated with interference, whereas the third is assumed to be universal and an instance of explicitation. We therefore expect trees based on the first two feature sets to be much better than those based on the third.

3.3 The Indo-European phylogenetic tree

The last few decades produced a large body of research on the evolution of individual languages and language families. While the existence of the Indo-European (IE) family of languages is an established fact, its history and origins are still a matter of much controversy (Pereltsvaig and Lewis, 2015). Furthermore, the actual subgroupings of languages within this family are not clear-cut (Ringe et al., 2002). Consequently, algorithms that attempt to reconstruct the IE languages tree face a serious evaluation challenge (Ringe et al., 2002; Rexová et al., 2003; Nakhleh et al., 2005a).

To evaluate the quality of the reconstructed trees, we define a metric to accurately assess their distance from the "true" tree. The tree that we use as ground truth (Serva and Petroni, 2008) has

[3]For French we used the list of FW available at https://code.google.com/archive/p/stop-words/.

[4]For French we used http://utilisateurs.linguist.univ-paris-diderot.fr/~croze/D/Lexconn.xml.

several advantages. First, it is similar to a well-accepted tree (Gray and Atkinson, 2003) (which is not insusceptible to criticism (Pereltsvaig and Lewis, 2015)). The differences between the two are mostly irrelevant for the group of languages that we address in this research. Second, it is a binary tree, facilitating comparison with the trees we produce, which are also binary branching. Third, its branches are decorated with the approximate year in which splitting occurred. This provides a way to induce the distance between two languages, modeled as lengths of paths in the tree, based on chronological information.

We projected the gold tree (Serva and Petroni, 2008) onto the set of 17 languages we considered in this work, preserving branch lengths. Figure 1 depicts the resulting gold-standard subtree.

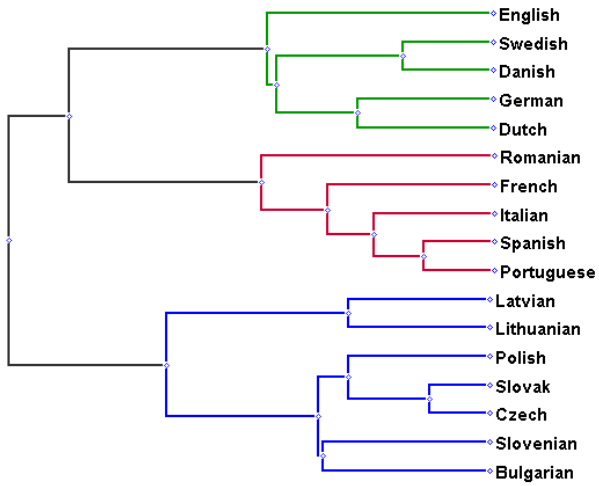

Figure 1: Gold standard tree, pruned

We reconstructed phylogenetic language trees by performing agglomerative (hierarchical) clustering of feature vectors extracted separately from English and French translations. We performed clustering using the variance minimization algorithm (Ward Jr, 1963) with Euclidean distance (the implementation available in the Python SciPy library). All feature values were normalized to a zero-one scale prior to clustering.

3.4 Evaluation methodology

To evaluate the quality of the trees we generate, we compute their similarity to the gold standard via two metrics: *unweighted*, assessing only structural (topological) similarity, and *weighted*, estimating similarity based on both structure and branching length.

Several methods have been proposed for evaluating the quality of phylogenetic language trees (Pompei et al., 2011; Wichmann and Grant, 2012; Nouri and Yangarber, 2016). A popular metric is the Robinson-Foulds (RF) methodology (Robinson and Foulds, 1981), which is based on the symmetric difference in the number of *bi-partitions*, the ways in which an edge can split the leaves of a tree into two sets. The distance between two trees is then defined as the number of splits induced by one of the trees, but not the other. Despite its popularity, the RF metric has well-known shortcomings; for example, relocating a single leaf can result in a tree maximally distant from the original one (Böcker et al., 2013). Additional methodologies for evaluating phylogenetic trees include *branch score distance* (Kuhner and Felsenstein, 1994), enhancing RF with branch lengths, *purity score* (Heller and Ghahramani, 2005), and *subtree score* (Teh et al., 2009). The latter two ignore branch lengths and only consider structural similarities for evaluation.

We opted for a simple yet powerful adaptation of the L2-norm to leaf-pair distance, inherently suitable for both unweighted and weighted evaluation. Given a tree of N leaves, l_i, $i \in [1..N]$, the *weighted distance* between two leaves l_i, l_j in a tree τ, denoted $D_\tau(l_i, l_j)$, is the sum of the weights of all edges on the shortest path between l_i and l_j. The *unweighted distance* sums up the *number* of the edges in this path (i.e., all weights are equal to 1). The distance $Dist(\tau, g)$ between a generated tree τ and the gold tree g is then calculated by summing the square differences between all leaf-pair distances (whether weighted or unweighted) in the two trees:

$$Dist(\tau, g) = \sum_{i,j \in [1..N]; i \neq j} (D_\tau(l_i, l_j) - D_g(l_i, l_j))^2$$

4 Detection of Translations and their Source Language

4.1 Identification of translation

We first reconfirmed that originals and translations are easily separable, extending results of supervised classification of O vs. T (where O refers to original English texts, and T to translated English) (Baroni and Bernardini, 2006; van Halteren, 2008; Volansky et al., 2015) to the 16 original languages considered in this work. We also conducted similar experiments with French originals and translations. We used 200 chunks of approximately 2K

tokens (respecting sentence boundaries) from both O and T, and normalized the values of lexical features by the number of tokens in each chunk. For classification, we used Platt's sequential minimal optimization algorithm (Keerthi et al., 2001; Hall et al., 2009) to train support vector machine classifiers with the default linear kernel. We evaluated the results with 10-fold cross-validation.

Table 1 presents the classification accuracy of (English and French) O vs. T using each feature set. In line with previous works (Ilisei et al., 2010; Volansky et al., 2015; Rabinovich and Wintner, 2015), the binary classification results are highly accurate, achieving over 95% accuracy using POS-trigrams and function words for both English and French, and above 85% using cohesive markers.

Feature	English	French
POS-trigrams	97.60	98.40
Function words	96.45	95.15
Cohesive markers	86.50	85.25

Table 1: Classification accuracy (%) of English and French O vs. T

4.2 Identification of source language

Identifying the source language of translated texts is a task in which machines clearly outperform humans (Baroni and Bernardini, 2006). Koppel and Ordan (2011) performed 5-way classification of texts translated from Italian, French, Spanish, German, and Finnish, achieving an accuracy of 92.7%. Furthermore, misclassified instances were more frequently assigned to genetically related languages.

We extended this experiment to 14 languages representing 3 language families (the number of languages was limited by the amount of data available). We extracted 100 chunks of 1,000 tokens each from each source language and classified the translated English (and, separately, French) texts into 14 classes using the best performing POS-trigrams feature set. Cross-validation evaluation yielded an accuracy of 75.61% on English translations (note that the baseline is $100/14 = 7.14\%$).

The corresponding confusion matrix, presented in Figure 2 (left), reveals interesting phenomena: much of the confusion resides within language families, framed by the bold line in the figure. For example, instances of Germanic languages are almost perfectly classified as Germanic, with only a few chunks assigned to other language families. The evident intra-family linguistic ties exposed by this experiment support the intuition that cross-linguistic transfer in translation is governed by typological properties of the source language. That is, translations from *related* sources tend to resemble each other to a greater extent than translations from more *distant* languages.

This observation is further supported by the evaluation of a three-way classification task, where the goal is to only identify the language family (Germanic, Romance, or Balto-Slavic): the accuracy of this task is 90.62%. Note also that the mis-classified instances of both Romance and Germanic languages are nearly never attributed to Balto-Slavic languages, since Germanic and Romance are much closer to each other than to Balto-Slavic.

Figure 2 (right) displays a similar confusion matrix, the only difference being that *French* translations are classified. We attribute the lower cross-validation accuracy (48.92%, reflected also by the lower number of correctly assigned instances on the matrix diagonal, compared to English) to the intervention of the pivot language in the translation process. Nevertheless, the confusion is still mainly constrained to intra-family boundaries.

5 Reconstruction of Phylogenetic Language Trees

5.1 Reconstructing language typology

Inspired by the results reported in Section 4.2, we generated phylogenetic language trees from both English and French texts translated from the other European languages. We hypothesized that interference from the source language was present in the translation product to an extent that would facilitate the construction of a tree sufficiently similar to the gold IE tree (Figure 1).

The best trees, those closest to the gold standard, were generated using POS-trigrams: these are the features that are most closely associated with source-language interference (see Section 3.2). Figure 3 depicts the trees produced from English and French translations using POS-trigrams. Both trees reasonably group individual languages into three language-family branches. In particular, they cluster the Germanic and Romance languages closer than the Balto-Slavic. Capturing the more subtle intra-family ties turned out to be

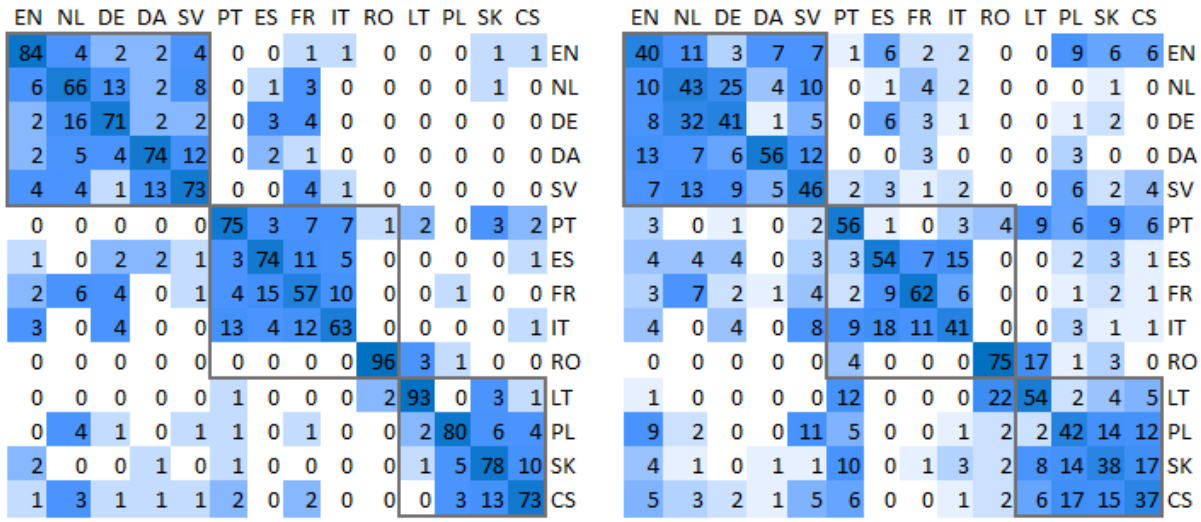

Figure 2: Confusion matrix of 14-way classification of English (left) and French (right) translations. The actual class is represented by rows and the predicted one by columns.

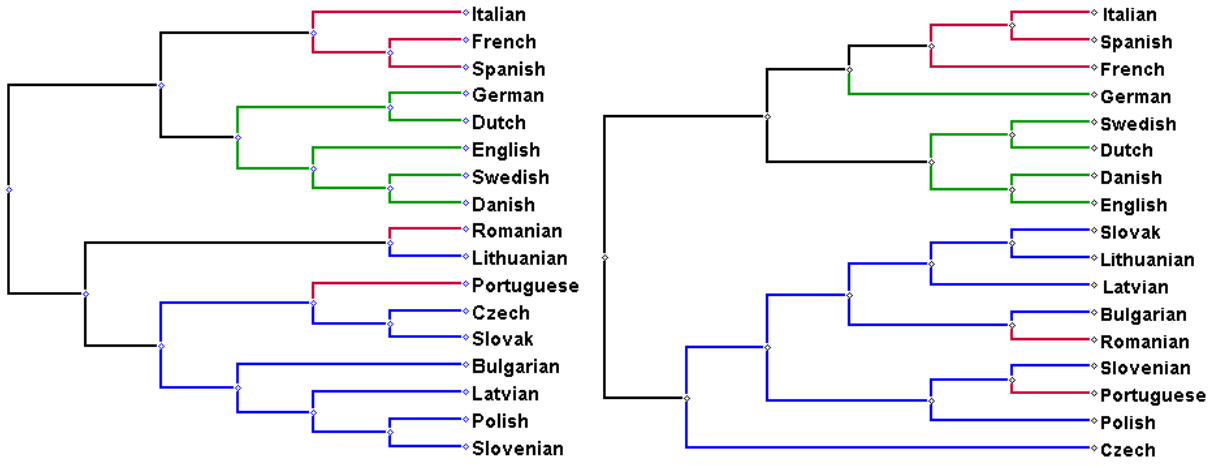

Figure 3: Phylogenetic language trees generated with English (left) and French (right) translations

more challenging, although English outperformed its French counterpart on this task by almost perfectly reconstructing the Germanic sub-tree.

We repeated the clustering experiments with various feature sets. For each feature set, we randomly sampled equally-sized subsets of the dataset (translated from each of the source languages), represented the data as feature vectors, generated a tree by clustering the feature vectors, and then computed the weighted and unweighted distances between the generated tree and the gold standard. We repeated this procedure 50 times for each feature set, and then averaged the resulting distances. We report this average and the standard deviation.[5]

5.2 Evaluation results

The *unweighted* evaluation results are listed in Table 2. For comparison, we also present the distance obtained for a random tree, generated by sampling a random distance matrix from the uniform $(0, 1)$ distribution. The reported random tree evaluation score is averaged over 1000 experiments. Similarly, we present *weighted* evaluation results in Table 3. All distances are normalized to a zero-one scale, where the bounds – zero and one – represent the identical and the most distant tree w.r.t. the gold standard, respectively.

The results reveal several interesting observations. First, as expected, POS-trigrams induce

[5]All the trees, both cladograms (with branches of equal length) and phylograms (with branch lengths proportional to the distance between two nodes), can be found at http://cl.haifa.ac.il/projects/translationese/acl2017_found-in-translation_trees.pdf

Target language	English		French	
Feature	AVG	STD	AVG	STD

Table 3: Weighted evaluation of generated trees. AVG represents the average distance of a tree from the gold standard. The lowest distance in a column is boldfaced.

trees closest to the gold standard among *distinct* feature sets. This corroborates our hypothesis that this feature set carries over interference of the source language to a considerable extent (see Section 1). Furthermore, function words achieve more moderate results, but still much better than random. This reflects the fact that these features carry over some grammatical constructs of the source language into the translation product.

Finally, in all cases, the least accurate tree, nearly random, is produced by cohesive markers; this is an evidence that this feature is source-language agnostic and reflects the universal effect of explicitation (see Section 3.2). While cohesive markers are a good indicator of translations, they reflect properties that are not indicative of the source language. The combination of POS-trigrams and FW yields the best tree in three out of four cases, implying that these feature sets capture different, complementary aspects of the source-language interference.

Surprisingly, reasonably good trees were also generated from French translations; yet, these trees are systematically worse than their English counterparts. The original signal of the source language is distorted twice: first via a Germanic language (English) and then via a Romance language (French). However, the signal is strong enough to yield a clear phylogenetic tree of the source languages. Interference is thus revealed to be an extremely powerful force, partially resistant to intermediate distortions.

6 Analysis

We demonstrated that source-language traces are dominant in translation products to an extent that facilitates reconstruction of the history of the source languages. We now inspect some of these phenomena in more detail to better understand the prominent characteristics of interference. For each phenomenon, we computed the frequencies of patterns that reflect it in texts translated to English from each individual language, and averaged the measures over each language family (Germanic, Romance, and Balto-Slavic). Figure 4 depicts the results.

6.1 Definite articles

Languages vary greatly in their use of articles. Like other Germanic languages, English has both definite (*'a'*) and indefinite (*'the'*) articles. However, many languages only have definite articles and some only have indefinite articles. Romance languages, and in particular the five Romance languages of our dataset, have definite articles that can sometimes be omitted, but not as commonly as in English. Balto-Slavic languages typically do not have any articles.

Mastering the use of articles in English is notoriously hard, leading to errors in non-native speakers (Han et al., 2006). For example, native speakers of Slavic languages tend to *over*use definite articles in German (Hirschmann et al., 2013). Similarly, we expect translations from Balto-Slavic languages to overuse *'the'*. We computed the frequencies of *'the'* in translations to English from each of the three language families. The results show a significant overuse of *'the'* in translations from Balto-Slavic languages, and some overuse in translations from Romance languages.

6.2 Possessive constructions

Languages also vary in the way they mark possession. English marks it in three ways: with the clitic *''s'* (*'the guest's room'*), with a prepositional phrase containing *'of'* (*'the room of the guest'*), and, like in other Germanic languages, with noun compounds (*'guest room'*). Compounds are considerably less frequent in Romance languages

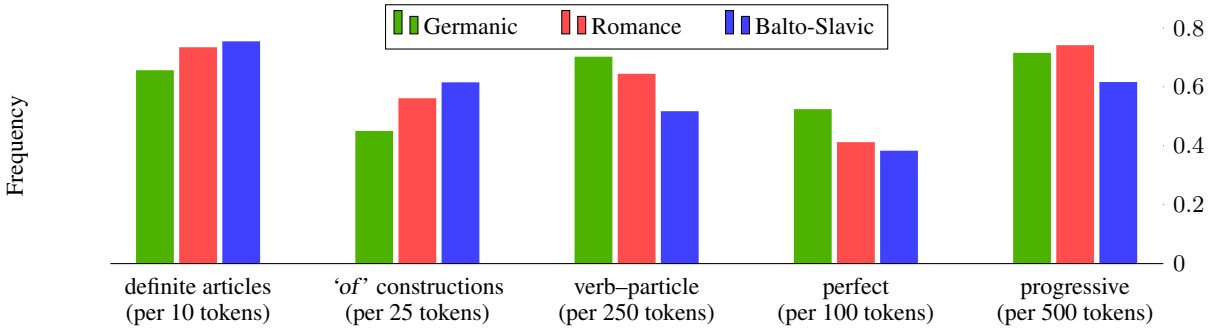

Figure 4: Frequencies reflecting various linguistic phenomena (Sections 6.1– 6.4) in English translations

(Swan and Smith, 2001); Balto-Slavic indicates possession using case-marking. Languages also vary with respect to whether or not possession is head-marked. In Balto-Slavic languages, the genitive case is head-marked, which reverses the order of the two nouns with respect to the common English *''s'* construction. Since copying word order, if possible across languages, is one of the major features of interference (Eetemadi and Toutanova, 2014), we anticipated that Balto-Slavic languages will exhibit the highest rate of noun-*'of'*-NP constructions. This would be followed by Romance languages, in which this construction is highly common, and then by Germanic languages, where noun compounds can often be copied as such. The results are consistent with our expectations.

6.3 Verb-particle constructions

Verb-particle constructions (e.g., *'turn down'*) consist of verbs that combine with a particle to create a new meaning (Dehé et al., 2002). Such constructions are much more common in Germanic languages (Iacobini and Masini, 2005), hence we expect to encounter their equivalents in English translations more frequently. We computed the frequencies of these constructions in the data; the results show a clear overuse of verb-particle constructions in translations from Germanic, and an underuse of such constructions in translations from Balto-Slavic.

6.4 Tense and aspect

Tense and aspect are expressed in different ways across languages. English, like other Germanic languages, uses a full system of aspectual distinctions, expressed via perfect and progressive forms (with the auxiliary verbs *'have'* or *'be'*). Balto-Slavic, in contrast, has no such system, and the distinction is marked lexically, by having two types of verbs. Romance languages are in between, with both lexical and grammatical distinctions. We computed the frequencies of perfect forms (defined as the auxiliary *'have'* followed by the past participle form), and the progressive forms (defined as the auxiliary *'be'* plus a present participle form). Indeed, Germanic overuses the perfect aspect significantly; the use of the progressive aspect also varies across language families, exhibiting the lowest frequency in translations from Balto-Slavic.

7 Conclusion

Translations may be considered distortions of the original text, but this distortion is far from random. It depicts a very clear picture, reflecting language typology to the extent that disregarding the sources altogether, a phylogenetic tree can be reconstructed from a monolingual corpus consisting of multiple translations. This holds for the product of highly professional translators, who conform to a common standard, and whose products are edited by native speakers, like themselves. It even holds after two phases of translations. We are presently trying to extend these results to translations in a different domain (literary texts) into a very different language (Hebrew).

Postulated universals in linguistics (Greenberg, 1963) were confronted with much contradicting evidence in recent years (Evans and Levinson, 2009), and the long quest for translation universals (Mauranen and Kujamäki, 2004) should now be viewed in light of our finding: more than anything else, translations are typified by interference. This does not undermine the force of translation universals: we demonstrated how explicitation, in the form of cohesive markers, can help identify translations. It may be possible to define classi-

fiers implementing other universal facets of translation, e.g., simplification, which will yield good separation between O and T. However, explicitation fails in the reproduction of language typology, whereas interference-based features produce trees of considerable quality.

Remarkably, translations to contemporary English and French capture part of the millennium-old history of the source languages from which the translations were made. Our trees reflect some of the historical connections among the languages, but of course they are related in other ways, too (whether incidental, areal, etc.). This may explain the case of Romanian in our reconstructed trees: it has been isolated for many years from other Romance languages and was under heavy influence from Balto-Slavic languages.

Very little research has been done in historical linguistics on how translations impact the evolvement of languages. The major trends relate to loan translations (Jahr, 1999), or the impact of canonical texts, such as Luther's translation of the Bible to German (Russ, 1994) or the case of the King James translation to English (Crystal, 2010). It has been attested that for certain languages, up to 30% of published materials are mediated through translation (Pym and Chrupała, 2005). Given the fingerprints left on target language texts, translations very likely play a role in language change. We leave this as a direction for future research.

Abstract

A fundamental question in language learning concerns the role of a speaker's first language in second language acquisition. We present a novel methodology for studying this question: analysis of eye-movement patterns in second language reading of free-form text. Using this methodology, we demonstrate for the first time that the native language of English learners can be predicted from their gaze fixations when reading English. We provide analysis of classifier uncertainty and learned features, which indicates that differences in English reading are likely to be rooted in linguistic divergences across native languages. The presented framework complements production studies and offers new ground for advancing research on multilingualism.[1]

1 Introduction

The influence of a speaker's native language on learning and performance in a foreign language, also known as cross-linguistic transfer, has been studied for several decades in linguistics and psychology (Odlin, 1989; Martohardjono and Flynn, 1995; Jarvis and Pavlenko, 2008; Berkes and Flynn, 2012; Alonso, 2015). The growing availably of learner corpora has also sparked interest in cross-linguistic influence phenomena in NLP, where studies have explored the task of Native Language Identification (NLI) (Tetreault et al., 2013), as well as analysis of textual features in relation to the author's native language (Jarvis and Crossley, 2012; Swanson and Charniak, 2013; Malmasi and Dras, 2014). Despite these advances, the extent and nature of first language influence in second language processing remains far from being established. Crucially, most prior work on this topic focused on production, while little is currently known about cross-linguistic influence in language comprehension.

In this work, we present a novel framework for studying cross-linguistic influence in language comprehension using *eyetracking for reading* and *free-form native English text*. We collect and analyze English newswire reading data from 182 participants, including 145 English as Second Language (ESL) learners from four different native language backgrounds: Chinese, Japanese, Portuguese and Spanish, as well as 37 native English speakers. Each participant reads 156 English sentences, half of which are shared across all participants, and the remaining half are individual to each participant. All the sentences are manually annotated with part-of-speech (POS) tags and syntactic dependency trees.

We then introduce the task of *Native Language Identification from Reading (NLIR)*, which requires predicting a subject's native language from gaze while reading text in a second language. Focusing on ESL participants and using a log-linear classifier with word fixation times normalized for reading speed as features, we obtain 71.03 NLIR accuracy in the shared sentences regime. We further demonstrate that NLIR can be generalized effectively to the individual sentences regime, in which each subject reads a different set of sentences, by grouping fixations according to linguistically motivated clustering criteria. In this regime, we obtain an NLIR accuracy of 51.03.

Further on, we provide classification and feature analyses, suggesting that the signal underlying NLIR is likely to be related to *linguistic* characteristics of the respective native languages. First, drawing on previous work on ESL production, we

[1] The experimental data collected in this study will be made publicly available.

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 541–551
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1050

observe that classifier uncertainty in NLIR correlates with global linguistic similarities across native languages. In other words, the more similar are the languages, the more similar are the reading patterns of their native speakers in English. Second, we perform feature analysis across native and non-native English speakers, and discuss structural and lexical factors that could potentially drive some of the non-native reading patterns in each of our native languages. Taken together, our results provide evidence for a systematic influence of native language properties on reading, and by extension, on online processing and comprehension in a second language.

To summarize, we introduce a novel framework for studying cross-linguistic influence in language learning by using eyetracking for reading free-form English text. We demonstrate the utility of this framework in the following ways. First, we obtain the first NLIR results, addressing both the shared and the individual textual input scenarios. We further show that reading preserves linguistic similarities across native languages of ESL readers, and perform feature analysis, highlighting key distinctive reading patterns in each native language. The proposed framework complements and extends production studies, and can inform linguistic inquiry on cross-linguistic influence.

This paper is structured as follows. In section 2 we present the data and our experimental setup. Section 3 describes our approach to NLIR and summarizes the classification results. We analyze cross-linguistic influence in reading in section 4. In section 4.1 we examine NLIR classification uncertainty in relation to linguistic similarities between native languages. In section 4.2 we discuss several key fixation features associated with different native languages. Section 5 surveys related work, and section 6 concludes.

2 Experimental Setup

Participants

We recruited 182 adult participants. Of those, 37 are native English speakers and 145 are ESL learners from four native language backgrounds: Chinese, Japanese, Portuguese and Spanish. All the participants in the experiment are native speakers of only one language. The ESL speakers were tested for English proficiency using the grammar and listening sections of the Michigan English test (MET), which consist of 50 multiple choice questions. The English proficiency score was calculated as the number of correctly answered questions on these modules. The majority of the participants scored in the intermediate-advanced proficiency range. Table 1 presents the number of participants and the mean English proficiency score for each native language group. Additionally, we collected metadata on gender, age, level of education, duration of English studies and usage, time spent in English speaking countries and proficiency in any additional language spoken.

	# Participants	English Score
Chinese	36	42.0
Japanese	36	40.3
Portuguese	36	41.1
Spanish	37	42.4
English	37	NA

Table 1: Number of participants and mean MET English score by native language group.

Reading Materials

We utilize 14,274 randomly selected sentences from the Wall Street Journal part of the Penn Treebank (WSJ-PTB) (Marcus et al., 1993). To support reading convenience and measurement precision, the maximal sentence length was set to 100 characters, leading to an average sentence length of 11.4 words. Word boundaries are defined as whitespaces. From this sentence pool, 78 sentences (900 words) were presented to all participants (henceforth *shared* sentences) and the remaining 14,196 sentences were split into 182 individual batches of 78 sentences (henceforth *individual* sentences, averaging 880 words per batch).

All the sentences include syntactic annotations from the Universal Dependency Treebank project (UDT) (McDonald et al., 2013). The annotations include PTB POS tags (Santorini, 1990), Google universal POS tags (Petrov et al., 2012) and dependency trees. The dependency annotations of the UDT are converted automatically from the manual phrase structure tree annotations of the WSJ-PTB.

Gaze Data Collection

Each participant read 157 sentences. The first sentence was presented to familiarize participants with the experimental setup and was discarded during analysis. The following 156 sentences consisted of 78 shared and 78 individual sen-

tences. The shared and the individual sentences were mixed randomly and presented to all participants in the same order. The experiment was divided into three parts, consisting of 52 sentences each. Participants were allowed to take a short break between experimental parts.

Each sentence was presented on a blank screen as a one-liner. The text appeared in Times font, with font size 23. To encourage attentive reading, upon completion of sentence reading participants answered a simple yes/no question about its content, and were subsequently informed if they answered the question correctly. Both the sentences and the questions were triggered by a 300ms gaze on a fixation target (fixation circle for sentences and the letter "Q" for questions) which appeared on a blank screen and was co-located with the beginning of the text in the following screen.

Throughout the experiment, participants held a joystick with buttons for indicating completion of sentence reading and answering the comprehension questions. Eye-movement of participants' dominant eye was recorded using a desktop mount Eyelink 1000 eyetracker, at a sampling rate of 1000Hz. Further details on the experimental setup are provided in appendix A.

3 Native Language Identification from Reading

Our first goal is to determine whether the native language of ESL learners can be decoded from their gaze patterns while reading English text. We address this question in two regimes, corresponding to our division of reading input into shared and individual sentences. In the *shared regime*, all the participants read the same set of sentences. Normalizing over the reading input, this regime facilitates focusing on differences in reading behavior across readers. In the *individual regime*, we use the individual batches from our data to address the more challenging variant of the NLIR task in which the reading material given to each participant is different.

3.1 Features

We seek to utilize features that can provide robust, simple and interpretable characterizations of reading patterns. To this end, we use speed normalized *fixation duration* measures over word sequences.

Fixation Measures

We utilize three measures of word fixation duration:

- *First Fixation duration (FF)* Duration of the first fixation on a word.
- *First Pass duration (FP)* Time spent from first entering a word to first leaving it (including re-fixations within the word).
- *Total Fixation duration (TF)* The sum of all fixation times on a word.

We experiment with fixations over unigram, bigram and trigram sequences $seq_{i,k} = w_i, ..., w_{i+k-1}, k \in \{1, 2, 3\}$, where for each metric $M \in \{FF, FP, TF\}$ the fixation time for a sequence $M_{seq_{i,k}}$ is defined as the sum of fixations on individual tokens M_w in the sequence[2].

$$M_{seq_{i,k}} = \sum_{w' \in seq_{i,k}} M_{w'} \quad (1)$$

Importantly, we control for variation in reading speeds across subjects by normalizing each subjects's sequence fixation times. For each metric M and sequence $seq_{i,k}$ we normalize the sequence fixation time $M_{seq_{i,k}}$ relative to the subject's sequence fixation times in the textual context of the sequence. The context C is defined as the sentence in which the sequence appears for the *Words in Fixed Context* feature-set and the entire textual input for the *Syntactic* and *Information* clusters feature-sets (see definitions of feature-sets below). The normalization term $S_{M,C,k}$ is accordingly defined as the metric's fixation time per sequence of length k in the context:

$$S_{M,C,k} = \frac{1}{|C|} \sum_{seq_k \in C} M_{seq_k} \quad (2)$$

We then obtain a normalized fixation time $Mnorm_{seq_{i,k}}$ as:

$$Mnorm_{seq_{i,k}} = \frac{M_{seq_{i,k}}}{S_{M,C,k}} \quad (3)$$

[2]Note that for bigrams and trigrams, one could also measure FF and FP for interest regions spanning the sequence, instead, or in addition to summing these fixation times over individual tokens.

Feature Types

We use the above presented speed normalized fixation metrics to extract three feature-sets, *Words in Fixed Context (WFC)*, *Syntactic Clusters* (SC) and *Information Clusters (IC)*. WFC is a token-level feature-set that presupposes a fixed textual input for all participants. It is thus applicable only in the shared sentences regime. SC and IC are type-level features which provide abstractions over sequences of words. Crucially, they can also be applied when participants read different sentences.

- **Words in Fixed Context (WFC)** The WFC features capture fixation times on word sequences in a specific sentence. This feature-set consists of FF, FP and TF times for each of the 900 unigram, 822 bigram, and 744 trigram word sequences comprising the shared sentences. The fixation times of each metric are normalized for each participant relative to their fixations on sequences of the same length in the surrounding sentence. As noted above, the WFC feature-set is not applicable in the individual regime, as it requires identical sentences for all participants.

- **Syntactic Clusters (SC)** CS features are average globally normalized FF, FP and TF times for word sequences clustered by our three types of syntactic labels: universal POS, PTB POS, and syntactic relation labels. An example of such a feature is the average of speed-normalized TF times spent on the PTB POS bigram sequence DT NN. We take into account labels that appear at least once in the reading input of all participants. On the four non-native languages, considering all three label types, we obtain 104 unigram, 636 bigram and 1,310 trigram SC features per fixation metric in the shared regime, and 56 unigram, 95 bigram and 43 trigram SC features per fixation metric in the individual regime.

- **Information Clusters (IC)** We also obtain average FF, FP and TF for words clustered according to their *length*, measured in number of characters. Word length was previously shown to be a strong predictor of *information content* (Piantadosi et al., 2011). As such, it provides an alternative abstraction to the syntactic clusters, combining both syntactic and lexical information. As with SC features, we take into account features that appear at least once in the textual input of all participants. For our set of non-native languages, we obtain for each fixation metric 15 unigram, 21 bigram and 23 trigram IC features in the shared regime, and 12 unigram, 18 bigram and 18 trigram IC features in the individual regime. Notably, this feature-set is very compact, and differently from the syntactic clusters, does not rely on the availability of external annotations.

In each feature-set, we perform a final preprocessing step for each individual feature, in which we derive a zero mean unit variance scaler from the training set feature values, and apply it to transform both the training and the test values of the feature to Z scores.

3.2 Model

The experiments are carried out using a log-linear model:

$$p(y|x;\theta) = \frac{\exp(\theta \cdot f(x,y))}{\sum_{y' \in Y} \exp(\theta \cdot f(x,y'))} \quad (4)$$

where y is the reader's native language, x is the reading input and θ are the model parameters. The classifier is trained with gradient descent using L-BFGS (Byrd et al., 1995).

3.3 Experimental Results

In table 2 we report 10-fold cross-validation results on NLIR in the shared and the individual experimental regimes for native speakers of Chinese, Japanese, Portuguese and Spanish. We introduce two baselines against which we compare the performance of our feature-sets. The *majority* baseline selects the native language with the largest number of participants. The *random clusters* baseline clusters words into groups randomly, with the number of groups set to the number of syntactic categories in our data.

In the shared regime, WFC fixations yield the highest classification rates, substantially outperforming the cluster feature-sets and the two baselines. The strongest result using this feature-set, 71.03, is obtained by combining unigram, bigram and trigram fixation times. In addition to this outcome, we note that training binary classifiers in this setup yields accuracies ranging from 68.49 for the language pair Portuguese and Spanish, to 93.15 for Spanish and Japanese. These results confirm the effectiveness of the shared input

	Shared Sentences Regime			Individual Sentences Regime		
Majority Class	25.52			25.52		
Random Clusters	22.76			22.07		
	unigrams	+bigrams	+trigrams	unigrams	+bigrams	+trigrams
Information Clusters (IC)	41.38	44.14	46.21	38.62	32.41	32.41
Syntactic Clusters (SC)	45.52	57.24	58.62	48.97	43.45	48.28
SC+IC	51.72	57.24	60.0	**51.03**	46.21	49.66
Words in Fixed Context (WFC)	64.14	68.28	**71.03**	NA		

Table 2: Native Language Identification from Reading results with 10-fold cross-validation for native speakers of Chinese, Japanese, Portuguese and Spanish. In the *Shared* regime all the participants read the same 78 sentences. In the *Individual* regime each participant reads a different set of 78 sentences.

regime for performing reliable NLIR, and suggest a strong native language signal in non-native reading fixation times.

SC features yield accuracies of 45.52 to 58.62 on the shared sentences, while IC features exhibit weaker performance in this regime, with accuracies of 41.38 to 46.21. Both results are well above chance, but lower than WFC fixations due to the information loss imposed by the clustering step. Crucially, both feature-sets remain effective in the individual input regime, with 43.45 to 48.97 accuracy for SC features and 32.41 to 38.62 accuracy for IC features. The strongest result in the individual regime is 51.03, obtained by concatenating IC and SC features over unigrams. We also note that using this setup in a binary classification scheme yields results ranging from chance level 49.31 for Portuguese versus Spanish, to 84.93 on Spanish versus Japanese.

Generally, we observe that adding bigram and trigram fixations in the shared regime leads to performance improvements compared to using unigram features only. This trend does not hold for the individual sentences, presumably due to a combination of feature sparsity and context variation in this regime. We also note that IC and SC features tend to perform better together than in separation, suggesting that the information encoded using these feature-sets is to some extent complementary.

The generalization power of our cluster based feature-sets has both practical and theoretical consequences. Practically, they provide useful abstractions for performing NLIR over arbitrary textual input. That is, they enable performing this task using *any* textual input during both training and testing phases. Theoretically, the effectiveness of linguistically motivated features in discerning native languages suggests that linguistic factors play an important role in the ESL reading process. The analysis presented in the following sections will further explore this hypothesis.

4 Analysis of Cross-Linguistic Influence in ESL Reading

As mentioned in the previous section, the ability to perform NLIR in general, and the effectiveness of linguistically motivated features in particular, suggest that linguistic factors in the native and second languages are pertinent to ESL reading. In this section we explore this hypothesis further, by analyzing classifier uncertainty and the features learned in the NLIR task.

4.1 Preservation of Linguistic Similarity

Previous work in NLP suggested a link between textual patterns in ESL production and linguistic similarities of the respective native languages (Nagata and Whittaker, 2013; Nagata, 2014; Berzak et al., 2014, 2015). In particular, Berzak et al. (2014) has demonstrated that NLI classification uncertainty correlates with similarities between languages with respect to their typological features. Here, we extend this framework and examine if preservation of native language similarities in ESL production is paralleled in reading.

Similarly to Berzak et al. (2014) we define the classification uncertainty for a pair of native languages y and y' in our data collection D, as the average probability assigned by the NLIR classifier to one language given the other being the true native language. This approach provides a robust measure of classification confusion that does not rely on the actual performance of the classifier. We interpret the classifier uncertainty as a similarity measure between the respective languages and de-

note it as English Reading Similarity ERS.

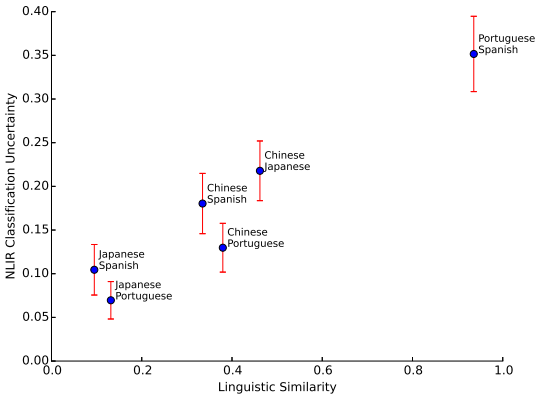
$$ERS_{y,y'} = \frac{\sum_{(x,y)\in D_y} p(y'|x;\theta) + \sum_{(x,y')\in D_{y'}} p(y|x;\theta)}{|D_y| + |D_{y'}|} \quad (5)$$

We compare these reading similarities to the linguistic similarities between our native languages. To approximate these similarities, we utilize feature vectors from the URIEL Typological Compendium (Littel et al., 2016) extracted using the *lang2vec* tool (Littell et al., 2017). URIEL aggregates, fuses and normalizes typological, phylogenetic and geographical information about the world's languages.

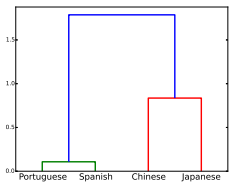
We obtain all the 103 available morpho-syntactic features in URIEL, which are derived from the World Atlas of Language Structures (WALS) (Dryer and Haspelmath, 2013), Syntactic Structures of the World's Languages (SSWL) (Collins and Kayne, 2009) and Ethnologue (Lewis et al., 2015). Missing feature values are completed with a KNN classifier. We also extract URIEL's 3,718 language family features derived from Glottolog (Hammarström et al., 2015). Each of these features represents membership in a branch of Glottolog's world language tree. Truncating features with the same value for all our languages, we remain with 76 features, consisting of 49 syntactic features and 27 family tree features. The linguistic similarity LS between a pair of languages y and y' is then determined by the cosine similarity of their URIEL feature vectors.

$$LS_{y,y'} = \frac{v_y \cdot v_{y'}}{\|v_y\| \|v_{y'}\|} \quad (6)$$

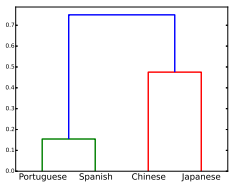
Figure 1 presents the URIEL based linguistic similarities for our set of non-native languages against the average NLIR classification uncertainties on the cross-validation test samples. The results presented in this figure are based on the unigram IC+SC feature-set in the individual sentences regime. We also provide a graphical illustration of the language similarities for each measure, using the Ward clustering algorithm (Ward Jr, 1963). We observe a correlation between the two measures which is also reflected in similar hierarchies in the two language trees. Thus, linguistically motived features in English reveal linguistic similarities across native languages. This outcome supports the hypothesis that English reading differences across native languages are related to linguistic factors.



(a) Linguistic similarities against mean NLIR classification uncertainty. Error bars denote standard error.



(b) Linguistic tree



(c) English reading tree

Figure 1: (a) Linguistic versus English reading language similarities. The horizontal axis represents typological and phylogenetic similarity between languages, obtained by vectorizing linguistic features form URIEL, and measuring their cosine similarity. The vertical axis represents the average uncertainty of the NLIR classifier in distinguishing ESL readers of each language pair. (b) Ward hierarchical clustering of linguistic similarities between languages. (c) Ward hierarchical clustering of NLIR average pairwise classification uncertainties.

We note that while comparable results are obtained for the IC and SC feature-sets, together and in separation in the shared regime, WFC features in the shared regime do not exhibit a clear uncertainty distinction when comparing across the pairs Japanese and Spanish, Japanese and Portuguese, Chinese and Spanish, and Chinese and Portuguese. Instead, this feature-set yields very low uncertainty, and correspondingly very high performance ranging from 90.41 to 93.15, for all four language pairs.

4.2 Feature Analysis

Our framework enables not only native language classification, but also exploratory analysis of native language specific reading patterns in English. The basic question that we examine in this respect is on which features do readers of different native language groups spend more versus less time. We also discuss several potential relations of the observed reading time differences to usage patterns and grammatical errors committed by speakers of our four native languages in production. We obtain this information by extracting grammatical error counts from the CLC FCE corpus (Yannakoudakis et al., 2011), and from the ngram frequency analysis in Nagata and Whittaker (2013).

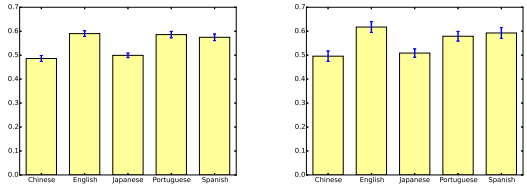
In order to obtain a common benchmark for reading time comparisons across non-native speakers, in this analysis we also consider our group of native English speakers. In this context, we train four binary classifiers that discern each of the non-native groups from native English speakers based on TF times over unigram PTB POS tags in the shared regime. The features with the strongest positive and negative weights learned by these classifiers are presented in table 3. These features serve as a reference point for selecting the case studies discussed below.

Interestingly, some of the reading features that are most predictive of each native language lend themselves to linguistic interpretation with respect to *structural* factors. For example, in Japanese and Chinese we observe shorter reading times for determiners (DT), which do not exist in these languages. Figure 2a presents the mean TF times for determiners in all five native languages, suggesting that native speakers of Portuguese and Spanish, which do have determiners, do not exhibit reduced reading times on this structure compared to natives. In ESL production, missing determiner errors are the most frequent error for native speakers of Japanese and third most common error for native speakers of Chinese.

In figure 2b we present the mean TF reading times for pronouns (PRP), where we also see shorter reading times by natives of Japanese and Chinese as compared to English natives. In both languages pronouns can be omitted both in object and subject positions. Portuguese and Spanish, in which pronoun omission is restricted to the subject position present similar albeit weaker tendency.

	Negative (Fast)	Positive (Slow)
Chinese	**DT**	JJR
	PRP	**NN**
Japanese	**DT**	**NN**
	CD	VBD
Portuguese	NNS	**NN-POS**
	PRP	VBZ
Spanish	NNS	MD
	PRP	RB

Table 3: PTB POS features with the strongest weights learned in non-native versus native classification for each native language in the shared regime. Feature types presented in figure 2 are highlighted in bold.



(a) Determiners (DT) (b) Pronouns (PRP)

(c) Possessives (NN+POS) (d) Nouns (NN)

Figure 2: Mean speed-normalized Total Fixation duration for Determiners (DT), Pronouns (PRP), singular noun possessives (NN+POS), and singular nouns (NN) appearing in the shared sentences. Error bars denote standard error.

In figure 2c we further observe that differently from natives of Chinese and Japanese, native speakers of Portuguese and Spanish spend more time on NN+POS in head final possessives such as "the *public's* confidence". While similar constructions exist in Chinese and Japanese, the NN+POS combination is expressed in Portuguese and Spanish as a head initial NN *of NN*. This form exists in English (e.g. "the confidence of the public") and is preferred by speakers of these languages in ESL writing (Nagata and Whittaker, 2013). As an additional baseline for this construction, we provide the TF times for NN in figure 2d. There, relative to English natives, we observe longer reading times for Japanese and Chinese and comparable times for Portuguese and Spanish.

The reading times of NN in figure 2d also give

rise to a second, potentially competing interpretation of differences in ESL reading times, which highlights *lexical* rather than structural factors. According to this interpretation, increased reading times of nouns are the result of substantially smaller lexical sharing with English by Chinese and Japanese as compared to Spanish and Portuguese. Given the utilized speed normalization, lexical effects on nouns could in principle account for reduced reading times on determiners and pronouns. Conversely, structural influence leading to reduced reading times on determiners and pronouns could explain longer dwelling on nouns. A third possibility consistent with the observed reading patterns would allow for both structural and lexical effects to impact second language reading. Importantly, in each of these scenarios, ESL reading patterns are related to linguistic factors of the reader's native language.

We note that the presented analysis is preliminary in nature, and warrants further study in future research. In particular, reading times and classifier learned features may in some cases differ between the shared and the individual regimes. In the examples presented above, similar results are obtained in the individual sentences regime for DT, PRP and NN. The trend for the NN+POS construction, however, diminishes in that setup with similar reading times for all languages. On the other hand, one of the strongest features for predicting Portuguese and Spanish in the individual regime are longer reading times for prepositions (IN), an outcome that holds in the shared regime only relative to Chinese and Japanese, but not relative to native speakers of English.

Despite these caveats, our results suggest that reading patterns can potentially be related to linguistic factors of the reader's native language. This analysis can be extended in various ways, such as inclusion of additional feature types and fixation metrics, as well as utilization of other comparative methodologies. Combined with evidence from language production, this line of investigation can be instrumental for informing linguistic theory of cross-linguistic influence.

5 Related Work

Eyetracking and second language reading Second language reading has been studied using eyetracking, with much of the work focusing on processing of syntactic ambiguities and analysis of specific target word classes such as cognates (Dussias, 2010; Roberts and Siyanova-Chanturia, 2013). In contrast to our work, such studies typically use controlled, rather than free-form sentences. Investigation of global metrics in free-form second language reading was introduced only recently by Cop et al. (2015). This study compared ESL and native reading of a novel by native speakers of Dutch, observing longer sentence reading times, more fixations and shorter saccades in ESL reading. Differently from this study, our work focuses on comparison of reading patterns between different native languages. We also analyze a related, but different metric, namely speed normalized fixation durations on word sequences.

Eyetracking for NLP tasks Recent work in NLP has demonstrated that reading gaze can serve as a valuable supervision signal for standard NLP tasks. Prominent examples of such work include POS tagging (Barrett and Søgaard, 2015a; Barrett et al., 2016), syntactic parsing (Barrett and Søgaard, 2015b) and sentence compression (Klerke et al., 2016). Our work also tackles a traditional NLP task with free-form text, but differs from this line of research in that it addresses this task only in comprehension. Furthermore, while these studies use gaze recordings of native readers, our work focuses on non-native readers.

NLI in production NLI was first introduced in Koppel et al. (2005) and has been drawing considerable attention in NLP, including a recent shared-task challenge with 29 participating teams (Tetreault et al., 2013). NLI has also been driving much of the work on identification of native language related features in writing (Tsur and Rappoport, 2007; Jarvis and Crossley, 2012; Brooke and Hirst, 2012; Tetreault et al., 2012; Swanson and Charniak, 2013, 2014; Malmasi and Dras, 2014; Bykh and Meurers, 2016). Several studies have also linked usage patterns and grammatical errors in production to linguistic properties of the writer's native language (Nagata and Whittaker, 2013; Nagata, 2014; Berzak et al., 2014, 2015). Our work departs from NLI in writing and introduces NLI and related feature analysis in reading.

6 Conclusion and Outlook

We present a novel framework for studying cross-linguistic influence in multilingualism by measuring gaze fixations during reading of free-form En-

glish text. We demonstrate for the first time that this signal can be used to determine a reader's native language. The effectiveness of linguistically motivated criteria for fixation clustering and our subsequent analysis suggest that the ESL reading process is affected by linguistic factors. Specifically, we show that linguistic similarities between native languages are reflected in similarities in ESL reading. We also identify several key features that characterize reading in different native languages, and discuss their potential connection to structural and lexical properties of the native langauge. The presented results demonstrate that eyetracking data can be instrumental for developing predictive and explanatory models of second language reading.

While this work is focused on NLIR from fixations, our general framework can be used to address additional aspects of reading, such as analysis of saccades and gaze trajectories. In future work, we also plan to explore the role of native and second language writing system characteristics in second language reading. More broadly, our methodology introduces parallels with production studies in NLP, creating new opportunities for integration of data, methodologies and tasks between production and comprehension. Furthermore, it holds promise for formulating language learning theory that is supported by empirical findings in naturalistic setups across language processing domains.

A Supplemental Material

Eyetracking Setup We use a 44.5x30cm screen with 1024x768px resolution to present the reading materials, and a desktop mount Eyelink 1000 eyetracker (1000Hz) to record gaze. The screen, eyetracker camera and chinrest are horizontally aligned on a table surface. The screen center (x=512, y=384) is 79cm away from the center of

the forehead bar, and 13cm below it. The eye-tracker camera knob is 65cm away from forehead bar. Throughout the experiment participants hold a joystick with a button for indicating sentence completion, and two buttons for answering yes/no questions. We record gaze of the participant's dominant eye.

Text Parameters All the textual material in the experiment is presented using Times font, normal style, with font size 23. In our setup, this corresponds to 0.36 degrees (11.3px) average lower case letter width, and 0.49 degrees (15.7px) average upper case letter width. We chose a non-monospace font, as such fonts are generally more common in reading. They are also more compact compared to monospace fonts, allowing to substantially increase the upper limit for sentence length.

Calibration We use 3H line calibration with point repetition on the central horizontal line (y=384), using 16px outer circle, 6px inner circle, fixation points. At least three calibrations are performed during the experiment, one at the beginning of each experimental section. We also recalibrate upon failure to produce a 300ms fixation on any fixation trigger preceding a sentence or a question within 4 seconds after its appearance. The mean validation error for calibrations across subjects is 0.146 degrees (std 0.038).

MORSE: Semantic-ally Drive-n MORpheme SEgment-er

Abstract

In this paper we present a novel framework for morpheme segmentation which uses the morpho-syntactic regularities preserved by word representations, in addition to orthographic features, to segment words into morphemes. This framework is the first to consider vocabulary-wide syntactico-semantic information for this task. We also analyze the deficiencies of available benchmarking datasets and introduce our own dataset that was created on the basis of compositionality. We validate our algorithm across different datasets and languages and present new state-of-the-art results.

1 Introduction

Morpheme segmentation is a core natural language processing (NLP) task used as an integral component in related-fields such as information retrieval (IR) (Zieman and Bleich, 1997; Kurimo et al., 2007), automatic speech recognition (ASR) (Bilmes and Kirchhoff, 2003; Kurimo et al., 2006), and machine translation (MT) (Lee, 2004; Virpioja et al., 2007). Most previous works have relied solely on orthographic features (Harris, 1970; Goldsmith, 2000; Creutz and Lagus, 2002, 2005, 2007), neglecting the underlying semantic information. This has led to an over-segmentation of words because a change of the surface form pattern is a necessary but insufficient indication of a morphological change. For example, the surface form of "freshman", hints that it should be segmented to "fresh-man", although "freshman" does not describe semantically the compositional meaning of "fresh" and "man".

To compensate for this lack of semantic knowledge, previous works (Schone and Jurafsky, 2000; Baroni et al., 2002; Narasimhan et al., 2015) have incorporated semantic knowledge *locally* by checking the semantic relatedness of possibly morphologically related pair of words. Narasimhan et al. (2015) check for semantic relatedness using cosine similarity in word representations (Mikolov et al., 2013a; Pennington et al., 2014). A limitation of such an approach is the inherent "sample noise" in specific word representations (exacerbated in the case of rare words). Moreover, limitation to local comparison enforces modeling morphological relations via semantic relatedness, although it has been shown that difference vectors model morphological relations more accurately (Mikolov et al., 2013b). To address this issue, we introduce a new framework (MORSE), the first to bring semantics into morpheme segmentation both on a local and a vocabulary-wide level. That is, when checking for the morphological relation between two words, we not only check for the semantic relatedness of the pair at hand (*local*), but also check if the difference vectors of pairs showing similar orthographic change are consistent (*vocabulary-wide*).

In summary, MORSE clusters pairs of words which only vary by an affix; for example, pairs such as ("quick", "quickly") and ("hopeful", "hopefully") get clustered together. To verify the cluster of a specific affix from a semantic corpus-wide standpoint, we check for the consistency of the difference vectors (Mikolov et al., 2013b). To evaluate it from an orthographic corpus-wide perspective, we check for the size of each cluster of an affix. To evaluate each pair in a cluster locally from a semantic standpoint, we check if a pair of words in a valid affix cluster are morphologically related by checking if its difference vector is consistent with other members in the cluster and if the words in the pair are semantically related (i.e. close in the vector space). The reason for local

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 552–561
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1051

evaluations is exemplified by ("on","only") which belongs to the cluster of a valid affix ("ly"), although they are not (obviously) morphologically related. We would expect such a pair to fail the last two local evaluation methods.

Our proposed segmentation algorithm is evaluated using benchmarking datasets from the Morpho Challenge (MC) for multiple languages and a newly introduced dataset for English which compensates for lack of discriminating capabilities in the MC dataset. Experiments reveal that our proposed framework not only outperforms the widely used approach, but also performs better than published state-of-the-art results.

The central contribution of this work is a novel framework that performs morpheme segmentation resulting in new state-of-the-art results. To the best of our knowledge this is the first unsupervised approach to consider the vocabulary-wide semantic knowledge of words and their affixes in addition to relying on their surface forms. Moreover we point out the deficiencies in the MC datasets with respect to the compositionality of morphemes and introduce our own dataset free of these deficiencies.

2 Related Work

Extensive work has been done in morphology learning, with tasks such as morphological analysis (Baayen et al., 1993), morphological reinflection (Cotterell et al., 2016), and morpheme segmentation. Given the less complex nature of morpheme segmentation in comparison to the other tasks, most systems developed for morpheme segmentation have been unsupervised or minimally supervised (mostly for parameter tuning).

Unsupervised morpheme segmentation traces back to (Harris, 1970), which falls under the framework of Letter Successor Variety (LSV) which builds on the hypothesis that predictability of successor letters is high within morphemes and low otherwise. The most dominant pieces of work on unsupervised morpheme segmentation, Morfessor (Creutz and Lagus, 2002, 2005, 2007) and Linguistica (Goldsmith, 2000) adopt the Minimum Description Length (MDL) principle (Rissanen, 1998): they aim to minimize describing the lexicon of morphs as well as minimizing the description of an input corpus. Morfessor has a widely used API and has inspired a large body of following work (Kohonen et al., 2010; Grönroos et al., 2014).

The unsupervised original implementation was later adapted (Kohonen et al., 2010; Grönroos et al., 2014) to allow for minimal supervision. Another work on minimally supervised morpheme segmentation is (Sirts and Goldwater, 2013) which relies on Adaptor Grammars (AGs) (Johnson et al., 2006). AGs learn latent tree structures over an input corpus using a nonparametric Bayesian model (Sirts and Goldwater, 2013).

(Lafferty et al., 2001) use Conditional Random Fields (CRF) for morpheme segmentation. In this supervised method, the morpheme segmentation task is modeled as a sequence-to-sequence learning problem, whereby the sequence of labels defines the boundaries of morphemes (Ruokolainen et al., 2013, 2014). In contrast to the previously mentioned generative approaches of MDL and AG, this method takes a discriminative approach and allows for the inclusion of a larger set of features. In this approach, CRF learns a conditional probability of a segmentation given a word (Ruokolainen et al., 2013, 2014).

All these morpheme segmenters rely solely on orthographic features of morphemes. Semantics were initially introduced to morpheme segmenters by (Schone and Jurafsky, 2000), using LSA to generate word representations and then evaluate if two words are morphologically related based on semantic relatedness, as well as deterministic orthographic methods. Similarly, (Baroni et al., 2002) use edit distance and mutual information as metrics for semantic and orthographic validity of a morphological relation between two words. Recent work in (Narasimhan et al., 2015), inspired by the log-linear model in (Poon et al., 2009) incorporates semantic relatedness into the model via word representations. Other systems such as (Üstün and Can, 2016) rely solely on evaluating two words from a semantic standpoint by the use of a two-layer neural network.

MORSE introduces semantic information into its morpheme segmenters via distributed word representations while also relying on orthographic features. Inspired by the work of (Soricut and Och, 2015), instead of merely evaluating semantic relatedness, we are the first to evaluate the morphological relationship via the difference vector of morphologically related words. Comparing the difference vectors of multiple pairs across the corpus following the same morphological relation, gives

MORSE a vocabulary-wide evaluation of morphological relations learned.

3 System

The key limitation of previous frameworks that rely solely on orthographic features is the resulting over-segmentation. As an example, MDL-based frameworks segment "sing" to "s-ing" due to the high frequency of the morphemes: "s" and "ing". Our framework combines semantic relatedness with orthographic relatedness to eliminate such error. For the example mentioned, MORSE validates morphemes such as "s" and "ing" from an orthographic perspective, yet invalidates the relation between "s" and "sing" from a local and vocabulary-wide semantic perspective. Hence, MORSE will segment "jumping" as "jump-ing", and perform no segmentations on "sing".

To bring in semantic understanding into MORSE, we rely on word representations (Mikolov et al., 2013a; Pennington et al., 2014). These word representations capture the semantics of the vocabulary through statistics over the context in which they appear. Moreover, morpho-syntactic regularities have been shown over these word representations, whereby pairs of words sharing the same relationship exhibit equivalent difference vectors (Mikolov et al., 2013b). For example, it is expected in the vector space of word representations that $\vec{w}_{\text{jumping}} - \vec{w}_{\text{jump}} \approx \vec{w}_{\text{playing}} - \vec{w}_{\text{play}}$, but $\vec{w}_{\text{sing}} - \vec{w}_{\text{s}} \not\approx \vec{w}_{\text{playing}} - \vec{w}_{\text{play}}$.

As a high level description, we first learn all possible affix transformations (morphological rules) in the language from pairs of words from an orthographic standpoint. For example, the pair ("jump", "jumping") corresponds to the valid affix transformation $\phi \xrightarrow{\text{suffix}}$ "ing" (where ϕ represents the empty string), and the pair ("slow", "slogan") corresponds to the invalid rule "w" $\xrightarrow{\text{suffix}}$ "gan". Then we invalidate the rules, such as "w" $\xrightarrow{\text{suffix}}$ "gan", that do not conform to the linear relation in the vector space. We also invalidate pairs of words which, due to randomness, are orthographically related via a valid rule although they are not morphologically related, such as ("on", "only").

Now we formalize the objects we learn in MORSE and the scores (orthographic and semantic) used for validation. This constitutes the training stage. Finally, we formalize the inference stage, where we use these objects and scores to perform morpheme segmentation.

3.1 Training Stage

Objects:

- Rule set **R** made of all possible affix transformations in a language. **R** is populated via the following definition: $\mathbf{R}_{\text{suffix}} = \{\text{aff}_1 \xrightarrow{\text{suffix}} \text{aff}_2 \colon \exists\ (w_1, w_2) \in \text{V}^2, \text{stem}(w_1) = \text{stem}(w_2), w_1 = \text{stem}(w_1) + \text{aff}_1, w_2 = \text{stem}(w_2) + \text{aff}_2\}$, $\mathbf{R}_{\text{prefix}}$ is defined similarly for prefixes, and $\mathbf{R} = \mathbf{R}_{\text{suffix}} \cup \mathbf{R}_{\text{prefix}}$. An example **R** would be equal to $\{\phi \xrightarrow{\text{suffix}}$ "ly", $\phi \xrightarrow{\text{prefix}}$ "un", "ing" $\xrightarrow{\text{suffix}}$ "ed",$\dots\}$.

- Support set $\mathbf{SS}_r$ for a rule $r \in \mathbf{R}$ consists of all pairs of words related via r on a surface level. $\mathbf{SS}_r$ is populated via the following definition: $\mathbf{SS}_r = \{(w_1, w_2)\colon w_1, w_2 \in \text{V}, w_1 \xrightarrow{r} w_2\}$. An example support set of the rule "ing" $\xrightarrow{\text{suffix}}$ "ed" would be {("playing", "played"), ("crafting", "crafted"),$\dots$}.

Scores:

- $\mathbf{score}_{\text{r\_orth}}(r)$ is a vocabulary-wide orthographic confidence score for rule $r \in$ R. It reflects the validity of an affix transformation in a language from an orthographic perspective. This score is evaluated as $\mathbf{score}_{\text{r\_orth}}(r) = |\text{SS}_r|$.
- $\mathbf{score}_{\text{r\_sem}}(r)$ is a vocabulary-wide semantic confidence score for rule $r \in$ R. It reflects the validity of an affix transformation in a language from a semantic perspective. This score is evaluated as: $\mathbf{score}_{\text{r\_sem}}(r) = |\text{cluster}_{\text{r}}|/|\text{SS}_r|^2$ where $\text{cluster}_r = \{((w_1, w_2), (w_3, w_4))\colon (w_1, w_2), (w_3, w_4) \in \text{SS}_r, \vec{w}_1 - \vec{w}_2 \approx \vec{w}_3 - \vec{w}_4\}$. We consider $\vec{w}_1 - \vec{w}_2 \approx \vec{w}_3 - \vec{w}_4$ if $\cos(\vec{w}_4, \vec{w}_2 - \vec{w}_1 + \vec{w}_3) > 0.1$.
- $\mathbf{score}_{\text{w\_sem}}((w_1, w_2) \in \text{SS}_r)$ is a vocabulary-wide semantic confidence score for a pair of words (w_1, w_2). The pair of words is related via r on an orthographic level, but the score reflects the validity of the morphological relation via r on a semantic level. This score is evaluated as: $\mathbf{score}_{\text{w\_sem}}((w_1, w_2) \in \text{SS}_r) = |\{(w_3, w_4)\colon (w_3, w_4) \in \text{SS}_r, \vec{w}_1 - \vec{w}_2 \approx \vec{w}_3 - \vec{w}_4\}|/|\text{SS}_r|$. In other words, it is the fraction of pairs of words in the support set that exhibit a similar linear relation as (w_1, w_2) in the vector space.

- **score**$_{\text{loc\_sem}}((w_1, w_2) \in \text{SS}_r)$ is a local semantic confidence score for a pair of words (w_1, w_2). The pair of words is related via r on an orthographic level, but the score reflects the semantic relatedness between the pair. The score is evaluated as: **score**$_{\text{loc\_sem}}((w_1, w_2) \in \text{SS}_r) = \cos(\vec{w_1}, \vec{w_2})$.

3.2 Inference Stage

In this stage we perform morpheme segmentation using the knowledge gained from the first stage. We begin with some notation: let $\text{R}_{\text{add}} = \{r : r \in \text{R}, r = \text{aff}_1 \xrightarrow{r} \text{aff}_2, \text{aff}_1 = \phi, \text{aff}_2 \neq \phi\}$, $\text{R}_{\text{rep}} = \{r : r \in \text{R}, r = \text{aff}_1 \xrightarrow{r} \text{aff}_2, \text{aff}_1 \neq \phi, \text{aff}_2 \neq \phi\}$. In other words, we divide the rules to those where an affix is added (R_{add}) and to those where an affix is replaced (R_{rep}).

Given a word w to segment, we search for r^*, the solution to the following optimization problem[1]. The search space is limited to the rules that include w in their support set, a fairly small search space and the corresponding computation readily tractable:

$$\max_{\mathbf{r}} \quad \sum_{t_1} \text{score}_{t_1}((w', w) \in \text{SS}_{\mathbf{r}}) + \sum_{t_2} \text{score}_{t_2}(\mathbf{r})$$

$$s.t. \quad \mathbf{r} \in \text{R}_{\text{add}}$$
$$\text{score}_{\text{r\_sem}}(\mathbf{r}) > \text{t}_{\text{r\_sem}}$$
$$\text{score}_{\text{r\_orth}}(\mathbf{r}) > \text{t}_{\text{r\_orth}}$$
$$\text{score}_{\text{w\_sem}}((w', w) \in \text{SS}_{\mathbf{r}}) > \text{t}_{\text{w\_sem}}$$
$$\text{score}_{\text{loc\_sem}}((w', w) \in \text{SS}_{\mathbf{r}}) > \text{t}_{\text{loc\_sem}}$$

Where t_1 = {w_sem, loc_sem}, t_2 = {r_sem, r_orth}, and $\text{t}_{\text{r\_sem}}$, $\text{t}_{\text{r\_orth}}$, $\text{t}_{\text{w\_sem}}$, $\text{t}_{\text{loc\_sem}}$ are hyperparameters of the system. Now given $\text{r}^* = \phi \xrightarrow{\text{suffix}}$ suf, w' is defined as $w' \xrightarrow{\text{r}^*} w$. Thus the algorithm segments $w \rightarrow w'$-suf. We treat prefixes similarly. Next, the algorithm iterates over w'. Figure 1 shows the segmentation process of the word "unhealthy" based on the sequentially retrieved r^*.

The reason we restrict our rule set to R_{add} in the optimization problem is to avoid rules such as "er" $\xrightarrow{\text{suffix}}$ "ing" like in ("player", "playing") leading to false segmentations such as "playing" → "playering". Yet we cannot completely restrict our search to R_{add} due to rules such as "y" → "ies" in words like ("sky", "skies"). To be able to segment words such as "skies", we'd have to consider rules in R_{rep} but only after searching in R_{add}. Thus if the first optimization problem was unfeasible, we repeat it while replacing R_{add} with R_{rep}. The program terminates when both optimization problems are infeasible.

[1] r and w uniquely identify w', and thus the search space is defined only over r.

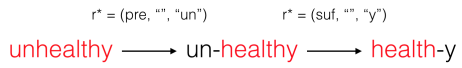

Figure 1: Illustration of the iterative process of segmentation in MORSE

4 Experiments

We conduct a variety of experiments to assess the performance of MORSE, and compare it with prior works. First, the performance is assessed intrinsically on the task of morpheme segmentation and against the most widely used morpheme segmenter: Morfessor 2.0. We evaluate the performance across three languages of varying morphology levels: English, Turkish, Finnish, with Finnish being the richest in morphology and English being the poorest. Second, we show the inadequacies of benchmarking gold datasets for this task and describe a new dataset that we create to address the inadequacy. Third, in order to highlight the effect of including semantic information, we compare MORSE against Morfessor on a set of words which should not be segmented from a semantic perspective although orthographically they seem to be segmentable (such as "freshman").

In all of our experiments (unless specified otherwise), we report precision and recall (and corresponding F1 scores) with locations of morpheme boundaries being considered positives and the rest of the locations considered negatives. It should be noted that we disregard starting and ending positions of words, since they form trivial boundaries (Virpioja et al., 2011).

4.1 Setup

Both systems, Morfessor and MORSE, were trained on the same monolingual corpus: Wikipedia[2] (as of September 20, 2016) to control for affecting factors within the experiment. For each language considered, the respective Wikipedia dump was preprocessed using an available code[3]. We use Word2Vec (Mikolov

et al., 2013a) to train word representations of 300 dimensions and based on a context window of size 5. Also, for computational efficiency, MORSE was limited to a vocabulary of size 1M, a restriction not enforced on Morfessor.

MORSE's hyperparameters are tuned based on a tuning set of gold morpheme segmentations. We have publicly released the source code of a pre-trained MORSE[4] as described in this paper.

4.2 Morpho Challenge Dataset

As our first intrinsic experiment, we consider the Morpho Challenge (MC) gold segmentations available online[5]. For every language, two datasets are supplied: training and development. For the purpose of our experiments, all systems use the development dataset as a test dataset, and the training dataset is used for tuning MORSE's hyperparameters. MC dataset sizes are reported in Table 1.

4.3 Semantically Driven Dataset

There are a variety of weaknesses in the MC dataset, specifically related to whether the segmentation is semantically appropriate or not. We introduce a new semantically driven dataset (SD17) for morpheme segmentation along with the methodology used for creation; this new dataset is publicly available in the canonical[6] and non-canonical[7] versions (Cotterell and Vieira, 2016).

Non-compositional segmentation: One of the key requirements of morpheme segmentation is the compositionality of the meaning of the word from the meaning of its morphemes. This requirement is violated on multiple occasions in the MC dataset. One example from Table 2 is segmenting the word "business" into "busi-ness", which falsely assumes that "business" means the act of being busy. Such a segmentation might be consistent with the historic origin of the word, but with radical semantic changes over time, the segmentation no longer semantically represents the compositionality of the words' components (Wijaya and Yeniterzi, 2011). Not only does such a weakness contribute to false segmentations, but it also favors segmentation methods following the MDL principle.

Word	Gold Segmentation
freshman	fresh man
airline	air line
business'	busi ness '
ahead	a head
adultery	adult ery

Table 2: Examples of gold morpheme segmentations from the Morpho Challenge 2010 dataset deemed invalid from a compositionality viewpoint.

Trivial instances: The second weakness in the MC dataset is due to abundance of trivial instances. These instances lack discriminating capability since all methods can easily predict them (Baker, 2001). These instances are comprised of genetive cases (such as teacher's) as well as hyphenated words (such as turning-point). For genetive cases, segmenting at the apostrophe leads to perfect precision and recall, and thus such instances are deemed trivial. In the case of hyphenated words, segmenting at the hyphen is a correct segmentation with a very high probability. In the MC tuning dataset, in 43 times out of 46, the hyphen was a correct indication of segmentation.

Other issues exist in the Morpho Challenge dataset although less abundantly. There are instances of **wrong segmentations** possibly due to human error. One example of such instance is "turning-point" segmented to "turning - point" instead of "turn ing - point". Another issue, which is hard to avoid, is **ambiguity** of segmentation boundaries. Take for example the word "strafed", the segmentations "straf-ed" and "strafe-d" are equally justified. In such situations, the MC dataset favors complete affixes rather than complete lemmas. This also favors MDL-based segmenters. We note that the MC dataset also provides segmentations in a canonical version such as "strafe-ed", yet for the sake of a fair comparison with Morfessor and all previously evaluated systems on the MC dataset, we consider only the former version of segmentations.

Table 3: Performance of MORSE on the MC dataset across three languages: English, Turkish, Finnish.

Due to these reasons, we create a new dataset SD17 for English gold morpheme segmentations with compositionality guiding the annotations. We select 2000 words randomly from the 10K most frequent words in the English Wikipedia dump and have them annotated by two proficient English speakers. The segmentation criterion was to segment the word to the largest extent possible while preserving its compositionality from the segments. The inter-annotator agreement reached 91% on a word level. Based on post annotation discussions, annotators agreed on 99% of the words, and words not agreed on were eliminated along with words containing non-alpha characters to avoid trivial instances.

SD17 is used to evaluate the performance of both Morfessor and MORSE. We claim that the performance on SD17 is a better indication of the performance of a morpheme segmenter. By the use of SD17 we expect to gain insights on the extent to which morpheme segmentation is a function of semantics in addition to orthography.

4.4 Handling Compositionality

We have hypothesized that following the MDL principle (such as Morfessor) leads to over-segmentation. This over-segmentation happens specifically when the meaning of the word does not follow from the meaning of its morphemes. Examples include words such as "red head", "duck face", "how ever", "s ing". A subset of these words are defined by linguists as exocentric compounds (Bauer, 2008). MORSE does not suffer from this issue owing to its use of a semantic model.

We use a collection of 100 English words which appear to be segmentable but actually are not (example: "however"). Such a collection will highlight a system's capability of distinguishing frequent letter sequences from the semantic contribution of this letter sequence in a word. We make this collection publicly available[8].

5 Results

We compare MORSE with Morfessor, and place the performance alongside the state-of-the-art published results.

5.1 Morpho Challenge Dataset

As demonstrated in Table 3, MORSE performs better than Mofessor on English and Turkish, and worse on Finnish. Considering English first, using MORSE instead of Morfessor, resulted in a 6% absolute increase in F1 scores. This supports our claim for the need of semantic cues in morpheme segmentation, and also validates the method used in this paper. Since English is a less systematic language in terms of the orthographic structure of words, semantic cues are of greater need, and hence a system which relies on semantic cues is expected to perform better; indeed this is the case. Similarly, MORSE performs better on Turkish with a 7% absolute margin in terms of F1 score. On the other hand, Morfessor surpasses MORSE in performance on Finnish by a large margin as well, especially in terms of recall.

5.1.1 Discussion

We hypothesize that the richness of morphology in Finnish led to suboptimal performance of MORSE. This is because richness in morphology leads to word level sparsity which directly leads to: (1) Degradation of quality of word representations (2) Increased vocabulary size exacerbating the issue of limited vocabulary (recall MORSE was limited to a vocabulary of 1M). In a language with productive morphology, limiting its vocabulary results in a lower chance of finding morphologically related word pairs. This negatively im-

pacts the training stage of MORSE which relies on the availability of such pairs. In order to detect the suffix "ly" from the word "cheerfully" MORSE needs to come across "cheerful" as well. Coming across "cheerful" is now a lower probability event due to high sparsity. This is not as much of an issue for Morfessor under the MDL principle, since it might detect "ly" just by coming across multiple words ending with "ly" even without encountering the base forms of those words. We show how the detection of rules is affected by considering the number of candidate rules detected as well as the number of candidate morphologically related word pairs detected. As shown in Table 4, the number of detected candidate rules and candidate related words decreases with the increase in morphology in a language. This confirms our hypothesis; we note that this issue can be directly attributed to the limited vocabulary size in MORSE. With the increase in processing power, and thus larger vocabulary coverage, MORSE is expected to perform better.

5.2 Semantically Driven Dataset

The performance of MORSE and Morfessor on SD17 is shown in Table 5. The use of MC data (which does not adhere to the compositionality principle) to tune MORSE to be evaluated on SD17 (which does adhere to the compositionality principle) is not optimal. Thus, we evaluate MORSE on SD17 using 5-fold cross validation, where 80% of the dataset is used to tune and 20% is used to evaluate. Precision, Recall, and F1 scores are averaged and reported in Table 5 using the label MORSE-CV.

Based on the results in Table 5, we make the following observations. Comparing MORSE-CV to MORSE reflects the fundamental difference between SD17 and MC datasets. Knowing the basis of construction of SD17 and the fundamental weaknesses in MC datasets, we attribute the performance increase to the lack of compositionality in MC dataset. Comparing MORSE-CV to Morfessor, we observe a significant jump in performance (an increase of 24%). In comparison, the increase on the MC dataset (6%) shows that the Morpho Challenge dataset underestimates the performance gap between Morfessor and MORSE due its inherent weaknesses.

Since MORSE is equipped with the capability to retrieve full morphemes even when not present in full orthographically, a capability that Morfessor lacks, we evaluated both systems on the canonical version of SD17. The results are reported in Table 6. We notice that evaluating on the canonical form of SD17 gives a further edge for MORSE over Morfessor. For evaluation on the canonical version of SD17, we switch to morpheme-level evaluation instead of boundary-level as a more suitable method for Morfessor. Morpheme-level evaluation is distinguished from boundary-level evaluation in that we evaluate the detection of morphemes instead of the boundary locations in the segmented word.

Table 6: Performance of MORSE against Morfessor on the canonical version of SD17

We next compare MORSE against published state-of-the-art results[9]. As one can see in Table 7 MORSE significantly performs better than published state-of-the-art results, most notably (Narasimhan et al., 2015) referred to as LLSM in the Table. Comparison is also made against the top results in the latest Morpho Challenge: Morfessor S+W and Morfessor S+W+L (Kohonen et al., 2010), and Base Inference (Lignos, 2010).

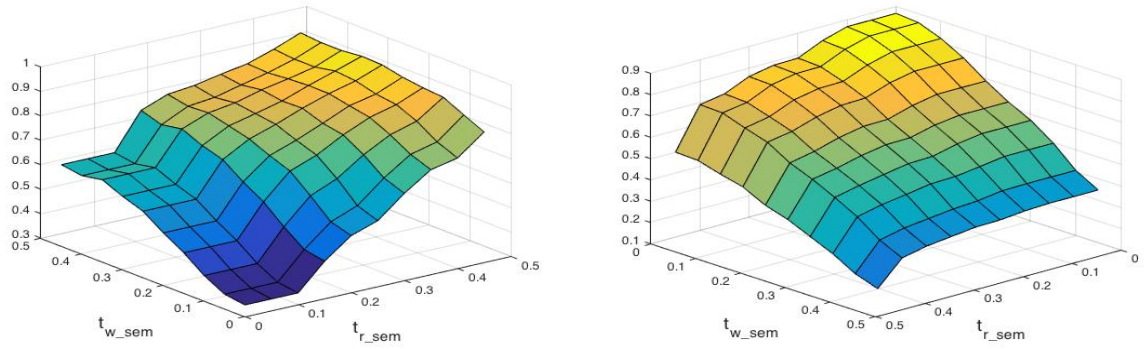

Figure 2: Precision (left) and Recall (right) of MORSE as a function of the hyperparameters: t_{r_sem}, t_{w_sem}

5.3 Handling Compositionality

We compare the performance of MORSE and Morfessor on a set of words made up of morphemes which don't compose the meaning of the word. Since all the boundaries in this dataset are negative, to evaluate both systems (with MORSE tuned on SD17), we only report the number of segments generated. The more segments a system generates, the worse is its performance.

We find that MORSE generates **7** false morphemes whereas Morfessor generates **43** false morphemes. This shows MORSE's robustness to such examples through its semantic knowledge and validates our claim that Morfessor oversegments on such examples.

6 Discussion

One of the benefits of MORSE against other frameworks such as MDL is its ability to identify the lemma within the segmentation. The lemma would be the last non-segmented word in the iterative process of segmentation. Hence, an advantage of our framework is its easy adaptability into a lemmatizer and even a stemmer.

Another key aspect which is not present in some of the competitive systems is the need for a small tuning dataset. This is a point in favor of completely unsupervised systems such as Morfessor. On the other hand, these hyperparameters could allow for flexibility. Figure 2 shows how precision and recall changes as a function of the hyperparameter selection[10]. As one would expect, increasing the hyperparameters, in general, leads to a stricter search space and thus increases precision and decreases recall. Putting these results in perspective, the user of MORSE is given the capability of controlling for precision and recall based on the needs of the downstream task.

Moreover, to check for the level of dependency of MORSE on a set of gold morpheme segmentations for tuning, we check for the variation in performance with respect to size of tuning data. For the purpose of this experiment we take an 80-20 split of SD17 and vary the size of the tuning set. We notice that the performance (81.90% F1) reaches a steady state at 20% ($\approx$ 300 gold segmentations) of the tuning data. This reflects the minimal dependency on a tuning dataset.

Regarding the training stage, homomorphs are treated as one rule and allomorphs are treated as separate rules. For example, ("tall", "taller") and ("fast", "faster") are wrongly considered to have the same morphological relation, besides ("cat", "cats") and ("butterfly", "butterflies") are wrongly considered to have different morphological relations. The separate clustering of the different forms of a homomorph leads to the underestimation of the respective orthographic scores. Moreover, the clustering of allomorphs together would lead to the underestimation of the semantic score of the rule as well as the underestimation of the vocabulary-wide semantic score of word pairs in the support set of this rule. This does not significantly affect the performance of MORSE, since the tuned thresholds are able to distinguish between the low scores of an invalid rule and the mediocre underestimated scores of allomorphs and homomorphs.

As for the inference stage of MORSE, the greedy inference approach limits its performance. In other words, a wrong segmentation at the be-

[9]The five published state-of-the-art results are on different datasets

[10]Only a subset of the hyperparameters is used for display purposes

ginning will propagate and result in consequent wrong segmentations. Also, MORSE's limitation to concatenative morphology decreases its efficacy on languages that include non-concatenative morphology. This opens the stage for further research on a more optimal inference stage and a more global modeling of orthographic morphological transformations.

7 Conclusions and Future Work

In this paper, we have presented MORSE, a first morpheme segmenter to consider semantic structure at this scale (local and vocabulary-wide). We show its superiority over state-of-the-art algorithms using intrinsic evaluation on a variety of languages. We also pinpointed the weaknesses in current benchmarking datasets, and presented a new dataset free of these weaknesses. With a relative increase in performance reaching 24% absolute increase over Morfessor, this work proves the significance of semantic cues as well as validates a new state-of-the-art morpheme segmenter. For future work, we plan to address the limitations of MORSE: minimal supervision, greedy inference, and concatenative orthographic model. Moreover, we plan to computationally optimize the training stage for the sake of wider adoption by the community.

Abstract

This paper proposes a *low-complexity* word-level deep convolutional neural network (CNN) architecture for text categorization that can efficiently represent *long-range* associations in text. In the literature, several deep and complex neural networks have been proposed for this task, assuming availability of relatively large amounts of training data. However, the associated computational complexity increases as the networks go deeper, which poses serious challenges in practical applications. Moreover, it was shown recently that shallow word-level CNNs are more accurate and much faster than the state-of-the-art very deep nets such as character-level CNNs even in the setting of large training data. Motivated by these findings, we carefully studied deepening of word-level CNNs to capture global representations of text, and found a simple network architecture with which the best accuracy can be obtained by increasing the network depth without increasing computational cost by much. We call it *deep pyramid CNN*. The proposed model with 15 weight layers outperforms the previous best models on six benchmark datasets for sentiment classification and topic categorization.

1 Introduction

Text categorization is an important task whose applications include spam detection, sentiment classification, and topic classification. In recent years, neural networks that can make use of word order have been shown to be effective for text categorization. While simple and shallow *convolutional neural networks (CNNs)* (Kim, 2014; Johnson and Zhang, 2015a) were proposed for this task earlier, more recently, deep and more complex neural networks have also been studied, assuming availability of relatively large amounts of training data (e.g., one million documents). Examples are deep character-level CNNs (Zhang et al., 2015; Conneau et al., 2016), a complex combination of CNNs and *recurrent neural networks (RNNs)* (Tang et al., 2015), and RNNs in a word-sentence hierarchy (Yang et al., 2016).

A CNN is a feedforward network with convolution layers interleaved with pooling layers. Essentially, a convolution layer converts to a vector every small patch of data (either the original data such as text or image or the output of the previous layer) at every location (e.g., 3-word windows around every word), which can be processed in parallel. By contrast, an RNN has connections that form a cycle. In its typical application to text, a recurrent unit takes words one by one as well as its own output on the previous word, which is parallel-processing unfriendly. While both CNNs and RNNs can take advantage of word order, the simple nature and parallel-processing friendliness of CNNs make them attractive particularly when large training data causes computational challenges.

There have been several recent studies of CNN for text categorization in the large training data setting. For example, in (Conneau et al., 2016), very deep 32-layer character-level CNNs were shown to outperform deep 9-layer character-level CNNs of (Zhang et al., 2015). However, in (Johnson and Zhang, 2016), very shallow 1-layer word-level CNNs were shown to be more accurate and much faster than the very deep character-level CNNs of (Conneau et al., 2016). Although character-level approaches have merit in not having to deal with millions of distinct words, shallow word-level CNNs turned out to be superior even

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 562–570
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1052

when used with only a manageable number (30K) of the most frequent words. This demonstrates the basic fact – knowledge of *word* leads to a powerful representation. These results motivate us to pursue an effective and efficient design of *deep word-level* CNNs for text categorization. Note, however, that it is not as simple as merely replacing characters with words in character-level CNNs; doing so rather degraded accuracy in (Zhang et al., 2015).

We carefully studied deepening of word-level CNNs in the large-data setting and found a deep but low-complexity network architecture with which the best accuracy can be obtained by increasing the depth but not the order of computation time – the total computation time is bounded by a constant. We call it *deep pyramid CNN (DPCNN)*, as the computation time per layer decreases exponentially in a '*pyramid* shape'. After converting discrete text to continuous representation, the DPCNN architecture simply alternates a convolution block and a downsampling layer over and over[1], leading to a deep network in which internal data size (as well as per-layer computation) shrinks in a *pyramid* shape. The network depth can be treated as a meta-parameter. The computational complexity of this network is bounded to be no more than twice that of one convolution block. At the same time, as described later, the 'pyramid' enables efficient discovery of long-range associations in the text (and so more global information), as the network is deepened. This is why DPCNN can achieve better accuracy than the shallow CNN mentioned above (hereafter *ShallowCNN*), which can use only short-range associations. Moreover, DPCNN can be regarded as a deep extension of ShallowCNN, which we proposed in (Johnson and Zhang, 2015b) and later tested with large datasets in (Johnson and Zhang, 2016).

We show that DPCNN with 15 weight layers outperforms the previous best models on six benchmark datasets for sentiment classification and topic classification.

2 Word-level deep pyramid CNN (DPCNN) for text categorization

Overview of DPCNN: DPCNN is illustrated in Figure 1a. The first layer performs *text region embedding*, which generalizes commonly used *word embedding* to the embedding of text regions covering one or more words. It is followed by stacking of *convolution blocks* (two convolution layers and a shortcut) interleaved with pooling layers with stride 2 for downsampling. The final pooling layer aggregates internal data for each document into one vector. We use max pooling for all pooling layers. The key features of DPCNN are as follows.

- Downsampling *without* increasing the *number of feature maps* (dimensionality of layer output, 250 in Figure 1a). Downsampling enables efficient representation of long-range associations (and so more global information) in the text. By keeping the same number of feature maps, every 2-stride downsampling reduces the per-block computation by half and thus the total computation time is bounded by a constant.

- Shortcut connections with pre-activation and identity mapping (He et al., 2016) for enabling training of deep networks.

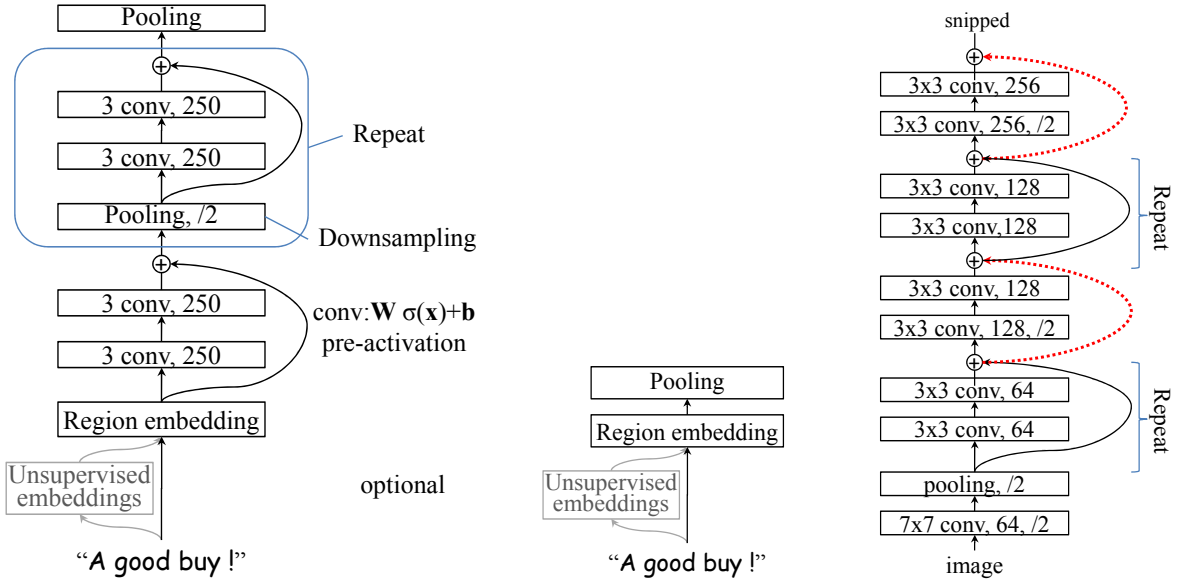
- Text region embedding enhanced with *unsupervised embeddings* (embeddings trained in an unsupervised manner) (Johnson and Zhang, 2015b) for improving accuracy.

2.1 Network architecture

Downsampling with the number of feature maps fixed After each convolution block, we perform max-pooling with size 3 and stride 2. That is, the pooling layer produces a new internal representation of a document by taking the component-wise maximum over 3 contiguous internal vectors, representing 3 overlapping text regions, but it does this only for every other possible triplet (stride 2) instead of all the possible triplets (stride 1). This 2-stride downsampling reduces the size of the internal representation of each document by half.

A number of models (Simonyan and Zisserman, 2015; He et al., 2015, 2016; Conneau et al., 2016) increase the number of feature maps whenever downsampling is performed, causing the total computational complexity to be a function of the depth. In contrast, we fix the number of feature maps, as we found that increasing the number of feature maps only does harm – increasing computation time substantially without accuracy improvement, as shown later in the experiments.

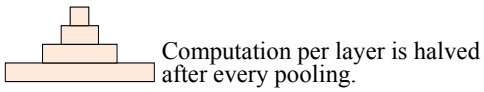
[1]Previous deep CNNs (either on image or text) tend to be more complex and irregular, having occasional increase of the number of feature maps.



(a) Our proposed model DPCNN (b) cf. ShallowCNN [JZ15b] (c) cf. ResNet for image [HZRS15]

Figure 1: (a) Our proposed model DPCNN. (b,c) Previous models for comparison. $\oplus$ indicates addition. The dotted red shortcuts in (c) perform dimension matching. DPCNN is dimension-matching free.

With the number of feature maps fixed, the computation time for each convolution layer is halved (as the data size is halved) whenever 2-stride downsampling is performed, thus, forming a '*pyramid*'.



Therefore, with DPCNNs, the total computation time is bounded by a constant – twice the computation time of a single block, which makes our deep pyramid networks computationally attractive.

In addition, downsampling with stride 2 essentially doubles the effective coverage (i.e., coverage in the original document) of the convolution kernel; therefore, after going through downsampling L times, associations among words within a distance in the order of 2^L can be represented. Thus, deep pyramid CNN is computationally efficient for representing long-range associations and so more global information.

Shortcut connections with pre-activation To enable training of deep networks, we use additive shortcut connections with identity mapping, which can be written as $\mathbf{z} + f(\mathbf{z})$ where f represents the skipped layers (He et al., 2016). In DPCNN, the skipped layers $f(\mathbf{z})$ are two convolution layers with *pre-activation*. Here, pre-activation refers to activation being done *before* weighting instead of *after* as is typically done. That is, in the convolution layer of DPCNN, $\mathbf{W}\sigma(\mathbf{x}) + \mathbf{b}$ is computed at every location of each document where a column vector $\mathbf{x}$ represents a small region (overlapping with each other) of input at each location, $\sigma(\cdot)$ is a component-wise nonlinear activation, and weights $\mathbf{W}$ and biases $\mathbf{b}$ (unique to each layer) are the parameters to be trained. The number of $\mathbf{W}$'s rows is the *number of feature maps* (also called the *number of filters* (He et al., 2015)) of this layer. We set activation $\sigma(\cdot)$ to the rectifier $\sigma(x) = \max(x, 0)$. In our implementation, we fixed the number of feature maps to 250 and the kernel size (the size of the small region covered by $\mathbf{x}$) to 3, as shown in Figure 1a.

With pre-activation, it is the results of linear weighting ($\mathbf{W}\sigma(\mathbf{x}) + \mathbf{b}$) that travel through the shortcut, and what is added to them at a $\oplus$ (Figure 1a) is also the results of linear weighting, instead of the results of nonlinear activation ($\sigma(\mathbf{W}\mathbf{x} + \mathbf{b})$). Intuitively, such 'linearity' eases training of deep networks, similar to the role of *constant error carousels* in LSTM (Hochreiter and Schmidhuber, 1997). We empirically observed that pre-activation indeed outperformed 'post-activation', which is in line with the image results (He et al., 2016).

No need for dimension matching Although the shortcut with pre-activation was adopted from the *improved ResNet* of (He et al., 2016), our model is simpler than ResNet (Figure 1c), as all the

shortcuts are exactly simple *identity mapping* (i.e., passing data exactly as it is) without any complication for dimension matching. When a shortcut meets the 'main street', the data from two paths need to have the same dimensionality so that they can be added; therefore, if a shortcut skips a layer that changes the dimensionality, e.g., by downsampling or by use of a different number of feature maps, then a shortcut must perform dimension matching. Dimension matching for increased number of feature maps, in particular, is typically done by projection, introducing more weight parameters to be trained. We eliminate the complication of dimension matching by not letting any shortcut skip a downsampling layer, and by fixing the number of feature maps throughout the network. The latter also substantially saves computation time as mentioned above, and we will show later in our experiments that on our tasks, we do not sacrifice anything for such a substantial efficiency gain.

2.2 Text region embedding

A CNN for text categorization typically starts with converting each word in the text to a word vector (word embedding). We take a more general viewpoint as in (Johnson and Zhang, 2015b) and consider *text region embedding* – embedding of a region of text covering one or more words.

Basic region embedding We start with the basic setting where there is no unsupervised embedding. In the region embedding layer we compute $\mathbf{W}\mathbf{x} + \mathbf{b}$ for each word of a document where input $\mathbf{x}$ represents a k-word region (i.e., window) around the word in some straightforward manner, and weights $\mathbf{W}$ and bias $\mathbf{b}$ are trained with the parameters of other layers. Activation is delayed to the pre-activation of the next layer. Now let v be the size of vocabulary, and let us consider the following three types of straightforward representation of a k-word region for $\mathbf{x}$: (1) *sequential input*: the kv-dimensional concatenation of k one-hot vectors; (2) *bow input*: a v-dimensional bag-of-word (bow) vector; and (3) *bag-of-n-gram input*: e.g., a bag of word uni, bi, and trigrams contained in the region. Setting the region size $k = 1$, they all become word embedding.

A region embedding layer with the sequential input is equivalent to a convolution layer applied to a sequence of one-hot vectors representing a document, and this viewpoint was taken to describe the first layer of ShallowCNN in (Johnson and Zhang, 2015a,b). From the region embedding viewpoint, ShallowCNN is DPCNN's special case in which a region embedding layer is directly followed by the final pooling layer (Figure 1b).

A region embedding layer with region size $k > 1$ seeks to capture more complex concepts than single words in *one* weight layer, whereas a network with word embedding uses *multiple* weight layers to do this, e.g., word embedding followed by a convolution layer. In general, having fewer layers has a practical advantage of easier optimization. Beyond that, the optimum input type and the optimum region size can only be determined empirically. Our preliminary experiments indicated that when used with DPCNN (but not ShallowCNN), the sequential input has no advantage over the bow input – comparable accuracy with k times more weight parameters; therefore, we excluded the sequential input from our experiments[2]. The n-gram input turned out to be prone to overfitting in the supervised setting, likely due to its high representation power, but it is very useful as the input to unsupervised embeddings, which we discuss next.

Enhancing region embedding with unsupervised embeddings In (Johnson and Zhang, 2015b, 2016), it was shown that accuracy was substantially improved by extending ShallowCNN with unsupervised embeddings obtained by *tv-embedding* training ('tv' stands for *two views*). We found that accuracy of DPCNN can also be improved in this manner. Below we briefly review tv-embedding training and then describe how we use the resulting unsupervised embeddings with DPCNN.

The tv-embedding training requires two views. For text categorization, we define a region of text as view-1 and its adjacent regions as view-2. Then using unlabeled data, we train a neural network of one hidden layer with an artificial task of predicting view-2 from view-1. The obtained hidden layer, which is an embedding function that takes view-1 as input, serves as an unsupervised embedding function in the model for text categorization. In (Johnson and Zhang, 2015b), we showed theoretical conditions on views and labels under which

[2]This differs from ShallowCNN where the sequential input is often superior to bow input. We conjecture that when bow input is used in DPCNN, convolution layers following region embedding make up for the loss of local word order caused by bow input, as they use word order.

	AG	Sogou	Dbpedia	Yelp.p	Yelp.f	Yahoo	Ama.f	Ama.p

Table 1: Data. Note that Yelp.f is a balanced subset of Yelp 2015. The results on these two datasets are not comparable.

unsupervised embeddings obtained this way are useful for classification.

For use with DPCNN, we train several unsupervised embeddings in this manner, which differ from one another in the region size and the vector representations of view-1 (input region) so that we can benefit from diversity. The region embedding layer of DPCNN computes $\mathbf{W}\mathbf{x} + \sum_{u \in U} \mathbf{W}^{(u)}\mathbf{z}^{(u)} + \mathbf{b}$, where $\mathbf{x}$ is the discrete input as in the basic region embedding, and $\mathbf{z}^{(u)}$ is the output of an unsupervised embedding function indexed by u. We will show below that use of unsupervised embeddings in this way consistently improves the accuracy of DPCNN.

3 Experiments

We report the experiments with DPCNNs in comparison with previous models and alternatives. The code is publicly available on the internet.

3.1 Experimental setup

Data and data preprocessing To facilitate comparisons with previous results, we used the eight datasets compiled by Zhang et al. (2015), summarized in Table 1. AG and Sogou are news. Dbpedia is an ontology. Yahoo consists of questions and answers from the 'Yahoo! Answers' website. Yelp and Amazon ('Ama') are reviews where '.p' (polarity) in the names indicates that labels are binary (positive/negative), and '.f' (full) indicates that labels are the number of stars. Sogou is in Romanized Chinese, and the others are in English. Classes are balanced on all the datasets. Data preprocessing was done as in (Johnson and Zhang, 2016). That is, upper-case letters were converted to lower-case letters. Unlike (Kim, 2014; Zhang et al., 2015; Conneau et al., 2016), variable-sized documents were handled as variable-sized without any shortening or padding; however, the vocabulary size was limited to 30K words. For example, as also mentioned in (Johnson and Zhang, 2016), the complete vocabulary of the Ama.p training set contains 1.3M words. A vocabulary of 30K words is only a small portion of it, but it covers about 98% of the text and produced good accuracy as reported below.

Training protocol We held out 10K documents from the training data for use as a validation set on each dataset, and meta-parameter tuning was done based on the performance on the validation set.

To minimize a log loss with softmax, mini-batch SGD with momentum 0.9 was conducted for n epochs (n was fixed to 50 for AG, 30 for Yelp.f/p and Dbpedia, and 15 for the rest) while the learning rate was set to η for the first $\frac{4}{5}n$ epochs and then 0.1η for the rest[3]. The initial learning rate η was considered to be a meta-parameter. The mini-batch size was fixed to 100. Regularization was done by weight decay with the parameter 0.0001 and by optional dropout (Hinton et al., 2012) with 0.5 applied to the input to the top layer. In some cases overfitting was observed, and so we performed early stopping, based on the validation performance, after reducing the learning rate to 0.1η. Weights were initialized by the Gaussian distribution with zero mean and standard deviation 0.01. The discrete input to the region embedding layer was fixed to the bow input, and the region size was chosen from {1,3,5}, while fixing output dimensionality to 250 (same as convolution layers).

Details of unsupervised embedding training To facilitate comparison with ShallowCNN, we matched our unsupervised embedding setting exactly with that of (Johnson and Zhang, 2016). That is, we trained the same four types of tv-embeddings, which are embeddings of 5- and 9-word regions, each of which represents the input regions by either 30K-dim bow or 200K-dim

[3]This learning rate scheduling method was used also in (Johnson and Zhang, 2015a,b, 2016). It was meant to reduce learning rate when error plateaus, as is often done on image tasks, e.g., (He et al., 2015), though for simplicity, the timing of reduction was fixed for each dataset.

	Models	Deep	Unsup. embed.	Yelp.p	Yelp.f	Yahoo	Ama.f	Ama.p

bags of {1,2,3}-grams, retaining only the most frequent 30K words or 200K {1,2,3}-grams. Training was done on the labeled data (disregarding the labels), setting the training objectives to the prediction of adjacent regions of the same size as the input region (i.e., 5 or 9). Weighted square loss $\sum_{i,j} \alpha_{i,j}(\mathbf{z}_i[j] - \mathbf{p}_i[j])^2$ was minimized where i goes through instances, $\mathbf{z}$ represents the target regions by bow, $\mathbf{p}$ is the model output, and the weights $\alpha_{i,j}$ were set to achieve the negative sampling effect. The dimensionality of unsupervised embeddings was set to 300 unless otherwise specified. Unsupervised embeddings were fixed during the supervised training – no fine-tuning.

3.2 Results

In the results below, the *depth* of DPCNN was fixed to 15 unless otherwise specified. Making it deeper did not substantially improve or degrade accuracy. Note that we count as *depth* the number of hidden weight layers including the region embedding layer but excluding unsupervised embeddings, therefore, 15 means 7 convolution blocks of 2 layers plus 1 layer for region embedding.

3.2.1 Main results

Large data results We first report the error rates of our full model (DPCNN with 15 weight layers plus unsupervised embeddings) on the larger five datasets (Table 2). To put it into perspective, we also show the previous results in the literature. The previous results are roughly sorted in the order of error rates from best to worst. On all the five datasets, DPCNN outperforms all of the previous results, which validates the effectiveness of our approach.

DPCNN can be regarded as a deep extension of ShallowCNN (row 2), sharing region embedding enhancement with diverse unsupervised embeddings. Note that ShallowCNN enhanced with unsupervised embeddings (row 2) was originally proposed in (Johnson and Zhang, 2015b) as a semi-supervised extension of (Johnson and Zhang, 2015a), and then it was tested on the large datasets in (Johnson and Zhang, 2016). The performance improvements of DPCNN over ShallowCNN indicates that the added depth is indeed useful, capturing more global information. Yang et al. (2016)'s hierarchical attention network (row 3) consists of RNNs in the word level and the sentence level. It is more complex than DPCNN due to the use of RNNs and linguistic knowledge for sentence segmentation. Similarly, Tang et al. (2015) proposed to use CNN or LSTM to represent each sentence in documents and then use RNNs. Although we do not have direct comparison with Tang et al.'s model, Yang et al. (2016) reports that their model outperformed Tang et al.'s model. Conneau et al. (2016) and Zhang et al. (2015) proposed deep character-level CNNs (row 4&6). Their models underperform our DPCNN with relatively large differences in spite of their deepness. Our mod-

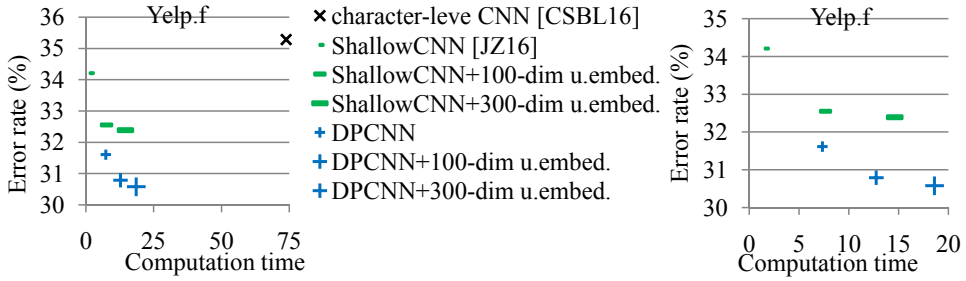

Figure 2: Error rates and computation time. DPCNN, ShallowCNN, and Conneau et al. (2016)'s character-level CNN. The x-axis is the time in seconds spent for categorizing 10K documents using our implementation on Tesla M2070. The right figure is a close-up of $x \in [0, 20]$ of the left figure. Though shown on one particular dataset Yelp.f, the trend is the same on the other four large datasets.

els are word-level and therefore use the knowledge of word boundaries which character-level models have no access to. While this is arguably not an apple-to-apple comparison, since word boundaries can be obtained for free in many languages, we view our model as much more useful in practice. Row 7 shows the performance of deep word-level CNN from (Zhang et al., 2015), which was designed to match their character-level models in complexity. Its relatively poor performance shows that it is not easy to design a high-performance deep word-level CNN.

Computation time In Figure 2, we plot error rates in relation to the computation time – the time spent for categorizing 10K documents using our implementation on a GPU. The right figure is a close-up of $x \in [0, 20]$ of the left figure. It stands out in the left figure that the character-level CNN of (Conneau et al., 2016) is much slower than DPCNNs. This is partly because it increases the number of feature maps with downsampling (i.e., no *pyramid*) while it is deeper (32 weight layers), and partly because it deals with characters – there are more characters than words in each document. DPCNNs are more accurate than ShallowCNNs at the expense of more computation time due to the depth (15 layers vs. 1 layer). Nevertheless, their computation time is comparable – the points of both fit in the same range $[0, 20]$. The efficiency of DPCNNs is due to the exponential decrease of per-layer computation due to downsampling with the number of feature maps being fixed.

Comparison with non-pyramid variants Furthermore, we tested the following two 'non-pyramid' models for comparison. The first model doubles the number of feature maps at every other downsampling so that per-layer computation is kept approximately constant[4]. The second model performs no downsampling. Otherwise, these two models are the same as DPCNN. We show in Figure 3 the error rates of these two variations (labeled as 'Increase #feature maps' and 'No downsampling', respectively) in comparison with DPCNN. The x-axis is the computation time, measured by the seconds spent for categorizing 10K documents. For all types, the models of depth 11 and 15 are shown. Clearly, DPCNN is more accurate and computes faster than the others. Figure 3 is on Yelp.f, and we observed the same performance trend on the other four large datasets.

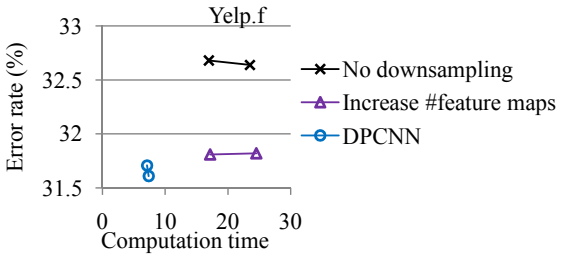

Figure 3: Comparison with non-pyramid models. Models of depth 11 and 15 are shown. No unsupervised embeddings.

Small data results Now we turn to the results on the three smaller datasets in Table 3. Again, the previous models are roughly sorted from best to worst. For these small datasets, the DPCNN performances with 100-dim unsupervised embed-

[4]Note that if we double the number of feature maps, it would increase the computation cost of the next layer by 4 times as it doubles the dimensionality of both input and output. On image, downsampling with stride 2 cancels it out as it makes data 4 times smaller by shrinking both horizontally and vertically, but text is one dimensional, and so downsampling with stride 2 merely halves data. That is why we doubled the number of feature maps at every other downsampling instead of at every downsampling to avoid exponential increase of computation time.

dings are shown, which turned out to be as good as those with 300-dim unsupervised embeddings. One difference from the large dataset results is that the strength of shallow models stands out. ShallowCNN (row 2) rivals DPCNN (row 1), and Zhang et al.'s best linear model (row 3) moved up from the worst performer to the third best performer. The results are in line with the general fact that more complex models require more training data, and with the paucity of training data, simpler models can outperform more complex ones.

3.2.2 Empirical studies

We present some empirical results to validate the design choices. For this purpose, the larger five datasets were used to avoid the paucity of training data.

Depth Figure 4 shows error rates of DPCNNs with 3, 7, and 15 weight layers (blue circles from left to right). For comparison, the ShallowCNN results (green 'x') from (Johnson and Zhang, 2016) are also shown. The x-axis represents the computation time (seconds for categorizing 10K documents on a GPU). For simplicity, the results without unsupervised embeddings are shown for all. The error rate improves as the depth increases. The results confirm the effectiveness of our strategy of deepening the network.

Unsupervised embeddings To study the effectiveness of unsupervised embeddings, we experimented with variations of DPCNN that differ only in whether/how to use unsupervised embeddings (Table 4). First, we compare DPCNNs with and without unsupervised embeddings. The model with unsupervised embeddings (row 1, copied from Table 2 for easy comparison) clearly outperforms the one without them (row 4), which confirms the effectiveness of the use of unsupervised embeddings. Second, in the proposed model (row 1), a region embedding layer receives two types of input, the output of unsupervised embedding functions and the high-dimensional discrete input such as a bow vector. Row 2 shows the results obtained by using unsupervised embeddings to produce sole input (i.e., no discrete vectors provided to the region embedding layer). Degradations of error rates are up to 0.32%, small but consistent. Since the discrete input add almost no computation cost due to its sparseness, its use is desirable. Third, a number of previous studies used unsupervised word embedding to initialize word embedding in neural networks and then fine-tune it as training proceeds (pretraining). The model in row 3 does this with DPCNN using word2vec (Mikolov et al., 2013). The word2vec training was done on the training data (ignoring the labels),

	Unsupervised embeddings	Yelp.p	Yelp.f	Yahoo	Ama.f	Ama.p
1	tv-embed. (additional input)	**2.64**	**30.58**	**23.90**	**34.81**	**3.32**
2	tv-embed. (sole input)	2.68	30.66	24.09	35.13	3.45
3	word2vec (pretraining)	2.93	32.08	24.11	35.30	3.65
4	–	3.30	31.61	24.64	35.61	3.64

Table 4: Error rates (%) of DPCNN variations that differ in use of unsupervised embeddings. The rows are roughly sorted from best to worst.

same as tv-embedding training. This model (row 3) underperformed our proposed model (row 1). We attribute the superiority of the proposed model to its use of richer information than a word embedding. These results support our approach.

4 Conclusion

This paper tackled the problem of designing high-performance deep word-level CNNs for text categorization in the large training data setting. We proposed a deep pyramid CNN model which has low computational complexity, and can efficiently represent long-range associations in text and so more global information. It was shown to outperform the previous best models on six benchmark datasets.

Abstract

Relation detection is a core component of many NLP applications including Knowledge Base Question Answering (KBQA). In this paper, we propose a hierarchical recurrent neural network enhanced by residual learning which detects KB relations given an input question. Our method uses deep residual bidirectional LSTMs to compare questions and relation names via different levels of abstraction. Additionally, we propose a simple KBQA system that integrates entity linking and our proposed relation detector to make the two components enhance each other. Our experimental results show that our approach not only achieves outstanding relation detection performance, but more importantly, it helps our KBQA system achieve state-of-the-art accuracy for both single-relation (SimpleQuestions) and multi-relation (WebQSP) QA benchmarks.

1 Introduction

Knowledge Base Question Answering (KBQA) systems answer questions by obtaining information from KB tuples (Berant et al., 2013; Yao et al., 2014; Bordes et al., 2015; Bast and Haussmann, 2015; Yih et al., 2015; Xu et al., 2016). For an input question, these systems typically generate a KB query, which can be executed to retrieve the answers from a KB. Figure 1 illustrates the process used to parse two sample questions in a KBQA system: (a) a single-relation question, which can be answered with a single <*head-entity, relation, tail-entity*> KB tuple (Fader et al., 2013; Yih et al., 2014; Bordes et al., 2015); and (b) a more complex case, where some constraints need to be handled for multiple entities in the question. The KBQA system in the figure performs two key tasks: (1) *entity linking*, which links n-grams in questions to KB entities, and (2) *relation detection*, which identifies the KB relation(s) a question refers to.

The main focus of this work is to improve the *relation detection* subtask and further explore how it can contribute to the KBQA system. Although general relation detection[1] methods are well studied in the NLP community, such studies usually do not take the end task of KBQA into consideration. As a result, there is a significant gap between general relation detection studies and KB-specific relation detection. First, in most general relation detection tasks, the number of target relations is limited, normally smaller than 100. In contrast, in KBQA even a small KB, like Freebase2M (Bordes et al., 2015), contains more than 6,000 relation types. Second, relation detection for KBQA often becomes a zero-shot learning task, since some test instances may have unseen relations in the training data. For example, the SimpleQuestions (Bordes et al., 2015) data set has 14% of the golden test relations not observed in golden training tuples. Third, as shown in Figure 1(b), for some KBQA tasks like WebQuestions (Berant et al., 2013), we need to predict a chain of relations instead of a single relation. This increases the number of target relation types and the sizes of candidate relation pools, further increasing the difficulty of KB relation detection. Owing to these reasons, KB relation detection is significantly more challenging compared to general relation detection tasks.

This paper improves KB relation detection to cope with the problems mentioned above. First, in order to deal with the unseen relations, we propose to break the relation names into word sequences for question-relation matching. Second, noticing

[1]In the information extraction field such tasks are usually called *relation extraction* or *relation classification*.

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 571–581
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1053

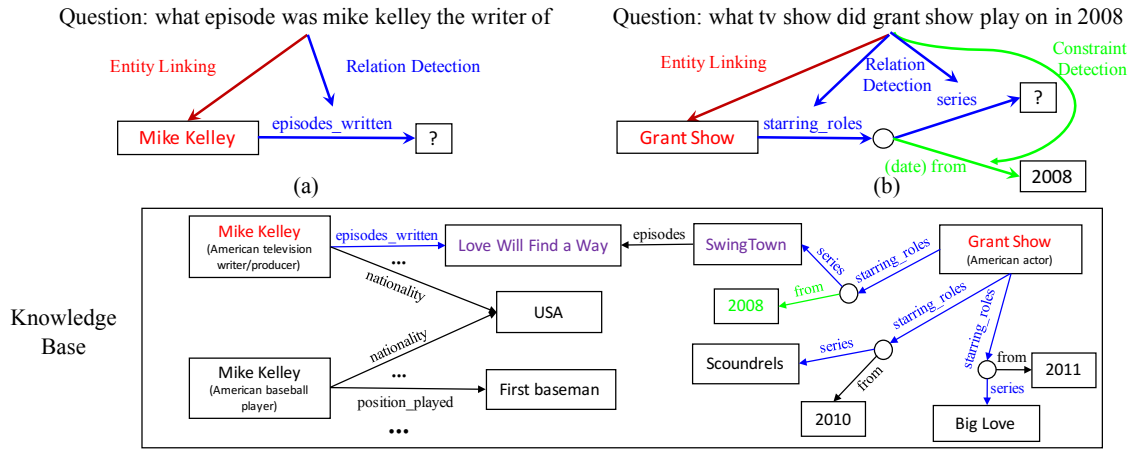

Figure 1: KBQA examples and its three key components. (a) A single relation example. We first identify the topic entity with ***entity linking*** and then detect the relation asked by the question with ***relation detection*** (from all relations connecting the topic entity). Based on the detected entity and relation, we form a query to search the KB for the correct answer "*Love Will Find a Way*". (b) A more complex question containing two entities. By using "*Grant Show*" as the topic entity, we could detect a chain of relations "*starring_roles-series*" pointing to the answer. An additional ***constraint detection*** takes the other entity "*2008*" as a constraint, to filter the correct answer "*SwingTown*" from all candidates found by the topic entity and relation.

that original relation names can sometimes help to match longer question contexts, we propose to build both relation-level and word-level relation representations. Third, we use deep bidirectional LSTMs (*BiLSTM*s) to learn different levels of question representations in order to match the different levels of relation information. Finally, we propose a residual learning method for sequence matching, which makes the model training easier and results in more abstract (deeper) question representations, thus improves hierarchical matching.

In order to assess how the proposed *improved relation detection* could benefit the KBQA end task, we also propose a simple KBQA implementation composed of *two-step relation detection*. Given an input question and a set of candidate entities retrieved by an entity linker based on the question, our proposed relation detection model plays a key role in the KBQA process: (1) Re-ranking the entity candidates according to whether they connect to high confident relations detected from the *raw question text* by the relation detection model. This step is important to deal with the ambiguities normally present in entity linking results. (2) Finding the core relation (chains) for each *topic entity*[2] selection from a much smaller candidate entity set after re-ranking. The above steps are followed by an optional constraint detection step, when the question cannot be answered by single relations (e.g., multiple entities in the question). Finally the highest scored query from the above steps is used to query the KB for answers.

Our main contributions include: (i) An improved relation detection model by hierarchical matching between questions and relations with residual learning; (ii) We demonstrate that the improved relation detector enables our simple KBQA system to achieve state-of-the-art results on both single-relation and multi-relation KBQA tasks.

2 Related Work

Relation Extraction Relation extraction (RE) is an important sub-field of information extraction. General research in this field usually works on a (small) pre-defined relation set, where given a text paragraph and two target entities, the goal is to determine whether the text indicates any types of relations between the entities or not. As a result RE is usually formulated as a **classification task**. Traditional RE methods rely on large amount of hand-crafted features (Zhou et al., 2005; Rink and Harabagiu, 2010; Sun et al., 2011). Recent research benefits a lot from the advancement of deep learning: from word embeddings (Nguyen and Grishman, 2014; Gormley et al., 2015) to deep networks like CNNs and LSTMs (Zeng et al., 2014; dos Santos et al., 2015; Vu et al., 2016) and attention models (Zhou et al., 2016; Wang et al., 2016).

The above research assumes there is a fixed (closed) set of relation types, thus no zero-shot learning capability is required. The number of relations is usually not large: The widely used ACE2005 has 11/32 coarse/fine-grained relations; SemEval2010 Task8 has 19 relations; TAC-

[2]Following Yih et al. (2015), here *topic entity* refers to the root of the (directed) query tree; and *core-chain* is the directed path of relation from root to the answer node.

KBP2015 has 74 relations although it considers open-domain Wikipedia relations. All are much fewer than thousands of relations in KBQA. As a result, few work in this field focuses on dealing with large number of relations or unseen relations. Yu et al. (2016) proposed to use relation embeddings in a low-rank tensor method. However their relation embeddings are still trained in supervised way and the number of relations is not large in the experiments.

Relation Detection in KBQA Systems Relation detection for KBQA also starts with feature-rich approaches (Yao and Van Durme, 2014; Bast and Haussmann, 2015) towards usages of deep networks (Yih et al., 2015; Xu et al., 2016; Dai et al., 2016) and attention models (Yin et al., 2016; Golub and He, 2016). Many of the above relation detection research could naturally support large relation vocabulary and open relation sets (especially for QA with OpenIE KB like ParaLex (Fader et al., 2013)), in order to fit the goal of open-domain question answering.

Different KBQA data sets have different levels of requirement about the above open-domain capacity. For example, most of the gold test relations in WebQuestions can be observed during training, thus some prior work on this task adopted the close domain assumption like in the general RE research. While for data sets like SimpleQuestions and ParaLex, the capacity to support large relation sets and unseen relations becomes more necessary. To the end, there are two main solutions: (1) use pre-trained relation embeddings (e.g. from TransE (Bordes et al., 2013)), like (Dai et al., 2016); (2) factorize the relation names to sequences and formulate relation detection as a **sequence matching and ranking** task. Such factorization works because that the relation names usually comprise meaningful word sequences. For example, Yin et al. (2016) split relations to word sequences for single-relation detection. Liang et al. (2016) also achieve good performance on WebQSP with word-level relation representation in an end-to-end neural programmer model. Yih et al. (2015) use character tri-grams as inputs on both question and relation sides. Golub and He (2016) propose a generative framework for single-relation KBQA which predicts relation with a character-level sequence-to-sequence model.

Another difference between relation detection in KBQA and general RE is that general RE research assumes that the two argument entities are both available. Thus it usually benefits from features (Nguyen and Grishman, 2014; Gormley et al., 2015) or attention mechanisms (Wang et al., 2016) based on the entity information (e.g. entity types or entity embeddings). For relation detection in KBQA, such information is mostly missing because: (1) one question usually contains single argument (the topic entity) and (2) one KB entity could have multiple types (type vocabulary size larger than 1,500). This makes KB entity typing itself a difficult problem so no previous used entity information in the relation detection model.[3]

3 Background: Different Granularity in KB Relations

Previous research (Yih et al., 2015; Yin et al., 2016) formulates KB relation detection as a sequence matching problem. However, while the questions are natural word sequences, how to represent relations as sequences remains a challenging problem. Here we give an overview of two types of relation sequence representations commonly used in previous work.

(1) Relation Name as a Single Token (*relation-level*). In this case, each relation name is treated as a unique token. The problem with this approach is that it suffers from the low relation coverage due to limited amount of training data, thus cannot generalize well to large number of open-domain relations. For example, in Figure 1, when treating relation names as single tokens, it will be difficult to match the questions to relation names "*episodes_written*" and "*starring_roles*" if these names do not appear in training data – their relation embeddings $\mathbf{h}^r$s will be random vectors thus are not comparable to question embeddings $\mathbf{h}^q$s.

(2) Relation as Word Sequence (*word-level*). In this case, the relation is treated as a sequence of words from the tokenized relation name. It has better generalization, but suffers from the lack of global information from the original relation names. For example in Figure 1(b), when doing only word-level matching, it is difficult to rank the target relation "*starring_roles*" higher compared to the incorrect relation "*plays_produced*". This is because the incorrect relation contains word "*plays*", which is more similar to the question

[3] Such entity information has been used in KBQA systems as features for the final answer re-rankers.

	Relation Token	Question 1	Question 2
		what tv episodes were <e> the writer of	what episode was written by <e>
relation-level	episodes_written	*tv episodes were <e> the writer of*	*episode was written by <e>*
word-level	episodes	*tv episodes*	*episode*
	written	*the writer of*	*written*

Table 1: An example of KB relation (*episodes_written*) with two types of relation tokens (relation names and words), and two questions asking this relation. The topic entity is replaced with token $<e>$ which could give the position information to the deep networks. The italics show the evidence phrase for each relation token in the question.

(containing word "*play*") in the embedding space. On the other hand, if the target relation co-occurs with questions related to "*tv appearance*" in training, by treating the whole relation as a token (i.e. relation id), we could better learn the correspondence between this token and phrases like "*tv show*" and "*play on*".

The two types of relation representation contain different levels of abstraction. As shown in Table 1, the word-level focuses more on local information (words and short phrases), and the relation-level focus more on global information (long phrases and skip-grams) but suffer from data sparsity. Since both these levels of granularity have their own pros and cons, we propose a hierarchical matching approach for KB relation detection: for a candidate relation, our approach matches the input question to both word-level and relation-level representations to get the final ranking score. Section 4 gives the details of our proposed approach.

4 Improved KB Relation Detection

This section describes our hierarchical sequence matching with residual learning approach for relation detection. In order to match the question to different aspects of a relation (with different abstraction levels), we deal with three problems as follows on learning question/relation representations.

4.1 Relation Representations from Different Granularity

We provide our model with both types of relation representation: word-level and relation-level. Therefore, the input relation becomes $\mathbf{r} = \{r_1^{word}, \cdots, r_{M_1}^{word}\} \cup \{r_1^{rel}, \cdots, r_{M_2}^{rel}\}$, where the first M_1 tokens are words (e.g. $\{$*episode, written*$\}$), and the last M_2 tokens are relation names, e.g., $\{$*episode_written*$\}$ or $\{$*starring_roles, series*$\}$ (when the target is a chain like in Figure 1(b)). We transform each token above to its word embedding then use two BiLSTMs (with shared parameters) to get their hidden representations $[\mathbf{B}_{1:M_1}^{word} : \mathbf{B}_{1:M_2}^{rel}]$ (each row vector $\boldsymbol{\beta}_i$ is the concatenation between forward/backward representations at i). We initialize the relation sequence LSTMs with the final state representations of the word sequence, as a back-off for unseen relations. We apply *one* max-pooling on these two sets of vectors and get the final relation representation $\mathbf{h}^r$.

4.2 Different Abstractions of Questions Representations

From Table 1, we can see that different parts of a relation could match different contexts of question texts. Usually relation names could match longer phrases in the question and relation words could match short phrases. Yet different words might match phrases of different lengths.

As a result, we hope the question representations could also comprise vectors that summarize various lengths of phrase information (different levels of abstraction), in order to match relation representations of different granularity. We deal with this problem by applying deep BiLSTMs on questions. The first-layer of BiLSTM works on the word embeddings of question words $\mathbf{q} = \{q_1, \cdots, q_N\}$ and gets hidden representations $\mathbf{\Gamma}_{1:N}^{(1)} = [\boldsymbol{\gamma}_1^{(1)}; \cdots; \boldsymbol{\gamma}_N^{(1)}]$. The second-layer BiLSTM works on $\mathbf{\Gamma}_{1:N}^{(1)}$ to get the second set of hidden representations $\mathbf{\Gamma}_{1:N}^{(2)}$. Since the second BiLSTM starts with the hidden vectors from the first layer, intuitively it could learn more general and abstract information compared to the first layer.

Note that the first(second)-layer of question representations does not necessarily correspond to the word(relation)-level relation representations, instead either layer of question representations could potentially match to either level of relation representations. This raises the difficulty of matching between different levels of relation/question representations; the following section gives our proposal to deal with such problem.

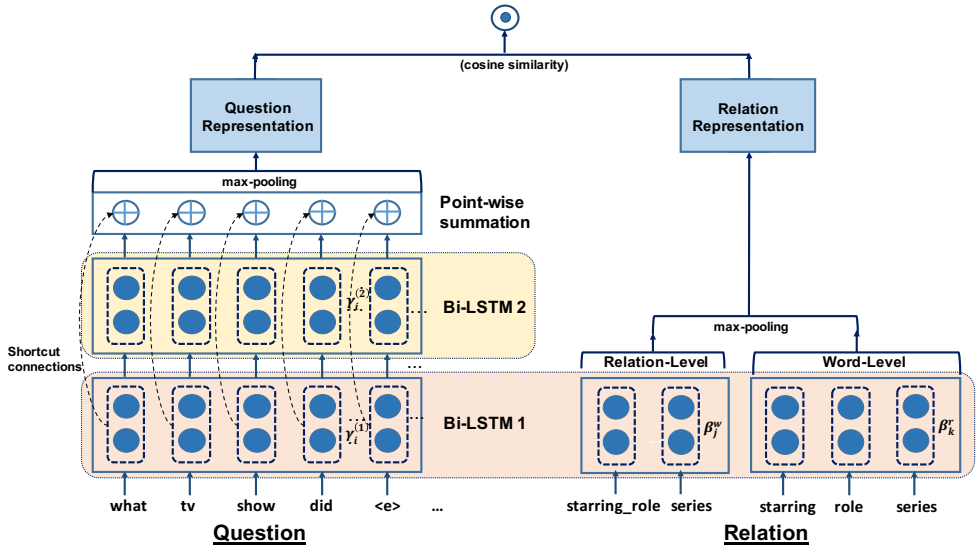

Figure 2: The proposed Hierarchical Residual BiLSTM (HR-BiLSTM) model for relation detection. Note that without the dotted arrows of shortcut connections between two layers, the model will only compute the similarity between the second-layer of questions representations and the relation, thus is not doing hierarchical matching.

4.3 Hierarchical Matching between Relation and Question

Now we have question contexts of different lengths encoded in $\mathbf{\Gamma}^{(1)}_{1:N}$ and $\mathbf{\Gamma}^{(2)}_{1:N}$. Unlike the standard usage of deep BiLSTMs that employs the representations in the final layer for prediction, here we expect that two layers of question representations can be complementary to each other and both should be compared to the relation representation space (*Hierarchical Matching*). This is important for our task since each relation token can correspond to phrases of different lengths, mainly because of syntactic variations. For example in Table 1, the relation word *written* could be matched to either the same single word in the question or a much longer phrase *be the writer of*.

We could perform the above hierarchical matching by computing the similarity between each layer of $\mathbf{\Gamma}$ and $\mathbf{h}^r$ separately and doing the (weighted) sum between the two scores. However this does not give significant improvement (see Table 2). Our analysis in Section 6.2 shows that this naive method suffers from the training difficulty, evidenced by that the converged training loss of this model is much higher than that of a single-layer baseline model. This is mainly because (1) Deep BiLSTMs do not guarantee that the two-levels of question hidden representations are comparable, the training usually falls to local optima where one layer has good matching scores and the other always has weight close to 0. (2) The training of deeper architectures itself is more difficult.

To overcome the above difficulties, we adopt the idea from Residual Networks (He et al., 2016) for hierarchical matching by adding shortcut connections between two BiLSTM layers. We proposed two ways of such *Hierarchical Residual Matching*: (1) Connecting each $\boldsymbol{\gamma}^{(1)}_i$ and $\boldsymbol{\gamma}^{(2)}_i$, resulting in a $\boldsymbol{\gamma}'_i = \boldsymbol{\gamma}^{(1)}_i + \boldsymbol{\gamma}^{(2)}_i$ for each position i. Then the final question representation $\mathbf{h}^q$ becomes a max-pooling over all $\boldsymbol{\gamma}'_i$s, $1 \leq i \leq N$. (2) Applying max-pooling on $\mathbf{\Gamma}^{(1)}_{1:N}$ and $\mathbf{\Gamma}^{(2)}_{1:N}$ to get $\mathbf{h}^{(1)}_{max}$ and $\mathbf{h}^{(2)}_{max}$, respectively, then setting $\mathbf{h}^q = \mathbf{h}^{(1)}_{max} + \mathbf{h}^{(2)}_{max}$. Finally we compute the matching score of $\mathbf{r}$ given $\mathbf{q}$ as $s_{rel}(\mathbf{r}; \mathbf{q}) = cos(\mathbf{h}^r, \mathbf{h}^q)$.

Intuitively, the proposed method should benefit from hierarchical training since the second layer is fitting the residues from the first layer of matching, so the two layers of representations are more likely to be complementary to each other. This also ensures the vector spaces of two layers are comparable and makes the second-layer training easier.

During training we adopt a ranking loss to maximizing the margin between the gold relation $\mathbf{r}^+$ and other relations $\mathbf{r}^-$ in the candidate pool R.

$$l_{\text{rel}} = \max\{0, \gamma - s_{\text{rel}}(\mathbf{r}^+; \mathbf{q}) + s_{\text{rel}}(\mathbf{r}^-; \mathbf{q})\}$$

where γ is a constant parameter. Fig 2 summarizes the above *Hierarchical Residual BiLSTM* (***HR-BiLSTM***) model.

Remark: Another way of hierarchical matching consists in relying on **attention mechanism**, e.g. (Parikh et al., 2016), to find the correspondence between different levels of representations. This performs below the HR-BiLSTM (see Table 2).

5 KBQA Enhanced by Relation Detection

This section describes our KBQA pipeline system. We make minimal efforts beyond the training of the relation detection model, making the whole system easy to build.

Following previous work (Yih et al., 2015; Xu et al., 2016), our KBQA system takes an existing entity linker to produce the top-K linked entities, $EL_K(q)$, for a question q ("*initial entity linking*"). Then we generate the KB queries for q following the four steps illustrated in Algorithm 1.

Algorithm 1: KBQA with two-step relation detection

Input : Question q, Knowledge Base KB, the initial top-K entity candidates $EL_K(q)$
Output: Top query tuple $(\hat{e}, \hat{r}, \{(c, r_c)\})$

1. **Entity Re-Ranking** (*first-step relation detection*): Use the *raw question text* as input for a relation detector to score all relations in the KB that are associated to the entities in $EL_K(q)$; use the relation scores to re-rank $EL_K(q)$ and generate a shorter list $EL'_{K'}(q)$ containing the top-K' entity candidates (Section 5.1)
2. **Relation Detection**: Detect relation(s) using the *reformatted question text* in which the topic entity is replaced by a special token <*e*> (Section 5.2)
3. **Query Generation**: Combine the scores from step 1 and 2, and select the top pair $(\hat{e}, \hat{r})$ (Section 5.3)
4. **Constraint Detection** (optional): Compute similarity between q and any neighbor entity c of the entities along $\hat{r}$ (connecting by a relation r_c) , add the high scoring c and r_c to the query (Section 5.4).

Compared to previous approaches, the main difference is that we have an additional *entity re-ranking* step after the *initial entity linking*. We have this step because we have observed that entity linking sometimes becomes a bottleneck in KBQA systems. For example, on SimpleQuestions the best reported linker could only get 72.7% top-1 accuracy on identifying topic entities. This is usually due to the ambiguities of entity names, e.g. in Fig 1(a), there are *TV writer* and *baseball player* "*Mike Kelley*", which is impossible to distinguish with only entity name matching.

Having observed that different entity candidates usually connect to different relations, here we propose to help entity disambiguation in the *initial entity linking* with relations detected in questions.

Sections 5.1 and 5.2 elaborate how our relation detection help to re-rank entities in the initial entity linking, and then those re-ranked entities enable more accurate relation detection. The KBQA end task, as a result, benefits from this process.

5.1 Entity Re-Ranking

In this step, we use the *raw question text* as input for a relation detector to score all relations in the KB with connections to at least one of the entity candidates in $EL_K(q)$. We call this step *relation detection on entity set* since it does not work on a single topic entity as the usual settings. We use the HR-BiLSTM as described in Sec. 4. For each question q, after generating a score $s_{rel}(r; q)$ for each relation using HR-BiLSTM, we use the top l best scoring relations (R_q^l) to re-rank the original entity candidates. Concretely, for each entity e and its associated relations R_e, given the original entity linker score s_{linker}, and the score of the most confident relation $r \in R_q^l \cap R_e$, we sum these two scores to re-rank the entities:

$$s_{\text{rerank}}(e; q) = \alpha \cdot s_{\text{linker}}(e; q) + (1 - \alpha) \cdot \max_{r \in R_q^l \cap R_e} s_{\text{rel}}(r; q).$$

Finally, we select top $K' < K$ entities according to score s_{rerank} to form the re-ranked list $EL'_{K'}(q)$.

We use the same example in Fig 1(a) to illustrate the idea. Given the input question in the example, a relation detector is very likely to assign high scores to relations such as "*episodes_written*", "*author_of*" and "*profession*". Then, according to the connections of entity candidates in KB, we find that the TV writer "*Mike Kelley*" will be scored higher than the baseball player "*Mike Kelley*", because the former has the relations "*episodes_written*" and "*profession*". This method can be viewed as exploiting entity-relation collocation for entity linking.

5.2 Relation Detection

In this step, for each candidate entity $e \in EL'_K(q)$, we use the question text as the input to a relation detector to score all the relations $r \in R_e$ that are associated to the entity e in the KB.[4] Because we have a single topic entity input in this step, we do the following question reformatting: we replace the the candidate e's entity mention in

[4]Note that the number of entities and the number of relation candidates will be much smaller than those in the previous step.

q with a token "<e>". This helps the model better distinguish the relative position of each word compared to the entity. We use the HR-BiLSTM model to predict the score of each relation $r \in R_e$: $s_{rel}(r; e, q)$.

5.3 Query Generation

Finally, the system outputs the <entity, relation (or core-chain)> pair $(\hat{e}, \hat{r})$ according to:

$$s(\hat{e}, \hat{r}; q) = \max_{e \in EL'_{K'}(q), r \in R_e} (\beta \cdot s_{\text{rerank}}(e; q) + (1 - \beta) \cdot s_{\text{rel}}(r; e, q)),$$

where β is a hyperparameter to be tuned.

5.4 Constraint Detection

Similar to (Yih et al., 2015), we adopt an additional constraint detection step based on text matching. Our method can be viewed as entity-linking on a KB sub-graph. It contains two steps: (1) **Sub-graph generation**: given the top scored query generated by the previous 3 steps[5], for each node v (answer node or the CVT node like in Figure 1(b)), we collect all the nodes c connecting to v (with relation r_c) with any relation, and generate a sub-graph associated to the original query. (2) **Entity-linking on sub-graph nodes**: we compute a matching score between each n-gram in the input question (without overlapping the topic entity) and entity name of c (except for the node in the original query) by taking into account the maximum overlapping sequence of characters between them (see Appendix A for details and B for special rules dealing with date/answer type constraints). If the matching score is larger than a threshold θ (tuned on training set), we will add the constraint entity c (and r_c) to the query by attaching it to the corresponding node v on the core-chain.

6 Experiments

6.1 Task Introduction & Settings

We use the SimpleQuestions (Bordes et al., 2015) and WebQSP (Yih et al., 2016) datasets. Each question in these datasets is labeled with the gold semantic parse. Hence we can directly evaluate relation detection performance independently as well as evaluate on the KBQA end task.

SimpleQuestions (SQ): It is a single-relation KBQA task. The KB we use consists of a Freebase subset with 2M entities (FB2M) (Bordes et al., 2015), in order to compare with previous research. Yin et al. (2016) also evaluated their relation extractor on this data set and released their proposed question-relation pairs, so we run our relation detection model on their data set. For the KBQA evaluation, we also start with their entity linking results[6]. Therefore, our results can be compared with their reported results on both tasks.

WebQSP (WQ): A multi-relation KBQA task. We use the entire Freebase KB for evaluation purposes. Following Yih et al. (2016), we use S-MART (Yang and Chang, 2015) entity-linking outputs.[7] In order to evaluate the relation detection models, we create a new relation detection task from the WebQSP data set.[8] For each question and its labeled semantic parse: (1) we first select the topic entity from the parse; and then (2) select all the relations and relation chains (length ≤ 2) connected to the topic entity, and set the core-chain labeled in the parse as the positive label and all the others as the negative examples.

We tune the following hyper-parameters on development sets: (1) the size of hidden states for LSTMs ($\{50, 100, 200, 400\}$)[9]; (2) learning rate ($\{0.1, 0.5, 1.0, 2.0\}$); (3) whether the shortcut connections are between hidden states or between max-pooling results (see Section 4.3); and (4) the number of training epochs.

For both the relation detection experiments and the second-step relation detection in KBQA, we have *entity replacement* first (see Section 5.2 and Figure 1). All word vectors are initialized with 300-d pretrained word embeddings (Mikolov et al., 2013). The embeddings of relation names are randomly initialized, since existing pre-trained relation embeddings (e.g. TransE) usually support limited sets of relation names. We leave the usage of pre-trained relation embeddings to future work.

6.2 Relation Detection Results

Table 2 shows the results on two relation detection tasks. The AMPCNN result is from (Yin et al., 2016), which yielded state-of-the-art scores by outperforming several attention-based meth-

[5]Starting with the top-1 query suffers more from error propagation. However we still achieve state-of-the-art on WebQSP in Sec.6, showing the advantage of our relation detection model. We leave in future work beam-search and feature extraction on beam for final answer re-ranking like in previous research.

[6]The two resources have been downloaded from https://github.com/Gorov/SimpleQuestions-EntityLinking

[7]https://github.com/scottyih/STAGG

[8]The dataset is available at https://github.com/Gorov/SimpleQuestions-EntityLinking.

[9]For CNNs we double the size for fair comparison.

Model	Relation Input Views	Accuracy	
		SimpleQuestions	WebQSP
AMPCNN (Yin et al., 2016)	words	91.3	-
BiCNN (Yih et al., 2015)	char-3-gram	90.0	77.74
BiLSTM w/ words	words	91.2	79.32
BiLSTM w/ relation names	rel_names	88.9	78.96
Hier-Res-BiLSTM (HR-BiLSTM)	words + rel_names	**93.3**	**82.53**
w/o rel_name	words	91.3	81.69
w/o rel_words	rel_names	88.8	79.68
w/o residual learning (weighted sum on two layers)	words + rel_names	92.5	80.65
replacing residual with attention (Parikh et al., 2016)	words + rel_names	92.6	81.38
single-layer BiLSTM question encoder	words + rel_names	92.8	78.41
replacing BiLSTM with CNN (HR-CNN)	words + rel_names	92.9	79.08

Table 2: Accuracy on the SimpleQuestions and WebQSP relation detection tasks (test sets). The top shows performance of baselines. On the bottom we give the results of our proposed model together with the ablation tests.

ods. We re-implemented the BiCNN model from (Yih et al., 2015), where both questions and relations are represented with the word hash trick on character tri-grams. The baseline BiLSTM with relation word sequence appears to be the best baseline on WebQSP and is close to the previous best result of AMPCNN on SimpleQuestions. Our proposed HR-BiLSTM outperformed the best baselines on both tasks by margins of 2-3% ($p < 0.001$ and 0.01 compared to the best baseline *BiLSTM w/ words* on SQ and WQ respectively).

Note that using only relation names instead of words results in a weaker baseline BiLSTM model. The model yields a significant performance drop on SimpleQuestions (91.2% to 88.9%). However, the drop is much smaller on WebQSP, and it suggests that unseen relations have a much bigger impact on SimpleQuestions.

Ablation Test: The bottom of Table 2 shows ablation results of the proposed HR-BiLSTM. First, hierarchical matching between questions and both relation names and relation words yields improvement on both datasets, especially for SimpleQuestions (93.3% vs. 91.2/88.8%). Second, residual learning helps hierarchical matching compared to weighted-sum and attention-based baselines (see Section 4.3). For the attention-based baseline, we tried the model from (Parikh et al., 2016) and its one-way variations, where the one-way model gives better results[10]. Note that residual learning significantly helps on WebQSP (80.65% to 82.53%), while it does not help as much on SimpleQuestions. On SimpleQuestions, even removing the deep layers only causes a small drop in performance. WebQSP benefits more from residual and deeper architecture, possibly because in this dataset it is more important to handle larger scope of context matching.

Finally, on WebQSP, replacing BiLSTM with CNN in our hierarchical matching framework results in a large performance drop. Yet on SimpleQuestions the gap is much smaller. We believe this is because the LSTM relation encoder can better learn the composition of chains of relations in WebQSP, as it is better at dealing with longer dependencies.

Analysis Next, we present empirical evidences, which show why our HR-BiLSTM model achieves the best scores. We use WebQSP for the analysis purposes. First, we have the hypothesis that *training of the weighted-sum model usually falls to local optima, since deep BiLSTMs do not guarantee that the two-levels of question hidden representations are comparable*. This is evidenced by that during training one layer usually gets a weight close to 0 thus is ignored. For example, one run gives us weights of -75.39/0.14 for the two layers (we take exponential for the final weighted sum). It also gives much lower training accuracy (91.94%) compared to HR-BiLSTM (95.67%), suffering from training difficulty.

Second, compared to our deep BiLSTM with shortcut connections, we have the hypothesis that for KB relation detection, *training deep BiLSTMs is more difficult without shortcut connections*. Our experiments suggest that deeper BiLSTM does not always result in lower training accuracy. In the experiments a two-layer BiLSTM converges to 94.99%, even lower than the 95.25% achieved by a

[10]We also tried to apply the same attention method on deep BiLSTM with residual connections, but it does not lead to better results compared to HR-BiLSTM. We hypothesize that the idea of hierarchical matching with attention mechanism may work better for long sequences, and the new advanced attention mechanisms (Wang and Jiang, 2016; Wang et al., 2017) might help hierarchical matching. We leave the above directions to future work.

single-layer BiLSTM. Under our setting the two-layer model captures the single-layer model as a special case (so it could potentially better fit the training data), this result suggests that the deep BiLSTM without shortcut connections might suffers more from training difficulty.

Finally, we hypothesize that *HR-BiLSTM is more than combination of two BiLSTMs with residual connections, because it encourages the hierarchical architecture to learn different levels of abstraction*. To verify this, we replace the deep BiLSTM question encoder with two single-layer BiLSTMs (both on words) with shortcut connections between their hidden states. This decreases test accuracy to 76.11%. It gives similar training accuracy compared to HR-BiLSTM, indicating a more serious over-fitting problem. This proves that the residual and deep structures both contribute to the good performance of HR-BiLSTM.

6.3 KBQA End-Task Results

Table 3 compares our system with two published baselines (1) STAGG (Yih et al., 2015), the state-of-the-art on WebQSP[11] and (2) AMPCNN (Yin et al., 2016), the state-of-the-art on SimpleQuestions. Since these two baselines are specially designed/tuned for one particular dataset, they do not generalize well when applied to the other dataset. In order to highlight the effect of different relation detection models on the KBQA end-task, we also implemented another baseline that uses our KBQA system but replaces HR-BiLSTM with our implementation of AMPCNN (for SimpleQuestions) or the char-3-gram BiCNN (for WebQSP) relation detectors (second block in Table 3).

Compared to the *baseline relation detector* (3rd row of results), our method, which includes an improved relation detector (HR-BiLSTM), improves the KBQA end task by 2-3% (4th row). Note that in contrast to previous KBQA systems, our system does not use joint-inference or feature-based re-ranking step, nevertheless it still achieves better or comparable results to the state-of-the-art.

The third block of the table details two ablation tests for the proposed components in our KBQA systems: (1) Removing the entity re-ranking step significantly decreases the scores. Since the re-ranking step relies on the relation detection models, this shows that our HR-BiLSTM model contributes to the good performance in multiple ways.

[11]The STAGG score on SQ is from (Bao et al., 2016).

System	Accuracy	
	SQ	**WQ**
STAGG	72.8	**63.9**
AMPCNN (Yin et al., 2016)	*76.4*	-
Baseline: Our Method w/ baseline relation detector	75.1	60.0
Our Method	**77.0**	63.0
w/o entity re-ranking	74.9	60.6
w/o constraints	-	58.0
Our Method (multi-detectors)	**78.7**	**63.9**

Table 3: KBQA results on SimpleQuestions (SQ) and WebQSP (WQ) test sets. The numbers in *green* color are directly comparable to our results since we start with the same entity linking results.

Appendix C gives the detailed performance of the re-ranking step. (2) In contrast to the conclusion in (Yih et al., 2015), constraint detection is crucial for our system[12]. This is probably because our joint performance on topic entity and core-chain detection is more accurate (77.5% top-1 accuracy), leaving a huge potential (77.5% vs. 58.0%) for the constraint detection module to improve.

Finally, like STAGG, which uses multiple relation detectors (see Yih et al. (2015) for the three models used), we also try to use the top-3 relation detectors from Section 6.2. As shown on the last row of Table 3, this gives a significant performance boost, resulting in a new state-of-the-art result on SimpleQuestions and a result comparable to the state-of-the-art on WebQSP.

7 Conclusion

KB relation detection is a key step in KBQA and is significantly different from general relation extraction tasks. We propose a novel KB relation detection model, HR-BiLSTM, that performs hierarchical matching between questions and KB relations. Our model outperforms the previous methods on KB relation detection tasks and allows our KBQA system to achieve state-of-the-arts. For future work, we will investigate the integration of our HR-BiLSTM into end-to-end systems. For example, our model could be integrated into the decoder in (Liang et al., 2016), to provide better sequence prediction. We will also investigate new emerging datasets like GraphQuestions (Su et al., 2016) and ComplexQuestions (Bao et al., 2016) to handle more characteristics of general QA.

[12]Note that another reason is that we are evaluating on accuracy here. When evaluating on F1 the gap will be smaller.

Abstract

Keyphrase provides highly-summative information that can be effectively used for understanding, organizing and retrieving text content. Though previous studies have provided many workable solutions for automated keyphrase extraction, they commonly divided the to-be-summarized content into multiple text chunks, then ranked and selected the most meaningful ones. These approaches could neither identify keyphrases that do not appear in the text, nor capture the real semantic meaning behind the text. We propose a generative model for keyphrase prediction with an encoder-decoder framework, which can effectively overcome the above drawbacks. We name it as *deep keyphrase generation* since it attempts to capture the deep semantic meaning of the content with a deep learning method. Empirical analysis on six datasets demonstrates that our proposed model not only achieves a significant performance boost on extracting keyphrases that appear in the source text, but also can generate absent keyphrases based on the semantic meaning of the text. Code and dataset are available at https://github.com/memray/seq2seq-keyphrase.

1 Introduction

A keyphrase or keyword is a piece of short, summative content that expresses the main semantic meaning of a longer text. The typical use of a keyphrase or keyword is in scientific publications to provide the core information of a paper. We use the term "keyphrase" interchangeably with "keyword" in the rest of this paper, as both terms have an implication that they may contain multiple words. High-quality keyphrases can facilitate the understanding, organizing, and accessing of document content. As a result, many studies have focused on ways of automatically extracting keyphrases from textual content (Liu et al., 2009; Medelyan et al., 2009a; Witten et al., 1999). Due to public accessibility, many scientific publication datasets are often used as test beds for keyphrase extraction algorithms. Therefore, this study also focuses on extracting keyphrases from scientific publications.

Automatically extracting keyphrases from a document is called *keypharase extraction*, and it has been widely used in many applications, such as information retrieval (Jones and Staveley, 1999), text summarization (Zhang et al., 2004), text categorization (Hulth and Megyesi, 2006), and opinion mining (Berend, 2011). Most of the existing keyphrase extraction algorithms have addressed this problem through two steps (Liu et al., 2009; Tomokiyo and Hurst, 2003). The first step is to acquire a list of keyphrase candidates. Researchers have tried to use n-grams or noun phrases with certain part-of-speech patterns for identifying potential candidates (Hulth, 2003; Le et al., 2016; Liu et al., 2010; Wang et al., 2016). The second step is to rank candidates on their importance to the document, either through supervised or unsupervised machine learning methods with a set of manually-defined features (Frank et al., 1999; Liu et al., 2009, 2010; Kelleher and Luz, 2005; Matsuo and Ishizuka, 2004; Mihalcea and Tarau, 2004; Song et al., 2003; Witten et al., 1999).

There are two major drawbacks in the above keyphrase extraction approaches. First, these methods can only extract the keyphrases that ap-

https://doi.org/10.18653/v1/P17-1054

pear in the source text; they fail at predicting meaningful keyphrases with a slightly different sequential order or those that use synonyms. However, authors of scientific publications commonly assign keyphrases based on their semantic meaning, instead of following the written content in the publication. In this paper, we denote phrases that do not match any contiguous subsequence of source text as **absent keyphrases**, and the ones that fully match a part of the text as **present keyphrases**. Table 1 shows the proportion of present and absent keyphrases from the document abstract in four commonly-used datasets, from which we can observe large portions of absent keyphrases in all the datasets. The absent keyphrases cannot be extracted through previous approaches, which further prompts the development of a more powerful keyphrase prediction model.

Second, when ranking phrase candidates, previous approaches often adopted machine learning features such as TF-IDF and PageRank. However, these features only target to detect the importance of each word in the document based on the statistics of word occurrence and co-occurrence, and are unable to reveal the full semantics that underlie the document content.

Table 1: Proportion of the present keyphrases and absent keyphrases in four public datasets

Dataset	# Keyphrase	% Present	% Absent
Inspec	19,275	55.69	44.31
Krapivin	2,461	44.74	52.26
NUS	2,834	67.75	32.25
SemEval	12,296	42.01	57.99

To overcome the limitations of previous studies, we re-examine the process of *keyphrase prediction* with a focus on how real human annotators would assign keyphrases. Given a document, human annotators will first read the text to get a basic understanding of the content, then they try to digest its essential content and summarize it into keyphrases. Their generation of keyphrases relies on an understanding of the content, which may not necessarily use the exact words that occur in the source text. For example, when human annotators see "*Latent Dirichlet Allocation*" in the text, they might write down "*topic modeling*" and/or "*text mining*" as possible keyphrases. In addition to the semantic understanding, human annotators might also go back and pick up the most important parts, based on syntactic features. For example, the phrases following "*we propose/apply/use*" could be important in the text. As a result, a better keyphrase prediction model should understand the semantic meaning of the content, as well as capture the contextual features.

To effectively capture both the semantic and syntactic features, we use recurrent neural networks (RNN) (Cho et al., 2014; Gers and Schmidhuber, 2001) to compress the semantic information in the given text into a dense vector (i.e., semantic understanding). Furthermore, we incorporate a copying mechanism (Gu et al., 2016) to allow our model to find important parts based on positional information. Thus, our model can generate keyphrases based on an understanding of the text, regardless of the presence or absence of keyphrases in the text; at the same time, it does not lose important in-text information.

The contribution of this paper is three-fold. First, we propose to apply an RNN-based generative model to keyphrase prediction, as well as incorporate a copying mechanism in RNN, which enables the model to successfully predict phrases that rarely occur. Second, this is the first work that concerns the problem of absent keyphrase prediction for scientific publications, and our model recalls up to 20% of absent keyphrases. Third, we conducted a comprehensive comparison against six important baselines on a broad range of datasets, and the results show that our proposed model significantly outperforms existing supervised and unsupervised extraction methods.

In the remainder of this paper, we first review the related work in Section 2. Then, we elaborate upon the proposed model in Section 3. After that, we present the experiment setting in Section 4 and results in Section 5, followed by our discussion in Section 6. Section 7 concludes the paper.

2 Related Work

2.1 Automatic Keyphrase Extraction

A keyphrase provides a succinct and accurate way of describing a subject or a subtopic in a document. A number of extraction algorithms have been proposed, and the process of extracting keyphrases can typically be broken down into two steps.

The first step is to generate a list of phrase can-

didates with heuristic methods. As these candidates are prepared for further filtering, a considerable number of candidates are produced in this step to increase the possibility that most of the correct keyphrases are kept. The primary ways of extracting candidates include retaining word sequences that match certain part-of-speech tag patterns (e.g., nouns, adjectives) (Liu et al., 2011; Wang et al., 2016; Le et al., 2016), and extracting important n-grams or noun phrases (Hulth, 2003; Medelyan et al., 2008).

The second step is to score each candidate phrase for its likelihood of being a keyphrase in the given document. The top-ranked candidates are returned as keyphrases. Both supervised and unsupervised machine learning methods are widely employed here. For supervised methods, this task is solved as a binary classification problem, and various types of learning methods and features have been explored (Frank et al., 1999; Witten et al., 1999; Hulth, 2003; Medelyan et al., 2009b; Lopez and Romary, 2010; Gollapalli and Caragea, 2014). As for unsupervised approaches, primary ideas include finding the central nodes in text graph (Mihalcea and Tarau, 2004; Grineva et al., 2009), detecting representative phrases from topical clusters (Liu et al., 2009, 2010), and so on.

Aside from the commonly adopted two-step process, another two previous studies realized the keyphrase extraction in entirely different ways. Tomokiyo and Hurst (2003) applied two language models to measure the phraseness and informativeness of phrases. Liu et al. (2011) share the most similar ideas to our work. They used a word alignment model, which learns a translation from the documents to the keyphrases. This approach alleviates the problem of vocabulary gaps between source and target to a certain degree. However, this translation model is unable to handle semantic meaning. Additionally, this model was trained with the target of title/summary to enlarge the number of training samples, which may diverge from the real objective of generating keyphrases.

Zhang et al. (2016) proposed a joint-layer recurrent neural network model to extract keyphrases from tweets, which is another application of deep neural networks in the context of keyphrase extraction. However, their work focused on sequence labeling, and is therefore not able to predict absent keyphrases.

2.2 Encoder-Decoder Model

The RNN Encoder-Decoder model (which is also referred as sequence-to-sequence Learning) is an end-to-end approach. It was first introduced by Cho et al. (2014) and Sutskever et al. (2014) to solve translation problems. As it provides a powerful tool for modeling variable-length sequences in an end-to-end fashion, it fits many natural language processing tasks and can rapidly achieve great successes (Rush et al., 2015; Vinyals et al., 2015; Serban et al., 2016).

Different strategies have been explored to improve the performance of the Encoder-Decoder model. The attention mechanism (Bahdanau et al., 2014) is a soft alignment approach that allows the model to automatically locate the relevant input components. In order to make use of the important information in the source text, some studies sought ways to copy certain parts of content from the source text and paste them into the target text (Allamanis et al., 2016; Gu et al., 2016; Zeng et al., 2016). A discrepancy exists between the optimizing objective during training and the metrics during evaluation. A few studies attempted to eliminate this discrepancy by incorporating new training algorithms (Marc'Aurelio Ranzato et al., 2016) or by modifying the optimizing objectives (Shen et al., 2016).

3 Methodology

This section will introduce our proposed deep keyphrase generation method in detail. First, the task of keyphrase generation is defined, followed by an overview of how we apply the RNN Encoder-Decoder model. Details of the framework as well as the copying mechanism will be introduced in Sections 3.3 and 3.4.

3.1 Problem Definition

Given a keyphrase dataset that consists of $\mathbf{N}$ data samples, the i-th data sample $(\mathbf{x^{(i)}}, \mathbf{p^{(i)}})$ contains one source text $\mathbf{x^{(i)}}$, and M_i target keyphrases $\mathbf{p^{(i)}} = (\mathbf{p^{(i,1)}}, \mathbf{p^{(i,2)}}, \ldots, \mathbf{p^{(i,M_i)}})$. Both the source text $\mathbf{x^{(i)}}$ and keyphrase $\mathbf{p^{(i,j)}}$ are sequences of words:

$$\mathbf{x^{(i)}} = x_1^{(i)}, x_2^{(i)}, \ldots, x_{L_{\mathbf{x^i}}}^{(i)}$$

$$\mathbf{p^{(i,j)}} = y_1^{(i,j)}, y_2^{(i,j)}, \ldots, y_{L_{\mathbf{p^{(i,j)}}}}^{(i,j)}$$

$L_{\mathbf{x^{(i)}}}$ and $L_{\mathbf{p^{(i,j)}}}$ denotes the length of word sequence of $\mathbf{x^{(i)}}$ and $\mathbf{p^{(i,j)}}$ respectively.

Each data sample contains one source text sequence and multiple target phrase sequences. To apply the RNN Encoder-Decoder model, the data need to be converted into text-keyphrase pairs that contain only one source sequence and one target sequence. We adopt a simple way, which splits the data sample $(\mathbf{x^{(i)}}, \mathbf{p^{(i)}})$ into M_i pairs: $(\mathbf{x^{(i)}}, \mathbf{p^{(i,1)}}), (\mathbf{x^{(i)}}, \mathbf{p^{(i,2)}}), \ldots, (\mathbf{x^{(i)}}, \mathbf{p^{(i,M_i)}})$. Then the Encoder-Decoder model is ready to be applied to learn the mapping from the source sequence to target sequence. For the purpose of simplicity, $(\mathbf{x}, \mathbf{y})$ is used to denote each data pair in the rest of this section, where $\mathbf{x}$ is the word sequence of a source text and $\mathbf{y}$ is the word sequence of its keyphrase.

3.2 Encoder-Decoder Model

The basic idea of our keyphrase generation model is to compress the content of source text into a hidden representation with an encoder and to generate corresponding keyphrases with the decoder, based on the representation . Both the encoder and decoder are implemented with recurrent neural networks (RNN).

The encoder RNN converts the variable-length input sequence $\mathbf{x} = (x_1, x_2, ..., x_T)$ into a set of hidden representation $\mathbf{h} = (h_1, h_2, \ldots, h_T)$, by iterating the following equations along time t:

$$\mathbf{h}_t = f(x_t, \mathbf{h}_{t-1}) \tag{1}$$

where f is a non-linear function. We get the context vector $\mathbf{c}$ acting as the representation of the whole input $\mathbf{x}$ through a non-linear function q.

$$\mathbf{c} = q(h_1, h_2, ..., h_T) \tag{2}$$

The decoder is another RNN; it decompresses the context vector and generates a variable-length sequence $\mathbf{y} = (y_1, y_2, ..., y_{T'})$ word by word, through a conditional language model:

$$\begin{aligned} \mathbf{s}_t &= f(y_{t-1}, \mathbf{s}_{t-1}, \mathbf{c}) \\ p(y_t | y_{1,\ldots,t-1}, \mathbf{x}) &= g(y_{t-1}, \mathbf{s}_t, \mathbf{c}) \end{aligned} \tag{3}$$

where $\mathbf{s}_t$ is the hidden state of the decoder RNN at time t. The non-linear function g is a softmax classifier, which outputs the probabilities of all the words in the vocabulary. y_t is the predicted word at time t, by taking the word with largest probability after $g(\cdot)$.

The encoder and decoder networks are trained jointly to maximize the conditional probability of the target sequence, given a source sequence. After training, we use the beam search to generate phrases and a max heap is maintained to get the predicted word sequences with the highest probabilities.

3.3 Details of the Encoder and Decoder

A bidirectional gated recurrent unit (GRU) is applied as our encoder to replace the simple recurrent neural network. Previous studies (Bahdanau et al., 2014; Cho et al., 2014) indicate that it can generally provide better performance of language modeling than a simple RNN and a simpler structure than other Long Short-Term Memory networks (Hochreiter and Schmidhuber, 1997). As a result, the above non-linear function f is replaced by the **GRU** function (see in (Cho et al., 2014)).

Another forward GRU is used as the decoder. In addition, an attention mechanism is adopted to improve performance. The attention mechanism was firstly introduced by Bahdanau et al. (2014) to make the model dynamically focus on the important parts in input. The context vector $\mathbf{c}$ is computed as a weighted sum of hidden representation $\mathbf{h} = (h_1, \ldots, h_T)$:

$$\begin{aligned} \mathbf{c}_i &= \sum_{j=1}^{T} \alpha_{ij} h_j \\ \alpha_{ij} &= \frac{\exp(a(s_{i-1}, h_j))}{\sum_{k=1}^{T} \exp(a(s_{i-1}, h_k))} \end{aligned} \tag{4}$$

where $a(s_{i-1}, h_j)$ is a soft alignment function that measures the similarity between s_{i-1} and h_j; namely, to which degree the inputs around position j and the output at position i match.

3.4 Copying Mechanism

To ensure the quality of learned representation and reduce the size of the vocabulary, typically the RNN model considers a certain number of frequent words (e.g. 30,000 words in (Cho et al., 2014)), but a large amount of long-tail words are simply ignored. Therefore, the RNN is not able to recall any keyphrase that contains out-of-vocabulary words. Actually, important phrases can also be identified by positional and syntactic information in their contexts, even though their exact meanings are not known. The copying mechanism (Gu et al., 2016) is one feasible solution that enables RNN to predict out-of-vocabulary words by selecting appropriate words from the source text.

By incorporating the copying mechanism, the probability of predicting each new word y_t consists of two parts. The first term is the probability of generating the term (see Equation 3) and the second one is the probability of copying it from the source text:

$$\begin{aligned} &p(y_t|y_{1,\ldots,t-1}, \mathbf{x}) \\ &= p_g(y_t|y_{1,\ldots,t-1}, \mathbf{x}) + p_c(y_t|y_{1,\ldots,t-1}, \mathbf{x}) \end{aligned} \tag{5}$$

Similar to attention mechanism, the copying mechanism weights the importance of each word in source text with a measure of positional attention. But unlike the generative RNN which predicts the next word from all the words in vocabulary, the copying part $p_c(y_t|y_{1,\ldots,t-1}, \mathbf{x})$ only considers the words in source text. Consequently, on the one hand, the RNN with copying mechanism is able to predict the words that are out of vocabulary but in the source text; on the other hand, the model would potentially give preference to the appearing words, which caters to the fact that most keyphrases tend to appear in the source text.

$$\begin{aligned} p_c(y_t|y_{1,\ldots,t-1}, \mathbf{x}) &= \frac{1}{Z} \sum_{j:x_j=y_t} \exp(\psi_c(x_j)), y \in \chi \\ \psi_c(x_j) &= \sigma(\mathbf{h}_j^T \mathbf{W}_c)\mathbf{s}_t \end{aligned} \tag{6}$$

where χ is the set of all of the unique words in the source text $\mathbf{x}$, σ is a non-linear function and $\mathbf{W_c} \in \mathbb{R}$ is a learned parameter matrix. $\mathbf{Z}$ is the sum of all the scores and is used for normalization. Please see (Gu et al., 2016) for more details.

4 Experiment Settings

This section begins by discussing how we designed our evaluation experiments, followed by the description of training and testing datasets. Then, we introduce our evaluation metrics and baselines.

4.1 Training Dataset

There are several publicly-available datasets for evaluating keyphrase generation. The largest one came from Krapivin et al. (2008), which contains 2,304 scientific publications. However, this amount of data is unable to train a robust recurrent neural network model. In fact, there are millions of scientific papers available online, each of which contains the keyphrases that were assigned by their authors. Therefore, we collected a large amount of high-quality scientific metadata in the computer science domain from various online digital libraries, including ACM Digital Library, ScienceDirect, Wiley, and Web of Science etc. (Han et al., 2013; Rui et al., 2016). In total, we obtained a dataset of 567,830 articles, after removing duplicates and overlaps with testing datasets, which is 200 times larger than the one of Krapivin et al. (2008). Note that our model is only trained on 527,830 articles, since 40,000 publications are randomly held out, among which 20,000 articles were used for building a new test dataset **KP20k**. Another 20,000 articles served as the validation dataset to check the convergence of our model, as well as the training dataset for supervised baselines.

4.2 Testing Datasets

For evaluating the proposed model more comprehensively, four widely-adopted scientific publication datasets were used. In addition, since these datasets only contain a few hundred or a few thousand publications, we contribute a new testing dataset **KP20k** with a much larger number of scientific articles. We take the title and abstract as the source text. Each dataset is described in detail below.

- **Inspec** (Hulth, 2003): This dataset provides 2,000 paper abstracts. We adopt the 500 testing papers and their corresponding uncontrolled keyphrases for evaluation, and the remaining 1,500 papers are used for training the supervised baseline models.

- **Krapivin** (Krapivin et al., 2008): This dataset provides 2,304 papers with full-text and author-assigned keyphrases. However, the author did not mention how to split testing data, so we selected the first 400 papers in alphabetical order as the testing data, and the remaining papers are used to train the supervised baselines.

- **NUS** (Nguyen and Kan, 2007): We use the author-assigned keyphrases and treat all 211 papers as the testing data. Since the NUS dataset did not specifically mention the ways of splitting training and testing data, the results of the supervised baseline models are obtained through a five-fold cross-validation.

- **SemEval-2010** (Kim et al., 2010): 288 articles were collected from the ACM Digital

Library. 100 articles were used for testing and the rest were used for training supervised baselines.

– **KP20k**: We built a new testing dataset that contains the titles, abstracts, and keyphrases of 20,000 scientific articles in computer science. They were randomly selected from our obtained 567,830 articles. Due to the memory limits of implementation, we were not able to train the supervised baselines on the whole training set. Thus we take the 20,000 articles in the validation set to train the supervised baselines. It is worth noting that we also examined their performance by enlarging the training dataset to 50,000 articles, but no significant improvement was observed.

4.3 Implementation Details

In total, there are 2,780,316 ⟨text, keyphrase⟩ pairs for training, in which text refers to the concatenation of the title and abstract of a publication, and keyphrase indicates an author-assigned keyword. The text pre-processing steps including tokenization, lowercasing and replacing all digits with symbol ⟨digit⟩ are applied. Two encoder-decoder models are trained, one with only attention mechanism (RNN) and one with both attention and copying mechanism enabled (CopyRNN). For both models, we choose the top 50,000 frequently-occurred words as our vocabulary, the dimension of embedding is set to 150, the dimension of hidden layers is set to 300, and the word embeddings are randomly initialized with uniform distribution in [-0.1,0.1]. Models are optimized using Adam (Kingma and Ba, 2014) with initial learning rate = 10^{-4}, gradient clipping = 0.1 and dropout rate = 0.5. The max depth of beam search is set to 6, and the beam size is set to 200. The training is stopped once convergence is determined on the validation dataset (namely early-stopping, the cross-entropy loss stops dropping for several iterations).

In the generation of keyphrases, we find that the model tends to assign higher probabilities for shorter keyphrases, whereas most keyphrases contain more than two words. To resolve this problem, we apply a simple heuristic by preserving only the first single-word phrase (with the highest generating probability) and removing the rest.

4.4 Baseline Models

Four unsupervised algorithms (Tf-Idf, TextRank (Mihalcea and Tarau, 2004), SingleRank (Wan and Xiao, 2008), and ExpandRank (Wan and Xiao, 2008)) and two supervised algorithms (KEA (Witten et al., 1999) and Maui (Medelyan et al., 2009a)) are adopted as baselines. We set up the four unsupervised methods following the optimal settings in (Hasan and Ng, 2010), and the two supervised methods following the default setting as specified in their papers.

4.5 Evaluation Metric

Three evaluation metrics, the macro-averaged *precision*, *recall* and *F-measure* (F_1) are employed for measuring the algorithm's performance. Following the standard definition, precision is defined as the number of correctly-predicted keyphrases over the number of all predicted keyphrases, and recall is computed by the number of correctly-predicted keyphrases over the total number of data records. Note that, when determining the match of two keyphrases, we use Porter Stemmer for preprocessing.

5 Results and Analysis

We conduct an empirical study on three different tasks to evaluate our model.

5.1 Predicting Present Keyphrases

This is the same as the keyphrase extraction task in prior studies, in which we analyze how well our proposed model performs on a commonly-defined task. To make a fair comparison, we only consider the present keyphrases for evaluation in this task. Table 2 provides the performances of the six baseline models, as well as our proposed models (i.e., RNN and CopyRNN). For each method, the table lists its F-measure at top 5 and top 10 predictions on the five datasets. The best scores are highlighted in bold and the underlines indicate the second best performances.

The results show that the four unsupervised models (Tf-idf, TextTank, SingleRank and ExpandRank) have a robust performance across different datasets. The ExpandRank fails to return any result on the KP20k dataset, due to its high time complexity. The measures on NUS and SemEval here are higher than the ones reported in (Hasan and Ng, 2010) and (Kim et al., 2010), probably because we utilized the paper abstract instead of the full text for training, which may

Table 2: The performance of predicting present keyphrases of various models on five benchmark datasets

filter out some noisy information. The performance of the two supervised models (i.e., Maui and KEA) were unstable on some datasets, but Maui achieved the best performances on three datasets among all the baseline models.

As for our proposed keyphrase prediction approaches, the RNN model with the attention mechanism did not perform as well as we expected. It might be because the RNN model is only concerned with finding the hidden semantics behind the text, which may tend to generate keyphrases or words that are too general and may not necessarily refer to the source text. In addition, we observe that 2.5% (70,891/2,780,316) of keyphrases in our dataset contain out-of-vocabulary words, which the RNN model is not able to recall, since the RNN model can only generate results with the 50,000 words in vocabulary. This indicates that a pure generative model may not fit the extraction task, and we need to further link back to the language usage within the source text. The CopyRNN model, by considering more contextual information, significantly outperforms not only the RNN model but also all baselines, exceeding the best baselines by more than 20% on average. This result demonstrates the importance of source text to the extraction task. Besides, nearly 2% of all correct predictions contained out-of-vocabulary words.

The example in Figure 1(a) shows the result of predicted present keyphrases by RNN and CopyRNN for an article about video search. We see that both models can generate phrases that relate to the topic of information retrieval and video. However most of RNN predictions are high-level terminologies, which are too general to be selected as keyphrases. CopyRNN, on the other hand, predicts more detailed phrases like "video metadata" and "integrated ranking". An interesting bad case, "rich content" coordinates with a keyphrase "video metadata", and the CopyRNN mistakenly puts it into prediction.

5.2 Predicting Absent Keyphrases

As stated, one important motivation for this work is that we are interested in the proposed model's capability for predicting absent keyphrases based on the "understanding" of content. It is worth noting that such prediction is a very challenging task, and, to the best of our knowledge, no existing methods can handle this task. Therefore, we only provide the RNN and CopyRNN performances in the discussion of the results of this task. Here, we evaluate the performance within the recall of the top 10 and top 50 results, to see how many absent keyphrases can be correctly predicted. We use the absent keyphrases in the testing datasets for evaluation.

Dataset	RNN		CopyRNN	
	R@10	R@50	R@10	R@50
Inspec	0.031	0.061	**0.047**	**0.100**
Krapivin	0.095	0.156	**0.113**	**0.202**
NUS	0.050	0.089	**0.058**	**0.116**
SemEval	0.041	0.060	**0.043**	**0.067**
KP20k	0.083	0.144	**0.125**	**0.211**

Table 3: Absent keyphrases prediction performance of RNN and CopyRNN on five datasets

Table 3 presents the recall results of the top 10/50 predicted keyphrases for our RNN and CopyRNN models, in which we observe that the CopyRNN can, on average, recall around 8%

(15%) of keyphrases at top 10 (50) predictions. This indicates that, to some extent, both models can capture the hidden semantics behind the textual content and make reasonable predictions. In addition, with the advantage of features from the source text, the CopyRNN model also outperforms the RNN model in this condition, though it does not show as much improvement as the present keyphrase extraction task. An example is shown in Figure 1(b), in which we see that two absent keyphrases, "video retrieval" and "video indexing", are correctly recalled by both models. Note that the term "indexing" does not appear in the text, but the models may detect the information "index videos" in the first sentence and paraphrase it to the target phrase. And the CopyRNN successfully predicts another two keyphrases by capturing the detailed information from the text (highlighted text segments).

Model	F_1	Model	F_1
Tf-Idf	0.270	**ExpandRank**	0.269
TextRank	0.097	**KeyCluster**	0.140
SingleRank	0.256	**CopyRNN**	0.164

Table 4: Keyphrase prediction performance of CopyRNN on DUC-2001. The model is trained on scientific publication and evaluated on news.

5.3 Transferring the Model to the News Domain

RNN and CopyRNN are supervised models, and they are trained on data in a specific domain and writing style. However, with sufficient training on a large-scale dataset, we expect the models to be able to learn universal language features that are also effective in other corpora. Thus in this task, we will test our model on another type of text, to see whether the model would work when being transferred to a different environment.

We use the popular news article dataset **DUC-2001** (Wan and Xiao, 2008) for analysis. The dataset consists of 308 news articles and 2,488 manually annotated keyphrases. The result of this analysis is shown in Table 4, from which we could see that the CopyRNN can extract a portion of correct keyphrases from a unfamiliar text. Compared to the results reported in (Hasan and Ng, 2010), the performance of CopyRNN is better than TextRank (Mihalcea and Tarau, 2004) and KeyCluster (Liu et al., 2009), but lags behind the other three baselines.

As it is transferred to a corpus in a completely different type and domain, the model encounters more unknown words and has to rely more on the positional and syntactic features within the text. In this experiment, the CopyRNN recalls 766 keyphrases. 14.3% of them contain out-of-vocabulary words, and many names of persons and places are correctly predicted.

6 Discussion

Our experimental results demonstrate that the CopyRNN model not only performs well on predicting present keyphrases, but also has the ability to generate topically relevant keyphrases that are absent in the text. In a broader sense, this model attempts to map a long text (i.e., paper abstract) with representative short text chunks (i.e., keyphrases), which can potentially be applied to improve information retrieval performance by generating high-quality index terms, as well as assisting user browsing by summarizing long documents into short, readable phrases.

Thus far, we have tested our model with scientific publications and news articles, and have demonstrated that our model has the ability to capture universal language patterns and extract key information from unfamiliar texts. We believe that our model has a greater potential to be generalized to other domains and types, like books, online reviews, etc., if it is trained on a larger data corpus. Also, we directly applied our model, which was trained on a publication dataset, into generating keyphrases for news articles without any adaptive training. We believe that with proper training on news data, the model would make further improvement.

Additionally, this work mainly studies the problem of discovering core content from textual materials. Here, the encoder-decoder framework is applied to model language; however, such a framework can also be extended to locate the core information on other data resources, such as summarizing content from images and videos.

7 Conclusions and Future Work

In this paper, we proposed an RNN-based generative model for predicting keyphrases in scientific text. To the best of our knowledge, this is the first application of the encoder-decoder model to a keyphrase prediction task. Our model summarizes phrases based the deep semantic meaning

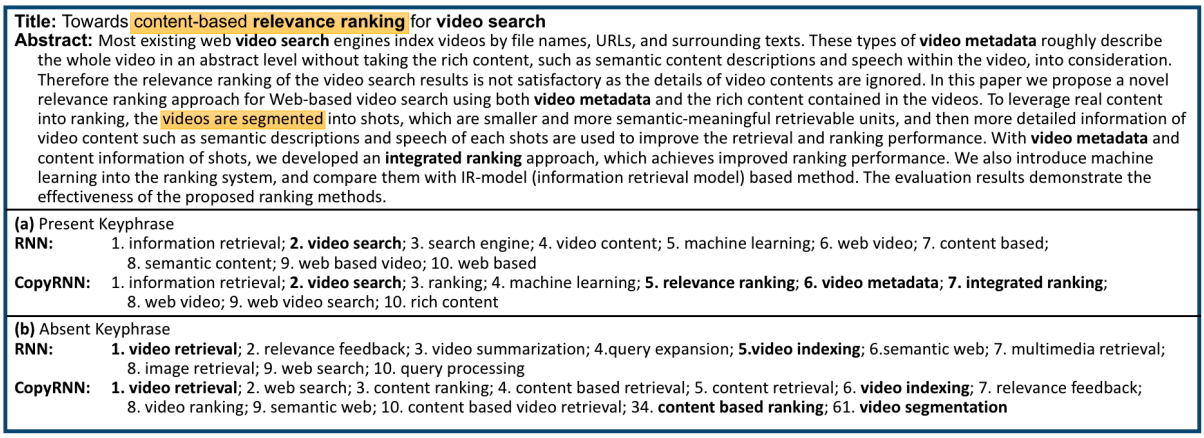

Figure 1: An example of predicted keyphrase by RNN and CopyRNN. Phrases shown in bold are correct predictions.

of the text, and is able to handle rarely-occurred phrases by incorporating a copying mechanism. Comprehensive empirical studies demonstrate the effectiveness of our proposed model for generating both present and absent keyphrases for different types of text. Our future work may include the following two directions.

– In this work, we only evaluated the performance of the proposed model by conducting off-line experiments. In the future, we are interested in comparing the model to human annotators and using human judges to evaluate the quality of predicted phrases.

– Our current model does not fully consider correlation among target keyphrases. It would also be interesting to explore the multiple-output optimization aspects of our model.

Acknowledgments

We would like to thank Jiatao Gu and Miltiadis Allamanis for sharing the source code and giving helpful advice. We also thank Wei Lu, Yong Huang, Qikai Cheng and other IRLAB members at Wuhan University for the assistance of dataset development. Abstract

Cloze-style reading comprehension is a representative problem in mining relationship between document and query. In this paper, we present a simple but novel model called *attention-over-attention* reader for better solving cloze-style reading comprehension task. The proposed model aims to place another attention mechanism over the document-level attention and induces "attended attention" for final answer predictions. One advantage of our model is that it is simpler than related works while giving excellent performance. In addition to the primary model, we also propose an N-best re-ranking strategy to double check the validity of the candidates and further improve the performance. Experimental results show that the proposed methods significantly outperform various state-of-the-art systems by a large margin in public datasets, such as CNN and Children's Book Test.

1 Introduction

To read and comprehend the human languages are challenging tasks for the machines, which requires that the understanding of natural languages and the ability to do reasoning over various clues. Reading comprehension is a general problem in the real world, which aims to read and comprehend a given article or context, and answer the questions based on it. Recently, the cloze-style reading comprehension problem has become a popular task in the community. The cloze-style query (Taylor, 1953) is a problem that to fill in an appropriate word in the given sentences while taking the context information into account.

To teach the machine to do cloze-style reading comprehensions, large-scale training data is necessary for learning relationships between the given document and query. To create large-scale training data for neural networks, Hermann et al. (2015) released the CNN/Daily Mail news dataset, where the document is formed by the news articles and the queries are extracted from the summary of the news. Hill et al. (2015) released the Children's Book Test dataset afterwards, where the training samples are generated from consecutive 20 sentences from books, and the query is formed by 21st sentence. Following these datasets, a vast variety of neural network approaches have been proposed (Kadlec et al., 2016; Cui et al., 2016; Chen et al., 2016; Dhingra et al., 2016; Sordoni et al., 2016; Trischler et al., 2016; Seo et al., 2016; Xiong et al., 2016), and most of them stem from the attention-based neural network (Bahdanau et al., 2014), which has become a stereotype in most of the NLP tasks and is well-known by its capability of learning the "importance" distribution over the inputs.

In this paper, we present a novel neural network architecture, called *attention-over-attention* model. As we can understand the meaning literally, our model aims to place another attention mechanism over the existing document-level attention. Unlike the previous works, that are using heuristic merging functions (Cui et al., 2016), or setting various pre-defined non-trainable terms (Trischler et al., 2016), our model could automatically generate an "attended attention" over various document-level attentions, and make a mutual look not only from *query-to-document* but also *document-to-query*, which will benefit from the interactive information.

To sum up, the main contributions of our work are listed as follows.

- To our knowledge, this is the first time that

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 593–602
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1055

the mechanism of nesting another attention over the existing attentions is proposed, i.e. *attention-over-attention* mechanism.

- Unlike the previous works on introducing complex architectures or many non-trainable hyper-parameters to the model, our model is much more simple but outperforms various state-of-the-art systems by a large margin.

- We also propose an N-best re-ranking strategy to re-score the candidates in various aspects and further improve the performance.

The following of the paper will be organized as follows. In Section 2, we will give a brief introduction to the cloze-style reading comprehension task as well as related public datasets. Then the proposed attention-over-attention reader will be presented in detail in Section 3 and N-best re-ranking strategy in Section 4. The experimental results and analysis will be given in Section 5 and Section 6. Related work will be discussed in Section 7. Finally, we will give a conclusion of this paper and envisions on future work.

2 Cloze-style Reading Comprehension

In this section, we will give a brief introduction to the cloze-style reading comprehension task at the beginning. And then, several existing public datasets will be described in detail.

2.1 Task Description

Formally, a general Cloze-style reading comprehension problem can be illustrated as a triple:

$$\langle \mathcal{D}, \mathcal{Q}, \mathcal{A} \rangle$$

The triple consists of a document $\mathcal{D}$, a query $\mathcal{Q}$ and the answer to the query $\mathcal{A}$. Note that the answer is usually a *single* word in the document, which requires the human to exploit context information in both document and query. The type of the answer word varies from predicting a preposition given a fixed collocation to identifying a named entity from a factual illustration.

2.2 Existing Public Datasets

Large-scale training data is essential for training neural networks. Several public datasets for the cloze-style reading comprehension has been released. Here, we introduce two representative and widely-used datasets.

- **CNN / Daily Mail**

Hermann et al. (2015) have firstly published two datasets: CNN and Daily Mail news data [1]. They construct these datasets with web-crawled CNN and Daily Mail news data. One of the characteristics of these datasets is that the news article is often associated with a summary. So they first regard the main body of the news article as the *Document*, and the *Query* is formed by the summary of the article, where one entity word is replaced by a special placeholder to indicate the missing word. The replaced entity word will be the *Answer* of the *Query*. Apart from releasing the dataset, they also proposed a methodology that anonymizes the named entity tokens in the data, and these tokens are also re-shuffle in each sample. The motivation is that the news articles are containing limited named entities, which are usually celebrities, and the world knowledge can be learned from the dataset. So this methodology aims to exploit general relationships between anonymized named entities within a single document rather than the common knowledge. The following research on these datasets showed that the entity word anonymization is not as effective as expected (Chen et al., 2016).

- **Children's Book Test**

There was also a dataset called the Children's Book Test (CBTest) released by Hill et al. (2015), which is built on the children's book story through Project Gutenberg [2]. Different from the CNN/Daily Mail datasets, there is no summary available in the children's book. So they proposed another way to extract query from the original data. The document is composed of 20 consecutive sentences in the story, and the 21st sentence is regarded as the query, where one word is blanked with a special placeholder. In the CBTest datasets, there are four types of sub-datasets available which are classified by the part-of-speech and named entity tag of the answer word, containing Named Entities (NE), Common Nouns (CN), Verbs and Prepositions. In their studies, they have found that the answering of verbs and prepositions are relatively less dependent on the content of document, and the humans can even do preposi-

[1] The pre-processed CNN and Daily Mail datasets are available at http://cs.nyu.edu/~kcho/DMQA/

[2] The CBTest datasets are available at http://www.thespermwhale.com/jaseweston/babi/CBTest.tgz

tion blank-filling without the presence of the document. The studies shown by Hill et al. (2015), answering verbs and prepositions are less dependent with the presence of document. Thus, most of the related works are focusing on solving NE and CN types.

3 Attention-over-Attention Reader

In this section, we will give a detailed introduction to the proposed Attention-over-Attention Reader (AoA Reader). Our model is primarily motivated by Kadlec et al., (2016), which aims to directly estimate the answer from the document-level attention instead of calculating blended representations of the document. As previous studies by Cui et al. (2016) showed that the further investigation of query representation is necessary, and it should be paid more attention to utilizing the information of query. In this paper, we propose a novel work that placing another attention over the primary attentions, to indicate the "importance" of each attentions.

Now, we will give a formal description of our proposed model. When a cloze-style training triple $\langle \mathcal{D}, \mathcal{Q}, \mathcal{A} \rangle$ is given, the proposed model will be constructed in the following steps.

- **Contextual Embedding**

We first transform every word in the document $\mathcal{D}$ and query $\mathcal{Q}$ into one-hot representations and then convert them into continuous representations with a shared embedding matrix W_e. By sharing word embedding, both the document and query can participate in the learning of embedding and both of them will benefit from this mechanism. After that, we use two bi-directional RNNs to get contextual representations of the document and query individually, where the representation of each word is formed by concatenating the forward and backward hidden states. After making a trade-off between model performance and training complexity, we choose the Gated Recurrent Unit (GRU) (Cho et al., 2014) as recurrent unit implementation.

$$e(x) = W_e \cdot x, \ where \ \ x \in \mathcal{D}, \mathcal{Q} \quad (1)$$

$$\overrightarrow{h_s(x)} = \overrightarrow{GRU}(e(x)) \quad (2)$$

$$\overleftarrow{h_s(x)} = \overleftarrow{GRU}(e(x)) \quad (3)$$

$$h_s(x) = [\overrightarrow{h_s(x)}; \overleftarrow{h_s(x)}] \quad (4)$$

We take $h_{doc} \in \mathbb{R}^{|\mathcal{D}|*2d}$ and $h_{query} \in \mathbb{R}^{|\mathcal{Q}|*2d}$ to denote the contextual representations of document and query, where d is the dimension of GRU (one-way).

- **Pair-wise Matching Score**

After obtaining the contextual embeddings of the document h_{doc} and query h_{query}, we calculate a pair-wise matching matrix, which indicates the pair-wise matching degree of one document word and one query word. Formally, when given ith word of the document and jth word of query, we can compute a matching score by their dot product.

$$M(i, j) = h_{doc}(i)^T \cdot h_{query}(j) \quad (5)$$

In this way, we can calculate every pair-wise matching score between each document and query word, forming a matrix $M \in \mathbb{R}^{|\mathcal{D}|*|\mathcal{Q}|}$, where the value of ith row and jth column is filled by $M(i, j)$.

- **Individual Attentions**

After getting the pair-wise matching matrix M, we apply a column-wise softmax function to get probability distributions in each column, where each column is an individual document-level attention when considering a single query word. We denote $\alpha(t) \in \mathbb{R}^{|\mathcal{D}|}$ as the document-level attention regarding query word at time t, which can be seen as a *query-to-document* attention.

$$\alpha(t) = softmax(M(1, t), ..., M(|\mathcal{D}|, t)) \quad (6)$$

$$\alpha = [\alpha(1), \alpha(2), ..., \alpha(|\mathcal{Q}|)] \quad (7)$$

- **Attention-over-Attention**

Different from Cui et al. (2016), instead of using naive heuristics (such as *summing* or *averaging*) to combine these individual attentions into a final attention, we introduce another attention mechanism to automatically decide the importance of each individual attention.

First, we calculate a reversed attention, that is, for every document word at time t, we calculate the "importance" distribution on the query, to indicate which query words are more important given a single document word. We apply a row-wise softmax function to the pair-wise matching matrix M to get query-level attentions. We denote $\beta(t) \in \mathbb{R}^{|\mathcal{Q}|}$ as the query-level attention regarding document word at time t, which can be seen as a

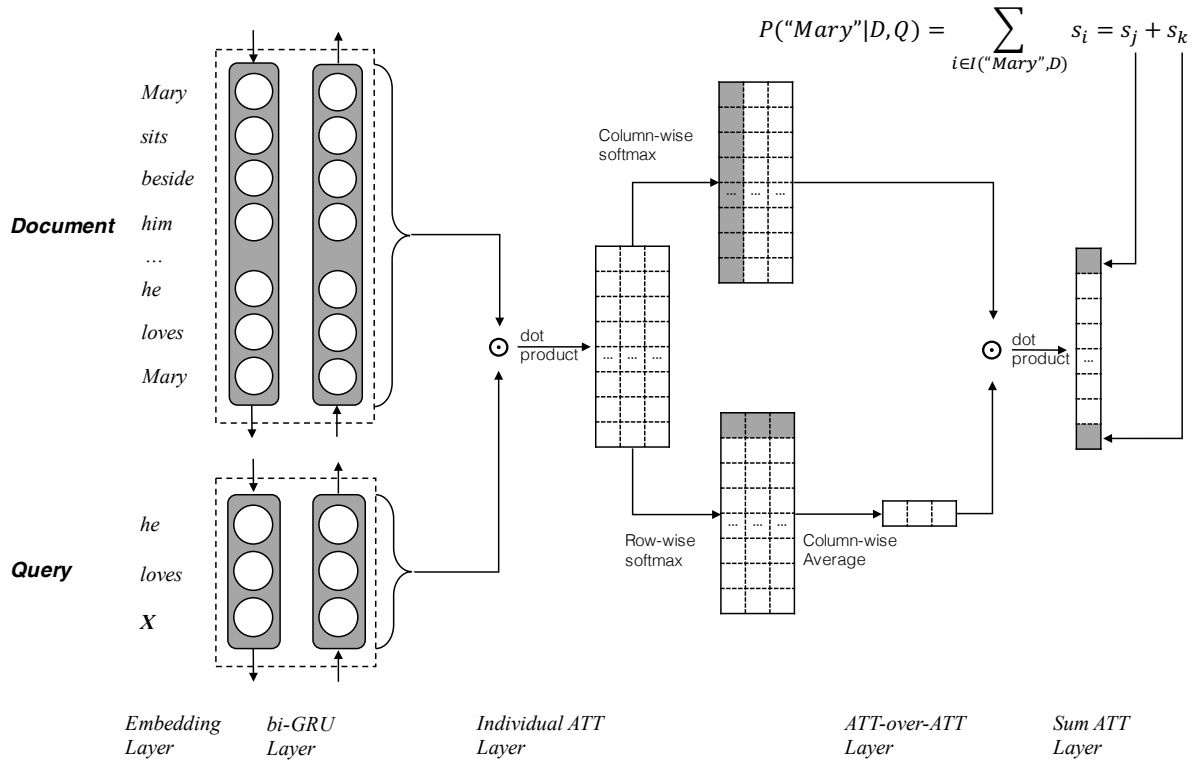

Figure 1: Neural network architecture of the proposed Attention-over-Attention Reader (AoA Reader).

document-to-query attention.

$$\beta(t) = softmax(M(t,1), ..., M(t,|\mathcal{Q}|)) \quad (8)$$

So far, we have obtained both *query-to-document* attention α and *document-to-query* attention β. Our motivation is to exploit mutual information between the document and query. However, most of the previous works are only relying on *query-to-document* attention, that is, only calculate one document-level attention when considering the whole query.

Then we average all the $\beta(t)$ to get an averaged query-level attention β. Note that, we do not apply another softmax to the β, because averaging individual attentions do not break the normalizing condition.

$$\beta = \frac{1}{n} \sum_{t=1}^{|\mathcal{D}|} \beta(t) \quad (9)$$

Finally, we calculate dot product of α and β to get the "attended document-level attention" $s \in \mathbb{R}^{|\mathcal{D}|}$, i.e. the *attention-over-attention* mechanism. Intuitively, this operation is calculating a weighted sum of each individual document-level attention $\alpha(t)$ when looking at query word at time t. In this way, the contributions by each query word can be learned explicitly, and the final decision (document-level attention) is made through the voted result by the importance of each query word.

$$s = \alpha^T \beta \quad (10)$$

- **Final Predictions**

Following Kadlec et al. (2016), we use *sum attention* mechanism to get aggregated results. Note that the final output should be reflected in the vocabulary space V, rather than document-level attention $|\mathcal{D}|$, which will make a significant difference in the performance, though Kadlec et al. (2016) did not illustrate this clearly.

$$P(w|\mathcal{D},\mathcal{Q}) = \sum_{i \in I(w,\mathcal{D})} s_i, \quad w \in V \quad (11)$$

where $I(w,\mathcal{D})$ indicate the positions that word w appears in the document $\mathcal{D}$. As the training objectives, we seek to maximize the log-likelihood of the correct answer.

$$\mathcal{L} = \sum_i \log(p(x)) \quad , x \in \mathcal{A} \quad (12)$$

Table 1: Statistics of cloze-style reading comprehension datasets: CNN news and CBTest NE / CN.

The proposed neural network architecture is depicted in Figure 1. Note that, as our model mainly adds limited steps of calculations to the AS Reader (Kadlec et al., 2016) and does not employ any additional weights, the computational complexity is similar to the AS Reader.

4 N-best Re-ranking Strategy

Intuitively, when we do cloze-style reading comprehensions, we often refill the candidate into the blank of the query to double-check its appropriateness, fluency and grammar to see if the candidate we choose is the most suitable one. If we do find some problems in the candidate we choose, we will choose the second possible candidate and do some checking again.

To mimic the process of double-checking, we propose to use N-best re-ranking strategy after generating answers from our neural networks. The procedure can be illustrated as follows.

- **N-best Decoding**

Instead of only picking the candidate that has the highest possibility as answer, we can also extract follow-up candidates in the decoding process, which forms an N-best list.

- **Refill Candidate into Query**

As a characteristic of the cloze-style problem, each candidate can be refilled into the blank of the query to form a complete sentence. This allows us to check the candidate according to its context.

- **Feature Scoring**

The candidate sentences can be scored in many aspects. In this paper, we exploit three features to score the N-best list.

  - Global N-gram LM: This is a fundamental metric in scoring sentence, which aims to evaluate its fluency. This model is trained on the document part of training data.
  - Local N-gram LM: Different from global LM, the local LM aims to explore the information with the given document, so the statistics are obtained from the test-time document. It should be noted that the local LM is trained sample-by-sample, it is not trained on the entire test set, which is not legal in the real test case. This model is useful when there are many unknown words in the test sample.
  - Word-class LM: Similar to global LM, the word-class LM is also trained on the document part of training data, but the words are converted to its word class ID. The word class can be obtained by using clustering methods. In this paper, we simply utilized the *mkcls* tool for generating 1000 word classes (Josef Och, 1999).

- **Weight Tuning**

To tune the weights among these features, we adopt the K-best MIRA algorithm (Cherry and Foster, 2012) to automatically optimize the weights on the validation set, which is widely used in statistical machine translation tuning procedure.

- **Re-scoring and Re-ranking**

After getting the weights of each feature, we calculate the weighted sum of each feature in the N-best sentences and then choose the candidate that has the lowest cost as the final answer.

5 Experiments

5.1 Experimental Setups

The general settings of our neural network model are listed below in detail.

- Embedding Layer: The embedding weights are randomly initialized with the uniformed distribution in the interval $[-0.05, 0.05]$.

Table 2: Results on the CNN news, CBTest NE and CN datasets. The best baseline results are depicted in italics, and the overall best results are in bold face.

For regularization purpose, we adopted l_2-regularization to 0.0001 and dropout rate of 0.1 (Srivastava et al., 2014). Also, it should be noted that we do not exploit any pre-trained embedding models.

- Hidden Layer: Internal weights of GRUs are initialized with random orthogonal matrices (Saxe et al., 2013).

- Optimization: We adopted ADAM optimizer for weight updating (Kingma and Ba, 2014), with an initial learning rate of 0.001. As the GRU units still suffer from the gradient exploding issues, we set the gradient clipping threshold to 5 (Pascanu et al., 2013). We used batched training strategy of 32 samples.

Dimensions of embedding and hidden layer for each task are listed in Table 3. In re-ranking step, we generate 5-best list from the baseline neural network model, as we did not observe a significant variance when changing the N-best list size. All language model features are trained on the training proportion of each dataset, with 8-gram word-based setting and Kneser-Ney smoothing (Kneser and Ney, 1995) trained by SRILM toolkit (Stolcke, 2002). The results are reported with the best model, which is selected by the performance of validation set. The ensemble model is made up of four best models, which are trained using different random seed. Implementation is done with Theano (Theano Development Team, 2016) and Keras (Chollet, 2015), and all models are trained on Tesla K40 GPU.

5.2 Overall Results

Our experiments are carried out on public datasets: CNN news datasets (Hermann et al., 2015) and CBTest NE/CN datasets (Hill et al., 2015). The statistics of these datasets are listed in Table 1, and the experimental results are given in Table 2.

As we can see that, our AoA Reader outperforms state-of-the-art systems by a large margin, where 2.3% and 2.0% absolute improvements over EpiReader in CBTest NE and CN test sets, which demonstrate the effectiveness of our model. Also by adding additional features in the re-ranking step, there is another significant boost 2.0% to 3.7% over AoA Reader in CBTest NE/CN test sets. We have also found that our single model could stay on par with the previous best ensemble system, and even we have an absolute improvement of 0.9% beyond the best ensemble model (Iterative Attention) in the CBTest NE validation set. When it comes to ensemble model, our AoA Reader also shows significant improvements over previous best ensemble models by a large margin and set up a new state-of-the-art system.

To investigate the effectiveness of employing *attention-over-attention* mechanism, we also compared our model to CAS Reader, which used pre-defined merging heuristics, such as *sum* or *avg* etc. Instead of using pre-defined merging heuristics, and letting the model explicitly learn the weights between individual attentions results in a significant boost in the performance, where 4.1% and 3.7% improvements can be made in CNN validation and test set against CAS Reader.

5.3 Effectiveness of Re-ranking Strategy

As we have seen that the re-ranking approach is effective in cloze-style reading comprehension task, we will give a detailed ablations in this section to show the contributions by each feature. To have a thorough investigation in the re-ranking step, we listed the detailed improvements while adding each feature mentioned in Section 4.

From the results in Table 4, we found that the NE and CN category both benefit a lot from the re-ranking features, but the proportions are quite different. Generally speaking, in NE category, the performance is mainly boosted by the LM_{local} feature. However, on the contrary, the CN category benefits from LM_{global} and LM_{wc} rather than the LM_{local}.

Also, we listed the weights of each feature in Table 5. The LM_{global} and LM_{wc} are all trained by training set, which can be seen as *Global Feature*. However, the LM_{local} is only trained within the respective document part of test sample, which can be seen as *Local Feature*.

$$\eta = \frac{LM_{global} + LM_{wc}}{LM_{local}} \tag{13}$$

	CBTest NE		CBTest CN	
	Valid	Test	Valid	Test
AoA Reader	77.8	72.0	72.2	69.4
+Global LM	78.3	72.6	73.9	71.2
+Local LM	79.4	73.8	74.7	71.7
+Word-class LM	79.6	74.0	75.7	73.1

Table 4: Detailed results of 5-best re-ranking on CBTest NE/CN datasets. Each row includes all of the features from previous rows. LM_{global} denotes the global LM, LM_{local} denotes the local LM, LM_{wc} denotes the word-class LM.

	CBTest NE	CBTest CN
NN	0.64	0.20
Global LM	0.16	0.10
Word-class LM	0.04	0.39
Local LM	0.16	0.31
RATIO η	1.25	1.58

Table 5: Weight of each feature in N-best re-ranking step. *NN* denotes the feature (probability) produced by baseline neural network model.

We calculated the ratio between the global and local features and found that the NE category is much more dependent on local features than CN category. Because it is much more likely to meet a new named entity than a common noun in the test phase, so adding the local LM provides much more information than that of common noun. However, on the contrary, answering common noun requires less local information, which can be learned in the training data relatively.

6 Quantitative Analysis

In this section, we will give a quantitative analysis to our AoA Reader. The following analyses are carried out on CBTest NE dataset. First, we investigate the relations between the length of the document and corresponding accuracy. The result is depicted in Figure 2.

As we can see that the AoA Reader shows consistent improvements over AS Reader on the different length of the document. Especially, when the length of document exceeds 700, the improvements become larger, indicating that the AoA Reader is more capable of handling long documents.

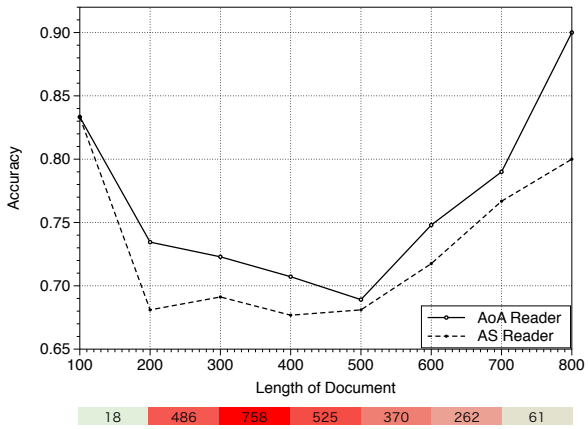

Figure 2: Test accuracy against the length of the document. The bar below the figure indicates the number of samples in each interval.

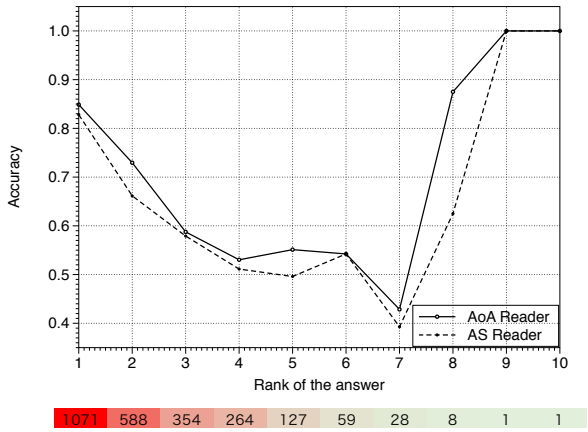

Figure 3: Test accuracy against the frequency rank of the answer. The bar below the figure indicates the number of samples in each rank.

Furthermore, we also investigate if the model tends to choose a high-frequency candidate than a lower one, which is shown in Figure 3. Not surprisingly, we found that both models do a good job when the correct answer appears more frequent in the document than the other candidates. This is because that the correct answer that has the highest frequency among the candidates takes up over 40% of the test set (1071 out of 2500). But interestingly we have also found that, when the frequency rank of correct answer exceeds 7 (less frequent among candidates), these models also give a relatively high performance. Empirically, we think that these models tend to choose extreme cases in terms of candidate frequency (either too high or too low). One possible reason is that it is hard for the model to choose a candidate that has a neutral frequency as the correct answer, because of its ambiguity (neutral choices are hard to made).

7 Related Work

Cloze-style reading comprehension tasks have been widely investigated in recent studies. We will take a brief revisit to the related works.

Hermann et al. (2015) have proposed a method for obtaining large quantities of $\langle \mathcal{D}, \mathcal{Q}, \mathcal{A} \rangle$ triples through news articles and its summary. Along with the release of cloze-style reading comprehension dataset, they also proposed an attention-based neural network to handle this task. Experimental results showed that the proposed neural network is effective than traditional baselines.

Hill et al. (2015) released another dataset, which stems from the children's books. Different from Hermann et al. (2015)'s work, the document and query are all generated from the raw story without any summary, which is much more general than previous work. To handle the reading comprehension task, they proposed a window-based memory network, and self-supervision heuristics is also applied to learn hard-attention.

Unlike previous works, that using blended representations of document and query to estimate the answer, Kadlec et al. (2016) proposed a simple model that directly pick the answer from the document, which is motivated by the Pointer Network (Vinyals et al., 2015). A restriction of this model is that the answer should be a single word and appear in the document. Results on various public datasets showed that the proposed model is effective than previous works.

Liu et al. (2016) proposed to exploit reading comprehension models to other tasks. They first applied the reading comprehension model into Chinese zero pronoun resolution task with automatically generated large-scale pseudo training data. The experimental results on OntoNotes 5.0 data showed that their method significantly outperforms various state-of-the-art systems.

Our work is primarily inspired by Cui et al. (2016) and Kadlec et al. (2016) , where the latter model is widely applied to many follow-up works (Sordoni et al., 2016; Trischler et al., 2016; Cui et al., 2016). Unlike the CAS Reader (Cui et al., 2016), we do not assume any heuristics to our model, such as using merge functions: sum, avg etc. We used a mechanism called "attention-

over-attention" to explicitly calculate the weights between different individual document-level attentions, and get the final attention by computing the weighted sum of them. Also, we find that our model is typically general and simple than the recently proposed model, and brings significant improvements over these cutting edge systems.

8 Conclusion

We present a novel neural architecture, called attention-over-attention reader, to tackle the cloze-style reading comprehension task. The proposed AoA Reader aims to compute the attentions not only for the document but also the query side, which will benefit from the mutual information. Then a weighted sum of attention is carried out to get an attended attention over the document for the final predictions. Among several public datasets, our model could give consistent and significant improvements over various state-of-the-art systems by a large margin.

The future work will be carried out in the following aspects. We believe that our model is general and may apply to other tasks as well, so firstly we are going to fully investigate the usage of this architecture in other tasks. Also, we are interested to see that if the machine really "comprehend" our language by utilizing neural networks approaches, but not only serve as a "document-level" language model. In this context, we are planning to investigate the problems that need comprehensive reasoning over several sentences.

Alignment at Work: Using Language to Distinguish the Internalization and Self-Regulation Components of Cultural Fit in Organizations

Abstract

Cultural fit is widely believed to affect the success of individuals and the groups to which they belong. Yet it remains an elusive, poorly measured construct. Recent research draws on computational linguistics to measure cultural fit but overlooks asymmetries in cultural adaptation. By contrast, we develop a directed, dynamic measure of cultural fit based on linguistic alignment, which estimates the influence of one person's word use on another's and distinguishes between two enculturation mechanisms: internalization and self-regulation. We use this measure to trace employees' enculturation trajectories over a large, multi-year corpus of corporate emails and find that patterns of alignment in the first six months of employment are predictive of individuals downstream outcomes, especially involuntary exit. Further predictive analyses suggest referential alignment plays an overlooked role in linguistic alignment.

1 Introduction

Entering a new group is rarely easy. Adjusting to unfamiliar behavioral norms and donning a new identity can be cognitively and emotionally taxing, and failure to do so can lead to exclusion. But successful enculturation to the group often yields significant rewards, especially in organizational contexts. Fitting in has been tied to positive career outcomes such as faster time-to-promotion, higher performance ratings, and reduced risk of being fired (O'Reilly et al., 1991; Goldberg et al., 2016).

A major challenge for enculturation research is distinguishing between *internalization* and *self-regulation*. Internalization, a more inwardly focused process, involves identifying as a group member and accepting group norms, while self-regulation, a more outwardly oriented process, entails deciphering the group's normative code and adjusting one's behavior to comply with it. Existing approaches, which generally rely on self-reports, are subject to various forms of reporting bias and typically yield only static snapshots of this process. Recent computational approaches that use language as a behavioral signature of group integration uncover dynamic traces of enculturation but cannot distinguish between internalization and self-regulation.

To overcome these limitations, we introduce a dynamic measure of *directed* linguistic accommodation between a newcomer and existing group members. Our approach differentiates between an individual's (1) *base rate* of word use and (2) *linguistic alignment* to interlocutors. The former corresponds to internalization of the group's linguistic norms, whereas the latter reflects the capacity to regulate one's language in response to peers' language use. We apply this language model to a corpus of internal email communications and personnel records, spanning a seven-year period, from a mid-sized technology firm. We show that changes in base rates and alignment, especially with respect to pronoun use, are consistent with successful assimilation into a group and can predict eventual employment outcomes—continued employment, involuntary exit, or voluntary exit—at levels above chance. We use this predictive problem to investigate the nature of linguistic alignment. Our results suggest that the common formulation of alignment as a lexical-level phenomenon is incomplete.

2 Linguistic Alignment and Group Fit

Linguistic alignment Linguistic alignment is the tendency to use the same or similar words as one's conversational partner. Alignment is an instance of a widespread and socially important human behavior: *communication accommodation*, the tendency of two interacting people to nonconsciously adopt similar behaviors. Evidence of accommodation appears in many behavioral dimensions, including gestures, postures, speech rate, self-disclosure, and language or dialect choice (see Giles et al. (1991) for a review). More accommodating people are rated by their interlocutors as more intelligible, attractive, and cooperative (Feldman, 1968; Ireland et al., 2011; Triandis, 1960). These perceptions have material consequences—for example, high accommodation requests are more likely to be fulfilled, and pairs who accommodate more in how they express uncertainty perform better in lab-based tasks (Buller and Aune, 1988; Fusaroli et al., 2012).

Although accommodation is ubiquitous, individuals vary in their levels of accommodation in ways that are socially informative. Notably, more powerful people are accommodated more strongly in many settings, including trials (Gnisci, 2005), online forums (Danescu-Niculescu-Mizil et al., 2012), and Twitter (Doyle et al., 2016). Most relevant for this work, speakers may increase their accommodation to signal camaraderie or decrease it to differentiate from the group. For example, Bourhis and Giles (1977) found that Welsh English speakers increased their use of the Welsh accent and language in response to an English speaker who dismissed it.

Person-group fit and linguistic alignment These findings suggest that linguistic alignment is a useful avenue for studying how people assimilate into a group. Whereas traditional approaches to studying person-group fit rely on self-reports that are subject to various forms of reporting bias and cannot feasibly be collected with high granularity across many points in time, recent studies have proposed language-based measures as a means to tracing the dynamics of person-group fit without having to rely on self-reports. Building on Danescu-Niculescu-Mizil et al. (2013)'s research into language use similarities as a proxy for social distance between individuals, Srivastava et al. (forthcoming) and Goldberg et al. (2016) developed a measure of cultural fit based on the similarity in linguistic style between individuals and their colleagues in an organization. Their time-varying measure highlights linguistic compatibility as an important facet of cultural fit and reveals distinct trajectories of enculturation for employees with different career outcomes.

While this approach can help uncover the dynamics and consequences of an individual's fit with her colleagues in an organization, it cannot disentangle the underlying reasons for this alignment. For two primary reasons, it cannot distinguish between fit that arises from internalization and fit produced by self-regulation. First, Goldberg et al. (2016) and Srivastava et al. (forthcoming) define fit using a symmetric measure, the Jensen-Shannon divergence, which does not take into account the direction of alignment. Yet the distinction between an individual adapting to peers versus peers adapting to the individual would appear to be consequential. Second, this prior work considers fit across a wide range of linguistic categories but does not interrogate the role of particular categories, such as pronouns, that can be especially informative about enculturation. For example, a person's base rate use of the first-person singular (*I*) or plural (*we*) might indicate the degree of group identity internalization, whereas adjustment to *we* usage in response to others' use of the pronoun might reveal the degree of self-regulation to the group's normative expectations.

Modeling fit with WHAM To address these limitations, we build upon and extend the WHAM alignment framework (Doyle and Frank, 2016) to analyze the dynamics of internalization and self-regulation using the complete corpus of email communications and personnel records from a mid-sized technology company over a seven-year period. WHAM uses a conditional measure of alignment, separating overall homophily (unconditional similarity in people's language use, driven by *internalized* similarity) from in-the-moment adaptation (adjusting to another's usage, corresponding to *self-regulation*). WHAM also provides a directed measure of alignment, in that it estimates a *replier's* adaptation to the other conversational participant separately from the participant's adaptation to the replier.

Level(s) of alignment The convention within linguistic alignment research, dating back to early

work on Linguistic Style Matching (Niederhoffer and Pennebaker, 2002), is to look at lexical alignment: the repetition of the same or similar words across conversation participants. From a communication accommodation standpoint, this is justified by assuming that one's choice of words represents a stylistic signal that is partially independent of the meaning one intends to express—similar to the accommodation on paralinguistic signals discussed above. The success of previous linguistic alignment research shows that this is valid.

However, words are difficult to divorce from their meanings, and sometimes repeating a word conflicts with repeating its referent. In particular, pronouns often refer to different people depending on who uses the pronoun. While there is evidence that one person using a first-person singular pronoun increases the likelihood that her conversation partner will as well (Chung and Pennebaker, 2007), we may also expect that one person using first-person singular pronouns may cause the other to use more second-person pronouns, so that both people are referring to the same person. This is especially important under the Interactive Alignment Model view (Pickering and Garrod, 2004), where conversants align their entire mental representations, which predicts both lexical and referential alignment behaviors will be observed. Discourse-strategic explanations for alignment also predict alignment at multiple levels (Doyle and Frank, 2016).

Since we have access to a high-quality corpus with meaningful outcome measures, we can investigate the relative importance of these two types of alignment. We will show that referential alignment is more predictive of employment outcomes than is lexical alignment, suggesting a need for alignment research to consider both levels rather than just the latter.

3 Data: Corporate Email Corpus

We use the complete corpus of internal emails exchanged among full-time employees at a mid-sized US-based technology company between 2009 to 2014 (Srivastava et al., forthcoming). Each email was summarized as a count of word categories in its text. These categories are a subset of the Linguistic Information and Word Count system (Pennebaker et al., 2007). The categories were chosen because they are likely to be indicative of one's standing/role within a group.[1]

We divided email chains into message-reply pairs to investigate conditional alignment between a message and its reply. To limit these pairs to cases where the reply was likely related to the preceding message, we removed all emails with more than one sender or recipient (including CC/BCC), identical sender and recipient, or where the sender or recipient was an automatic notification system or any other mailbox that was not specific to a single employee. We also excluded emails with no body text or more than 500 words in the body text, and pairs with more than a week's latency between message and reply.

Finally, because our analyses involve enculturation dynamics over the first six months of employment, we excluded replies sent by an employee whose overall tenure was less than six months. This resulted in a collection of 407,779 message-reply pairs, with 485 distinct replying employees. We combined this with monthly updates of employees joining and leaving the company and whether they left voluntarily or involuntarily. Of the 485, 66 left voluntarily, 90 left involuntarily, and 329 remained employed at the end of the observation period.

Privacy protections and ethical considerations Research based on employees' archived electronic communications in organizational settings poses potential threats to employee privacy and company confidentiality. To address these concerns, and following established ethical guidelines for the conduct of such research (Borgatti and Molina, 2003), we implemented the following procedures: (a) raw data were stored on secure research servers behind the company's firewall; (b) messages exchanged with individuals outside the firm were eliminated; (c) all identifying information such as email addresses was transformed into hashed identifiers, with the company retaining access to the key code linking identifying information to hashed identifiers; and (d) raw message content was transformed into linguistic categories so that identities could not be inferred from message content. Per terms of the non-disclosure agreement we signed with the firm, we are not able to share the data underlying the analyses reported below.

[1] Six pronoun categories (first singular (*I*), first plural (*we*), second (*you*), third singular personal (*he, she*), third singular impersonal (*it, this*), and third plural (*they*)) and five time/certainty categories (past tense, present tense, future tense, certainty, and tentativity).

We can, however, share the code and dummy test data, both of which can be accessed at http://github.com/gabedoyle/acl2017.

4 Model: An Extended WHAM Framework

To assess alignment, we use the Word-Based Hierarchical Alignment Model (WHAM) framework (Doyle and Frank, 2016). The core principle of WHAM is that alignment is a change, usually an increase, in the frequency of using a word category in a reply when the word category was used in the preceding message. For instance, a reply to the message *What **will** we discuss at the meeting?*, is likely to have more instances of future tense than a reply to the message *What **did** we discuss at the meeting?* Under this definition, alignment is the log-odds shift from the *baseline* reply frequency, the frequency of the word in a reply when the preceding message did **not** contain the word.

WHAM is a hierarchical generative modeling framework, so it uses information from related observations (e.g., multiple repliers with similar demographics) to improve its robustness on sparse data (Doyle et al., 2016). There are two key parameters, shown in Figure 2: η^{base}, the log-odds of a given word category c when the preceding message did not contain c, and η^{align}, the increase in the log-odds of c when the preceding message did contain c.

A dynamic extension To understand enculturation, we need to track changes in both the alignment and baseline over time. We add a month-by-month change term to WHAM, yielding a piecewise linear model of these factors over the course of an employee's tenure. Each employee's tenure is broken into two or three segments: their first six months after being hired, their last six months before leaving (if they leave), and the rest of their tenure.[2] The linear segments for their alignment are fit as an intercept term η^{align}, based at their first month (for the initial period) or their last month (for the final period), and per-month slopes α. Baseline segments are fit similarly, with parameters η^{base} and β.[3] To visualize the alignment behaviors and the parameter values, we create "sawhorse" plots, with an example in Figure 1.

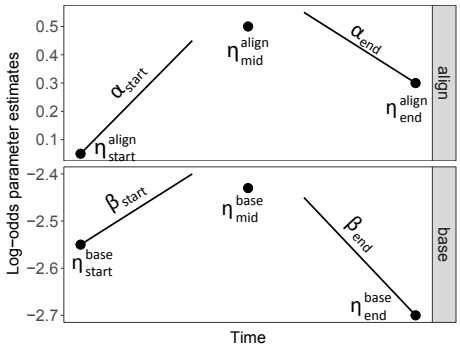

Figure 1: Sample sawhorse plot with key variables labelled. The η point parameters (first month, last month, and middle average) and α (or β) by-month slope (start, end) parameters are estimated by WHAM for each word category and employee group.

In our present work, we are focused on changes in cultural fit during the transitions into or out of the group, so we collapse observations outside the first/last six months into a stable point estimate, constraining their slopes to be zero. This simplification also circumvents the issue of different employees having different middle-period lengths.[4]

Model structure The graphical model for our instantiation of WHAM is shown in Figure 2. For each word category c, WHAM's generative model represents each reply as a series of token-by-token independent draws from a binomial distribution. The binomial probability μ is dependent on whether the preceding message did (μ^{align}) or did not (μ^{base}) contain a word from category c, and the inferred alignment value is the difference between these probabilities in log-odds space (η^{align}).

The specific values of these variables depend on three hierarchical features: the word category c, the group g that a given employee falls into, and the time period t (a piece of the piece-wise

[2]Within each segment, the employee's alignment model is similar to that of Yurovsky et al. (2016), who introduced a constant by-month slope parameter to model changes in parent-child alignment during early linguistic development.

[3]The six month timeframe was chosen as previous research has found it to be a critical period for early enculturation (Bauer et al., 1998). Pilot investigations into the change in baseline usage over time showed roughly linear changes over the first/last six months, but our linearity assumption may mask interesting variation in the enculturation trajectories.

[4]As shown in Figure 1, the pieces do not need to define a continuous function. Alignment behaviors continue to change in the middle of an employee's tenure (Srivastava et al., forthcoming), so alignment six months in to the job is unlikely to be equal to alignment six months from leaving, or the average alignment over the middle tenure.

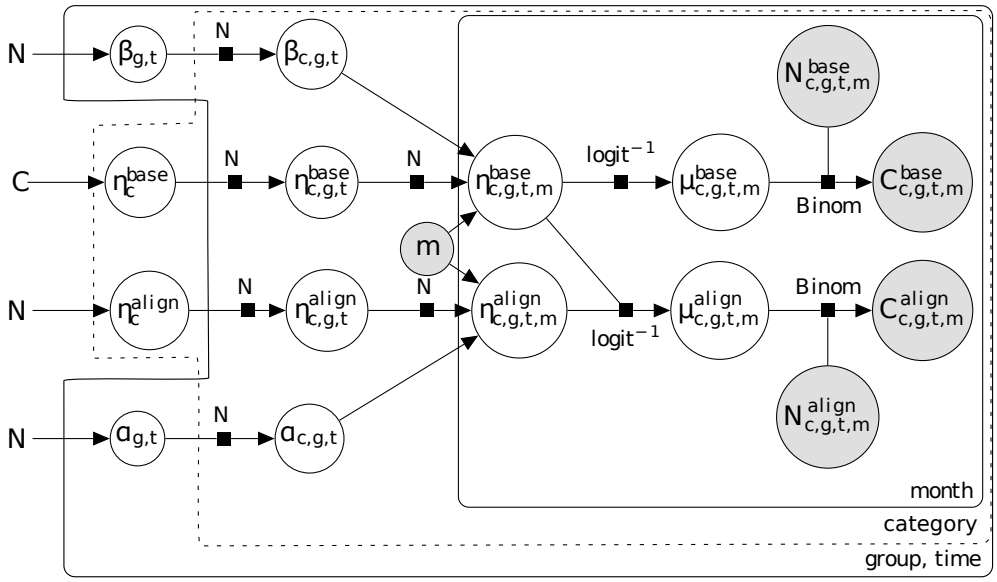

Figure 2: The Word-Based Hierarchical Alignment Model (WHAM). Hierarchical chains of normal distributions capture relationships between word categories, individuals, outcome groups, and time, and generate linear predictors η, which are converted into probabilities μ for binomial draws of the words in replies.

linear function: beginning, middle, or end). Note that the hierarchical ordering is different for the η chains and the α/β chains; c is above g and t for the η chains, but below them for the α/β chains. This is because we expect the static (η) values for a given word category to be relatively consistent across different groups and at different times, but we expect the values to be independent across the different word categories. Conversely, we expect that the enculturation trajectories across word categories (α/β) will be similar, while the trajectories may vary substantially across different groups and different times. Lastly, the month m in which a reply is written (measured from the start of the time period t) has a linear effect on the η value, as described below.

To estimate alignment, we first divide the replies up by group, time period, and calendar month. We separate the replies into two sets based on whether the preceding message contained the category c (the "alignment" set) or not (the "baseline" set). All replies within a set are then aggregated in a single bag-of-words representation, with category token counts $C^{align}_{c,g,t,m}$ and $C^{base}_{c,g,t,m}$, and total token counts $N^{base}_{c,g,t,m}$ and $N^{base}_{c,g,t,m}$ comprising the observed variables on the far right of the model. Moving from right to left, these counts are assumed to come from binomial draws with probability $\mu^{align}_{c,g,t,m}$ or $\mu^{base}_{c,g,t,m}$. The μ values are then in turn generated from η values in log-odds space by an inverse-logit transform, similar to linear predictors in logistic regression.

The η^{base} variables are representations of the baseline frequency of a marker in log-odds space, and μ^{base} is simply a conversion of η^{base} to probability space, the equivalent of an intercept term in a logistic regression. η^{align} is an additive value, with $\mu^{align} = \text{logit}^{-1}(\eta^{base} + \eta^{align})$, the equivalent of a binary feature coefficient in a logistic regression. The specific month's η variables are calculated as a linear function: $\eta^{align}_{c,g,t,m} = \eta^{align}_{c,g,t} + m\alpha_{c,g,t}$, and similarly with β for the baseline.

The remainder of the model is a hierarchy of normal distributions that integrate social structure into the analysis. In the present work, we have three levels in the hierarchy: category, group, and time period. In Analysis 1, employees are grouped by their employment outcome (stay, leave voluntarily, leave involuntarily); in Analyses 2 & 3, where we predict the employment outcomes, each group is a single employee. The normal distributions that connect these levels have identical standard deviations $\sigma^2 = .25$.[5] The hierarchies

[5]The deviation is not a theoretically motivated choice, and was chosen as a good empirical balance between reasonable parameter convergence (improved by smaller σ^2) and good model log-probability (improved by larger σ^2).

are headed by a normal distribution centered at 0, except for the η_{base} hierarchy, which has a $Cauchy(0, 2.5)$ distribution.[6]

Message and reply length can affect alignment estimates; the WHAM model was developed in part to reduce this effect. As different employees had different email length distributions, we further accounted for length by dividing all replies into five quintile length bins, and treated each bin as separate observations for each employee. This design choice adds an additional control factor, but results were qualitatively similar without it. All of our analyses are based on parameter estimates from RStan fits of WHAM with 500 iterations over four chains.

While previous research on cultural fit has emphasized either its internalization (O'Reilly et al., 1991) or self-regulation (Goldberg et al., 2016) components, our extension to the WHAM framework helps disentangle them by estimating them as separate baseline and alignment trajectories. For example, we can distinguish between an archetypal individual who initially aligns to her colleagues and then internalizes this style of communication such that her baseline use also shifts and another archetypal person who aligns to her colleagues but does not change her baseline usage. The former exhibits high correspondence between internalization and self-regulation, whereas the latter demonstrates an ability to decouple them.

5 Analyses

We perform three analyses on this data. First, we examine the qualitative behaviors of pronoun alignment and how they map onto employee outcomes in the data. Second, we show that these qualitative differences in early enculturation are meaningful, with alignment behaviors predicting employment outcome above chance. Lastly, we consider lexical versus referential levels of alignment and show that predictions are improved under the referential formulation, suggesting that alignment is not limited to low-level word-repetition effects.

[6] As η^{base} is the log-odds of each word in a reply being a part of the category c, it is expected to be substantially negative. For example, second person pronouns (*you*), are around 2% of the words in replies, approximately -4 in log-odds space. We follow Gelman et al. (2008)'s recommendation of the Cauchy prior as appropriate for parameter estimation in logistic regression.

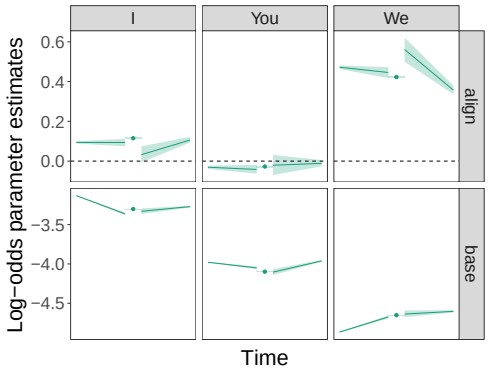

Figure 3: Sawhorse plots showing the dynamics of pronoun alignment behavior across employees. Vertical axis shows log-odds for baseline and alignment. Top row shows estimated alignment, highest for *we* and smallest for *you*. Bottom row shows baseline dynamics, with employees shifting toward the average usage as they enculturate. The shaded region is one standard deviation over parameter samples.

5.1 Analysis 1: Dynamic Qualitative Changes

We begin with descriptive analyses of the behavior of pronouns, which are likely to reflect incorporation into the company. In particular, we look at first-person singular (*I*), first-person plural (*we*), and second-person pronouns (*you*). We expect that increases in *we* usage will occur as the employee is integrated into the group, while *I* and *you* usage will decrease, and want to understand whether these changes manifest on baseline usage (i.e., internalization), alignment (i.e., self-regulation), or both.

Design We divided each employee's emails by calendar month, and separated them into the employee's first six months, their last six months (if an employee left the company within the observation period), and the middle of their tenure. Employees with fewer than twelve months at the company were excluded from this analysis, so that their first and last months did not overlap.

We fit two WHAM models in this analysis. The first aggregated all employees, regardless of employment outcome, to minimize noise; the second separated them by outcome to analyze cultural fit differences.

Outcome-aggregated model We start with the aggregated behavior of all employees, shown in Figure 3. For baselines, we see decreased use of *I*

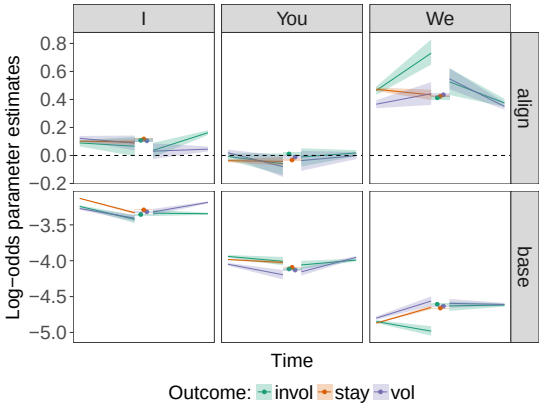

Figure 4: Sawhorse plots split by employment outcome. Mid-tenure points are jittered for improved readability.

and *you* over the first six months, with *we* usage increasing over the same period, confirming the expected result that incorporating into the group is accompanied by more inclusive pronoun usage. Despite the baseline changes, alignment is fairly stable through the first six months. Alignment on first-person singular and second-person pronouns is lower than first-person plural pronouns, likely due to the fact that *I* or *you* have different referents when used by the two conversants, while both conversants could use *we* to refer to the same group. We will consider this referential alignment in more detail in Analysis 3. Since employees with different outcomes have much different experiences over their last six months, we will not discuss them in aggregate, aside from noting the sharp decline in *we* alignment near the end of the employees' tenures.

Outcome-separated model Figure 4 shows outcome-specific trajectories, with green lines showing involuntary leavers (i.e., those who are fired or downsized), blue showing voluntary leavers, and orange showing employees who remained at the company through the final month of the data. The use of *I* and *you* is similar to the aggregates in Figure 3, regardless of group. The last six months of *I* usage show an interesting difference, where involuntary leavers align more on *I* but retain a stable baseline while voluntary leavers retain a stable alignment but increase *I* overall, which is consistent with group separation.

The most compelling result we see here, though, is the changes in *we* usage by different groups of employees. Employees who eventually leave the company involuntarily show signs of more self-regulation than internalization over the first six months, increasing their alignment while decreasing their baseline use (though they return to more similar levels as other employees later in their tenure). Employees who stay at the company, as well as those who later leave voluntarily, show signs of internalization, increasing their baseline usage to the company average, as well as adapting their alignment levels to the mean. This finding suggests that how quickly the employees internalize culturally-standard language use predicts their eventual employment outcome, even if they eventually end up near the average.

5.2 Analysis 2: Predicting Outcomes

This analysis tests the hypothesis that there are meaningful differences in employees' initial enculturation, captured by alignment behaviors. We examine the first six months of communications and attempt to predict whether the employee will leave the company. We find that, even with a simple classifier, alignment behaviors are predictive of employment outcome.

Design We fit the WHAM model to only the first six months of email correspondence for all employees who had at least six months of email. The model estimated the initial level of baseline use (η_{base}) and alignment (η_{align}) for each employee, as well as the slope (α, β) for baseline and alignment over those first six months, over all 11 word categories mentioned in Section 3.

We then created logistic regression classifiers, using the parameter estimates to predict whether an employee would leave the company. We fit separate classifiers for leaving voluntarily or involuntarily. Our results show that early alignment behaviors are better at identifying employees who will leave involuntarily than voluntarily, consistent with Srivastava et al.'s (forthcoming) findings that voluntary leavers are similar to stayers until late in their tenure. We fit separate classifiers using the alignment parameters and the baseline parameters to investigate their relative informativity.

For each model, we report the area under the curve (AUC). This value is estimated from the receiver operating characteristic (ROC) curve, which plots the true positive rate against the false positive rate over different classification thresholds. An AUC of 0.5 represents chance performance. We use balanced, stratified cross-

validation to reduce AUC misestimation due to unbalanced outcome frequencies and high noise (Parker et al., 2007).

Results The left column of Figure 5 shows the results over 10 runs of 10-fold balanced logistic classifiers with stratified cross-validation in R. The alignment-based classifiers are both above chance at predicting that an employee will leave the company, whether involuntarily or voluntarily. The baseline-based classifiers perform worse, especially on voluntary leavers. This finding is consistent with the idea that voluntary leavers resemble stayers (who form the bulk of the employees) until late in their tenure when their cultural fit declines.

We fit a model using both alignment and baseline parameters, but this model yielded an AUC value below the alignment-only classifier. This suggests that where alignment and baseline behaviors are both predictive, they do not provide substantially different predictive power and lead to overfitting. A more sophisticated classifier may overcome these challenges; our goal here was not to achieve maximal classification performance but to test whether alignment provided any useful information about employment outcomes.

5.3 Analysis 3: Types of Alignment

Our final analysis investigates the nature of linguistic alignment: specifically, whether there is an effect of referential alignment beyond that of the more commonly used lexical alignment.

Testing this hypothesis requires a small change to the alignment calculations. Lexical alignment is based on the conditional probability of the replier using a word category c given that the preceding message used that same category c. For referential alignment, we examine the conditional probability of the replier using a word category c_j given that the preceding message used the category c_i, where c_i and c_j are likely to be referentially linked. We also consider cases where c_i is likely to transition to c_j throughout the course of the conversation, such as present tense verbs turning into past tense as the event being described recedes into the past. The pairs of categories that are likely to be referentially or transitionally linked are: (*you, I*); (*we, I*); (*you, we*); (past, present); (present, future); and (certainty, tentativity). We include both directions of these pairs, so this provides approximately the same number of predictor variables for both situations to maximize comparability (12 for the referential alignments, 11 for the lexical). This modification does not change the structure of the WHAM model, but rather changes its C and N counts by reclassifying replies between the baseline or alignment pathways.

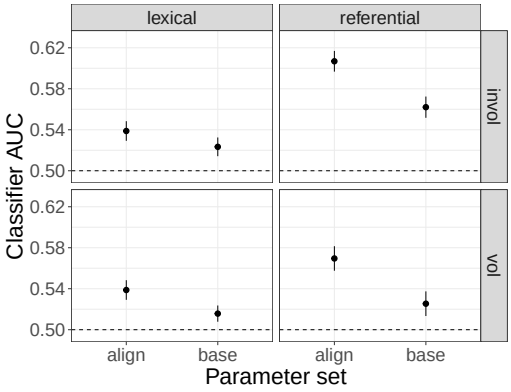

Figure 5: AUC values for 10 runs of 10-fold cross-validated logistic classifiers, with 95% confidence intervals on the mean AUC. Both lexical (left column) and referential (right column) alignment parameters lead to above chance classifier performance, but referential alignment outperforms lexical alignment at predicting both voluntary and involuntary departures.

Results Figure 5 plots the differences in predictive model performance using lexical versus referential alignment parameters. We find that the semantic parameters provide more accurate classification than the lexical both for voluntarily and involuntarily-leaving employees. This suggests that while previous work looking at lexical alignment successfully captures social structure, referential alignment may reflect a deeper and more accurate representation of the social structure. It is unclear if this behavior holds in less formal situations or with weaker organizational structure and shared goals, but these results suggest that the traditional alignment approach of only measuring lexical alignment should be augmented with referential alignment measures for a more complete analysis.

6 Discussion

A key finding from this work is that pronoun usage behaviors in employees' email communication are consistent with social integration into the group; employees use "I" pronouns less and

"we" pronouns more as they integrate. Furthermore, we see the importance of using an alignment measure such as WHAM for distinguishing the base rate and alignment usage of words. Employees who leave the company involuntarily show increased "we" usage through greater alignment, using "we" more when prompted by a colleague, but introducing it less of their own accord. This suggests that these employees do not feel fully integrated into the group, although they are willing to identify as a part of it when a more fully-integrated group member includes them, corresponding to self-regularization over internalization. The fact that these alignment measures alone, without any job productivity or performance metrics, have some predictive capability for employees' leaving the company suggests the potential for support or intervention programs to help high-performing but poorly-integrated employees integrate into the company better.

More generally, the prominence of pronominally-driven communication changes suggest that alignment analyses can provide insight into a range of social integration settings. This may be especially helpful in cases where there is great pressure to integrate smoothly, and people would be likely to adopt a self-regulating approach even if they do not internalize their group membership. Such settings not only include the high-stakes situation of keeping one's job, but of transitioning from high school to college or moving to a new country or region. Maximizing the chances for new members to become comfortable within a group is critical both for spreading useful aspects of the group's existing culture to new members and for integrating new ideas from the new members' knowledge and practices. Alignment-based approaches can be a useful tool in separating effective interventions that cause internalization of the group dynamics from those that lead to more superficial self-regularization changes.

7 Conclusions

This paper described an effort to use directed linguistic alignment as a measure of cultural fit within an organization. We adapted a hierarchical alignment model from previous work to estimate fit within corporate email communications, focusing on changes in language during employees' entry to and exit from the company. Our results showed substantial changes in the use of pronouns, with pronoun patterns varying by employees' outcomes within the company.The use of the first-person plural "we" during an employee's first six months is particularly instructive. Whereas stayers exhibited increased baseline use, indicating internalization, those eventually departing involuntarily were on the one hand decreasingly likely to introduce "we" into conversation, but increasingly responsive to interlocutors' use of the pronoun. While not internalizing a shared identity with their peers, involuntarily departed employees were overly self-regulating in response to its invocation by others.

Quantitatively, rates of usage and alignment in the first six months of employment carried information about whether employees left involuntarily, pointing towards fit within the company culture early on as an indicator of eventual employment outcomes. Finally, we saw ways in which the application of alignment to cultural fit might help to refine ideas about alignment itself: preliminary analysis suggested that referential, rather than lexical, alignment was more predictive of employment outcomes. More broadly, these results suggest ways that quantitative methods can be used to make precise application of concepts like "cultural fit" at scale.

Abstract

We present a visually grounded model of speech perception which projects spoken utterances and images to a joint semantic space. We use a multi-layer recurrent highway network to model the temporal nature of spoken speech, and show that it learns to extract both form and meaning-based linguistic knowledge from the input signal. We carry out an in-depth analysis of the representations used by different components of the trained model and show that encoding of semantic aspects tends to become richer as we go up the hierarchy of layers, whereas encoding of form-related aspects of the language input tends to initially increase and then plateau or decrease.

1 Introduction

Speech recognition is one of the success stories of language technology. It works remarkably well in a range of practical settings. However, this success relies on the use of very heavy supervision where the machine is fed thousands of hours of painstakingly transcribed audio speech signal. Humans are able to learn to recognize and understand speech from notably weaker and noisier supervision: they manage to learn to extract structure and meaning from speech by simply being exposed to utterances situated and grounded in their daily sensory experience. Modeling and emulating this remarkable skill has been the goal of numerous studies; however in the overwhelming majority of cases researchers used severely simplified settings where either the language input or the extralinguistic sensory input, or both, are small scale and symbolically represented. Section 2 provides a brief overview of this research.

More recently several lines of work have moved towards more realistic inputs while modeling or emulating language acquisition in a grounded setting. Gelderloos and Chrupała (2016) use the image captioning dataset MS COCO (Lin et al., 2014) to mimic the setting of grounded language learning: the sensory input consists of images of natural scenes, while the language input are phonetically transcribed descriptions of these scenes. The use of such moderately large and low-level data allows the authors to train a multi-layer recurrent neural network model, and to explore the nature and localization of the emerging hierarchy of linguistic representations learned in the process. Furthermore, in a series of recent studies Harwath and Glass (2015); Harwath et al. (2016); Harwath and Glass (2017) use image captioning datasets to model learning to understand spoken language from visual context with convolutional neural network models. Finally, there is a small but growing body of work dedicated to elucidating the nature of representations learned by neural networks from language data (see Section 2.2 for a brief overview). In the current work we build on these three strands of research and contribute the following advances:

- We use a multi-layer gated recurrent neural network to properly model the temporal nature of speech signal and substantially improve performance compared to the convolutional architecture from Harwath and Glass (2015);
- We carry out an in-depth analysis of the representations used by different components of the trained model and correlate them to representations learned by a text-based model and to human patterns of judgment on linguistic stimuli. This analysis is especially novel for a model with speech signal as input.

The general pattern of findings in our analysis is

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 613–622
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1057

as follows: The model learns to extract from the acoustic input both form-related and semantics-related information, and encodes it in the activations of the hidden layers. Encoding of semantic aspects tends to become richer as we go up the hierarchy of layers. Meanwhile, encoding of form-related aspects of the language input, such as utterance length or the presence of specific words, tends to initially increase and then decay.

We release the code for our models and analyses as open source, available at https://github.com/gchrupala/visually-grounded-speech. We also release a dataset of synthetically spoken image captions based on MS COCO, available at https://doi.org/10.5281/zenodo.400926.

2 Related work

Children learn to recognize and assign meaning to words from continuous perceptual data in extremely noisy context. While there have been many computational studies of human word meaning acquisition, they typically make strong simplifying assumptions about the nature of the input. Often language input is given in the form of word symbols, and the context consists of a set of symbols representing possible referents (e.g. Siskind, 1996; Frank et al., 2007; Fazly et al., 2010). In contrast, several studies presented models that learn from sensory rather than symbolic input, which is rich with regards to the signal itself, but very limited in scale and variation (e.g. Roy and Pentland, 2002; Yu and Ballard, 2004; Lazaridou et al., 2016).

2.1 Multimodal language acquisition

Chrupała et al. (2015) introduce a model that learns to predict the visual context from image captions. The model is trained on image-caption pairs from MSCOCO (Lin et al., 2014), capturing both rich visual input as well as larger scale input, but the language input still consists of word symbols. Gelderloos and Chrupała (2016) propose a similar architecture that instead takes phoneme-level transcriptions as language input, thereby incorporating the word segmentation problem into the learning task. In this work, we introduce an architecture that learns from continuous speech and images directly.

This work is related to research on visual grounding of language. The field is large and growing, with most work dedicated to the grounding of written text, particularly in image captioning tasks (see Bernardi et al. (2016) for an overview). However, learning to ground language to visual information is also interesting from an automatic speech recognition point of view. Potentially, ASR systems could be trained from naturally co-occurring visual context information, without the need for extensive manual annotation – a particularly promising prospect for speech recognition in low-resource languages. There have been several attempts along these lines. Synnaeve et al. (2014) present a method of learning to recognize spoken words in isolation from co-occurrence with image fragments. Harwath and Glass (2015) present a model that learns to map pre-segmented spoken words in sequence to aspects of the visual context, while in Harwath and Glass (2017) the model also learns to recognize words in the unsegmented signal.

Most closely related to our work is that of Harwath et al. (2016), as it presents an architecture that learns to project images and unsegmented spoken captions to the same embedding space. The sentence representation is obtained by feeding the spectrogram to a convolutional network. The architecture is trained on crowd-sourced spoken captions for images from the Places dataset (Zhou et al., 2014), and evaluated on image search and caption retrieval. Unfortunately this dataset is not currently available and we were thus unable to directly compare the performance of our model to Harwath et al. (2016). We do compare to Harwath and Glass (2015) which was tested on a public dataset. We make different architectural choices, as our models are based on recurrent highway networks (Zilly et al., 2016). As in human cognition, speech is processed incrementally. This also allows our architecture to integrate information sequentially from speech of arbitrary duration.

2.2 Analysis of neural representations

While analysis of neural methods in NLP is often limited to evaluation of the performance on the training task, recently methods have been introduced to *peek inside the black box* and explore what it is that enables the model to perform the task. One approach is to look at the contribution of specific parts of the input, or specific units in the model, to final representations or decisions. Kádár et al. (2016) propose *omission scores*, a method to estimate the contribution of input tokens to the fi-

nal representation by removing them from the input and comparing the resulting representations to the ones generated by the original input. In a similar approach, Li et al. (2016) study the contribution of individual input tokens as well as hidden units and word embedding dimensions by erasing them from the representation and analyzing how this affects the model.

Miao et al. (2016) and Tang et al. (2016) use visualization techniques for fine-grained analysis of GRU and LSTM models for ASR. Visualization of input and forget gate states allows Miao et al. (2016) to make informed adaptations to gated recurrent architectures, resulting in more efficiently trainable models. Tang et al. (2016) visualize qualitative differences between LSTM- and GRU-based architectures, regarding the encoding of information, as well as how it is processed through time.

We specifically study linguistic properties of the information encoded in the trained model. Adi et al. (2016) introduce prediction tasks to analyze information encoded in sentence embeddings about word order, sentence length, and the presence of individual words. We use related techniques to explore encoding of aspects of form and meaning within components of our stacked architecture.

3 Models

We use a multi-layer, gated recurrent neural network (RHN) to model the temporal nature of speech signal. Recurrent neural networks are designed for modeling sequential data, and gated variants (GRUs, LSTMs) are widely used with speech and text in both cognitive modeling and engineering contexts. RHNs are a simple generalization of GRU networks such that the transform between time points can consist of several steps.

Our multimodal model projects spoken utterances and images to a joint semantic space. The idea of projecting different modalities to a shared semantic space via a pair of encoders has been used in work on language and vision (among them Vendrov et al. (2015)). The core idea is to encourage inputs representing the same meaning in different modalities to end up nearby, while maintaining a distance from unrelated inputs.

The model consists of two parts: an utterance encoder, and an image encoder. The utterance encoder starts from MFCC speech features, while the image encoder starts from features extracted with a VGG-16 pre-trained on ImageNet. Our loss function attempts to make the cosine distance between encodings of matching utterances and images greater than the distance between encodings of mismatching utterance/image pairs, by a margin:

$$\sum_{u,i}\left(\sum_{u'}\max[0,\alpha+d(u,i)-d(u',i)] + \sum_{i'}\max[0,\alpha+d(u,i)-d(u,i')]\right) \quad (1)$$

where $d(u,i)$ is the cosine distance between the encoded utterance u and encoded image i. Here (u,i) is the matching utterance-image pair, u' ranges over utterances not describing i and i' ranges over images not described by u.

The image encoder enc_i is a simple linear projection, followed by normalization to unit L2 norm:

$$\mathrm{enc}_i(\mathbf{i}) = \mathrm{unit}(\mathbf{A}\mathbf{i}+b) \quad (2)$$

where $\mathrm{unit}(x) = \frac{x}{(x^T x)^{0.5}}$ and with $(\mathbf{A}, b)$ as learned parameters. The utterance encoder enc_u consists of a 1-dimensional convolutional layer of length s, size d and stride z, whose output feeds into a Recurrent Highway Network with k layers and L microsteps, whose output in turn goes through an attention-like lookback operator, and finally L2 normalization:

$$\mathrm{enc}_u(\mathbf{u}) = \mathrm{unit}(\mathrm{Attn}(\mathrm{RHN}_{\mathrm{k,L}}(\mathrm{Conv}_{\mathrm{s,d,z}}(\mathbf{u})))) \quad (3)$$

The main function of the convolutional layer $\mathrm{Conv}_{s,d,z}$ is to subsample the input along the temporal dimension. We use a 1-dimensional convolution with full border mode padding. The attention operator simply computes a weighted sum of the RHN activation at all timesteps:

$$\mathrm{Attn}(\mathbf{x}) = \sum_t \alpha_t \mathbf{x}_t \quad (4)$$

where the weights α_t are determined by learned parameters $\mathbf{U}$ and $\mathbf{W}$, and passed through the timewise softmax function:

$$\alpha_t = \frac{\exp(\mathbf{U}\tanh(\mathbf{W}\mathbf{x}_t))}{\sum_{t'}\exp(\mathbf{U}\tanh(\mathbf{W}\mathbf{x}_{t'}))} \quad (5)$$

The main component of the utterance encoder is a recurrent network, specifically a Recurrent Highway Network (Zilly et al., 2016). The idea behind

RHN is to increase the depth of the transform between timesteps, or the recurrence depth. Otherwise they are a type of gated recurrent networks. The transition from timestep $t-1$ to t is then defined as:

$$\mathrm{rhn}(\mathbf{x}_t, \mathbf{s}_{t-1}^{(L)}) = \mathbf{s}_t^{(L)} \tag{6}$$

where $\mathbf{x}_t$ stands for input at time t, and $\mathbf{s}_t^{(l)}$ denotes the state at time t at recurrence layer l, with L being the top layer of recurrence. Furthermore,

$$\mathbf{s}_t^{(l)} = \mathbf{h}_t^{(l)} \odot \mathbf{t}_t^{(l)} + \mathbf{s}_t^{(l-1)} \odot \left(\mathbf{1} - \mathbf{t}_t^{(l)}\right) \tag{7}$$

where $\odot$ is elementwise multiplication, and

$$\mathbf{h}_t^{(l)} = \tanh\left(\mathbb{I}[l=1]\mathbf{W}_H\mathbf{x}_t + \mathbf{U}_{H_l}\mathbf{s}_t^{(l-1)}\right) \tag{8}$$

$$\mathbf{t}_t^{(l)} = \sigma\left(\mathbb{I}[l=1]\mathbf{W}_T\mathbf{x}_t + \mathbf{U}_{T_l}\mathbf{s}^{(l-1)}\right) \tag{9}$$

Here $\mathbb{I}$ is the indicator function: input is only included in the computation for the first layer of recurrence $l=1$. By applying the rhn function repeatedly, an RHN layer maps a sequence of inputs to a sequence of states:

$$\begin{aligned}&\mathrm{RHN}(\mathbf{X}, \mathbf{s}_0)\\ &\quad = \mathrm{rhn}(\mathbf{x}_n, \ldots, \mathrm{rhn}(\mathbf{x}_2, \mathrm{rhn}(\mathbf{x}_1, \mathbf{s}_0^{(L)})))\end{aligned} \tag{10}$$

Two or more RHN layers can be composed into a stack:

$$\mathrm{RHN}_2(\mathrm{RHN}_1(\mathbf{X}, \mathbf{s}_{\mathbf{1}_0}^{(L)}), \mathbf{s}_{\mathbf{2}_0}^{(L)}), \tag{11}$$

where $\mathbf{s}_{\mathbf{n}_t}^{(l)}$ stands for the state vector of layer n of the stack, at layer l of recurrence, at time t. In our version of the Stacked RHN architecture we use *residualized* layers:

$$\mathrm{RHN}_{\mathrm{res}}(\mathbf{X}, \mathbf{s}_0) = \mathrm{RHN}(\mathbf{X}, \mathbf{s}_0) + \mathbf{X} \tag{12}$$

This formulation tends to ease optimization in multi-layer models (cf. He et al., 2015; Oord et al., 2016).

In addition to the speech model described above, we also define a comparable text model. As it takes a sequence of words as input, we replace the convolutional layer with a word embedding lookup table. We found the text model did not benefit from the use of the attention mechanism, and thus the sentence embedding is simply the L2-normalized activation vector of the topmost layer, at the last timestep.

4 Experiments

Our main goal is to analyze the emerging representations from different components of the model and to examine the linguistic knowledge they encode. For this purpose, we employ a number of tasks that cover the spectrum from fully form-based to fully semantic.

In Section 4.2 we assess the effectiveness of our architecture by evaluating it on the task of ranking images given an utterance. Sections 4.3 to 4.6 present our analyses. In Sections 4.3 and 4.4 we define auxiliary tasks to investigate to what extent the network encodes information about the surface form of an utterance from the speech input. In Section 4.5 and 4.6 we focus on where semantic information is encoded in the model. In the analyses, we use the following features:

Utterance embeddings: the weighted sum of the unit activations on the last layer, as calculated by Equation (3).

Average unit activations: hidden layer activations averaged over time and L2-normalized for each hidden layer.

Average input vectors: the MFCC vectors averaged over time. We use this feature to examine how much information can be extracted from the input signal only.

4.1 Data

For the experiments reported in the remainder of the paper we use two datasets of images with spoken captions.

4.1.1 Flickr8K

The Flickr8k Audio Caption Corpus was constructed by having crowdsource workers read aloud the captions in the original Flickr8K corpus (Hodosh et al., 2013). For details of the data collection procedure refer to Harwath and Glass (2015). The datasets consist of 8,000 images, each image with five descriptions. One thousand images are held out for validation, and another one thousand for the final test set. We use the splits provided by (Karpathy and Fei-Fei, 2015). The image features come from the final fully connect layer of VGG-16 (Simonyan and Zisserman, 2014) pre-trained on Imagenet (Russakovsky et al., 2014).

We generate the input signal as follows: we extract 12-dimensional mel-frequency cepstral coefficients (MFCC) plus log of the total energy. We

then compute and add first order and second order differences (deltas) for a total of 37 dimensions. We use 25 milisecond windows, sampled every 10 miliseconds.[1]

4.1.2 Synthetically spoken COCO

We generated synthetic speech for the captions in the MS COCO dataset (Lin et al., 2014) via the Google Text-to-Speech API.[2] The audio and the corresponding MFCC features are released as Chrupała et al. (2017)[3]. This TTS system we used produces high-quality realistic-sounding speech. It is nevertheless much simpler than real human speech as it uses a single voice, and lacks tempo variation or ambient noise. The data consists of over 300,000 images, each with five spoken captions. Five thousand images each are held out for validation and test. We use the splits and image features provided by Vendrov et al. (2015).[4] The image features also come from the VGG-16 network, but are averages of feature vectors for ten crops of each image. For the MS COCO captions we extracted only plain MFCC and total energy features, and did not add deltas in order to keep the amount of computation manageable given the size of the dataset.

4.2 Image retrieval

We evaluate our model on the task of ranking images given a spoken utterance, such that highly ranked images contain scenes described by the utterance. The performance on this task on validation data is also used to choose the best variant of the model architecture and to tune the hyperparameters. We compare the speech models to models trained on written sentences split into words. The best settings found for the four models were the following:

Flickr8K Text RHN 300-dimensional word embeddings, 1 hidden layer with 1024 dimensions, 1 microstep, initial learning rate 0.001.

Flick8K Speech RHN convolutional layer with length 6, size 64, stride 2, 4 hidden layers with 1024 dimensions, 2 microsteps, attention MLP with 128 hidden units, initial learning rate 0.0002

COCO Text RHN 300-dimensional word embeddings, 1 hidden layer with 1024 dimensions, 1 microstep, initial learning rate 0.001

COCO Speech RHN convolutional layer with length 6, size 64, stride 3, 5 hidden layers with 512 dimensions, 2 microsteps, attention MLP with 512 hidden units, initial learning rate 0.0002

All models were optimized with Adam (Kingma and Ba, 2014) with early stopping: we kept the parameters for the epoch which showed the best recall@10 on validation data.

Model	R@1	R@5	R@10	$\tilde{r}$
Speech $\text{RHN}_{4,2}$	0.055	0.163	0.253	48
Spectr. CNN	-	-	0.179	-
Text $\text{RHN}_{1,1}$	0.127	0.364	0.494	11

Table 1: Image retrieval performance on Flickr8K. R@N stands for recall at N; $\tilde{r}$ stands for median rank of the correct image.

Model	R@1	R@5	R@10	$\tilde{r}$
Speech $\text{RHN}_{5,2}$	0.111	0.310	0.444	13
Text $\text{RHN}_{1,1}$	0.169	0.421	0.565	8

Table 2: Image retrieval performance on MS COCO. R@N stands for recall at N; $\tilde{r}$ stands for median rank of the correct image.

Table 1 shows the results for the human speech from the Flickr8K dataset. The Speech RHN model scores substantially higher than model of Harwath and Glass (2015) on the same data. However the large gap between its perfomance and the scores of the text model suggests that Flickr8K is rather small for the speech task. In Table 2 we present the results on the dataset of synthetic speech from MS COCO. Here the text model is still better, but the gap is much smaller than for Flickr8K. We attribute this to the much larger size of dataset, and to the less noisy and less variable synthetic speech.

While the MS COCO text model is overall better than the speech model, there are cases where it outperforms the text model. We listed the top hundred cases where the ratio of the ranks of the correct image according to the two models was the smallest, as well as another hundred cases where it was the largest. Manual inspection did not turn

[1] We noticed that for a number of utterances the audio signal was very long: on inspection it turned out that most of these involved failure to switch off the microphone on the part of the workers, and the audio contained ambient noise or unrelated speech. We thus trucated all audio for this dataset at 10,000 miliseconds.

[2] Available at https://github.com/pndurette/gTTS.

[3] Available at https://doi.org/10.5281/zenodo.400926.

[4] See https://github.com/ivendrov/order-embedding.

up any obvious patterns for the cases of text being better than speech. For the cases where speech outperformed text, two patterns stood out: (i) sentences with spelling mistakes, (ii) unusually long sentences. For example for the sentence *a yellow*

Figure 1: Images returned for utterance *a yellow and white birtd is in flight* by the text (left) and speech (right) models.

and white birtd is in flight the text model misses the misspelled word *birtd* and returns an irrelevant image, while the speech model seems robust to some degree of variation in pronunciation and returns the target image at rank 1 (see Figure 1). In an attempt to quantify this effect we counted the number of unique words with training set frequencies below 5 in the top 100 utterances with lowest and highest rank ratio: for the utterances where text was better there were 16 such words; for utterances where speech was better there were 28, among them misspellings such as *streeet*, *scears* (for *skiers*), *contryside, scull, birtd, devise*.

The distribution of utterance lengths in Figure 2 confirms pattern (ii): the set of 100 sentences where speech beats text by a large margin are longer on average and there are extremely long outliers among them. One of them is the 36-word-

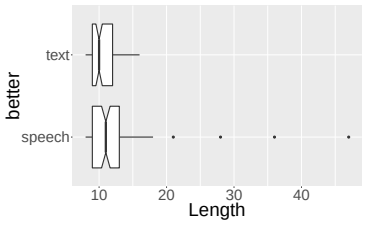

Figure 2: Length distribution for sentences where one model performs much better than the other.

long utterance depicted in Figure 3, with ranks 470 and 2 for text and speech respectively. We suspect that the speech model's attention mechanism enables it to cherry pick key fragments of such monster utterances, while the text model lacking this mechanism may struggle. Figure 3 shows the plot of the attention weights for this utterance from the speech model.

4.3 Predicting utterance length

Our first auxiliary task is to predict the length of the utterance, using the features explained at the beginning of Section 4. Since the length of an utterance directly corresponds to how long it takes to articulate, we also use the number of time steps[5] as a feature and expect it to provide the upper bound for our task, especially for synthetic speech. We use a Ridge Regression model for predicting utterance length using each set of features. The model is trained on 80% of the sentences in the validation set, and tested on the remaining 20%. For all features regularization penalty $\alpha = 1.0$ gave the best results.

Figure 4 shows the results for this task on human speech from Flickr8K and synthetic speech from COCO. With the exception of the average input vectors for Flickr8K, all features can explain a high proportion of variance in the predicted utterance length. The pattern observed for the two datasets is slightly different: due to the systematic conversion of words to synthetic speech in COCO, using the number of time steps for this dataset yields the highest R^2. However, this feature is not as informative for predicting the utterance length in Flickr8K due to noise and variation in human speech, and is in fact outperformed by some of the features extracted from the model. Also, the input vectors from COCO are much more informative than Flickr8K due to larger quantity and simpler structure of the speech signal. However, in both datasets the best (non-ceiling) performance is obtained by using average unit activations from the hidden layers (layer 2 for COCO, and layers 3 and 4 for Flickr8K). These features outperform utterance embeddings, which are optimized according to the visual grounding objective of the model and most probably learn to ignore the superficial characteristics of the utterance that do not contribute to matching the corresponding image.

Note that the performance on COCO plateaus after the second layer, which might suggest that form-based knowledge is learned by lower layers. Since Flickr8K is much smaller in size, the stabilising happens later in layer 3.

[5]This is approximately $\frac{\text{duration in milliseconds}}{10 \times \text{stride}}$.

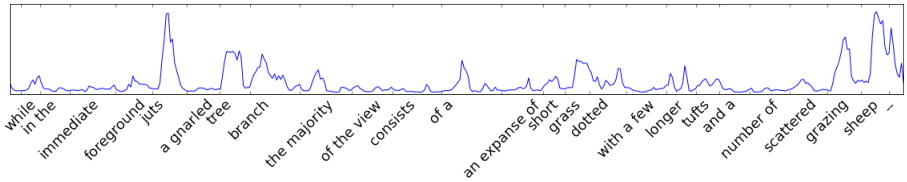

Figure 3: Attention weight distribution for a long utterance.

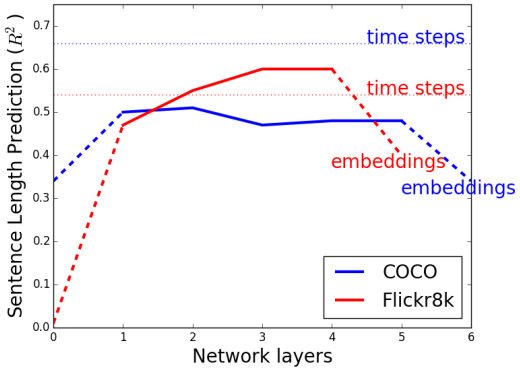

Figure 4: R^2 values for predicting utterance length for Flickr8K and COCO. Layers 1–5 represent (normalized) average unit activation, whereas the first (#0) and last point represent average input vectors and utterance embeddings, respectively.

4.4 Predicting word presence

Results from the previous experiment suggest that our model acquires information about higher level building blocks (words) in the continuous speech signal. Here we explore whether it can detect the presence or absence of individual words in an utterance. We formulate detecting a word in an utterance as a binary classification task, for which we use a multi-layer perceptron with a single hidden layer of size 1024, optimized by Adam. The input to the model is a concatenation of the feature vector representing an utterance and the one representing a target word. We again use utterance embeddings, average unit activations on each layer, and average input vectors as features, and represent each target word as a vector of MFCC features extracted from the audio signal synthetically produced for that word.

For each utterance in the validation set, we randomly pick one positive and one negative target (i.e., one word that does and one that does not appear in the utterance) that is not a stop word. To balance the probability of a word being positive or negative, we use each positive target as a negative target for another utterance in the validation set. The MLP model is trained on the positive and negative examples corresponding to 80% of the utterances in the validation set of each dataset, and evaluated on the remaining 20%.

Figure 5 shows the mean accuracy of the MLP on Flickr8K and COCO. All results using features extracted from the model are above chance (0.5), with the average unit activations of the hidden layers yielding the best results (0.65 for Flickr8K on layer 3, and 0.79 for COCO on layer 4). These numbers show that the speech model infers reliable information about word-level blocks from the low-level audio features it receives as input. The observed trend is similar to the previous task: average unit activations on the higher-level hidden layers are more informative for this task than the utterance embeddings, but the performance plateaus before the topmost layer.

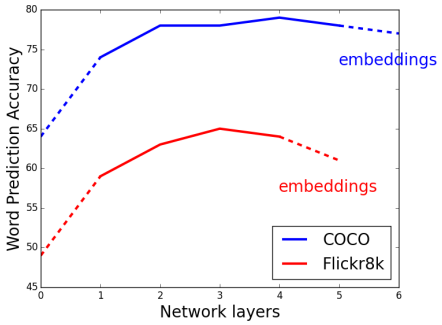

Figure 5: Mean accuracy values for predicting the presence of a word in an utterance for Flickr8K and COCO. Layers 1–5 represent the (normalized) average unit activations, whereas the first (#0) and last point represent average input vectors and utterance embeddings, respectively.

4.5 Sentence similarity

Next we explore to what extent the model's representations correspond to those of humans. We employ the Sentences Involving Compositional Knowledge (SICK) dataset (Marelli et al., 2014). SICK consists of image descriptions taken from

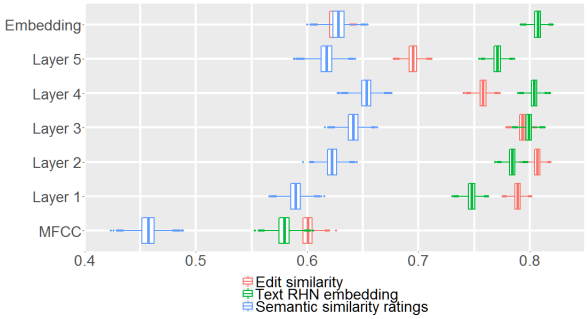

Figure 6: Pearson's r of cosine similarities of averaged input MFCCs and COCO Speech RHN hidden layer activation vectors and embeddings of sentence pairs with relatedness scores from SICK, cosine similarity of COCO Text RHN embeddings, and edit similarity.

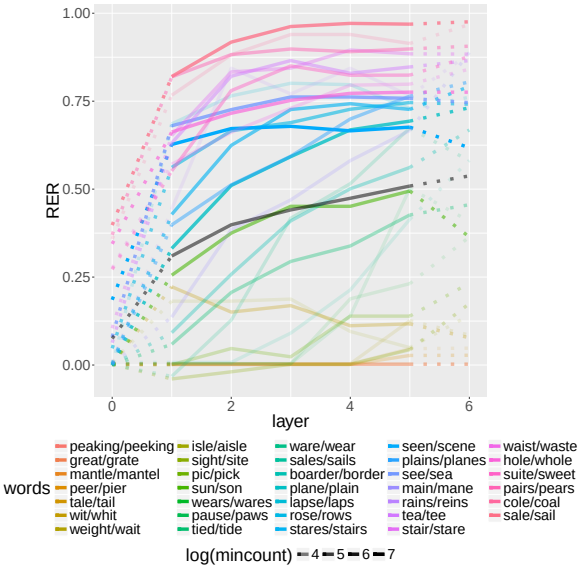

Figure 7: Disambiguation performance per layer. Points #0 and #6 (connected via dotted lines) represent the input vectors and utterance embeddings, respectively. The black line shows the overall mean RER.

Flickr8K and video captions from the SemEval 2012 STS MSRVideo Description data set (STS) (Agirre et al., 2012). Captions were paired at random, as well as modified to obtain semantically similar and contrasting counterparts, and the resulting pairs were rated for semantic similarity.

For all sentence pairs in SICK, we generate synthetic spoken sentences and feed them to the COCO Speech RHN, and calculate the cosine similarity between the averaged MFCC input vectors, the averaged hidden layer activation vectors, and the sentence embeddings. Z-score transformation was applied before calculating the cosine similarities. We then correlate these cosine similarities with

- semantic relatedness according to human ratings
- cosine similarities according to z-score transformed embeddings from COCO Text RHN
- *edit similarities*, a measure of how similar the sentences are in form, specifically, 1−normalized Levenshtein distance over character sequences

Figure 6 shows a boxplot over 10,000 bootstrap samples for all correlations. We observe that (i) correlation with edit similarity initially increases, then decreases; (ii) correlation with human relatedness scores and text model embeddings increases until layer 4, but decreases for hidden layer 5. The initially increasing and then decreasing correlation with edit similarity is consistent with the findings that information about form is encoded by lower layers. The overall growing correlation with both human semantic similarity ratings and the COCO Text RHN indicate that higher layers learn to represent semantic knowledge. We were somewhat surprised by the pattern for the correlation with human ratings and the Text model similarities which drops for layer 5. We suspect it may be caused by the model at this point in the layer hierarchy being strongly tuned to the specifics of the COCO dataset. To test this, we checked the correlations with COCO Text embeddings on validation sentences from the COCO dataset instead of SICK. These increased monotonically, in support of our conjecture.

4.6 Homonym disambiguation

Next we simulate the task of distinguishing between pairs of homonyms, i.e. words with the same acoustic form but different meaning. We group the words in the union of the training and validation data of the COCO dataset by their phonetic transcription. We then pick pairs of words which have the same pronunciation but different spelling, for example *suite/sweet*. We impose the following conditions: (a) both forms appear more than 20 times, (b) the two forms have different meaning (i.e. they are not simply variant spellings like *theater/theatre*), (c) neither form is a function word, and (d) the more frequent form constitutes less than 95% of the occurrences. This

gives us 34 word pairs. For each pair we generate a binary classification task by taking all the utterances where either form appears, using average input vectors, utterance embeddings, and average unit activations as features. Instances for all feature sets are normalized to unit L2 norm.

For each task and feature set we run stratified 10-fold cross validation using Logistic Regression to predict which of the two words the utterance contains. Figure 7 shows, for each pair, the relative error reduction of each feature set with respect to the majority baseline. There is substantial variation across word pairs, but overall the task becomes easier as the features come from higher layers in the network. Some forms can be disambiguated with very high accuracy (e.g. *sale/sail, cole/coal, pairs/pears*), while some others cannot be distinguished at all (*peaking/peeking, great/grate, mantle/mantel*). We examined the sentences containing the failing forms, and found out that almost all occurrences of *peaking* and *mantle* were misspellings of *peeking* and *mantel*, which explains the impossibility of disambiguating these cases.

5 Conclusion

We present a multi-layer recurrent highway network model of language acquisition from visually grounded speech signal. Through detailed analysis we uncover how information in the input signal is transformed as it flows through the network: formal aspects of language such as word identities that not directly present in the input are discovered and encoded low in the layer hierarchy, while semantic information is most strongly expressed in the topmost layers.

Going forward we would like to compare the representations learned by our model to the brain activity of people listening to speech in order to determine to what extent the patterns we found correspond to localized processing in the human cortex. This will hopefully lead to a better understanding of language learning and processing by both artificial and neural networks.

Spectral Analysis of Information Density in Dialogue Predicts Collaborative Task Performance

Yang Xu and **David Reitter**

Abstract

We propose a perspective on dialogue that focuses on relative information contributions of conversation partners as a key to successful communication. We predict the success of collaborative task in English and Danish corpora of task-oriented dialogue. Two features are extracted from the frequency domain representations of the lexical entropy series of each interlocutor, *power spectrum overlap* (PSO) and *relative phase* (RP). We find that PSO is a negative predictor of task success, while RP is a positive one. An SVM with these features significantly improved on previous task success prediction models. Our findings suggest that the strategic distribution of information density between interlocutors is relevant to task success.

1 Introduction

What factors affect whether information is conveyed effectively and reliably in conversations? Several theoretical frameworks have emerged that model dialogical behavior at different granularity levels. Can we use them to measure communicative effectiveness?

Grounding theory (Clark and Brennan, 1991) models a successful communication as a process during which "common ground" (i.e., mutual knowledge, beliefs etc.) is jointly built among interlocutors. The *interactive alignment model* (IAM) (Pickering and Garrod, 2004) proposes that the ultimate goal of dialogue is the alignment of interlocutors' situational model, which is helped by alignment at all other lower representation levels (e.g., lexical, syntactic etc.), driven by the psychologically well-documented priming effects.

Recently, empirical studies have verified the explanatory powers of the above-mentioned theories, especially the IAM, utilizing dialogues recorded and transcribed from various collaborative tasks conducted in laboratory settings (Reitter and Moore, 2007; Reitter and Moore, 2014; Fusaroli et al., 2012; Fusaroli and Tylén, 2016). In those studies, the quality of communication is directly reflected in the collaborative performance of interlocutors, i.e., how successful they are in accomplishing the task. Although they do not come to fully agree on which theoretical accounts of dialogue (e.g., interactive alignment vs. interpersonal synergy) provides better explanations (see Section 2.1 for details), the majority of these studies have confirmed that the alignment of certain linguistic markers, lexical items, or syntactic rules between interlocutors correlates with task success.

What is missing from the picture, however, is the computational understanding of how strategies of interaction and the mix of information contributions to the conversation facilitate successful communication. This is understandable because those higher level concepts do not directly map onto the atomic linguistic elements and thus are much more difficult to define and operationalize. In the present study, we intend to explore this missing part of work by characterizing how the interaction between interlocutors in terms of their information contributions affects the quality of communication.

1.1 An information-based approach

Recent work has already used information theory to study the dynamics of dialogue. Xu and Reitter (2016b) observed that the amount of lexical information (measured by entropy) from interlocutors of different roles, *converges* within the span of topic episodes in natural spoken dialogue. Anon (2017) interpret this converging pattern as a re-

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 623–633
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1058

flection of the dynamic process in which the information contributed by two interlocutors fluctuates in a complementary way at the early stage, and gradually reaches an equilibrium status. Xu and Reitter (2016b) also correlated this entropy converging pattern with the *topic shift* phenomenon that frequently occurs in natural conversation (Ng and Bradac, 1993), and proposed that it reflects the process of interlocutors building the *common ground* that is necessary for the ongoing topics of conversation.

Based on Xu and Reitter's (2016) finding that entropy converging pattern repeatedly occurs within dialogue (though not necessarily at strictly regular intervals), it is reasonable to expect that after applying some spectral analysis techniques (time space to frequency space conversion) to the entropy series of dialogue, the frequency space representations should demonstrate some patterns that are distinct from white noise, because the periodicity properties in time space are captured.

Furthermore, we expect that how the frequency representations of two interlocutors correlate provides some information about the higher level properties of dialogue, e.g., the task performance etc. The thought is intuitive: If we imagine the entropy series from two interlocutors as two ideal sinusoidal signals s_1 and s_2 (supposedly of different frequencies, f_1 and f_2) (Figure 1), then the observed converging pattern can be thought of as a segment from the full spans of the signals. Then the frequency space properties, such as how close f_1 and f_2 are, and the phase difference ϕ between them, will definitely affect the shape of the converging pattern (solid lines in Figure 1). As Xu and Reitter (2016b) argues that the converging segment reflects the *grounding* process between interlocutors, it is reasonable to expect that the shape and length of this segment are reflective of how well interlocutors understand each other, and the overall collaborative performance as well.

Based on the above considerations, the goal of the present study is to explore how the frequency space representations of the entropy series of dialogue are correlated with the collaborative performance of task. We first demonstrate that entropy series satisfy the prerequisites of spectral analysis techniques in Section 4. Then we use two frequency space statistics, *power spectrum overlap* (PSO) and *relative phase* (RP), to predict task success. The reasons of using these two specific indices are discussed in Section 2.3, and their definitions are given in Section 3.3. The results are shown in Sections 5 to 7, and the implications are discussed.

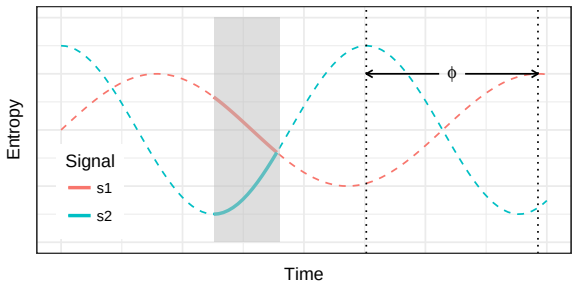

Figure 1: Analogizing the entropy converging patterns reported by Xu and Reitter (2016b) to a segment from two periodic signals. The shadowed area and the solid lines indicate the observed entropy convergence between interlocutors. The dashed lines are the imaginary parts of the ideal signals.

2 Related Work

2.1 The success of dialogue

The interactive-alignment model (IAM) (Pickering and Garrod, 2004) stipulates that communication is successful to the extent that communicators "understand relevant aspects of the world in the same way as each other" (Garrod and Pickering, 2009). Qualitative and quantitative studies (Garrod and A. Anderson, 1987; Pickering and Garrod, 2006; Reitter and Moore, 2014) have revealed that the alignment of linguistic elements at different representation levels between interlocutors facilitates the success of task-oriented dialogues.

More recently, different theoretical accounts other than IAM, such as *interpersonal synergy* (Fusaroli et al., 2014) and *complexity matching* (Abney et al., 2014) have been proposed to explain the mechanism of successful dialogue from the perspective of dynamic systems. Fusaroli and Tylén (2016) compare the approaches of interactive alignment and interpersonal synergy in terms of how well they predict the collective performance in a joint task. They find that the synergy approach is a better predictor than the alignment approach. Abney et al. (2014) differentiate the concepts of *behavior matching* and *complexity matching* in dyadic interaction. They demonstrate the acoustic onset events in speech signals exhibit power law clustering across timescales, and the

complexity matching in these power law functions is reflective of whether the conversation is affiliative or argumentative.

The perspective taken by the present study has some common places with Fusaroli and Tylén (2016) and Abney et al.'s (2014) work: we view dialogue as an interaction of two dynamic systems. The joint decision-making task used by Fusaroli and Tylén (2016) resulted in a small corpus of dialogue in Danish, which we will use for the present study.

2.2 Information density in natural language

Information Theory (Shannon, 1948) predicts that the optimal way to communicate is to send information at a constant rate, a.k.a. the principle of entropy rate constancy (ERC). The way humans use natural language to communicate also follows this principle: by computing the local per-word entropy of the sentence (which, under the prediction of ERC, will increase with sentence position), ERC is confirmed in both written text (Genzel and Charniak, 2002; Genzel and Charniak, 2003; Keller, 2004; Qian and Jaeger, 2011) and spoken dialogue (Xu and Reitter, 2016b; Xu and Reitter, 2016a). The theory of uniform information density (UID) extends ERC to syntactic representations (Jaeger, 2010) and beyond.

The information density in language, i.e., the distribution of entropy (predictability), reveal the discourse structure to some extent. For example, entropy drops at the boundaries between topics (Genzel and Charniak, 2003; Qian and Jaeger, 2011), and increases within a topic episode in dialogue (Xu and Reitter, 2016b) (see Section 1.1). The entropy of microblog text reflects changes in contextual information (e.g., an unexpected event in a sports game) (Doyle and Frank, 2015).

In sum, per-word entropy quantifies the amount of lexical information in natural language, and therefore fulfills the needs of modeling the information contribution from interlocutors.

2.3 Spectral analysis methodology

Spectral analysis, also referred to as frequency domain analysis, is a pervasively used technique in physics, engineering, economics and social sciences. The key idea of it is to decompose a complex signal in time space into simpler components in frequency space, using mathematical operations such as Fourier transform (Bracewell, 1986).

The application of spectral analysis in human language technology mainly focuses on processing the acoustic signals of human voice, and capturing the para-linguistics features relevant to certain tasks (Schuller et al., 2013). For example, Bitouk et al. (2010) find that utterance-level spectral features are useful for emotion recognition. Gregory Jr and Gallagher (2002) demonstrate that spectral information beneath 0.5 kHz can predict US president election outcomes. However, we are not aware of the usage of spectral analysis in studying linguistic phenomena at higher representation levels than the acoustic level.

For our study, we are looking for some techniques that can capture the coupling between two signals at frequency space. The nature of the signal (whether it is language-related or not) should not be the first concern from the perspective of methodology. Therefore, studies outside the field of speech communication and linguistics could also be enlightening to our work.

After searching the literature, we find that the spectral analysis techniques that Oullier et al. (2002) and Oullier et al. (2008) use to study the physical and social functions of human body movement are useful to our research goal. In Oullier et al.'s (2002) work, subjects stood in a moving room and were to track a target attached to the wall. A frequency space statistics, *power spectrum overlap* (PSO), was used to demonstrate the coupling between motion of the room and motion of the subject's head. Stronger coupling effect (higher PSO) was found in the tracking task than a no-tracking baseline. PSO in nature quantifies how much the frequency space representations of two signals (power spectrum density) overlap. It allows us to explore the frequency space coupling of two interlocutors' entropy series in dialogue.

Similarly, Oullier et al. (2008) used the metrics of *peak-to-peak relative phase* (RP) and PSO to study the spontaneous synchrony in behavior that emerges between interactants as a result of information exchange. The signals to be analyzed were the flexion-extension movement of index fingers of two subjects sitting in front of each other. Both metrics showed different patterns when the participants see each other or not. RP, in their work, measures the magnitude of delay between two signals, and it corresponds to the notion of ϕ in Section 1.1.

3 Methods

3.1 Corpus data

Two corpora are examined in this study: the HCRC Map Task Corpus (A. H. Anderson et al., 1991) and a smaller corpus in Danish from a joint decision-making study (Fusaroli et al., 2012), henceforth *DJD*.

Map Task contains a set of 128 dialogues between two subjects, who accomplished a cooperative task together. They were given two slightly different maps of imaginary landmarks. One of them plays as the instruction *giver*, who has routes marked on her map, and the other plays as the instruction *follower*, who does not have routes. The task for them is to reproduce the giver's route on the follower's map. The participants are free to speak, but they cannot see each other's map. The whole conversations were recorded, transcribed and properly annotated. The collaborative performance in the task is measured by the `PATHDEV` variable, which quantifies the deviation between the paths drawn by interlocutors. Larger values indicate poorer task performance.

DJD contains a set of 16 dialogues from native speakers of Danish (11,100 utterances and 56,600 words). In Fusaroli et al.'s (2012) original study the participants were to accomplish a series of visual perception task trials, by discussing the stimuli they saw and reaching a joint decision for each trial. The collaborative performance is measured by the `CollectivePerformance` variable, which is based on a psychometric function that measures the sensitivity of the dyad's joint decision to the actual contrast difference of the trial (Fusaroli et al., 2012). Higher value of this variable indicates better task performance.

The Switchboard Corpus (Godfrey et al., 1992) is used to train the language model for estimating the sentence entropy in Map Task. The Copenhagen Dependency Treebanks Corpus[1] is used for the same purpose for DJD.

3.2 Estimating information density in dialogue

The information density of language is estimated at the sentence level, by computing the per-word entropy of each sentence using a trigram language model trained from a different corpus. We consider a sentence to be a sequence of words, $S = \{w_1, w_2, \ldots, w_n\}$, and the per-word entropy is estimated by:

$$H(w_1 \ldots w_n) = -\frac{1}{n} \sum_{w_i \in W} \log P(w_i | w_1 \ldots w_{i-1}) \quad (1)$$

where $P(w_i|w_1 \ldots w_{i-1})$ is estimated by a trigram model that is trained from an outside corpus. The `SRILM` software (Stolcke, 2002) is used to train the language model and to compute sentence entropy.

Dialogue is a sequence of utterances contributed by two interlocutors. For the k th dialogue whose total utterance number is N_k, we mark it as $D_k = \{u_i^k \mid i = 1, 2, \ldots, N_k\}$, in which u_i^k is the i th utterance. Map Task contains annotations of sentence structure in utterances, and one utterance could consist of several sentences that are syntactically independent. Thus we further split D_k into a sequence of sentence, $D_k = \{s_i^k \mid i = 1, 2, \ldots, N_k'\}$, in which N_k' is number of sentences in D_k. Since DJD lacks the sentence annotations, we do not further split the utterance sequence, and simply treat an utterance as a complete sentence.

Given a sequence $\{s_i^k\}$ (Map Task), or $\{u_i^k\}$ (DJD), we calculate the per-word entropy for each item in the sequence:

$$H_k = \{H(s_i^k) \text{ or } H(u_i^k) \mid i = 1, 2, \ldots, N_k'(or N_k)\} \quad (2)$$

where $H(s_i^k)$ or $H(u_i^k)$ is computed according to Equation 1.

Then we split the entropy series H_k into two sub-series by the source of utterances (i.e., who speaks them), resulting in H_k^A for interlocutor *A*, and H_k^B for interlocutor *B*. For Map Task, the two interlocutors have distinct roles, instruction *giver* and *follower*. Thus the resulting two entropy series are H_k^g and H_k^f. These per-interlocutor entropy series will be the input of our next-step spectral analysis.

3.3 Computing power spectrum overlap and relative phase

The time intervals between utterances (or sentences) vary, but since we care about the average information contribution within a complete semantic unit, we treat entropy series as regular time series. The time scale is not measured in seconds but in turns (or sentences).

For a given dialogue D_k, we apply the fast Fourier transform (FFT) on its two entropy se-

[1] http://mbkromann.github.io/copenhagen-dependency-treebank/

ries H_k^A and H_k^B, and obtain the *power spectra* (or, power spectral density plots) of them, P_k^A and P_k^B. The power spectra are estimated with the *periodogram* method provided by the open source `R` software. The Y axis of a power spectrum is the squared amplitude of signal (or power), and X axis ranges from 0 to $\pi/2$ (we do not have sampling frequency, thus the X axis is in angular frequency but not in Hz).

The *power spectrum overlap*, PSO_k, is calculated by computing the common area under the curves of P_k^A and P_k^B is calculated, and normalizing by the total area of the two curves (see Figure 2). PSO_k ranges from 0 to 1, and a larger value indicates higher similarity between P_k^A and P_k^B.

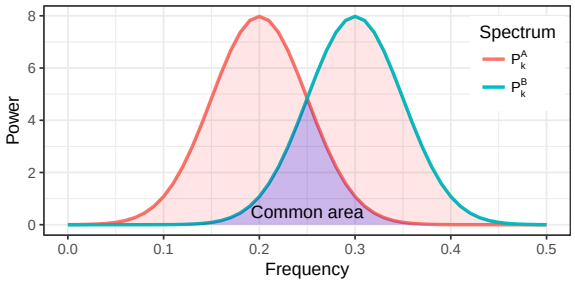

Figure 2: How PSO is computed. The blue shadow is the common area under two spectrums.

The *relative phase* (RP) between H_k^A and H_k^B is directly returned by the `spectrum` function in `R`. It is a vector of real numbers that range from 0 to π, and each element represent the phase difference between two signals at a particular frequency position of the spectrum.

4 Prerequisites of Spectral Analysis

Before proceeding to the actual analysis, we first examine whether the data we use satisfy some of the prerequisites of spectral analysis techniques. One common assumption of Fourier transforms is that the signals (time series) are *stationary* (Dwivedi and Subba Rao, 2011). Stationarity means that the mean, variance and other distributional properties do not change over time (Natrella, 2010). Another presumption we hold is that the entropy series contain some periodic patterns (see Section 1.1), which means their power spectrum should differ from that of white noise.

4.1 Examine stationarity

We use three pervasively used statistical tests to test the stationarity of our entropy series data: the augmented Dickey-Fuller (ADF) test (Dickey and Fuller, 1979), the Kwiatkowski-Phillips-Schmidt-Shin (KPSS) test (Kwiatkowski et al., 1992), and the Phillips-Perron (PP) test (Phillips and Perron, 1988). The percentage of entropy series that pass the stationarity tests are shown in Table 1. We can see that the majority of our data satisfy the assumption of stationarity, and thus it is valid to conduct Fourier transform on the entropy series.

Table 1: Percentage stationary data

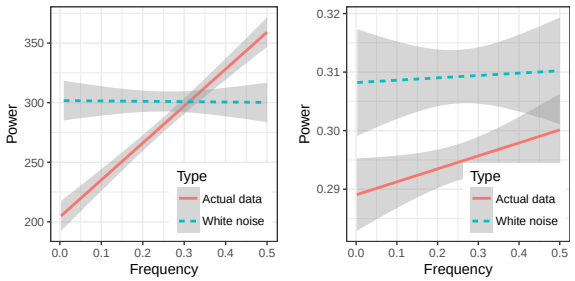
Corpus	ADF	KPSS	PP
Map Task	82.4%	95.5%	100%
DJD	100%	81.3%	100%

The stationarity property seems contradictory to the previous findings about entropy increase in written text and spoken dialogue (Genzel and Charniak, 2002; Genzel and Charniak, 2003; Xu and Reitter, 2016b), because stationarity predicts that the mean entropy stays constant over time. We examine this in our data by fitting a simple linear model with entropy as the dependent, and sentence position as the independent variable, which yields significant (marginal) effects of the latter: For Map Task, $\beta = 2.3 \times 10^{-3}$, $p < .05$, *Adj-*$R^2 = 1.7 \times 10^{-4}$; For DJD, $\beta = 7.2 \times 10^{-5}$, $p = .06$, *Adj-*$R^2 = 2.2 \times 10^{-4}$. It indicates that the stationarity of entropy series does not conflict with the entropy increasing trend predicted by the principle of ERC (Shannon, 1948). We conjecture that stationarity satisfies because the effect size (*Adj-*R^2) of entropy increase is very small.

4.2 Comparison with white noise

Power spectra for all entropy series are obtained with an FFT. We compare them with those of white noise. The white noise data are simulated with *i.i.d.* random data points that are generated from normal distributions (same means and standard deviations as the actual data). Figure 3 shows the smoothed average spectrums of the actual entropy data and the simulated white noise data.

White noise signals should demonstrate a constant power spectral density (Narasimhan and Veena, 2005), and if the entropy series is not completely random, then their average spectrum should be flat. Linear models show that the average spectrums of the entropy data have slopes that are significantly larger than zero (For Map Task,



(a) Map Task (b) DJD

Figure 3: Comparing the average power spectra of the actual entropy data and white noise. There are significant linear correlations between *power* (Y axis) and *frequency* (X axis) for the actual entropy data, which means the data are not completely random. Shadowed areas are 95% C.I.

$\beta = 2.3 \times 10^{-2}$, $SE = 9.4 \times 10^{-3}$, $p < .05$; for DJD, $\beta = 314.1$, $SE = 19.8$, $p < .001$), while the slopes of the white noise data are not significantly different from zero. This confirms our presumption that the entropy series of dialogue contains some periodic patterns that are identifiable in frequency space.

We also conduct Ljung-Box test (Ljung and Box, 1978) to examine how the entropy series is different from white noise. The null hypothesis is that the time series being tested is independent of the lagged sequence of itself. The test on a white noise series will give big p-values, for any lags greater than 0, because of its randomness nature. We try several lags on each entropy series, and pick the smallest p-value. Consequently, we obtain a mean p-value of .23 on MapTask, and a mean p-value of .27 on DJD. Therefore, we cannot reject the null hypothesis for all the entropy series data, but the Type-I error of considering them as different form white noise is pretty low.

5 PSO Predicts Task Success

5.1 Results of linear models

We compute PSO for all the dialogues in Map Task and DJD and fit two linear models using PSO as predictor, with `PATHDEV` and `CollectivePerformance` as dependent variables respectively.

PSO is a reliable predictor in both models ($p < .05$). The coefficients are shown in Table 2. Since `PATHDEV` is a measure of failure, but collaborative task performance is a measure of success, the negative correlation between PSO and collaborative task performance is consistent. Regression lines with residuals are plotted in Figure 4.

Table 2: Coefficients of PSO in predicting `PATHDEV` (Map Task) and `Collective-Performance` (DJD). * indicates $p < .05$.

Dependent	β	SE	F	$Adj\text{-}R^2$
`PATHDEV`	124.8	49.4	6.39*	.045
`Collective-Performance`	-40.9	15.9	6.60*	.271

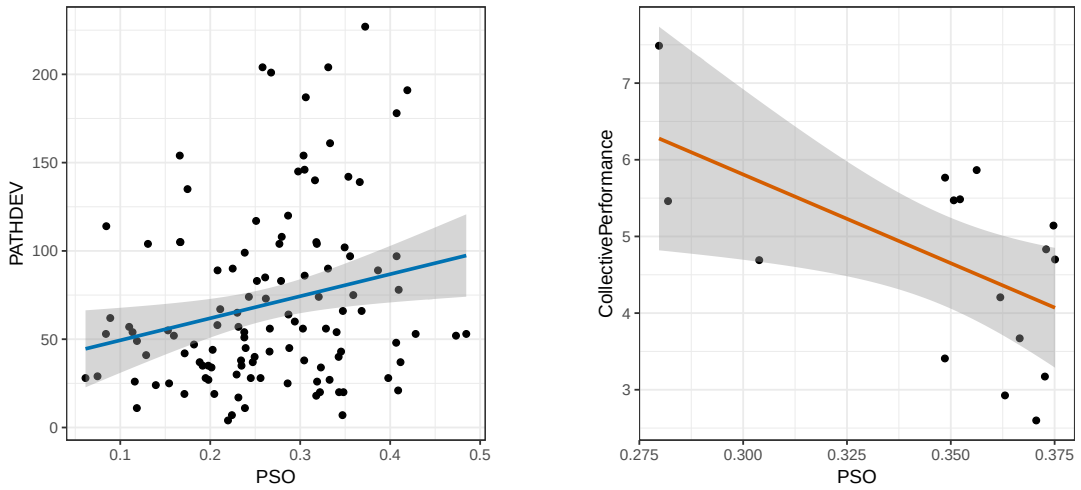
Figure 4 (a) suggests a heteroscedasticity problem, because the right half of data points seem to stretch up along the y axis. This was confirmed by a Breush-Pagan test (Breusch and Pagan, 1979) ($BP = 5.62$, $p < .05$). To rectify this issue, we adopt a Box-Cox transformation (Box and Cox, 1964) on the dependent variable, `PATHDEV`, which is a typical way of handling heteroscedasticity. The new model that uses PSO to predict the Box-Cox transformed `PATHDEV` also yields significant coefficients: $\beta = 3.85$, $SE = 1.67$, $F(1, 113) = 5.32$, $p < .05$. Therefore, the correlation between PSO and `PATHDEV` is reliable.

As for DJD, due to the lack of data (we only have 16 dialogues), we do not run further diagnostics analysis on the regression model.

5.2 Discussion

The coupling of entropy series in frequency space is negatively correlated with task success. In other words, synchrony between interlocutors in terms of their information distribution hinders the success of collaboration. By "synchrony", we mean an overlap in the frequencies at which they choose to inject novel information into the conversation.

This conclusion seems contradictory to the perspective of interactive alignment at the first glance. However, here we are starting with a very high-level model of dialogue that has does not refer to linguistic devices. Instead, we utilize the concept of "information density" and the entropy metric of natural language, to paint the picture of a system in which communicators inject novelty into the dialogue, and that each communicator does so regularly and with a set of overlapping frequencies. We assume that the rapid change of sentence entropy, i.e., the high frequency components in the spectrum, correspond to the moments in conversa-



(a) Map Task

(b) DJD

Figure 4: Regression lines of linear models using PSO to predict `PATHDEV` in Map Task (a) and `CollectivePerformance` in DJD (b). Shadowed areas are 95% C.I.

tion where one interlocutor brings relatively novel content to the table, such as a detailed instruction, a strange question, an unexpected response etc. This assumption is reasonable because previous work has shown that sudden change in entropy predicts topic change in dialogue (Genzel and Charniak, 2003; Qian and Jaeger, 2011; Xu and Reitter, 2016b).

We argue that higher synchrony (larger overlap in frequency space) in terms of how much novelty each interlocutor contributes, does not necessarily leads to better outcomes of communication. Rather, we would expect the correlation to be opposite (and our empirical results confirm this), because dialogue is a joint activity, in which a taking on different roles as interlocutors (e.g., the one who gives orders versus the one who follows) is often required to push the activity along (Clark, 1996). A dialogue with maximal synchrony or frequency overlap would be one where partners take turns at regular intervals. Perhaps because such regularity in turn-taking assigns no special roles to interlocutors, and because they engage in turn-taking with no regard for content, it is not strange that such synchrony is disadvantageous.

Let's look at several scenarios of different synchrony levels between interlocutors: First, high synchrony due to both interlocutors contributing large amount of new information, which means there is more overlap near the high frequency band of spectrums. In this case, they are more likely to have difficulty in comprehending each other due to the potential information overload. Situations such as arguing, or both speakers asking a lot of questions are good examples. Second, high synchrony due to both interlocutors providing ineffective information, which indicates overlap in spectrums near the low frequency band. Obviously this type of ineffective communication is not helpful to the collaborative task. Third, low synchrony due to one interlocutor providing more information and the other one providing less, which means the overlap in spectrums is minimum. An example of this case is that one interlocutor is saying something important, while the other one is producing short utterances such "uh-huh", "yes", or short questions to make sure that they are on the same page, which is known as the back-channel mechanism in conversation (Oreström, 1983). This complementary style of communication allows them to build mutual understand of each other's intention, and thus reaches better collaborative performance.

6 RP Predicts Task Success

6.1 Results of linear models

We obtain the relative phase (RP) vector (absolute values) of all frequency components, and fit linear models using the mean of RP as predictor, and task performance as the dependent variable. We get non-significant coefficients for both models: For Map Task, $F(1, 113) = .004,\ p > .05$; for DJD, $F(1, 14) = .772,\ p > .05$. This suggests that the phase information of all frequency components in spectrum is not very indicative of task success.

The power spectra describe the distribution of energy across the span of frequency components that compose the signal. The frequency components with higher energy (peaks in spectrum) are more dominant than those with lower energy (troughs) in determining the nature of the signal. Therefore it makes sense to only include the peak frequencies into the model, because they are more "representative" of the signal, and so the "noise" from the low energy frequencies are filtered out. Thus we obtain RP from the local peak frequency components, and use the mean, median, and maximum values of them as predictors. It turns out that for Map Task, the maximum of RP is a significant predictor (the mean and median are left out via stepwise analysis). For DJD, the mean of RP is a significant predictor of task success (when median and maximum are included in the model). (see Table 3).

Table 3: Coefficients of the linear models using the mean, median, and maximum values of RP from peak frequency components to predict task performance. $* \, p < .05$, $\dagger \, p < .1$.

Corpus	Predictor	β	SE	t score
Map Task	max	-64.9	30.3	**-2.14***
DJD	mean	15.6	5.7	**2.76***
	median	-7.4	3.6	-2.06†
	max	-11.5	7.2	-1.60

From the significant effect of maximum RP in Map Task and mean RP in DJD, it is safe to state that RP is positively correlated with task performance. However, this relationship is not as straight-forward as PSO, because of the marginal effect at the opposite direction. A more fine-grained analysis is required, but it is outside the scope of this study.

6.2 Discussion

The relative phase in frequency space can be understood as the "lag" between signals in time space. Imagine that we align the two entropy series from one dialogue onto the same time scale (just like Figure 1), the distance between the entropy "peaks" is proportionate to the relative phase in frequency space. Then, the positive correlation between relative phase and task performance suggests that relatively large delays between entropy "surges" seen in each interlocutor are beneficial to collaborative performance.

Table 4: R^2 performance on the HCRC MapTask task success prediction task (percentage of variance explained). 10-fold cross-validated by dialogue; same folds for each model. Reitter and Moore (2007) (R&M) contained length and lexical and syntactic repetition features.

Model	R^2
R&M	.17
R&M LENGTH only	.09
R&M LENGTH only (C=.5)	.1260
R&M (C=.5)	.1771
R&M + PSO + RP	**.2826**
R&M + PSO*RP	.2435
R&M LENGTH only + PSO*RP	.2494

The delay of entropy surges can be understood as a strategy for an interlocutor to distribute information in his or her own utterance accordingly with the information received. For example, after interlocutor *A* contributes a big piece of information, the other one, *B*, does not *rush* to make new substantial contributions, but instead keeps her utterances at low entropy until it is the proper time to take a turn to contribute. This does not have to coincide with dialogic turn-taking.

This delay gives *B* more time to "digest" the information provided by *A*, which could be an instruction that needs to be comprehended, or a question that needs to be thought about and so on. A relatively long delay guarantees enough time for interlocutors to reach mutual understanding. On the contrary, if *B* rushes to speak a lot shortly after the *A*'s input, then it will probably cause information overload and be harmful to communication.

Therefore, we believe that the RP statistic captures the extent to which interlocutors manage the proper "timing" of information contribution to maintain effective communication.

7 Prediction Task

Here we explore whether the frequency domain features, PSO and RP, can help with an existing framework that utilizes alignment features, such as the repetition of lexical and syntactic elements, to predict the success of dialogue in MapTask (Reitter and Moore, 2007).

R&M described an SVM model that takes into the repetition count of lexicons (LEXREP) and syntax structures (SYNREP), and the length of dialogues (LENGTH) as features. The full model achieves an R^2 score of .17, which means that it can account for 17% of the variance of task success.

We add the new PSO and RP (mean, median and maximum RP features per dialogue are included) covariates to the original SVM model. An RBF kernel ($\gamma = 5$) was used. The cost parameter C was (coarsely) tuned on different cross-validation folds to reduce overfitting on this relatively small dataset, and the R&M's original full model was recalculated (shown in Table 4 as R&M). Two models with PSO and RP interactions (once without the alignment/repetition features) are shown for comparison. (See Table 4).

Significant improvement in the model's explanatory power, i.e., R^2, is gained after the PSO and RP features are added. The best model we have is by adding PSO and RP as predictors without the interaction term (bold number in Table 4), which gives about 60% increase of R^2 compared to R&M's full model. Note that even if we exclude the alignment features, and include only (LENGTH) and the frequency features (last row in Table 4), the performance also exceeds R&M's full model.

The results indicate that the frequency domain features (PSO and RP) of the sentence information density can capture some hidden factors of task success that are unexplained by the alignment approach. It is not surprising that how people coordinate their information contribution matters a lot to the success of the collaboration. What we show here is that regular, repeated patterns of information-dense and information-sparse turns seem to make speakers more or less compatible with each other. Whether individuals have typical patterns (frequency distributions) of information density, or whether this is a result of dynamic interaction in each particular dialogue, remains to be seen.

8 Conclusions

The empirical results of the present study suggest that examining how the information contribution from interlocutors co-develops can provide a way to understand dialogue from a higher-level perspective, which has been missing in existing work.

Our work adds a brick to the series of endeavors on studying the linguistic and behavioral factors of successful dialogue, and for the first time (as far as we know) demonstrates quantitatively that the dynamics of not just "what" and "how" we say, but also "how much" we say and the "timing" of distributing what we say in dialogue, are relevant to the quality of communication. Although the way we model information in language is simply the entropy at lexical level, we believe the findings still reveal the nature of information production and processing in dialogue. We hope that by comparing and combining our methodology with other approaches of studying dialogue, we can reach a more comprehensive and holistic understanding of this common yet mysterious human practice.

Acknowledgments

We thank Riccardo Fusaroli for providing the DJD dataset. We have received very helpful input from Gesang Zeren in developing the initial ideas of this project. The work leading to this paper was funded by the National Science Foundation (IIS-1459300 and BCS-1457992).

Abstract

Human verbal communication includes affective messages which are conveyed through use of emotionally colored words. There has been a lot of research in this direction but the problem of integrating state-of-the-art neural language models with affective information remains an area ripe for exploration. In this paper, we propose an extension to an LSTM (Long Short-Term Memory) language model for generating conversational text, conditioned on affect categories. Our proposed model, *Affect-LM* enables us to customize the degree of emotional content in generated sentences through an additional design parameter. Perception studies conducted using Amazon Mechanical Turk show that *Affect-LM* generates naturally looking emotional sentences without sacrificing grammatical correctness. *Affect-LM* also learns affect-discriminative word representations, and perplexity experiments show that additional affective information in conversational text can improve language model prediction.

1 Introduction

Affect is a term that subsumes emotion and longer term constructs such as mood and personality and refers to the experience of feeling or emotion (Scherer et al., 2010). Picard (1997) provides a detailed discussion of the importance of affect analysis in human communication and interaction. Within this context the analysis of human affect from text is an important topic in natural language understanding, examples of which include sentiment analysis from Twitter (Nakov et al., 2016), affect analysis from poetry (Kao and Jurafsky, 2012) and studies of correlation between function words and social/psychological processes (Pennebaker, 2011). People exchange verbal messages which not only contain syntactic information, but also information conveying their mental and emotional states. Examples include the use of emotionally colored words (such as *furious* and *joy*) and swear words. The automated processing of affect in human verbal communication is of great importance to understanding spoken language systems, particularly for emerging applications such as dialogue systems and conversational agents.

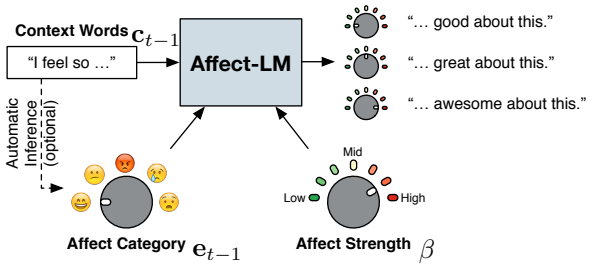

Figure 1: *Affect-LM* is capable of generating emotionally colored conversational text in five specific affect categories ($\mathbf{e}_{t-1}$) with varying affect strengths (β). Three generated example sentences for *happy* affect category are shown in three distinct affect strengths.

Statistical language modeling is an integral component of speech recognition systems, with other applications such as machine translation and information retrieval. There has been a resurgence of research effort in recurrent neural networks for language modeling (Mikolov et al., 2010), which have yielded performances far superior to baseline language models based on n-gram approaches. However, there has not been much effort in building neural language models of text that leverage affective information. Current literature on deep learning for language understanding focuses mainly on representations based on

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 634–642
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1059

word semantics (Mikolov et al., 2013), encoder-decoder models for sentence representations (Cho et al., 2015), language modeling integrated with symbolic knowledge (Ahn et al., 2016) and neural caption generation (Vinyals et al., 2015), but to the best of our knowledge there has been no work on augmenting neural language modeling with affective information, or on data-driven approaches to generate emotional text.

Motivated by these advances in neural language modeling and affective analysis of text, in this paper we propose a model for representation and generation of emotional text, which we call the *Affect-LM*. Our model is trained on conversational speech corpora, common in language modeling for speech recognition applications (Bulyko et al., 2007). Figure 1 provides an overview of our *Affect-LM* and its ability to generate emotionally colored conversational text in a number of affect categories with varying affect strengths. While these parameters can be manually tuned to generate conversational text, the affect category can also be automatically inferred from preceding context words. Specifically for model training, the affect category is derived from features generated using keyword spotting from a dictionary of emotional words, such as the LIWC (Linguistic Inquiry and Word Count) tool (Pennebaker et al., 2001). Our primary research questions in this paper are:
Q1: Can *Affect-LM* be used to generate affective sentences for a target emotion with varying degrees of affect strength through a customizable model parameter?
Q2: Are these generated sentences rated as emotionally expressive as well as grammatically correct in an extensive crowd-sourced perception experiment?
Q3: Does the automatic inference of affect category from the context words improve language modeling performance of the proposed *Affect-LM* over the baseline as measured by perplexity?

The remainder of this paper is organized as follows. In Section 2, we discuss prior work in the fields of neural language modeling, and generation of affective conversational text. In Section 3 we describe the baseline LSTM model and our proposed *Affect-LM* model. Section 4 details the experimental setup, and in Section 5, we discuss results for customizable emotional text generation, perception studies for each affect category, and perplexity improvements over the baseline model before concluding the paper in Section 6.

2 Related Work

Language modeling is an integral component of spoken language systems, and traditionally n-gram approaches have been used (Stolcke et al., 2002) with the shortcoming that they are unable to generalize to word sequences which are not in the training set, but are encountered in unseen data. Bengio et al. (2003) proposed neural language models, which address this shortcoming by generalizing through word representations. Mikolov et al. (2010) and Sundermeyer et al. (2012) extend neural language models to a recurrent architecture, where a target word w_t is predicted from a context of all preceding words $w_1, w_2, ..., w_{t-1}$ with an LSTM (Long Short-Term Memory) neural network. There also has been recent effort on building language models conditioned on other modalities or attributes of the data. For example, Vinyals et al. (2015) introduced the neural image caption generator, where representations learnt from an input image by a CNN (Convolutional Neural Network) are fed to an LSTM language model to generate image captions. Kiros et al. (2014) used an LBL model (Log-Bilinear language model) for two applications - image retrieval given sentence queries, and image captioning. Lower perplexity was achieved on text conditioned on images rather than language models trained only on text.

In contrast, previous literature on affective language generation has not focused sufficiently on customizable state-of-the-art neural network techniques to generate emotional text, nor have they quantitatively evaluated their models on multiple emotionally colored corpora. Mahamood and Reiter (2011) use several NLG (natural language generation) strategies for producing affective medical reports for parents of neonatal infants undergoing healthcare. While they study the difference between affective and non-affective reports, their work is limited only to heuristic based systems and do not include conversational text. Mairesse and Walker (2007) developed PERSONAGE, a system for dialogue generation conditioned on extraversion dimensions. They trained regression models on ground truth judge's selections to automatically determine which of the sentences selected by their model exhibit appropriate extroversion attributes. In Keshtkar and Inkpen (2011), the authors use heuristics and rule-based approaches

for emotional sentence generation. Their generation system is not training on large corpora and they use additional syntactic knowledge of parts of speech to create simple affective sentences. In contrast, our proposed approach builds on state-of-the-art approaches for neural language modeling, utilizes no syntactic prior knowledge, and generates expressive emotional text.

3 Model

3.1 LSTM Language Model

Prior to providing a formulation for our proposed model, we briefly describe a LSTM language model. We have chosen this model as a baseline since it has been reported to achieve state-of-the-art perplexities compared to other approaches, such as n-gram models with Kneser-Ney smoothing (Jozefowicz et al., 2016). Unlike an ordinary recurrent neural network, an LSTM network does not suffer from the vanishing gradient problem which is more pronounced for very long sequences (Hochreiter and Schmidhuber, 1997). Formally, by the chain rule of probability, for a sequence of M words $w_1, w_2, ..., w_M$, the joint probability of all words is given by:

$$P(w_1, w_2, ..., w_M) = \prod_{t=1}^{t=M} P(w_t | w_1, w_2, ..., w_{t-1}) \tag{1}$$

If the vocabulary consists of V words, the conditional probability of word w_t as a function of its context $\mathbf{c_{t-1}} = (w_1, w_2, ..., w_{t-1})$ is given by:

$$P(w_t = i | \mathbf{c_{t-1}}) = \frac{\exp(\mathbf{U_i}^T \mathbf{f}(\mathbf{c_{t-1}}) + b_i)}{\sum_{j=1}^{V} \exp(\mathbf{U_j}^T \mathbf{f}(\mathbf{c_{t-1}}) + b_j)} \tag{2}$$

$\mathbf{f}(.)$ is the output of an LSTM network which takes in the context words $w_1, w_2, ..., w_{t-1}$ as inputs through one-hot representations, $\mathbf{U}$ is a matrix of word representations which on visualization we have found to correspond to POS (Part of Speech) information, while $\mathbf{b_i}$ is a bias term capturing the unigram occurrence of word i. Equation 2 expresses the word w_t as a function of its context for a LSTM language model which does not utilize any additional affective information.

3.2 Proposed Model: *Affect-LM*

The proposed model *Affect-LM* has an additional energy term in the word prediction, and can be described by the following equation:

$$P(w_t = i | \mathbf{c_{t-1}}, \mathbf{e_{t-1}}) = \frac{\exp\left(\mathbf{U_i}^T \mathbf{f}(\mathbf{c_{t-1}}) + \beta \mathbf{V_i}^T \mathbf{g}(\mathbf{e_{t-1}}) + b_i\right)}{\sum_{j=1}^{V} \exp(\mathbf{U_j}^T \mathbf{f}(\mathbf{c_{t-1}}) + \beta \mathbf{V_j}^T \mathbf{g}(\mathbf{e_{t-1}}) + b_j)} \tag{3}$$

$\mathbf{e_{t-1}}$ is an input vector which consists of affect category information obtained from the words in the context during training, and $\mathbf{g}(.)$ is the output of a network operating on $\mathbf{e_{t-1}}$.$\mathbf{V_i}$ is an embedding learnt by the model for the i-th word in the vocabulary and is expected to be discriminative of the affective information conveyed by each word. In Figure 4 we present a visualization of these affective representations.

The parameter β defined in Equation 3, which we call the *affect strength* defines the influence of the affect category information (frequency of emotionally colored words) on the overall prediction of the target word w_t given its context. We can consider the formulation as an energy based model (EBM), where the additional energy term captures the degree of correlation between the predicted word and the affective input (Bengio et al., 2003).

3.3 Descriptors for Affect Category Information

Our proposed model learns a generative model of the next word w_t conditioned not only on the previous words $w_1, w_2, ..., w_{t-1}$ but also on the *affect category* $\mathbf{e_{t-1}}$ which is additional information about emotional content. During model training, the affect category is inferred from the context data itself. Thus we define a suitable feature extractor which can utilize an affective lexicon to *infer* emotion in the context. For our experiments, we have utilized the Linguistic Inquiry and Word Count (LIWC) text analysis program for feature extraction through keyword spotting. Introduced by Pennebaker et al. (2001), LIWC is based on a dictionary, where each word is assigned to a predefined LIWC category. The categories are chosen based on their association with social, affective, and cognitive processes. For example, the dictionary word *worry* is assigned to LIWC category *anxiety*. In our work, we have utilized all word categories of LIWC corresponding to affective processes: *positive emotion, angry, sad, anxious*, and *negative emotion*. Thus the descriptor $\mathbf{e_{t-1}}$ has five features with each feature denoting

SEMAINE	959	23706	6.55	Conversations
CMU-MOSI	93	26121	6.54	Monologues

Table 1: Summary of corpora used in this paper. CMU-MOSI and SEMAINE are observed to have higher emotional content than Fisher and DAIC corpora.

presence or absence of a specific emotion, which is obtained by binary thresholding of the features extracted from LIWC. For example, the affective representation of the sentence *i will fight in the war* is $\mathbf{e_{t-1}}$ ={"sad":0, "angry":1, "anxiety":0, "negative emotion":1, "positive emotion":0}.

3.4 *Affect-LM* for Emotional Text Generation

Affect-LM can be used to generate sentences conditioned on the input affect category, the affect strength β, and the context words. For our experiments, we have chosen the following affect categories - *positive emotion, anger, sad, anxiety*, and *negative emotion* (which is a superclass of anger, sad and anxiety). As described in Section 3.2, the affect strength β defines the degree of dominance of the affect-dependent energy term on the word prediction in the language model, consequently after model training we can change β to control the degree of how "emotionally colored" a generated utterance is, varying from $\beta = 0$ (neutral; baseline model) to $\beta = \infty$ (the generated sentences only consist of emotionally colored words, with no grammatical structure).

When *Affect-LM* is used for generation, the affect categories could be either (1) inferred from the context using LIWC (this occurs when we provide sentence beginnings which are emotionally colored themselves), or (2) set to an input emotion descriptor $\mathbf{e}$ (this is obtained by setting $\mathbf{e}$ to a binary vector encoding the desired emotion and works even for neutral sentence beginnings). Given an initial starting set of M words $w_1, w_2, ..., w_M$ to complete, affect strength β, and the number of words N to generate each i-th generated word is obtained by sampling from $P(w_i|w_1, w_2, ..., w_{i-1}, \mathbf{e}; \beta)$ for $i \in \{M+1, M+2, ..., M+N\}$.

4 Experimental Setup

In Section 1, we have introduced three primary research questions related to the ability of the proposed *Affect-LM* model to generate emotionally colored conversational text without sacrificing grammatical correctness, and to obtain lower perplexity than a baseline LSTM language model when evaluated on emotionally colored corpora. In this section, we discuss our experimental setup to address these questions, with a description of *Affect-LM*'s architecture and the corpora used for training and evaluating the language models.

4.1 Speech Corpora

The Fisher English Training Speech Corpus is the main corpus used for training the proposed model, in addition to which we have chosen three emotionally colored conversational corpora. A brief description of each corpus is given below, and in Table 1, we report relevant statistics, such as the total number of words, along with the fraction of emotionally colored words (those belonging to the LIWC affective word categories) in each corpus.

Fisher English Training Speech Parts 1 & 2: The Fisher dataset (Cieri et al., 2004) consists of speech from telephonic conversations of 10 minutes each, along with their associated transcripts. Each conversation is between two strangers who are requested to speak on a randomly selected topic from a set. Examples of conversation topics are *Minimum Wage*, *Time Travel* and *Comedy*.

Distress Assessment Interview Corpus (DAIC): The DAIC corpus introduced by Gratch (2014) consists of 70+ hours of dyadic interviews between a human subject and a virtual human, where the virtual human asks questions designed to diagnose symptoms of psychological distress in the subject such as depression or PTSD (Post Traumatic Stress Disorder).

SEMAINE dataset: SEMAINE (McKeown et al., 2012) is a large audiovisual corpus consisting of interactions between subjects and an operator simulating a SAL (Sensitive Artificial Listener). There are a total of 959 conversations which are approximately 5 minutes each, and are transcribed and annotated with affective dimensions.

Multimodal Opinion-level Sentiment Intensity Dataset (CMU-MOSI): (Zadeh et al., 2016) This is a multimodal annotated corpus of opinion

videos where in each video a speaker expresses his opinion on a commercial product. The corpus consist of speech from 93 videos from 89 distinct speakers (41 male and 48 female speakers). This corpus differs from the others since it contains monologues rather than conversations.

While we find that all corpora contain spoken language, they have the following characteristics different from the Fisher corpus: (1) More emotional content as observed in Table 1, since they have been generated through a human subject's spontaneous replies to questions designed to generate an emotional response, or from conversations on emotion-inducing topics (2) Domain mismatch due to recording environment (for example, the DAIC corpus was created in a mental health setting, while the CMU-MOSI corpus consisted of opinion videos uploaded online). (3) Significantly smaller than the Fisher corpus, which is 25 times the size of the other corpora combined. Thus, we perform training in two separate stages - training of the baseline and *Affect-LM* models on the Fisher corpus, and subsequent adaptation and fine-tuning on each of the emotionally colored corpora.

4.2 *Affect-LM* Neural Architecture

For our experiments, we have implemented a baseline LSTM language model in Tensorflow (Abadi et al., 2016), which follows the non-regularized implementation as described in Zaremba et al. (2014) and to which we have added a separate energy term for the affect category in implementing *Affect-LM*. We have used a vocabulary of 10000 words and an LSTM network with 2 hidden layers and 200 neurons per hidden layer. The network is unrolled for 20 time steps, and the size of each minibatch is 20. The affect category $\mathbf{e_{t-1}}$ is processed by a multi-layer perceptron with a single hidden layer of 100 neurons and sigmoid activation function to yield $\mathbf{g(e_{t-1})}$. We have set the output layer size to 200 for both $\mathbf{f(c_{t-1})}$ and $\mathbf{g(e_{t-1})}$. We have kept the network architecture constant throughout for ease of comparison between the baseline and *Affect-LM*.

4.3 Language Modeling Experiments

Affect-LM can also be used as a language model where the next predicted word is estimated from the words in the context, along with an affect category extracted from the context words themselves (instead of being encoded externally as in generation). To evaluate whether additional emotional information could improve the prediction performance, we train the corpora detailed in Section 4.1 in two stages as described below:

(1) **Training and validation of the language models on Fisher dataset**- The Fisher corpus is split in a 75:15:10 ratio corresponding to the training, validation and evaluation subsets respectively, and following the implementation in Zaremba et al. (2014), we train the language models (both the baseline and *Affect-LM*) on the training split for 13 epochs, with a learning rate of 1.0 for the first four epochs, and the rate decreasing by a factor of 2 after every subsequent epoch. The learning rate and neural architecture are the same for all models. We validate the model over the affect strength $\beta \in [1.0, 1.5, 1.75, 2.0, 2.25, 2.5, 3.0]$. The best performing model on the Fisher validation set is chosen and used as a seed for subsequent adaptation on the emotionally colored corpora.

(2) **Fine-tuning the seed model on other corpora**- Each of the three corpora - CMU-MOSI, DAIC and SEMAINE are split in a 75:15:10 ratio to create individual training, validation and evaluation subsets. For both the baseline and *Affect-LM*, the best performing model from Stage 1 (the seed model) is fine-tuned on each of the training corpora, with a learning rate of 0.25 which is constant throughout, and a validation grid of $\beta \in [1.0, 1.5, 1.75, 2.0]$. For each model adapted on a corpus, we compare the perplexities obtained by *Affect-LM* and the baseline model when evaluated on that corpus.

4.4 Sentence Generation Perception Study

We assess *Affect-LM's* ability to generate emotionally colored text of varying degrees without severely deteriorating grammatical correctness, by conducting an extensive perception study on Amazon's Mechanical Turk (MTurk) platform. The MTurk platform has been successfully used in the past for a wide range of perception experiments and has been shown to be an excellent resource to collect human ratings for large studies (Buhrmester et al., 2011). Specifically, we generated more than 200 sentences for four sentence beginnings (namely the three sentence beginnings listed in Table 2 as well as an end of sentence token indicating that the model should generate a new sentence) in five affect categories *happy(positive emotion), angry, sad, anxiety*, and *negative emotion*. The *Affect-LM* model trained

Beginning	Affect Category	Completed sentence
I feel so	Happy	good because i think that it's important to have a relationship with a friend
	Angry	bad that i hate it and i hate that because they they kill themselves and then they fight
	Sad	sad to miss because i i miss the feelings of family members who i lost feelings with
	Anxious	horrible i mean i think when we're going to you know war and alert alert and we're actually gonna die
	Neutral	bad if i didn't know that the decision was going on
I told him to	Happy	be honest and i said well i hope that i 'm going to be a better person
	Angry	see why he was fighting with my son
	Sad	leave the house because i hurt one and i lost his leg and hurt him
	Anxious	be afraid of him and he he just he just didn't care about the death penalty
	Neutral	do this position i think he is he's got a lot of money he has to pay himself a lot of money
Why did you	Happy	have a best friend
	Angry	say it was only a criminal being killed at a war or something
	Sad	miss your feelings
	Anxious	worry about fear factor
	Neutral	believe in divorce

Table 2: Example sentences generated by the model conditioned on different affect categories

on the Fisher corpus was used for sentence generation. Each sentence was evaluated by two human raters that have a minimum approval rating of 98% and are located in the United States. The human raters were instructed that the sentences should be considered to be taken from a conversational rather than a written context: repetitions and pause fillers (e.g., *um, uh*) are common and no punctuation is provided. The human raters evaluated each sentence on a seven-point Likert scale for the five affect categories, overall *affective valence* as well as the sentence's *grammatical correctness* and were paid 0.05USD per sentence. We measured inter-rater agreement using Krippendorffs α and observed considerable agreement between raters across all categories (e.g., for *valence* $\alpha = 0.510$ and *grammatical correctness* $\alpha = 0.505$).

For each *target emotion* (i.e., intended emotion of generated sentences) we conducted an initial MANOVA, with human ratings of affect categories the DVs (dependent variables) and the affect strength parameter β the IV (independent variable). We then conducted follow-up univariate ANOVAs to identify which DV changes significantly with β. In total we conducted 5 MANOVAs and 30 follow-up ANOVAs, which required us to update the significance level to $p<0.001$ following a Bonferroni correction.

5 Results

5.1 Generation of Emotional Text

In Section 3.4 we have described the process of sampling text from the model conditioned on input affective information (research question **Q1**). Table 2 shows three sentences generated by the model for input sentence beginnings *I feel so ...*, *Why did you ...* and *I told him to ...* for each of five affect categories - *happy(positive emotion), angry, sad anxiety*, and *neutral(no emotion)*. They have been selected from a pool of 20 generated sentences for each category and sentence beginning.

5.2 MTurk Perception Experiments

In the following we address research question **Q2** by reporting the main statistical findings of our MTurk study, which are visualized in Figures 2 and 3.

Positive Emotion Sentences. The multivariate result was significant for *positive emotion* generated sentences (Pillai's Trace=.327, $F(4,437)=6.44$, $p<.0001$). Follow up ANOVAs revealed significant results for all DVs except *angry* with $p<.0001$, indicating that both *affective valence* and *happy* DVs were successfully manipulated with β, as seen in Figure 2(a). *Grammatical correctness* was also significantly influenced by the affect strength parameter β and results show that the correctness deteriorates with increasing β (see Figure 3). However, a post-hoc Tukey test revealed that only the highest β value shows a significant drop in *grammatical correctness* at $p<.05$.

Negative Emotion Sentences. The multivariate result was significant for *negative emotion* generated sentences (Pillai's Trace=.130, $F(4,413)=2.30$, $p<.0005$). Follow up ANOVAs revealed significant results for *affective valence* and *happy* DVs with $p<.0005$, indicating that the *affective valence* DV was successfully manipulated with β, as seen in Figure 2(b). Further, as intended there were no significant differences for DVs *angry, sad* and *anxious*, indicating that the *negative emotion* DV refers to a more general affect related concept rather than a specific negative emotion. This finding is in concordance with the intended LIWC category of *negative affect* that forms a parent category above the more

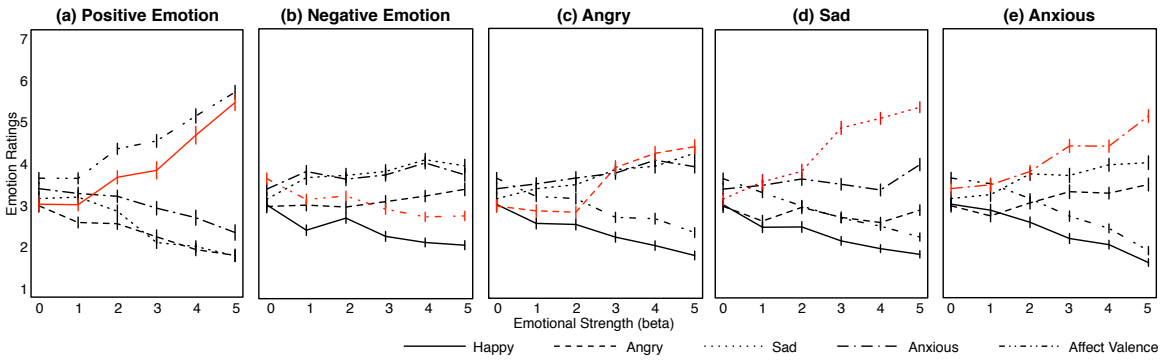

Figure 2: Amazon Mechanical Turk study results for generated sentences in the target affect categories *positive emotion, negative emotion, angry, sad*, and *anxious* (a)-(e). The most relevant human rating curve for each generated emotion is highlighted in red, while less relevant rating curves are visualized in black. Affect categories are coded via different line types and listed in legend below figure.

specific emotions, such as *angry, sad*, and *anxious* (Pennebaker et al., 2001). *Grammatical correctness* was also significantly influenced by the affect strength β and results show that the correctness deteriorates with increasing β (see Figure 3). As for *positive emotion*, a post-hoc Tukey test revealed that only the highest β value shows a significant drop in *grammatical correctness* at p<.05.

Angry Sentences. The multivariate result was significant for *angry* generated sentences (Pillai's Trace=.199, F(4,433)=3.76, p<.0001). Follow up ANOVAs revealed significant results for *affective valence, happy*, and *angry* DVs with p<.0001, indicating that both *affective valence* and *angry* DVs were successfully manipulated with β, as seen in Figure 2(c). *Grammatical correctness* was not significantly influenced by the affect strength parameter β, which indicates that angry sentences are highly stable across a wide range of β (see Figure 3). However, it seems that human raters could not successfully distinguish between *angry, sad*, and *anxious* affect categories, indicating that the generated sentences likely follow a general *negative affect* dimension.

Sad Sentences. The multivariate result was significant for *sad* generated sentences (Pillai's Trace=.377, F(4,425)=7.33, p<.0001). Follow up ANOVAs revealed significant results only for the *sad* DV with p<.0001, indicating that while the *sad* DV can be successfully manipulated with β, as seen in Figure 2(d). The *grammatical correctness* deteriorates significantly with β. Specifically, a post-hoc Tukey test revealed that only the two highest β values show a significant drop in *grammatical correctness* at p<.05 (see Figure 3).

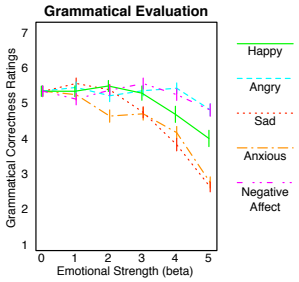

Figure 3: Mechanical Turk study results for *grammatical correctness* for all generated target emotions. Perceived *grammatical correctness* for each affect categories are color-coded.

A post-hoc Tukey test for *sad* reveals that $\beta = 3$ is optimal for this DV, since it leads to a significant jump in the perceived sadness scores at p<.005 for $\beta \in \{0, 1, 2\}$.

Anxious Sentences. The multivariate result was significant for *anxious* generated sentences (Pillai's Trace=.289, F(4,421)=6.44, p<.0001). Follow up ANOVAs revealed significant results for *affective valence, happy* and *anxious* DVs with p<.0001, indicating that both *affective valence* and *anxiety* DVs were successfully manipulated with β, as seen in Figure 2(e). *Grammatical correctness* was also significantly influenced by the affect strength parameter β and results show that the correctness deteriorates with increasing β. Similarly for *sad*, a post-hoc Tukey test revealed that only the two highest β values show a significant drop in *grammatical correctness* at p<.05 (see Figure 3). Again, a post-hoc Tukey test for *anxious* reveals that $\beta = 3$ is optimal for this DV, since it leads to a significant jump in the perceived

	Training (Fisher)		Adaptation	
Perplexity	**Baseline**	**Affect-LM**	**Baseline**	**Affect-LM**
Fisher	37.97	37.89	-	-
DAIC	65.02	64.95	55.86	55.55
SEMAINE	88.18	86.12	57.58	57.26
CMU-MOSI	104.74	101.19	66.72	64.99
Average	73.98	72.54	60.05	59.26

Table 3: Evaluation perplexity scores obtained by the baseline and *Affect-LM* models when trained on Fisher and subsequently adapted on DAIC, SEMAINE and CMU-MOSI corpora

anxiety scores at p<.005 for $\beta \in \{0, 1, 2\}$.

5.3 Language Modeling Results

In Table 3, we address research question **Q3** by presenting the perplexity scores obtained by the baseline model and *Affect-LM*, when trained on the Fisher corpus and subsequently adapted on three emotional corpora (each adapted model is individually trained on CMU-MOSI, DAIC and SEMAINE). The models trained on Fisher are evaluated on all corpora while each adapted model is evaluated only on it's respective corpus. For all corpora, we find that *Affect-LM* achieves lower perplexity on average than the baseline model, implying that affect category information obtained from the context words improves language model prediction. The average perplexity improvement is 1.44 (relative improvement 1.94%) for the model trained on Fisher, while it is 0.79 (1.31%) for the adapted models. We note that larger improvements in perplexity are observed for corpora with higher content of emotional words. This is supported by the results in Table 3, where *Affect-LM* obtains a larger reduction in perplexity for the CMU-MOSI and SEMAINE corpora, which respectively consist of 2.76% and 2.75% more emotional words than the Fisher corpus.

5.4 Word Representations

In Equation 3, *Affect-LM* learns a weight matrix $\mathbf{V}$ which captures the correlation between the predicted word w_t, and the affect category $\mathbf{e_{t-1}}$. Thus, each row of the matrix $\mathbf{V_i}$ is an emotionally meaningful embedding of the i-th word in the vocabulary. In Figure 4, we present a t-SNE visualization of these embeddings, where each data point is a separate word, and words which appear in the LIWC dictionary are colored based on which affect category they belong to (we have labeled only words in categories *positive emotion*, *negative emotion*, *anger*, *sad* and *anxiety* since

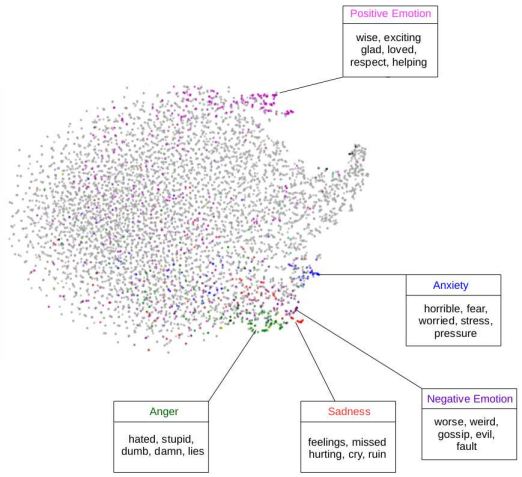

Figure 4: Embeddings learnt by *Affect-LM*

these categories contain the most frequent words). Words colored grey are those not in the LIWC dictionary. In Figure 4, we observe that the embeddings contain affective information, where the positive emotion is highly separated from the negative emotions (*sad*, *angry*, *anxiety*) which are clustered together.

6 Conclusions and Future Work

In this paper, we have introduced a novel language model *Affect-LM* for generating affective conversational text conditioned on context words, an affective category and an affective strength parameter. MTurk perception studies show that the model can generate expressive text at varying degrees of emotional strength without affecting grammatical correctness. We also evaluate *Affect-LM* as a language model and show that it achieves lower perplexity than a baseline LSTM model when the affect category is obtained from the words in the context. For future work, we wish to extend this model by investigating language generation conditioned on other modalities such as facial images and speech, and to applications such as dialogue generation for virtual agents.

Abstract

An important problem in domain adaptation is to quickly generalize to a new domain with limited supervision given K existing domains. One approach is to retrain a global model across all $K + 1$ domains using standard techniques, for instance Daumé III (2009). However, it is desirable to adapt without having to reestimate a global model from scratch each time a new domain with potentially new intents and slots is added. We describe a solution based on attending an ensemble of domain experts. We assume K domain-specific intent and slot models trained on respective domains. When given domain $K + 1$, our model uses a weighted combination of the K domain experts' feedback along with its own opinion to make predictions on the new domain. In experiments, the model significantly outperforms baselines that do not use domain adaptation and also performs better than the full retraining approach.

1 Introduction

An important problem in domain adaptation is to quickly generalize to a new domain with limited supervision given K existing domains. In spoken language understanding, new domains of interest for categorizing user utterances are added on a regular basis[1]. For instance, we may add `ORDERPIZZA` domain and desire a domain-specific intent and semantic slot tagger with a limited amount of training data. Training only on the target domain fails to utilize the existing resources in other domains that are relevant (e.g., labeled data for `PLACES` domain with `place_name`, `location` as the slot types), but naively training on the union of all domains does not work well since different domains can have widely varying distributions.

Domain adaptation offers a balance between these extremes by using all data but simultaneously distinguishing domain types. A common approach for adapting to a new domain is to retrain a global model across all $K + 1$ domains using well-known techniques, for example the feature augmentation method of Daumé III (2009) which trains a single model that has one domain-invariant component along with $K + 1$ domain-specific components each of which is specialized in a particular domain. While such a global model is effective, it requires re-estimating a model from scratch on all $K + 1$ domains each time a new domain is added. This is burdensome particularly in our scenario in which new domains can arise frequently.

In this paper, we present an alternative solution based on attending an ensemble of domain experts. We assume that we have already trained K domain-specific models on respective domains. Given a new domain $K+1$ with a small amount of training data, we train a model on that data alone but queries the K experts as part of the training procedure. We compute an attention weight for each of these experts and use their combined feedback along with the model's own opinion to make predictions. This way, the model is able to selectively capitalize on relevant domains much like in

[1]A scenario frequently arising in practice is having a request for creating a new virtual domain targeting a specific application. One typical use case is that of building natural language capability through intent and slot modeling (without actually building a domain classifier) targeting a specific application.

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 643–653
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1060

standard domain adaptation but without explicitly re-training on all domains together.

In experiments, we show clear gains in a domain adaptation scenario across 7 test domains, yielding average error reductions of 44.97% for intent classification and 32.30% for slot tagging compared to baselines that do not use domain adaptation. Moreover we have higher accuracy than the full re-training approach of Kim et al. (2016c), a neural analog of Daumé III (2009).

2 Related Work

2.1 Domain Adaptation

There is a venerable history of research on domain adaptation (Daume III and Marcu, 2006; Daumé III, 2009; Blitzer et al., 2006, 2007; Pan et al., 2011) which is concerned with the shift in data distribution from one domain to another. In the context of NLP, a particularly successful approach is the feature augmentation method of Daumé III (2009) whose key insight is that if we partition the model parameters to those that handle *common patterns* and those that handle *domain-specific patterns*, the model is forced to learn from all domains yet preserve domain-specific knowledge. The method is generalized to the neural paradigm by Kim et al. (2016c) who jointly use a domain-specific LSTM and also a global LSTM shared across all domains. In the context of SLU, Jaech et al. (2016) proposed K domain-specific feedforward layers with a shared word-level LSTM layer across domains; Kim et al. (2016c) instead employed $K + 1$ LSTMs. Hakkani-Tür et al. (2016) proposed to employ a sequence-to-sequence model by introducing a fictitious symbol at the end of an utterance of which tag represents the corresponding domain and intent.

All these methods require one to re-train a model from scratch to make it learn the correlation and invariance between domains. This becomes difficult to scale when there is a new domain coming in at high frequency. We address this problem by proposing a method that only calls K trained domain experts; we do not have to re-train these domain experts. This gives a clear computational advantage over the feature augmentation method.

2.2 Spoken Language Understanding

Recently, there has been much investment on the personal digital assistant (PDA) technology in industry (Sarikaya, 2015; Sarikaya et al., 2016). Apples Siri, Google Now, Microsofts Cortana, and Amazons Alexa are some examples of personal digital assistants. Spoken language understanding (SLU) is an important component of these examples that allows natural communication between the user and the agent (Tur, 2006; El-Kahky et al., 2014). PDAs support a number of scenarios including creating reminders, setting up alarms, note taking, scheduling meetings, finding and consuming entertainment (i.e. movie, music, games), finding places of interest and getting driving directions to them (Kim et al., 2016a).

Naturally, there has been an extensive line of prior studies for domain scaling problems to easily scale to a larger number of domains: pre-training (Kim et al., 2015c), transfer learning (Kim et al., 2015d), constrained decoding with a single model (Kim et al., 2016a), multi-task learning (Jaech et al., 2016), neural domain adaptation (Kim et al., 2016c), domainless adaptation (Kim et al., 2016b), a sequence-to-sequence model (Hakkani-Tür et al., 2016), adversary domain training (Kim et al., 2017) and zero-shot learning(Chen et al., 2016; Ferreira et al., 2015).

There are also a line of prior works on enhancing model capability and features: jointly modeling intent and slot predictions (Jeong and Lee, 2008; Xu and Sarikaya, 2013; Guo et al., 2014; Zhang and Wang, 2016; Liu and Lane, 2016a,b), modeling SLU models with web search click logs (Li et al., 2009; Kim et al., 2015a) and enhancing features, including representations (Anastasakos et al., 2014; Sarikaya et al., 2014; Celikyilmaz et al., 2016, 2010; Kim et al., 2016d) and lexicon (Liu and Sarikaya, 2014; Kim et al., 2015b).

3 Method

We use an LSTM simply as a mapping $\phi : \mathbb{R}^d \times \mathbb{R}^{d'} \rightarrow \mathbb{R}^{d'}$ that takes an input vector x and a state vector h to output a new state vector $h' = \phi(x, h)$. See Hochreiter and Schmidhuber (1997) for a detailed description. At a high level, the individual model consists of builds on several ingredients shown in Figure 1: character and word embedding, a bidirectional LSTM (BiLSTM) at a character layer, a BiLSTM at word level, and feedfoward network at the output.

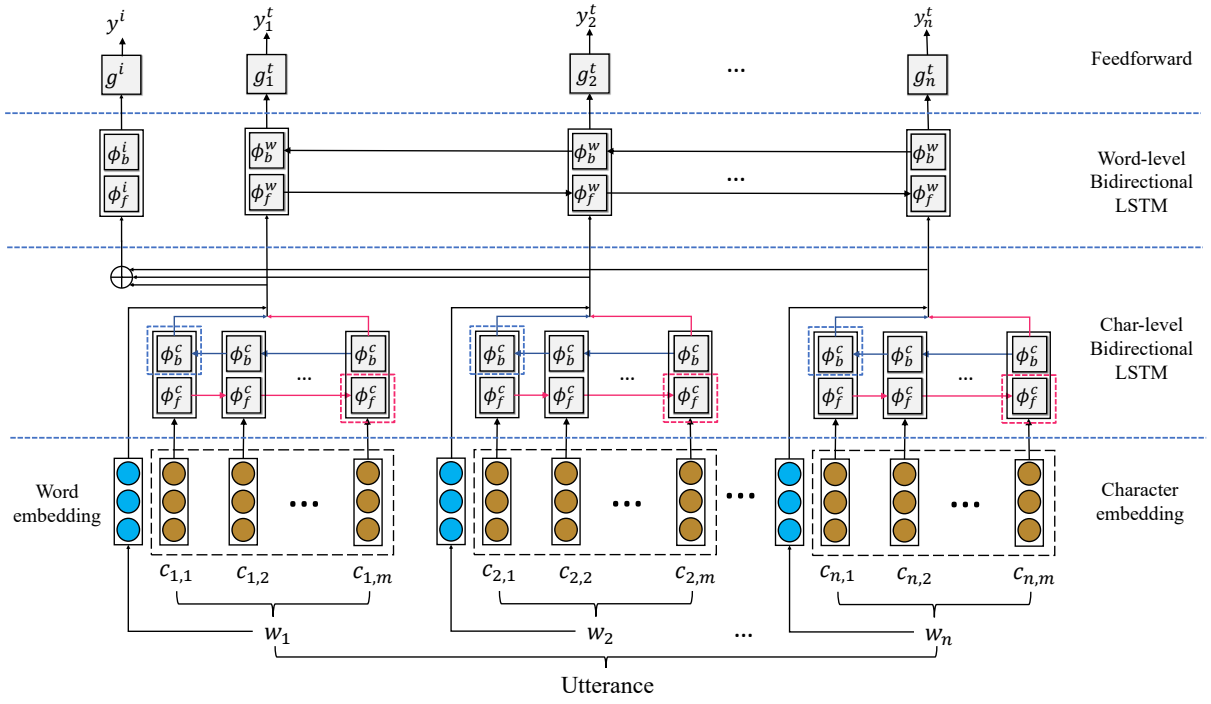

Figure 1: The overall network architecture of the individual model.

3.1 Individual Model Architecture

Let $\mathcal{C}$ denote the set of character types and $\mathcal{W}$ the set of word types. Let $\oplus$ denote the vector concatenation operation. A wildly successful architecture for encoding a sentence $(w_1 \dots w_n) \in \mathcal{W}^n$ is given by bidirectional LSTMs (BiLSTMs) (Schuster and Paliwal, 1997; Graves, 2012). Our model first constructs a network over an utterance closely following Lample et al. (2016). The model parameters Θ associated with this BiLSTM layer are

- Character embedding $e_c \in \mathbb{R}^{25}$ for each $c \in \mathcal{C}$
- Character LSTMs $\phi^{\mathcal{C}}_f, \phi^{\mathcal{C}}_b : \mathbb{R}^{25} \times \mathbb{R}^{25} \to \mathbb{R}^{25}$
- Word embedding $e_w \in \mathbb{R}^{100}$ for each $w \in \mathcal{W}$
- Word LSTMs $\phi^{\mathcal{W}}_f, \phi^{\mathcal{W}}_b : \mathbb{R}^{150} \times \mathbb{R}^{100} \to \mathbb{R}^{100}$

Let $w_1 \dots w_n \in \mathcal{W}$ denote a word sequence where word w_i has character $w_i(j) \in \mathcal{C}$ at position j. First, the model computes a character-sensitive word representation $v_i \in \mathbb{R}^{150}$ as

$$
\begin{aligned}
f^{\mathcal{C}}_j &= \phi^{\mathcal{C}}_f\left(e_{w_i(j)}, f^{\mathcal{C}}_{j-1}\right) && \forall j = 1 \dots |w_i| \\
b^{\mathcal{C}}_j &= \phi^{\mathcal{C}}_b\left(e_{w_i(j)}, b^{\mathcal{C}}_{j+1}\right) && \forall j = |w_i| \dots 1 \\
v_i &= f^{\mathcal{C}}_{|w_i|} \oplus b^{\mathcal{C}}_1 \oplus e_{w_i}
\end{aligned}
$$

for each $i = 1 \dots n$.[2] Next, the model computes

$$
\begin{aligned}
f^{\mathcal{W}}_i &= \phi^{\mathcal{W}}_f\left(v_i, f^{\mathcal{W}}_{i-1}\right) && \forall i = 1 \dots n \\
b^{\mathcal{W}}_i &= \phi^{\mathcal{W}}_b\left(v_i, b^{\mathcal{W}}_{i+1}\right) && \forall i = n \dots 1
\end{aligned}
$$

and induces a character- and context-sensitive word representation $h_i \in \mathbb{R}^{200}$ as

$$h_i = f^{\mathcal{W}}_i \oplus b^{\mathcal{W}}_i \tag{1}$$

for each $i = 1 \dots n$. These vectors can be used to perform intent classification or slot tagging on the utterance.

Intent Classification We can predict the intent of the utterance using $(h_1 \dots h_n) \in \mathbb{R}^{200}$ in (1) as follows. Let $\mathcal{I}$ denote the set of intent types. We introduce a single-layer feedforward network $g^i : \mathbb{R}^{200} \to \mathbb{R}^{|\mathcal{I}|}$ whose parameters are denoted by Θ^i. We compute a $|\mathcal{I}|$-dimensional vector

$$\mu^i = g^i\left(\sum_{i=1}^{n} h_i\right)$$

and define the conditional probability of the correct intent τ as

$$p(\tau | h_1 \dots h_n) \propto \exp\left(\mu^i_\tau\right) \tag{2}$$

[2] For simplicity, we assume some random initial state vectors such as $f^{\mathcal{C}}_0$ and $b^{\mathcal{C}}_{|w_i|+1}$ when we describe LSTMs.

The intent classification loss is given by the negative log likelihood:

$$L^i\left(\Theta, \Theta^i\right) = -\sum_l \log p\left(\tau^{(l)}|h^{(l)}\right) \quad (3)$$

where l iterates over intent-annotated utterances.

Slot Tagging We predict the semantic slots of the utterance using $(h_1 \ldots h_n) \in \mathbb{R}^{200}$ in (1) as follows. Let $\mathcal{S}$ denote the set of semantic types and $\mathcal{L}$ the set of corresponding BIO label types [3] that is, $\mathcal{L} = \{\texttt{B}\text{-}e : e \in \mathcal{E}\} \cup \{\texttt{I}\text{-}e : e \in \mathcal{E}\} \cup \{\texttt{O}\}$. We add a transition matrix $T \in \mathbb{R}^{|\mathcal{L}|\times|\mathcal{L}|}$ and a single-layer feedforward network $g^t : \mathbb{R}^{200} \rightarrow \mathbb{R}^{|\mathcal{L}|}$ to the network; denote these additional parameters by Θ^t. The conditional random field (CRF) tagging layer defines a joint distribution over label sequences of $y_1 \ldots y_n \in \mathcal{L}$ of $w_1 \ldots w_n$ as

$$p(y_1 \ldots y_n|h_1 \ldots h_n) \propto \exp\left(\sum_{i=1}^{n} T_{y_{i-1},y_i} \times g^t_{y_i}(h_i)\right) \quad (4)$$

The tagging loss is given by the negative log likelihood:

$$L^t\left(\Theta, \Theta^t\right) = -\sum_l \log p\left(y^{(l)}|h^{(l)}\right) \quad (5)$$

where l iterates over tagged sentences in the data. Alternatively, we can optimize the local loss:

$$L^{t-loc}\left(\Theta, \Theta^t\right) = -\sum_l \sum_i \log p\left(y_i^{(l)}|h_i^{(l)}\right) \quad (6)$$

where $p(y_i|h_i) \propto \exp\left(g^t_{y_i}(h_i)\right)$.

4 Method

4.1 Domain Attention Architecture

Now we assume that for each of the K domains we have an individual model described in Section 3.1. Denote these domain experts by $\Theta^{(1)} \ldots \Theta^{(K)}$. We now describe our model for a new domain $K+1$. Given an utterance $w_1 \ldots w_n$, it uses a BiLSTM layer to induce a feature representation $h_1 \ldots h_n$ as specified in (1). It further invokes K domain experts $\Theta^{(1)} \ldots \Theta^{(K)}$ on this utterance to obtain the feature representations $h_1^{(k)} \ldots h_n^{(k)}$ for

[3] For example, to/O San/B-Source Francisco/I-Source airport/O.

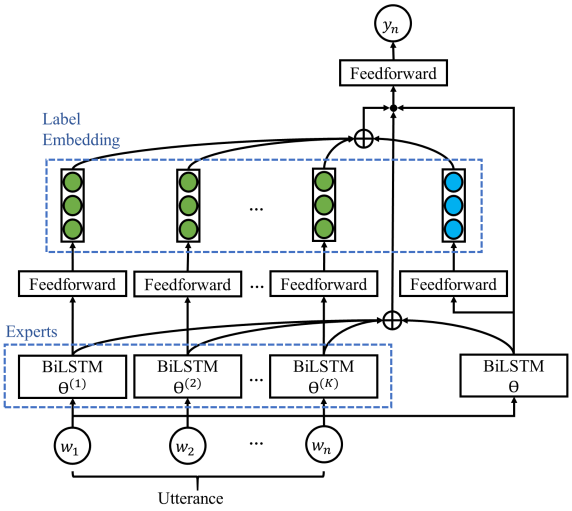

Figure 2: The overall network architecture of the domain attention, which consists of three components: (1) K domain experts + 1 target BiLSTM layer to induce a feature representation, (2) K domain experts + 1 target feedfoward layer to output pre-trained label embedding (3) a final feedforward layer to output an intent or slot. We have two separate attention mechanisms to combine feedback from domain experts.

$k = 1 \ldots K$. For each word w_i, the model computes an attention weight for each domain $k = 1 \ldots K$ domains as

$$q^{\text{dot}}_{i,k} = h_i^\top h^{(k)} \quad (7)$$

in the simplest case. We also experiment with the bilinear function

$$q^{\text{bi}}_{i,k} = h_i^\top B h^{(k)} \quad (8)$$

where B is an additional model parameter, and also the feedforward function

$$q^{\text{feed}}_{i,k} = W \tanh\left(U h_i^\top + V h^{(k)} + b^1\right) + b^2 \quad (9)$$

where U, V, W, b^1, b^2 are additional model parameters. The final attention weights $a_i^{(1)} \ldots a_i^{(1)}$ are obtained by using a softmax layer

$$a_{i,k} = \frac{\exp(q_{i,k})}{\sum_{k=1}^{K} \exp(q_{i,k})} \quad (10)$$

The weighted combination of the experts' feedback is given by

$$h_i^{\text{experts}} = \sum_{k=1}^{K} a_{i,k} h_i^{(k)} \quad (11)$$

and the model makes predictions by using $\bar{h}_1 \ldots \bar{h}_n$ where

$$\bar{h}_i = h_i \oplus h_i^{\text{experts}} \tag{12}$$

These vectors replace the original feature vectors h_i in defining the intent or tagging losses.

4.2 Domain Attention Variants

We also consider two variants of the domain attention architecture in Section 4.1.

Label Embedding In addition to the state vectors $h^{(1)} \ldots h^{(K)}$ produced by K experts, we further incorporate their final (discrete) label predictions using pre-trained label embeddings. We induce embeddings e^y for labels y from all domains using the method of Kim et al. (2015d). At the i-th word, we predict the most likely label $y^{(k)}$ under the k-th expert and compute an attention weight as

$$\bar{q}_{i,k}^{\text{dot}} = h_i^\top e^{y^{(k)}} \tag{13}$$

Then we compute an expectation over the experts' predictions

$$\bar{a}_{i,k} = \frac{\exp(\bar{q}_{i,k})}{\sum_{k=1}^{K} \exp(\bar{q}_{i,k})} \tag{14}$$

$$h_i^{\text{label}} = \sum_{k=1}^{K} \bar{a}_{i,k} e_i^{y^{(k)}} \tag{15}$$

and use it in conjunction with $\bar{h}_i$. Note that this makes the objective a function of discrete decision and thus non-differentiable, but we can still optimize it in a standard way treating it as learning a stochastic policy.

Selective Attention Instead of computing attention over all K experts, we only consider the top $K' \leq K$ that predict the highest label scores. We only compute attention over these K' vectors. We experiment with various values of K'

5 Experiments

In this section, we describe the set of experiments conducted to evaluate the performance of our model. In order to fully assess the contribution of our approach, we also consider several baselines and variants besides our primary expert model.

Domain	$\lvert I\rvert$	$\lvert S\rvert$	Description
EVENTS	10	12	Buy event tickets
FITNESS	10	9	Track health
M-TICKET	8	15	Buy movie tickets
ORDERPIZZA	19	27	Order pizza
REMINDER	19	20	Remind task
TAXI	8	13	Find/book an cab
TV	7	5	Control TV

Table 1: The number of intent types ($|I|$), the number of slot types ($|S|$), and a short description of the test domains.

	Overlapping	
Domain	Intents	Slots
EVENTS	70.00%	75.00%
FITNESS	30.00%	77.78%
M-TICKET	37.50%	100.00%
ORDERPIZZA	47.37%	74.07%
REMINDER	68.42%	85.00%
TAXI	50.00%	100.00%
TV	57.14%	60.00%
AVG	51.49%	81.69%

Table 2: The overlapping percentage of intent types and slot types with experts or source domains.

5.1 Test domains and Tasks

To test the effectiveness of our proposed approach, we apply it to a suite of 7 Microsoft Cortana domains with 2 separate tasks in spoken language understanding: (1) intent classification and (2) slot (label) tagging. The intent classification task is a multi-class classification problem with the goal of determining to which one of the $|I|$ intents a user utterance belongs within a given domain. The slot tagging task is a sequence labeling problem with the goal of identifying entities and chunking of useful information snippets in a user utterance. For example, a user could say "*reserve a table at joeys grill for thursday at seven pm for five people*". Then the goal of the first task would be to classify this utterance as "*make_reservation*" intent given the places domain, and the goal of the second task would be to tag "*joeys grill*" as `restaurant`, "*thursday*" as `date`, "*seven pm*" as `time`, and "*five*" as `number_people`.

The short descriptions on the 7 test domains are shown in Table 1. As the table shows, the test domains have different granularity and diverse semantics. For each personal assistant test domain,

we only used 1000 training utterances to simulate scarcity of newly labeled data. The amount of development and test utterance was 100 and 10k respectively.

The similarities of test domains, represented by overlapping percentage, with experts or source domains are represented in Table 2. The intent overlapping percentage ranges from 30% on FITNESS domain to 70% on EVENTS, which averages out at 51.49%. And the slots for test domains overlaps more with those of source domains ranging from 60% on TV domain to 100% on both M-TICKET and TAXI domains, which averages out at 81.69%.

5.2 Experimental Setup

Category	$\|D\|$	Example
Trans.	4	BUS, FLIGHT
Time	4	ALARM, CALENDAR
Media	5	MOVIE, MUSIC
Action	5	HOMEAUTO, PHONE
Loc.	3	HOTEL, BUSINESS
Info	4	WEATHER, HEALTH
TOTAL	25	

Table 3: Overview of experts or source domains: Domain categories which have been created based on the label embeddings. These categorizations are solely for the purpose of describing domains because of the limited space and they are completely unrelated to the model. The number of sentences in each domain is in the range of 50k to 660k and the number of unique intents and slots are 200 and 500 respectively. In total, we have 25 domain-specific expert models. For the average performance, intent accuracy is 98% and slot F1 score is 96%.

In testing our approach, we consider a domain adaptation (DA) scenario, where a target domain has a limited training data and the source domain has a sufficient amount of labeled data. We further consider a scenario, creating a new virtual domain targeting a specific scenario given a large inventory of intent and slot types and underlying models build for many different applications and scenarios. One typical use case is that of building natural language capability through intent and slot modeling (without actually building a domain classifier) targeting a specific application. Therefore, our experimental settings are rather different from previously considered settings for domain adaptation in two aspects:

- *Multiple source domains:* In most previous works, only a pair of domains (source vs. target) have been considered, although they can be easily generalized to $K > 2$. Here, we experiment with $K = 25$ domains shown in Table 3.

- *Variant output:* In a typical setting for domain adaptation, the label space is invariant across all domains. Here, the label space can be different in different domains, which is a more challenging setting. See Kim et al. (2015d) for details of this setting.

For this DA scenario, we test whether our approach can effectively make a system to quickly generalize to a new domain with limited supervision given K existing domain experts shown in 3 .

In summary, our approach is tested with 7 Microsoft Cortana personal assistant domains across 2 tasks of intent classification and slot tagging. Below shows more detail of our baselines and variants used in our experiments.

Baselines: All models below use same underlying architecture described in Section 3.1

- TARGET: a model trained on a targeted domain without DA techniques.

- UNION: a model trained on the union of a targeted domain and 25 domain experts.

- DA: a neural domain adaptation method of Kim et al. (2016c) which trains domain specific K LSTMs with a generic LSTM on all domain training data.

Domain Experts (DE) variants: All models below are based on attending on an ensemble of 25 domain experts (DE) described in Section 4.1, where a specific set of intent and slots models are trained for each domain. We have two feedback from domain experts: (1) feature representation from LSTM, and (2) label embedding from feedfoward described in Section 4.1 and Section 4.2, respectively.

- DE^B: DE without domain attention mechanism. It uses the unweighted combination of first feedback from experts like bag-of-word model.

- DE^1: DE with domain attention with the weighted combination of the first feedbacks from experts.
- DE^2: DE^1 with additional weighted combination of second feedbacks.
- DE^{S2}: DE^2 with selected attention mechanism, described in Section 4.2.

In our experiments, all the models were implemented using Dynet (Neubig et al., 2017) and were trained using Stochastic Gradient Descent (SGD) with Adam (Kingma and Ba, 2015)—an adaptive learning rate algorithm. We used the initial learning rate of 4×10^{-4} and left all the other hyper parameters as suggested in Kingma and Ba (2015). Each SGD update was computed without a minibatch with Intel MKL (Math Kernel Library)[4]. We used the dropout regularization (Srivastava et al., 2014) with the keep probability of 0.4 at each LSTM layer.

To encode user utterances, we used bidirectional LSTMs (BiLSTMs) at the character level and the word level, along with 25 dimensional character embedding and 100 dimensional word embedding. The dimension of both the input and output of the character LSTMs were 25, and the dimensions of the input and output of the word LSTMs were 150[5] and 100, respectively. The dimension of the input and output of the final feedforward network for intent, and slot were 200 and the number of their corresponding task. Its activation was rectified linear unit (ReLU).

To initialize word embedding, we used word embedding trained from (Lample et al., 2016). In the following sections, we report intent classification results in accuracy percentage and slot results in F1-score. To compute slot F1-score, we used the standard CoNLL evaluation script[6]

5.3 Results

We show our results in the DA setting where we had a sufficient labeled dataset in the 25 source domains shown in Table 3, but only 1000 labeled data in the target domain. The performance of the baselines and our domain experts DE variants are shown in Table 4. The top half of the table shows the results of intent classification and the results of slot tagging is in the bottom half.

The baseline which trained only on the target domain (TARGET) shows a reasonably good performance, yielding on average 87.7% on the intent classification and 83.9% F1-score on the slot tagging. Simply training a single model with aggregated utterance across all domains (UNION) brings the performance down to 77.4% and 75.3%. Using DA approach of Kim et al. (2016c) shows a significant increase in performance in all 7 domains, yielding on average 90.3% intent accuracy and 86.2%.

The DE without domain attention (DE^B) shows similar performance compared to DA. Using DE model with domain attention (DE^1) shows another increase in performance, yielding on average 90.9% intent accuracy and 86.9%. The performance increases again when we use both feature representation and label embedding (DE^2), yielding on average 91.4% and 88.2% and observe nearly 93.6% and 89.1% when using selective attention (DE^{S2}). Note that DE^{S2} selects the appropriate number of experts per layer by evaluation on a development set.

The results show that our expert variant approach (DE^{S2}) achieves a significant performance gain in all 7 test domains, yielding average error reductions of 47.97% for intent classification and 32.30% for slot tagging. The results suggest that our expert approach can quickly generalize to a new domain with limited supervision given K existing domains by having only a handful more data of 1k newly labeled data points. The poor performance of using the union of both source and target domain data might be due to the relatively very small size of the target domain data, overwhelmed by the data in the source domain. For example, a word such as "*home*" can be labeled as place_type under the TAXI domain, but in the source domains can be labeled as either home_screen under the PHONE domain or contact_name under the CALENDAR domain.

5.4 Training Time

The Figure 3 shows the time required for training DE^{S2} and DA of Kim et al. (2016c). The training time for DE^{S2} stays almost constant as the number of source domains increases. However, the training time for DA grows exponentially in the number of source domains. Specifically, when trained

Table 4: Intent classification accuracy (%) and slot tagging F1-score (%) of our baselines and variants of DE. The numbers in boldface indicate the best performing methods.

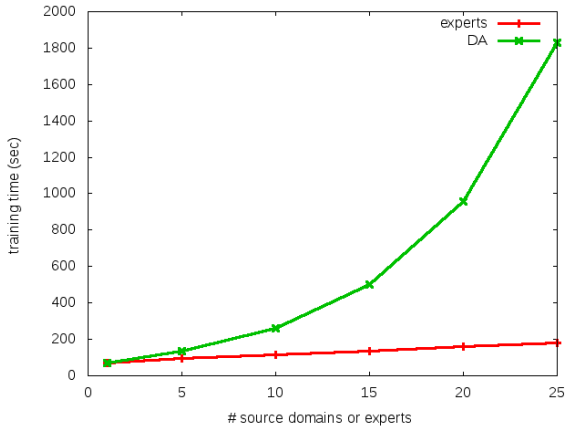

Figure 3: Comparison of training time between our DE^{S2} model and DA model of Kim et al. (2016c) as the number of domains increases. The horizontal axis means the number of domains, the vertical axis is training time per epoch in seconds. Here we use CALENDAR as the target domain, which has 1k training data.

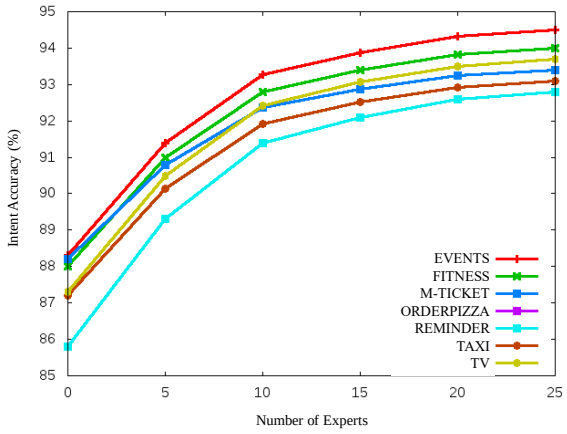

Figure 4: Learning curves in accuracy across all seven test domains as the number of expert domains increases.

with 1 source or expert domain, both took around a minute per epoch on average. When training with full 25 source domains, DE^{S2} took 3 minutes per epoch while DA took 30 minutes per epoch. Since we need to iterate over all 25+1 domains to re-train the global model, the net training time ratio could be over 250.

5.5 Learning Curve

We also measured the performance of our methods as a function of the number of domain experts. For each test domain, we consider all possible sizes of experts ranging from 1 to 25 and we then take the average of the resulting performances obtained from the expert sets of all different sizes. Figure 4 shows the resulting learning curves for each test domain. The overall trend is clear: as the more expert domains are added, the more the test performance improves. With ten or more expert domains added, our method starts to get saturated achiev-

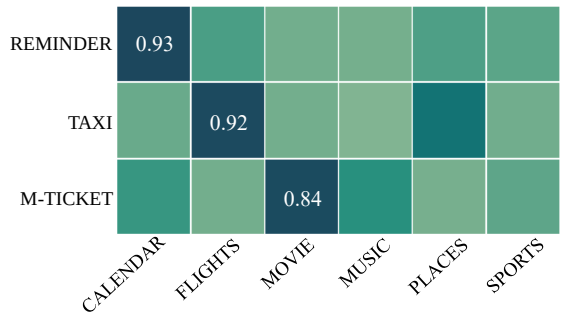

Figure 5: Heatmap visualizing attention weights.

ing more than 90% in accuracy across all seven domains.

5.6 Attention weights

From the heatmap shown in Figure 5, we can see that the attention strength generally agrees with common sense. For example, the M-TICKET and TAXI domain selected MOVIE and PLACES as their top experts, respectively.

5.7 Oracle Expert

Domain	TARGET	DE^2	Top 1
ALARM	70.1	**98.2**	ALARM (.99)
HOTEL	65.2	**96.9**	HOTEL (.99)

Table 5: Intent classification accuracy with an oracle expert in the expert pool.

The results in Table 5 show the intent classification accuracy of DE^2 when we already have the same domain expert in the expert pool. To simulate such a situation, we randomly sampled 1,000, 100, and 100 utterances from each domain as training, development and test data, respectively. In both ALARM and HOTEL domains, the trained models only on the 1,000 training utterances (TARGET) achieved only 70.1%and 65.2% in accuracy, respectively. Whereas, with our method (DE^2) applied, we reached almost the full training performance by selectively paying attention to the oracle expert, yielding 98.2% and 96.9%, respectively. This result again confirms that the behavior of the trained attention network indeed matches the semantic closeness between different domains.

5.8 Selective attention

The results in Table 6 examines how the intent prediction accuracy of DE^{S2} varies with respect to the number of experts in the pool. The rationale behind DE^{S2} is to alleviate the downside of soft attention, namely distributing probability mass over all items even if some are bad items. To deal with such issues, we apply a hard cut-off at top k domains. From the result, a threshold at top 3 or 5 yielded better results than that of either 1 or 25 experts. This matches our common sense that their are only a few of domains that are close enough to be of help to a test domain. Thus it is advisable to find the optimal k value through several rounds of experiments on a development dataset.

Domain	Top 1	Top 3	Top 5	Top 25
EVENTS	98.1	98.8	**99.2**	96.4
TV	81.4	**82.0**	81.7	80.9
AVG	89.8	90.4	**90.5**	88.7

Table 6: Accuracies of DE^{S2} using different number of experts.

6 Conclusion

In this paper, we proposed a solution for scaling domains and experiences potentially to a large number of use cases by reusing existing data labeled for different domains and applications. Our solution is based on attending an ensemble of domain experts. When given a new domain, our model uses a weighted combination of domain experts' feedback along with its own opinion to make prediction on the new domain. In both intent classification and slot tagging tasks, the model significantly outperformed baselines that do not use domain adaptation and also performed better than the full re-training approach. This approach enables creation of new virtual domains through a weighted combination of domain experts' feedback reducing the need to collect and annotate the similar intent and slot types multiple times for different domains. Future work can include an extension of domain experts to take into account dialog history aiming for a holistic framework that can handle contextual interpretation as well.

Abstract

While recent neural encoder-decoder models have shown great promise in modeling open-domain conversations, they often generate dull and generic responses. Unlike past work that has focused on diversifying the output of the decoder at word-level to alleviate this problem, we present a novel framework based on conditional variational autoencoders that captures the discourse-level diversity in the encoder. Our model uses latent variables to learn a distribution over potential conversational intents and generates diverse responses using only greedy decoders. We have further developed a novel variant that is integrated with linguistic prior knowledge for better performance. Finally, the training procedure is improved by introducing a *bag-of-word* loss. Our proposed models have been validated to generate significantly more diverse responses than baseline approaches and exhibit competence in discourse-level decision-making.

1 Introduction

The dialog manager is one of the key components of dialog systems, which is responsible for modeling the decision-making process. Specifically, it typically takes a new utterance and the dialog context as input, and generates discourse-level decisions (Bohus and Rudnicky, 2003; Williams and Young, 2007). Advanced dialog managers usually have a list of potential actions that enable them to have diverse behavior during a conversation, e.g. different strategies to recover from non-understanding (Yu et al., 2016). However, the conventional approach of designing a dialog manager (Williams and Young, 2007) does not scale well to open-domain conversation models because of the vast quantity of possible decisions. Thus, there has been a growing interest in applying encoder-decoder models (Sutskever et al., 2014) for modeling open-domain conversation (Vinyals and Le, 2015; Serban et al., 2016a). The basic approach treats a conversation as a transduction task, in which the dialog history is the source sequence and the next response is the target sequence. The model is then trained end-to-end on large conversation corpora using the maximum-likelihood estimation (MLE) objective without the need for manual crafting.

However recent research has found that encoder-decoder models tend to generate generic and dull responses (e.g., *I don't know*), rather than meaningful and specific answers (Li et al., 2015; Serban et al., 2016b). There have been many attempts to explain and solve this limitation, and they can be broadly divided into two categories (see Section 2 for details): (1) the first category argues that the dialog history is only one of the factors that decide the next response. Other features should be extracted and provided to the models as conditionals in order to generate more specific responses (Xing et al., 2016; Li et al., 2016a); (2) the second category aims to improve the encoder-decoder model itself, including decoding with beam search and its variations (Wiseman and Rush, 2016), encouraging responses that have long-term payoff (Li et al., 2016b), etc.

Building upon the past work in dialog managers and encoder-decoder models, the key idea of this paper is to model dialogs as a *one-to-many* problem at the discourse level. Previous studies indicate that there are many factors in open-domain dialogs that decide the next response, and it is non-trivial to extract all of them. Intuitively, given a similar dialog history (and other observed inputs), there may exist many valid responses (at the

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 654–664
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1061

discourse-level), each corresponding to a certain configuration of the latent variables that are not presented in the input. To uncover the potential responses, we strive to model a probabilistic distribution over the distributed utterance embeddings of the potential responses using a latent variable (Figure 1). This allows us to generate diverse responses by drawing samples from the learned distribution and reconstruct their words via a decoder neural network.

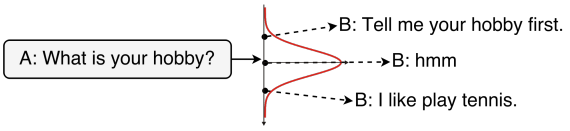

Figure 1: Given A's question, there exists many valid responses from B for different assumptions of the latent variables, e.g., B's hobby.

Specifically, our contributions are three-fold: 1. We present a novel neural dialog model adapted from conditional variational autoencoders (CVAE) (Yan et al., 2015; Sohn et al., 2015), which introduces a latent variable that can capture discourse-level variations as described above 2. We propose Knowledge-Guided CVAE (kgCVAE), which enables easy integration of expert knowledge and results in performance improvement and model interpretability. 3. We develop a training method in addressing the difficulty of optimizing CVAE for natural language generation (Bowman et al., 2015). We evaluate our models on human-human conversation data and yield promising results in: (a) generating appropriate and discourse-level diverse responses, and (b) showing that the proposed training method is more effective than the previous techniques.

2 Related Work

Our work is related to both recent advancement in encoder-decoder dialog models and generative models based on CVAE.

2.1 Encoder-decoder Dialog Models

Since the emergence of the neural dialog model, the problem of output diversity has received much attention in the research community. Ideal output responses should be both coherent and diverse. However, most models end up with generic and dull responses. To tackle this problem, one line of research has focused on augmenting the input of encoder-decoder models with richer context information, in order to generate more specific responses. Li et al., (2016a) captured speakers' characteristics by encoding background information and speaking style into the distributed embeddings, which are used to re-rank the generated response from an encoder-decoder model. Xing et al., (2016) maintain topic encoding based on Latent Dirichlet Allocation (LDA) (Blei et al., 2003) of the conversation to encourage the model to output more topic coherent responses.

On the other hand, many attempts have also been made to improve the architecture of encoder-decoder models. Li et al,. (2015) proposed to optimize the standard encoder-decoder by maximizing the mutual information between input and output, which in turn reduces generic responses. This approach penalized unconditionally high frequency responses, and favored responses that have high conditional probability given the input. Wiseman and Rush (2016) focused on improving the decoder network by alleviating the biases between training and testing. They introduced a search-based loss that directly optimizes the networks for beam search decoding. The resulting model achieves better performance on word ordering, parsing and machine translation. Besides improving beam search, Li et al., (2016b) pointed out that the MLE objective of an encoder-decoder model is unable to approximate the real-world goal of the conversation. Thus, they initialized a encoder-decoder model with MLE objective and leveraged reinforcement learning to fine tune the model by optimizing three heuristic rewards functions: informativity, coherence, and ease of answering.

2.2 Conditional Variational Autoencoder

The variational autoencoder (VAE) (Kingma and Welling, 2013; Rezende et al., 2014) is one of the most popular frameworks for image generation. The basic idea of VAE is to encode the input x into a probability distribution z instead of a point encoding in the autoencoder. Then VAE applies a decoder network to reconstruct the original input using samples from z. To generate images, VAE first obtains a sample of z from the prior distribution, e.g. $\mathcal{N}(0, \mathbf{I})$, and then produces an image via the decoder network. A more advanced model, the conditional VAE (CVAE), is a recent modification of VAE to generate diverse images conditioned on certain attributes, e.g. generating different human faces given skin color (Yan et al., 2015; Sohn et al., 2015). Inspired by CVAE, we view the dialog contexts as the conditional attributes and adapt CVAE

to generate diverse responses instead of images.

Although VAE/CVAE has achieved impressive results in image generation, adapting this to natural language generators is non-trivial. Bowman et al., (2015) have used VAE with Long-Short Term Memory (LSTM)-based recognition and decoder networks to generate sentences from a latent Gaussian variable. They showed that their model is able to generate diverse sentences with even a greedy LSTM decoder. They also reported the difficulty of training because the LSTM decoder tends to ignore the latent variable. We refer to this issue as the *vanishing latent variable problem*. Serban et al., (2016b) have applied a latent variable hierarchical encoder-decoder dialog model to introduce utterance-level variations and facilitate longer responses. To improve upon the past models, we firstly introduce a novel mechanism to leverage linguistic knowledge in training end-to-end neural dialog models, and we also propose a novel training technique that mitigates the vanishing latent variable problem.

3 Proposed Models

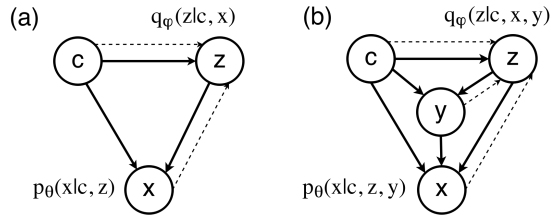

Figure 2: Graphical models of CVAE (a) and kgCVAE (b)

3.1 Conditional Variational Autoencoder (CVAE) for Dialog Generation

Each dyadic conversation can be represented via three random variables: the dialog context c (context window size $k-1$), the response utterance x (the k^{th} utterance) and a latent variable z, which is used to capture the latent distribution over the valid responses. Further, c is composed of the dialog history: the preceding k-1 utterances; conversational floor (1 if the utterance is from the same speaker of x, otherwise 0) and meta features m (e.g. the topic). We then define the conditional distribution $p(x, z|c) = p(x|z, c)p(z|c)$ and our goal is to use deep neural networks (parametrized by θ) to approximate $p(z|c)$ and $p(x|z, c)$. We refer to $p_\theta(z|c)$ as the *prior network* and $p_\theta(x, |z, c)$ as the *response decoder*. Then the generative process of x is (Figure 2 (a)):

1. Sample a latent variable z from the prior network $p_\theta(z|c)$.
2. Generate x through the response decoder $p_\theta(x|z, c)$.

CVAE is trained to maximize the conditional log likelihood of x given c, which involves an intractable marginalization over the latent variable z. As proposed in (Sohn et al., 2015; Yan et al., 2015), CVAE can be efficiently trained with the *Stochastic Gradient Variational Bayes* (SGVB) framework (Kingma and Welling, 2013) by maximizing the variational lower bound of the conditional log likelihood. We assume the z follows multivariate Gaussian distribution with a diagonal covariance matrix and introduce a *recognition network* $q_\phi(z|x, c)$ to approximate the true posterior distribution $p(z|x, c)$. Sohn and et al,. (2015) have shown that the variational lower bound can be written as:

$$\begin{aligned}\mathcal{L}(\theta, \phi; x, c) &= -KL(q_\phi(z|x, c)\|p_\theta(z|c)) \\ &\quad + \mathbf{E}_{q_\phi(z|c,x)}[\log p_\theta(x|z, c)] \\ &\leq \log p(x|c)\end{aligned} \tag{1}$$

Figure 3 demonstrates an overview of our model. The utterance encoder is a bidirectional recurrent neural network (BRNN) (Schuster and Paliwal, 1997) with a gated recurrent unit (GRU) (Chung et al., 2014) to encode each utterance into fixed-size vectors by concatenating the last hidden states of the forward and backward RNN $u_i = [\overrightarrow{h_i}, \overleftarrow{h_i}]$. x is simply u_k. The context encoder is a 1-layer GRU network that encodes the preceding k-1 utterances by taking $u_{1:k-1}$ and the corresponding conversation floor as inputs. The last hidden state h^c of the context encoder is concatenated with meta features and $c = [h^c, m]$. Since we assume z follows isotropic Gaussian distribution, the recognition network $q_\phi(z|x, c) \sim \mathcal{N}(\mu, \sigma^2\mathbf{I})$ and the prior network $p_\theta(z|c) \sim \mathcal{N}(\mu', \sigma'^2\mathbf{I})$, and then we have:

$$\begin{bmatrix}\mu \\ \log(\sigma^2)\end{bmatrix} = W_r \begin{bmatrix}x \\ c\end{bmatrix} + b_r \tag{2}$$

$$\begin{bmatrix}\mu' \\ \log(\sigma'^2)\end{bmatrix} = \text{MLP}_p(c) \tag{3}$$

We then use the reparametrization trick (Kingma and Welling, 2013) to obtain samples of z either

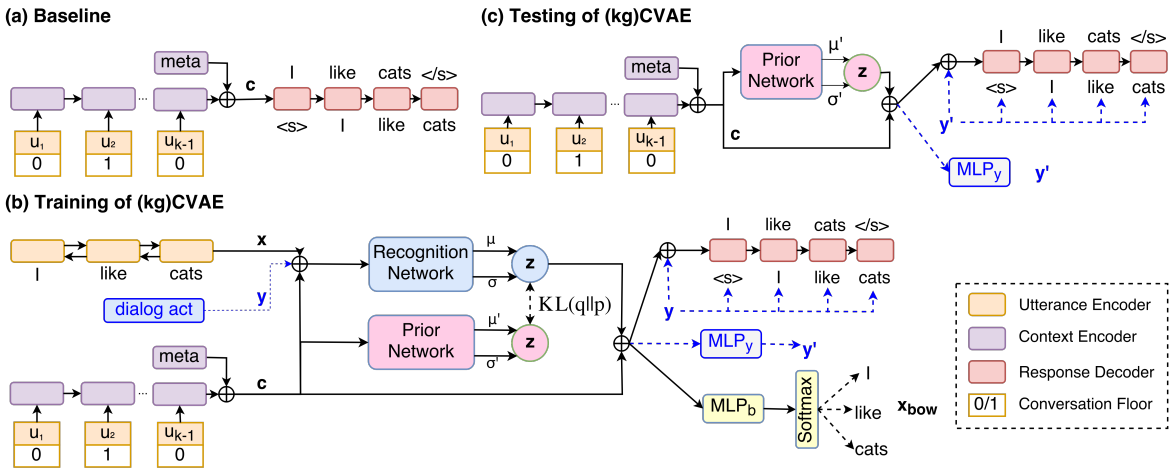

Figure 3: The neural network architectures for the baseline and the proposed CVAE/kgCVAE models. $\bigoplus$ denotes the concatenation of the input vectors. The dashed blue connections only appear in kgCVAE.

from $\mathcal{N}(z; \mu, \sigma^2\mathbf{I})$ predicted by the recognition network (training) or $\mathcal{N}(z; \mu', \sigma'^2\mathbf{I})$ predicted by the prior network (testing). Finally, the response decoder is a 1-layer GRU network with initial state $s_0 = W_i[z, c]+b_i$. The response decoder then predicts the words in x sequentially.

3.2 Knowledge-Guided CVAE (kgCVAE)

In practice, training CVAE is a challenging optimization problem and often requires large amount of data. On the other hand, past research in spoken dialog systems and discourse analysis has suggested that many linguistic cues capture crucial features in representing natural conversation. For example, dialog acts (Poesio and Traum, 1998) have been widely used in the dialog managers (Litman and Allen, 1987; Raux et al., 2005; Zhao and Eskenazi, 2016) to represent the propositional function of the system. Therefore, we conjecture that it will be beneficial for the model to learn meaningful latent z if it is provided with explicitly extracted discourse features during the training.

In order to incorporate the linguistic features into the basic CVAE model, we first denote the set of linguistic features as y. Then we assume that the generation of x depends on c, z and y. y relies on z and c as shown in Figure 2. Specifically, during training the initial state of the response decoder is $s_0 = W_i[z, c, y] + b_i$ and the input at every step is $[e_t, y]$ where e_t is the word embedding of t^{th} word in x. In addition, there is an MLP to predict $y' = \text{MLP}_y(z, c)$ based on z and c. In the testing stage, the predicted y' is used by the response decoder instead of the oracle decoders. We denote the modified model as knowledge-guided CVAE (kgCVAE) and developers can add desired discourse features that they wish the latent variable z to capture. KgCVAE model is trained by maximizing:

$$\begin{aligned}\mathcal{L}(\theta, \phi; x, c, y) = &-KL(q_\phi(z|x, c, y)\|P_\theta(z|c)) \\ &+ \mathbf{E}_{q_\phi(z|c,x,y)}[\log p(x|z, c, y)] \\ &+ \mathbf{E}_{q_\phi(z|c,x,y)}[\log p(y|z, c)] \quad (4)\end{aligned}$$

Since now the reconstruction of y is a part of the loss function, kgCVAE can more efficiently encode y-related information into z than discovering it only based on the surface-level x and c. Another advantage of kgCVAE is that it can output a high-level label (e.g. dialog act) along with the word-level responses, which allows easier interpretation of the model's outputs.

3.3 Optimization Challenges

A straightforward VAE with RNN decoder fails to encode meaningful information in z due to the *vanishing latent variable problem* (Bowman et al., 2015). Bowman et al., (2015) proposed two solutions: (1) *KL annealing*: gradually increasing the weight of the KL term from 0 to 1 during training; (2) *word drop decoding*: setting a certain percentage of the target words to 0. We found that CVAE suffers from the same issue when the decoder is an RNN. Also we did not consider word drop decoding because Bowman et al,. (2015) have shown that it may hurt the performance when the drop rate is too high.

As a result, we propose a simple yet novel technique to tackle the vanishing latent variable problem: *bag-of-word loss*. The idea is to introduce

an auxiliary loss that requires the decoder network to predict the bag-of-words in the response x as shown in Figure 3(b). We decompose x into two variables: x_o with word order and x_{bow} without order, and assume that x_o and x_{bow} are conditionally independent given z and c: $p(x, z|c) = p(x_o|z, c)p(x_{bow}|z, c)p(z|c)$. Due to the conditional independence assumption, the latent variable is forced to capture global information about the target response. Let $f = \text{MLP}_b(z, x) \in \mathcal{R}^V$ where V is vocabulary size, and we have:

$$\log p(x_{bow}|z, c) = \log \prod_{t=1}^{|x|} \frac{e^{f_{x_t}}}{\sum_j^V e^{f_j}} \quad (5)$$

where $|x|$ is the length of x and x_t is the word index of t_{th} word in x. The modified variational lower bound for CVAE with bag-of-word loss is (see Appendix A for kgCVAE):

$$\mathcal{L}'(\theta, \phi; x, c) = \mathcal{L}(\theta, \phi; x, c) + \mathbf{E}_{q_\phi(z|c,x,y)}[\log p(x_{bow}|z, c)] \quad (6)$$

We will show that the bag-of-word loss in Equation 6 is very effective against the vanishing latent variable and it is also complementary to the KL annealing technique.

4 Experiment Setup

4.1 Dataset

We chose the Switchboard (SW) 1 Release 2 Corpus (Godfrey and Holliman, 1997) to evaluate the proposed models. SW has 2400 two-sided telephone conversations with manually transcribed speech and alignment. In the beginning of the call, a computer operator gave the callers recorded prompts that define the desired topic of discussion. There are 70 available topics. We randomly split the data into $2316/60/62$ dialogs for train/validate/test. The pre-processing includes (1) tokenize using the NLTK tokenizer (Bird et al., 2009); (2) remove non-verbal symbols and repeated words due to false starts; (3) keep the top 10K frequent word types as the vocabulary. The final data have $207,833/5,225/5,481$ (c, x) pairs for train/validate/test. Furthermore, a subset of SW was manually labeled with dialog acts (Stolcke et al., 2000). We extracted dialog act labels based on the dialog act recognizer proposed in (Ribeiro et al., 2015). The features include the uni-gram and bi-gram of the utterance, and the contextual features of the last 3 utterances. We trained a Support Vector Machine (SVM) (Suykens and Vandewalle, 1999) with linear kernel on the subset of SW with human annotations. There are 42 types of dialog acts and the SVM achieved 77.3% accuracy on held-out data. Then the rest of SW data are labelled with dialog acts using the trained SVM dialog act recognizer.

4.2 Training

We trained with the following hyperparameters (according to the loss on the validate dataset): word embedding has size 200 and is shared across everywhere. We initialize the word embedding from Glove embedding pre-trained on Twitter (Pennington et al., 2014). The utterance encoder has a hidden size of 300 for each direction. The context encoder has a hidden size of 600 and the response decoder has a hidden size of 400. The prior network and the MLP for predicting y both have 1 hidden layer of size 400 and $tanh$ non-linearity. The latent variable z has a size of 200. The context window k is 10. All the initial weights are sampled from a uniform distribution [-0.08, 0.08]. The mini-batch size is 30. The models are trained end-to-end using the Adam optimizer (Kingma and Ba, 2014) with a learning rate of 0.001 and gradient clipping at 5. We selected the best models based on the variational lower bound on the validate data. Finally, we use the BOW loss along with *KL annealing* of 10,000 batches to achieve the best performance. Section 5.4 gives a detailed argument for the importance of the BOW loss.

5 Results

5.1 Experiments Setup

We compared three neural dialog models: a strong baseline model, CVAE, and kgCVAE. The **baseline model** is an encoder-decoder neural dialog model without latent variables similar to (Serban et al., 2016a). The baseline model's encoder uses the same context encoder to encode the dialog history and the meta features as shown in Figure 3. The encoded context c is directly fed into the decoder networks as the initial state. The hyperparameters of the baseline are the same as the ones reported in Section 4.2 and the baseline is trained to minimize the standard cross entropy loss of the decoder RNN model without any auxiliary loss.

Also, to compare the diversity introduced by the stochasticity in the proposed latent variable versus the softmax of RNN at each decoding step, we generate N responses from the baseline by sam-

pling from the softmax. For CVAE/kgCVAE, we sample N times from the latent z and only use greedy decoders so that the randomness comes entirely from the latent variable z.

5.2 Quantitative Analysis

Automatically evaluating an open-domain generative dialog model is an open research challenge (Liu et al., 2016). Following our *one-to-many* hypothesis, we propose the following metrics. We assume that for a given dialog context c, there exist M_c reference responses r_j, $j \in [1, M_c]$. Meanwhile a model can generate N hypothesis responses h_i, $i \in [1, N]$. The generalized response-level precision/recall for a given dialog context is:

$$\text{precision(c)} = \frac{\sum_{i=1}^{N} max_{j \in [1,M_c]} d(r_j, h_i)}{N}$$

$$\text{recall(c)} = \frac{\sum_{j=1}^{M_c} max_{i \in [1,N]} d(r_j, h_i))}{M_c}$$

where $d(r_j, h_i)$ is a distance function which lies between 0 to 1 and measures the similarities between r_j and h_i. The final score is averaged over the entire test dataset and we report the performance with 3 types of distance functions in order to evaluate the systems from various linguistic points of view:

1. Smoothed Sentence-level BLEU (Chen and Cherry, 2014): BLEU is a popular metric that measures the geometric mean of modified n-gram precision with a length penalty (Papineni et al., 2002; Li et al., 2015). We use BLEU-1 to 4 as our lexical similarity metric and normalize the score to 0 to 1 scale.

2. Cosine Distance of Bag-of-word Embedding: a simple method to obtain sentence embeddings is to take the average or extrema of all the word embeddings in the sentences (Forgues et al., 2014; Adi et al., 2016). The $d(r_j, h_i)$ is the cosine distance of the two embedding vectors. We used Glove embedding described in Section 4 and denote the average method as A-bow and extrema method as E-bow.

3. Dialog Act Match: to measure the similarity at the discourse level, the same dialog-act tagger from 4.1 is applied to label all the generated responses of each model. We set $d(r_j, h_i) = 1$ if r_j and h_i have the same dialog acts, otherwise $d(r_j, h_i) = 0$.

One challenge of using the above metrics is that there is only one, rather than multiple reference responses/contexts. This impacts reliability of our measures. Inspired by (Sordoni et al., 2015), we utilized information retrieval techniques (see Appendix A) to gather 10 extra candidate reference responses/context from other conversations with the same topics. Then the 10 candidate references are filtered by two experts, which serve as the ground truth to train the reference response classifier. The result is 6.69 extra references in average per context. The average number of distinct reference dialog acts is 4.2. Table 1 shows the results.

Metrics	Baseline	CVAE	kgCVAE
perplexity (KL)	35.4	20.2	16.02
	(n/a)	(11.36)	(13.08)
BLEU-1 prec	0.405	0.372	**0.412**
BLEU-1 recall	0.336	0.381	**0.411**
BLEU-2 prec	0.300	0.295	**0.350**
BLEU-2 recall	0.281	0.322	**0.356**
BLEU-3 prec	0.272	0.265	**0.310**
BLEU-3 recall	0.254	0.292	**0.318**
BLEU-4 prec	0.226	0.223	**0.262**
BLEU-4 recall	0.215	0.248	**0.272**
A-bow prec	0.387	**0.389**	0.373
A-bow recall	0.337	**0.361**	0.336
E-bow prec	0.701	0.705	**0.711**
E-bow recall	0.684	0.709	**0.712**
DA prec	**0.736**	0.704	0.721
DA recall	0.514	**0.604**	0.598

Table 1: Performance of each model on automatic measures. The highest score in each row is in bold. Note that our BLEU scores are normalized to $[0, 1]$.

The proposed models outperform the baseline in terms of recall in all the metrics with statistical significance. This confirms our hypothesis that generating responses with discourse-level diversity can lead to a more comprehensive coverage of the potential responses than promoting only word-level diversity. As for precision, we observed that the baseline has higher or similar scores than CVAE in all metrics, which is expected since the baseline tends to generate the mostly likely and safe responses repeatedly in the N hypotheses. However, kgCVAE is able to achieve the highest precision and recall in the 4 metrics at the same time (BLEU1-4, E-BOW). One reason

for kgCVAE's good performance is that the predicted dialog act label in kgCVAE can regularize the generation process of its RNN decoder by forcing it to generate more coherent and precise words. We further analyze the precision/recall of BLEU-4 by looking at the average score versus the number of distinct reference dialog acts. A low number of distinct dialog acts represents the situation where the dialog context has a strong constraint on the range of the next response (low entropy), while a high number indicates the opposite (high-entropy). Figure 4 shows that CVAE/kgCVAE achieves significantly higher recall than the baseline in higher entropy contexts. Also it shows that CVAE suffers from lower precision, especially in low entropy contexts. Finally, kgCVAE gets higher precision than both the baseline and CVAE in the full spectrum of context entropy.

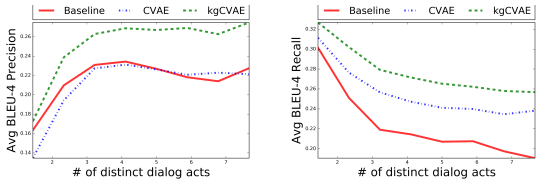

Figure 4: BLEU-4 precision/recall vs. the number of distinct reference dialog acts.

5.3 Qualitative Analysis

Table 2 shows the outputs generated from the baseline and kgCVAE. In example 1, caller A begins with an open-ended question. The kgCVAE model generated highly diverse answers that cover multiple plausible dialog acts. Further, we notice that the generated text exhibits similar dialog acts compared to the ones predicted separately by the model, implying the consistency of natural language generation based on y. On the contrary, the responses from the baseline model are limited to local n-gram variations and share a similar prefix, i.e. "I'm". Example 2 is a situation where caller A is telling B stories. The ground truth response is a back-channel and the range of valid answers is more constrained than example 1 since B is playing the role of a listener. The baseline successfully predicts "uh-huh". The kgCVAE model is also able to generate various ways of back-channeling. This implies that the latent z is able to capture context-sensitive variations, i.e. in low-entropy dialog contexts modeling lexical diversity while in high-entropy ones modeling discourse-level diversity. Moreover, kgCVAE is occasionally able to generate more sophisticated grounding (sample 4) beyond a simple back-channel, which is also an acceptable response given the dialog context.

In addition, past work (Kingma and Welling, 2013) has shown that the recognition network is able to learn to cluster high-dimension data, so we conjecture that posterior z outputted from the recognition network should cluster the responses into meaningful groups. Figure 5 visualizes the posterior z of responses in the test dataset in 2D space using t-SNE (Maaten and Hinton, 2008). We found that the learned latent space is highly correlated with the dialog act and length of responses, which confirms our assumption.

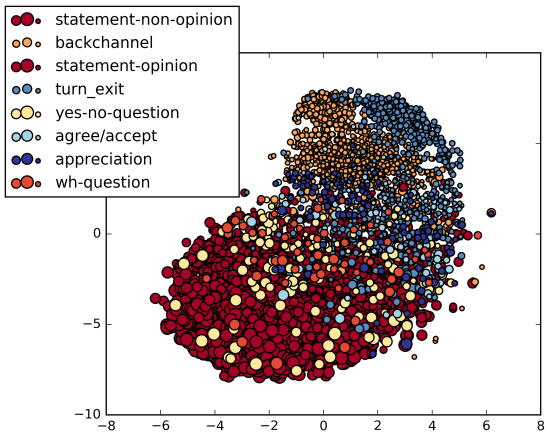

Figure 5: t-SNE visualization of the posterior z for test responses with top 8 frequent dialog acts. The size of circle represents the response length.

5.4 Results for Bag-of-Word Loss

Finally, we evaluate the effectiveness of bag-of-word (BOW) loss for training VAE/CVAE with the RNN decoder. To compare with past work (Bowman et al., 2015), we conducted the same language modelling (LM) task on Penn Treebank using VAE. The network architecture is same except we use GRU instead of LSTM. We compared four different training setups: (1) standard VAE without any heuristics; (2) VAE with KL annealing (KLA); (3) VAE with BOW loss; (4) VAE with both BOW loss and KLA. Intuitively, a well trained model should lead to a low reconstruction loss and small but non-trivial KL cost. For all models with KLA, the KL weight increases linearly from 0 to 1 in the first 5000 batches.

Table 3 shows the reconstruction perplexity and the KL cost on the test dataset. The standard VAE fails to learn a meaningful latent variable by hav-

Example 1-Topic: Recycling **Context**: A: are they doing a lot of recycling out in Georgia? **Target-B** (statement): well at my workplace we have palaces for aluminium cans and we have a separate trash can for recyclable paper	
Baseline+Sampling	**kgCVAE+Greedy**
1. well I'm a graduate student and have two kids	1. (non-understand) pardon
2. well I was in last year and so we've had lots of recycling	2. (statement) oh you're not going to have a curbside pick up here
3. I'm not sure	3. (statement) okay I am sure about a recycling center
4. well I don't know I just moved here in new york	4. (yes-answer) yeah so

Example 2-Topic: Child Care **Context**: A: you know a private home to take their children to when they're young until they hit the preschool age and they **Target-B** (backchannel): uh-huh	
Baseline+Sampling	**kgCVAE+Greedy**
1. um - hum	1. (backchannel) uh-huh
2. yeah	2. (turn-exit) um-hum
3. um - hum	3. (backchannel) yeah
4. uh-huh	4. (statement) oh yeah I think that's part of the problem

Table 2: Generated responses from the baselines and kgCVAE in two examples. KgCVAE also provides the predicted dialog act for each response. The context only shows the last utterance due to space limit (the actual context window size is 10).

ing a KL cost close to 0 and a reconstruction perplexity similar to a small LSTM LM (Zaremba et al., 2014). KLA helps to improve the reconstruction loss, but it requires early stopping since the models will fall back to the standard VAE after the KL weight becomes 1. At last, the models with BOW loss achieved significantly lower perplexity and larger KL cost.

Model	Perplexity	KL cost
Standard	122.0	0.05
KLA	111.5	2.02
BOW	97.72	7.41
BOW+KLA	73.04	15.94

Table 3: The reconstruction perplexity and KL terms on Penn Treebank test set.

Figure 6 visualizes the evolution of the KL cost. We can see that for the standard model, the KL cost crashes to 0 at the beginning of training and never recovers. On the contrary, the model with only KLA learns to encode substantial information in latent z when the KL cost weight is small. However, after the KL weight is increased to 1 (after 5000 batch), the model once again decides to ignore the latent z and falls back to the naive implementation. The model with BOW loss, however, consistently converges to a non-trivial KL cost even without KLA, which confirms the importance of BOW loss for training latent variable models with the RNN decoder. Last but not least, our experiments showed that the conclusions drawn from LM using VAE also apply to training CVAE/kgCVAE, so we used BOW loss together with KLA for all previous experiments.

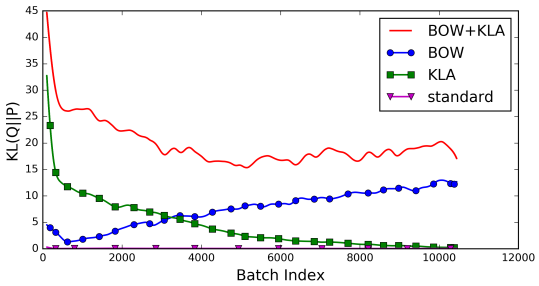

Figure 6: The value of the KL divergence during training with different setups on Penn Treebank.

6 Conclusion and Future Work

In conclusion, we identified the *one-to-many* nature of open-domain conversation and proposed two novel models that show superior performance in generating diverse and appropriate responses at the discourse level. While the current paper addresses diversifying responses in respect to dialogue acts, this work is part of a larger research direction that targets leveraging both past linguistic findings and the learning power of deep neural networks to learn better representation of the latent factors in dialog. In turn, the output of this novel neural dialog model will be easier to explain and control by humans. In addition to dialog acts, we plan to apply our kgCVAE model to capture other different linguistic phenomena including sentiment, named entities,etc. Last but not least, the recognition network in our model will serve as the foundation for designing a data-driven dialog manager, which automatically discovers useful high-level intents. All of the above suggest a promising research direction.

A Supplemental Material

Variational Lower Bound for kgCVAE

We assume that even with the presence of linguistic feature y regarding x, the prediction of x_{bow} still only depends on the z and c. Therefore, we have:

$$\begin{aligned}\mathcal{L}(\theta, \phi; x, c, y) = &-KL(q_\phi(z|x, c, y)\|P_\theta(z|c)) \\ &+ \mathbf{E}_{q_\phi(z|c,x,y)}[\log p(x|z, c, y)] \\ &+ \mathbf{E}_{q_\phi(z|c,x,y)}[\log p(y|z, c)] \\ &+ \mathbf{E}_{q_\phi(z|c,x,y)}[\log p(x_{bow}|z, c)]\end{aligned} \tag{7}$$

Collection of Multiple Reference Responses

We collected multiple reference responses for each dialog context in the test set by information retrieval techniques combining with traditional a machine learning method. First, we encode the dialog history using Term Frequency-Inverse Document Frequency (TFIDF) (Salton and Buckley, 1988) weighted bag-of-words into vector representation h. Then we denote the topic of the conversation as t and denote f as the conversation floor, i.e. if the speakers of the last utterance in the dialog history and response utterance are the same $f = 1$ otherwise $f = 0$. Then we computed the similarity $d(c_i, c_j)$ between two dialog contexts using:

$$d(c_i, c_j) = \mathbb{1}(t_i = t_j)\mathbb{1}(t_i = t_j)\frac{h_i \cdot h_j}{||h_i||||h_j||} \tag{8}$$

Unlike past work (Sordoni et al., 2015), this similarity function only cares about the distance in the context and imposes no constraints on the response, therefore is suitbale for finding diverse responses regarding to the same dialog context. Secondly, for each dialog context in the test set, we retrieved the 10 nearest neighbors from the training set and treated the responses from the training set as candidate reference responses. Thirdly, we further sampled 240 context-responses pairs from 5481 pairs in the total test set and post-processed the selected candidate responses by two human computational linguistic experts who were told to give a binary label for each candidate response about whether the response is appropriate regarding its dialog context. The filtered lists then served as the ground truth to train our reference response classifier. For the next step, we extracted bigrams, part-of-speech bigrams and word part-of-speech

pairs from both dialogue contexts and candidate reference responses with rare threshold for feature extraction being set to 20. Then L2-regularized logistic regression with 10-fold cross validation was applied as the machine learning algorithm. Cross validation accuracy on the human-labelled data was 71%. Finally, we automatically annotated the rest of test set with this trained classifier and the resulting data were used for model evaluation.

Hybrid Code Networks: practical and efficient end-to-end dialog control with supervised and reinforcement learning

Abstract

End-to-end learning of recurrent neural networks (RNNs) is an attractive solution for dialog systems; however, current techniques are data-intensive and require thousands of dialogs to learn simple behaviors. We introduce Hybrid Code Networks (HCNs), which combine an RNN with *domain-specific knowledge encoded as software* and *system action templates*. Compared to existing end-to-end approaches, HCNs considerably reduce the amount of training data required, while retaining the key benefit of inferring a latent representation of dialog state. In addition, HCNs can be optimized with supervised learning, reinforcement learning, or a mixture of both. HCNs attain state-of-the-art performance on the bAbI dialog dataset (Bordes and Weston, 2016), and outperform two commercially deployed customer-facing dialog systems.

1 Introduction

Task-oriented dialog systems help a user to accomplish some goal using natural language, such as making a restaurant reservation, getting technical support, or placing a phonecall. Historically, these dialog systems have been built as a pipeline, with modules for language understanding, state tracking, action selection, and language generation. However, dependencies between modules introduce considerable complexity – for example, it is often unclear how to define the dialog state and what history to maintain, yet action selection relies exclusively on the state for input. Moreover, training each module requires specialized labels.

Recently, end-to-end approaches have trained recurrent neural networks (RNNs) directly on text transcripts of dialogs. A key benefit is that the RNN infers a latent representation of state, obviating the need for state labels. However, end-to-end methods lack a general mechanism for injecting domain knowledge and constraints. For example, simple operations like sorting a list of database results or updating a dictionary of entities can expressed in a few lines of software, yet may take thousands of dialogs to learn. Moreover, in some practical settings, programmed constraints are essential – for example, a banking dialog system would require that a user is logged in before they can retrieve account information.

This paper presents a model for end-to-end learning, called *Hybrid Code Networks* (HCNs) which addresses these problems. In addition to learning an RNN, HCNs also allow a developer to express domain knowledge via software and action templates. Experiments show that, compared to existing recurrent end-to-end techniques, HCNs achieve the same performance with considerably less training data, while retaining the key benefit of end-to-end trainability. Moreover, the neural network can be trained with supervised learning or reinforcement learning, by changing the gradient update applied.

This paper is organized as follows. Section 2 describes the model, and Section 3 compares the model to related work. Section 4 applies HCNs to the bAbI dialog dataset (Bordes and Weston, 2016). Section 5 then applies the method to real customer support domains at our company. Section 6 illustrates how HCNs can be optimized with reinforcement learning, and Section 7 concludes.

2 Model description

At a high level, the four components of a Hybrid Code Network are a recurrent neural network; domain-specific software; domain-specific action templates; and a conventional entity extraction module for identifying entity mentions in text. Both the RNN and the developer code maintain state. Each action template can be a textual communicative action or an API call. The HCN model is summarized in Figure 1.

The cycle begins when the user provides an utterance, as text (step 1). The utterance is featurized in several ways. First, a bag of words vector is formed (step 2). Second, an utterance embedding is formed, using a pre-built utterance embedding model (step 3). Third, an entity extraction module identifies entity mentions (step 4) – for example, identifying "Jennifer Jones" as a `<name>` entity. The text and entity mentions are then passed to "Entity tracking" code provided by the developer (step 5), which grounds and maintains entities – for example, mapping the text "Jennifer Jones" to a specific row in a database. This code can optionally return an "action mask", indicating actions which are permitted at the current timestep, as a bit vector. For example, if a target phone number has not yet been identified, the API action to place a phone call may be masked. It can also optionally return "context features" which are features the developer thinks will be useful for distinguishing among actions, such as which entities are currently present and which are absent.

The feature components from steps 1-5 are concatenated to form a feature vector (step 6). This vector is passed to an RNN, such as a long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) or gated recurrent unit (GRU) (Chung et al., 2014). The RNN computes a hidden state (vector), which is retained for the next timestep (step 8), and passed to a dense layer with a softmax activation, with output dimension equal to the number of distinct system action templates (step 9).[1] Thus the output of step 9 is a distribution over action templates. Next, the action mask is applied as an element-wise multiplication, and the result is normalized back to a probability distribution (step 10) – this forces non-permitted actions to take on probability zero. From the resulting distribution (step 11), an action is selected (step 12). When RL is active, exploration is required, so in this case an action is *sampled* from the distribution; when RL is not active, the best action should be chosen, and so the action with the *highest probability* is always selected.

The selected action is next passed to "Entity output" developer code that can substitute in entities (step 13) and produce a fully-formed action – for example, mapping the template "`<city>`,

[1]Implementation details for the RNN such as size, loss, etc. are given with each experiment in Sections 4-6.

right?" to "Seattle, right?". In step 14, control branches depending on the type of the action: if it is an API action, the corresponding API call in the developer code is invoked (step 15) – for example, to render rich content to the user. APIs can act as sensors and return features relevant to the dialog, so these can be added to the feature vector in the next timestep (step 16). If the action is text, it is rendered to the user (step 17), and cycle then repeats. The action taken is provided as a feature to the RNN in the next timestep (step 18).

3 Related work

Broadly there are two lines of work applying machine learning to dialog control. The first decomposes a dialog system into a pipeline, typically including language understanding, dialog state tracking, action selection policy, and language generation (Levin et al., 2000; Singh et al., 2002; Williams and Young, 2007; Williams, 2008; Hori et al., 2009; Lee et al., 2009; Griol et al., 2008; Young et al., 2013; Li et al., 2014). Specifically related to HCNs, past work has implemented the policy as feed-forward neural networks (Wen et al., 2016), trained with supervised learning followed by reinforcement learning (Su et al., 2016). In these works, the policy has not been *recurrent* – i.e., the policy depends on the state tracker to summarize observable dialog history into state features, which requires design and specialized labeling. By contrast, HCNs use an RNN which automatically infers a representation of state. For learning efficiency, HCNs use an external lightweight process for tracking entity values, but the policy is not strictly dependent on it: as an illustration, in Section 5 below, we demonstrate an HCN-based dialog system which has no external state tracker. If there is context which is not apparent in the text in the dialog, such as database status, this can be encoded as a context feature to the RNN.

The second, more recent line of work applies recurrent neural networks (RNNs) to learn "end-to-end" models, which map from an observable dialog history directly to a sequence of output words (Sordoni et al., 2015; Shang et al., 2015; Vinyals and Le, 2015; Yao et al., 2015; Serban et al., 2016; Li et al., 2016a,c; Luan et al., 2016; Xu et al., 2016; Li et al., 2016b; Mei et al., 2016; Lowe et al., 2017; Serban et al., 2017). These systems can be applied to task-oriented domains by adding special "API call" actions, enumerating database output as a sequence of tokens (Bordes and Weston, 2016), then learning an RNN using Memory Networks (Sukhbaatar et al., 2015), gated memory networks (Liu and Perez, 2016), query reduction networks (Seo et al., 2016), and copy-augmented networks (Eric and Manning, 2017). In each of these architectures, the RNN learns to manipulate entity values, for example by saving them in a memory. Output is produced by generating a sequence of tokens (or ranking all possible surface forms), which can also draw from this memory. HCNs also use an RNN to accumulate dialog state and choose actions. However, HCNs differ in that they use developer-provided action templates, which can contain entity references, such as "`<city>`, right?". This design reduce learning complexity, and also enable the software to limit which actions are available via an action mask, at the expense of developer effort. To further reduce learning complexity in a practical system, entities are tracked separately, outside the the RNN, which also allows them to be substituted into action templates. Also, past end-to-end recurrent models have been trained using supervised learning, whereas we show how HCNs can also be trained with reinforcement learning.

4 Supervised learning evaluation I

In this section we compare HCNs to existing approaches on the public "bAbI dialog" dataset (Bordes and Weston, 2016). This dataset includes two end-to-end dialog learning tasks, in the restaurant domain, called task5 and task6.[2] Task5 consists of synthetic, simulated dialog data, with highly regular user behavior and constrained vocabulary. Dialogs include a database access action which retrieves relevant restaurants from a database, with results included in the dialog transcript. We test on the "OOV" variant of Task5, which includes entity values not observed in the training set. Task6 draws on human-computer dialog data from the second dialog state tracking challenge (DSTC2), where usability subjects (crowd-workers) interacted with several variants of a spoken dialog system (Henderson et al., 2014a). Since the database from DSTC2 was not provided, database calls have been inferred from the data and inserted into the dialog transcript. Example dialogs are provided in the Appendix Sections A.2 and A.3.

To apply HCNs, we wrote simple domain-

[2]Tasks 1-4 are sub-tasks of Task5.

specific software, as follows. First, for entity extraction (step 4 in Figure 1), we used a simple string match, with a pre-defined list of entity names – i.e., the list of restaurants available in the database. Second, in the context update (step 5), we wrote simple logic for tracking entities: when an entity is recognized in the user input, it is retained by the software, over-writing any previously stored value. For example, if the `price` "cheap" is recognized in the first turn, it is retained as `price=cheap`. If "expensive" is then recognized in the third turn, it over-writes "cheap" so the code now holds `price=expensive`. Third, system actions were templatized: for example, system actions of the form "prezzo is a nice restaurant in the west of town in the moderate price range" all map to the template "`<name>` is a nice restaurant in the `<location>` of town in the `<price>` price range". This results in 16 templates for Task5 and 58 for Task6.[3] Fourth, when database results are received into the entity state, they are sorted by rating. Finally, an action mask was created which encoded common-sense dependencies. These are implemented as simple if-then rules based on the presence of entity values: for example, only allow an API call if pre-conditions are met; only offer a restaurant if database results have already been received; do not ask for an entity if it is already known; etc.

For Task6, we noticed that the system can say that no restaurants match the current query *without* consulting the database (for an example dialog, see Section A.3 in the Appendix). In a practical system this information would be retrieved from the database and not encoded in the RNN. So, we mined the training data and built a table of search queries known to yield no results. We also added context features that indicated the state of the database – for example, whether there were any restaurants matching the current query. The complete set of context features is given in Appendix Section A.4. Altogether this code consisted of about 250 lines of Python.

We then trained an HCN on the training set, employing the domain-specific software described above. We selected an LSTM for the recurrent layer (Hochreiter and Schmidhuber, 1997), with the AdaDelta optimizer (Zeiler, 2012). We used the development set to tune the number of hidden units (128), and the number of epochs (12). Utterance embeddings were formed by averaging word embeddings, using a publicly available 300-dimensional word embedding model trained using word2vec on web data (Mikolov et al., 2013).[4] The word embeddings were static and not updated during LSTM training. In training, each dialog formed one minibatch, and updates were done on full rollouts (i.e., non-truncated back propagation through time). The training loss was categorical cross-entropy. Further low-level implementation details are in the Appendix Section A.1.

We ran experiments with four variants of our model: with and without the utterance embeddings, and with and without the action mask (Figure 1, steps 3 and 6 respectively).

Following past work, we report average turn accuracy – i.e., for each turn in each dialog, present the (true) history of user and system actions to the network and obtain the network's prediction as a string of characters. The turn is correct if the string matches the reference exactly, and incorrect if not. We also report dialog accuracy, which indicates if all turns in a dialog are correct.

We compare to four past end-to-end approaches (Bordes and Weston, 2016; Liu and Perez, 2016; Eric and Manning, 2017; Seo et al., 2016). We emphasize that past approaches have applied purely sequence-to-sequence models, or (as a baseline) purely programmed rules (Bordes and Weston, 2016). By contrast, Hybrid Code Networks are a hybrid of hand-coded rules and learned models.

Results are shown in Table 1. Since Task5 is synthetic data generated using rules, it is possible to obtain perfect accuracy using rules (line 1). The addition of domain knowledge greatly simplifies the learning task and enables HCNs to also attain perfect accuracy. On Task6, rules alone fare poorly, whereas HCNs outperform past learned models.

We next examined learning curves, training with increasing numbers of dialogs. To guard against bias in the ordering of the training set, we averaged over 5 runs, randomly permuting the order of the training dialogs in each run. Results are in Figure 2. In Task5, the action mask and utterance embeddings substantially reduce the number of training dialogs required (note the horizontal axis scale is logarithmic). For Task6, the bene-

[3] A handful of actions in Task6 seemed spurious; for these, we replaced them with a special "UNK" action in the training set, and masked this action at test time.

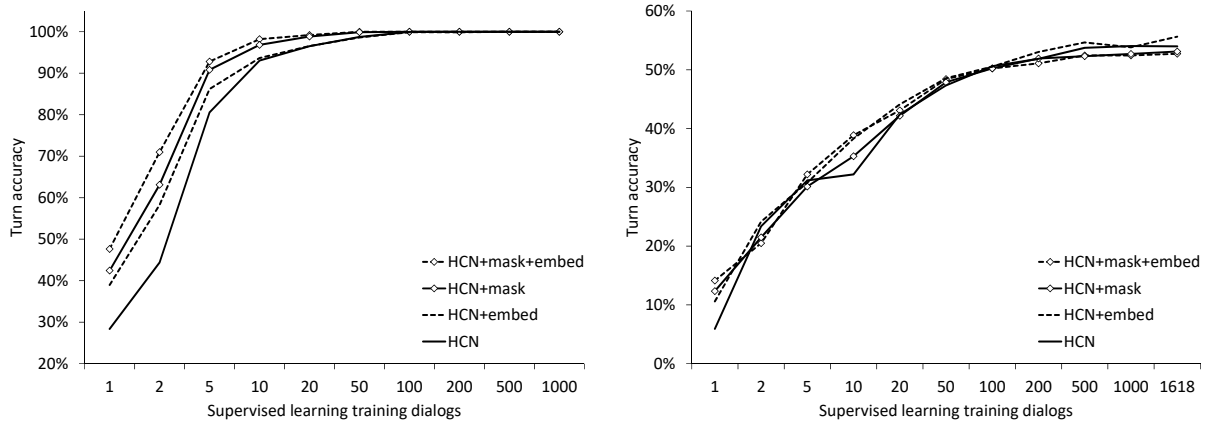
HCN+embed+mask	**100%**	**100%**	52.7%	1.5%

Table 1: Results on bAbI dialog Task5-OOV and Task6 (Bordes and Weston, 2016). Results for "Rules" taken from Bordes and Weston (2016). Note that, unlike cited past work, HCNs make use of domain-specific procedural knowledge.



(a) bAbI dialog Task5-OOV.

(b) bAbI dialog Task6.

Figure 2: Training dialog count vs. turn accuracy for bAbI dialog Task5-OOV and Task6. "embed" indicates whether utterance embeddings were included; "mask" indicates whether the action masking code was active.

fits of the utterance embeddings are less clear. An error analysis showed that there are several systematic differences between the training and testing sets. Indeed, DSTC2 intentionally used different dialog policies for the training and test sets, whereas our goal is to mimic the policy in the training set.

Nonetheless, these tasks are the best public benchmark we are aware of, and HCNs exceed performance of existing sequence-to-sequence models. In addition, they match performance of past models using an order of magnitude less data (200 vs. 1618 dialogs), which is crucial in practical settings where collecting realistic dialogs for a new domain can be expensive.

5 Supervised learning evaluation II

We now turn to comparing with purely hand-crafted approaches. To do this, we obtained logs from our company's text-based customer support dialog system, which uses a sophisticated rule-based dialog manager. Data from this system is attractive for evaluation because it is used by real customers – not usability subjects – and because its rule-based dialog manager was developed by customer support professionals at our company, and not the authors. This data is not publicly available, but we are unaware of suitable human-computer dialog data in the public domain which uses rules.

Customers start using the dialog system by entering a brief description of their problem, such

as "I need to update my operating system". They are then routed to one of several hundred domains, where each domain attempts to resolve a particular problem. In this study, we collected human-computer transcripts for the high-traffic domains "reset password" and "cannot access account".

We labeled the dialog data as follows. First, we enumerated unique system actions observed in the data. Then, for each dialog, starting from the beginning, we examined each system action, and determined whether it was "correct". Here, correct means that it was the most appropriate action among the set of existing system actions, given the history of that dialog. If multiple actions were arguably appropriate, we broke ties in favor of the existing rule-based dialog manager. Example dialogs are provided in the Appendix Sections A.5 and A.6.

If a system action was labeled as correct, we left it as-is and continued to the next system action. If the system action was not correct, we replaced it with the correct system action, and discarded the rest of the dialog, since we do not know how the user would have replied to this new system action. The resulting dataset contained a mixture of complete and partial dialogs, containing only correct system actions. We partitioned this set into training and test dialogs. Basic statistics of the data are shown in Table 2.

In this domain, no entities were relevant to the control flow, and there was no obvious mask logic since any question could follow any question. Therefore, we wrote no domain-specific software for this instance of the HCN, and relied purely on the recurrent neural network to drive the conversation. The architecture and training of the RNN was the same as in Section 4, except that here we did not have enough data for a validation set, so we instead trained until we either achieved 100% accuracy on the training set or reached 200 epochs.

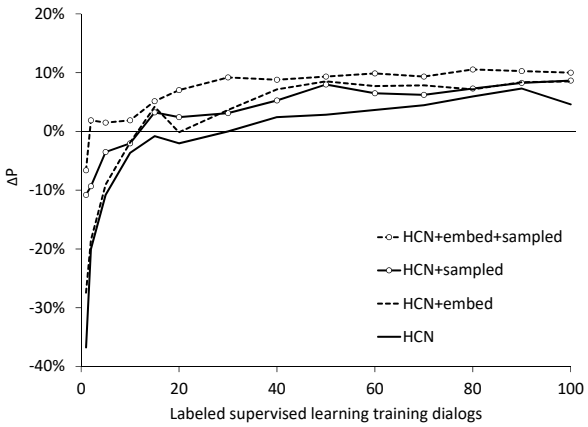
To evaluate, we observe that conventional measures like average dialog accuracy unfairly penalize the system used to collect the dialogs – in our case, the rule-based system. If the system used for collection makes an error at turn t, the labeled dialog only includes the sub-dialog up to turn t, and the system being evaluated off-line is only evaluated on that sub-dialog. In other words, in our case, reporting dialog accuracy would favor the HCN because it would be evaluated on fewer turns than the rule-based system. We therefore use a comparative measure that examines which method produces longer continuous sequences of correct system actions, starting from the beginning of the dialog. Specifically, we report $\Delta P = \frac{C(\text{HCN-win}) - C(\text{rule-win})}{C(\text{all})}$, where $C(\text{HCN-win})$ is the number of test dialogs where the rule-based approach output a wrong action before the HCN; $C(\text{rule-win})$ is the number of test dialogs where the HCN output a wrong action before the rule-based approach; and $C(\text{all})$ is the number of dialogs in the test set. When $\Delta P > 0$, there are more dialogs in which HCNs produce longer continuous sequences of correct actions starting from the beginning of the dialog. We run all experiments 5 times, each time shuffling the order of the training set. Results are in Figure 3. HCNs exceed performance of the existing rule-based system after about 30 dialogs.

	Forgot password	Account Access
Av. sys. turns/dialog	2.2	2.2
Max. sys. turns/dialog	5	9
Av. words/user turn	7.7	5.4
Unique sys. actions	7	16
Train dialogs	422	56
Test dialogs	148	60
Test acc. (rules)	64.9%	42.1%

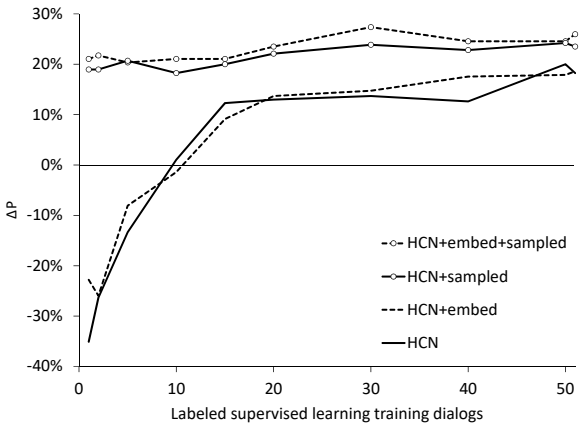
Table 2: Basic statistics of labeled customer support dialogs. Test accuracy refers to whole-dialog accuracy of the existing rule-based system.

In these domains, we have a further source of knowledge: the rule-based dialog managers themselves can be used to generate example "sunny-day" dialogs, where the user provides purely expected inputs. From each rule-based controller, synthetic dialogs were sampled to cover each expected user response at least once, and added to the set of labeled real dialogs. This resulted in 75 dialogs for the "Forgot password" domain, and 325 for the "Can't access account" domain. Training was repeated as described above. Results are also included in Figure 3, with the suffix "sampled". In the "Can't access account" domain, the sampled dialogs yield a large improvement, probably because the flow chart for this domain is large, so the sampled dialogs increase coverage. The gain in the "forgot password" domain is present but smaller.

In summary, HCNs can out-perform



(a) "Forgot password" domain.



(b) "Can't access account" domain.

Figure 3: Training dialogs vs. ΔP, where ΔP is the fraction of test dialogs where HCNs produced longer initial correct sequences of system actions than the rules, minus the fraction where rules produced longer initial correct sequences than the HCNs. "embed" indicates whether utterance embeddings were included; "sampled" indicates whether dialogs sampled from the rule-based controller were included in the training set.

production-grade rule-based systems with a reasonable number of labeled dialogs, and adding synthetic "sunny-day" dialogs improves performance further. Moreover, unlike existing pipelined approaches to dialog management that rely on an explicit state tracker, this HCN used no explicit state tracker, highlighting an advantage of the model.

6 Reinforcement learning illustration

In the previous sections, supervised learning (SL) was applied to train the LSTM to mimic dialogs provided by the system developer. Once a system operates at scale, interacting with a large number of users, it is desirable for the system to continue to learn *autonomously* using reinforcement learning (RL). With RL, each turn receives a measurement of goodness called a *reward*; the agent explores different sequences of actions in different situations, and makes adjustments so as to maximize the expected discounted sum of rewards, which is called the *return*, denoted G.

For optimization, we selected a *policy gradient* approach (Williams, 1992), which has been successfully applied to dialog systems (Jurčíček et al., 2011), robotics (Kohl and Stone, 2004), and the board game Go (Silver et al., 2016). In policy gradient-based RL, a model π is parameterized by $\mathbf{w}$ and outputs a distribution from which actions are sampled at each timestep. At the end of a trajectory – in our case, dialog – the return G for that trajectory is computed, and the gradients of the probabilities of the actions taken with respect to the model weights are computed. The weights are then adjusted by taking a gradient step proportional to the return:

$$\mathbf{w} \leftarrow \mathbf{w} + \alpha \Big(\sum_t \nabla_{\mathbf{w}} \log \pi(a_t|\mathbf{h_t}; \mathbf{w})\Big)(G - b) \quad (1)$$

where α is a learning rate; a_t is the action taken at timestep t; $\mathbf{h_t}$ is the dialog history at time t; G is the return of the dialog; $\nabla_{\mathbf{x}} F$ denotes the Jacobian of F with respect to $\mathbf{x}$; b is a baseline described below; and $\pi(a|\mathbf{h}; \mathbf{w})$ is the LSTM – i.e., a stochastic policy which outputs a distribution over a given a dialog history $\mathbf{h}$, parameterized by weights $\mathbf{w}$. The baseline b is an estimate of the average return of the current policy, estimated on the last 100 dialogs using weighted importance sampling.[5] Intuitively, "better" dialogs receive a positive gradient step, making the actions selected more likely; and "worse" dialogs receive a negative gradient step, making the actions selected less likely.

SL and RL correspond to different methods of updating weights, so both can be applied to the same network. However, there is no guarantee that the optimal RL policy will agree with the SL training set; therefore, after each RL gradient step, we

[5]The choice of baseline does not affect the long-term convergence of the algorithm (i.e., the bias), but can dramatically affect the speed of convergence (i.e., the variance) (Williams, 1992).

check whether the updated policy reconstructs the training set. If not, we re-run SL gradient steps on the training set until the model reproduces the training set. Note that this approach allows new training dialogs to be added at any time during RL optimization.

We illustrate RL optimization on a simulated dialog task in the name dialing domain. In this system, a contact's name may have synonyms ("Michael" may also be called "Mike"), and a contact may have more than one phone number, such as "work" or "mobile", which may in turn have synonyms like "cell" for "mobile". This domain has a database of names and phone numbers taken from the Microsoft personnel directory, 5 entity types – `firstname`, `nickname`, `lastname`, `phonenumber`, and `phonetype` – and 14 actions, including 2 API call actions. Simple entity logic was coded, which retains the most recent copy of recognized entities. A simple action mask suppresses impossible actions, such as placing a phonecall before a phone number has been retrieved from the database. Example dialogs are provided in Appendix Section A.7.

To perform optimization, we created a simulated user. At the start of a dialog, the simulated user randomly selected a name and phone type, including names and phone types not covered by the dialog system. When speaking, the simulated user can use the canonical name or a nickname; usually answers questions but can ignore the system; can provide additional information not requested; and can give up. The simulated user was parameterized by around 10 probabilities, set by hand.

We defined the reward as being 1 for successfully completing the task, and 0 otherwise. A discount of 0.95 was used to incentivize the system to complete dialogs faster rather than slower, yielding return 0 for failed dialogs, and $G = 0.95^{T-1}$ for successful dialogs, where T is the number of system turns in the dialog. Finally, we created a set of 21 labeled dialogs, which will be used for supervised learning.

For the RNN in the HCN, we again used an LSTM with AdaDelta, this time with 32 hidden units. RL policy updates are made after each dialog. Since a simulated user was employed, we did not have real user utterances, and instead relied on context features, omitting bag-of-words and utterance embedding features.

We first evaluate RL by randomly initializing an LSTM, and begin RL optimization. After 10 RL updates, we freeze the policy, and run 500 dialogs with the user simulation to measure task completion. We repeat all of this for 100 runs, and report average performance. In addition, we also report results by initializing the LSTM using supervised learning on the training set, consisting of 1, 2, 5, or 10 dialogs sampled randomly from the training set, then running RL as described above.

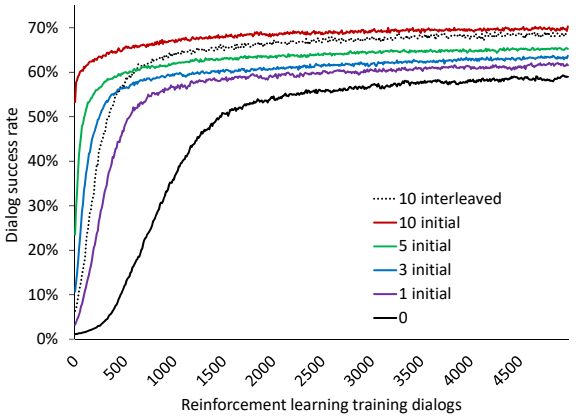


Figure 4: Dialog success rate vs. reinforcement learning training dialogs. Curve marked "0" begins with a randomly initialized LSTM. Curves marked "N initial" are pre-trained with N labeled dialogs. Curve marked "10, interleaved" adds one SL training dialog before RL dialog 0, 100, 200, ... 900.

Results are in Figure 4. Although RL alone can find a good policy, pre-training with just a handful of labeled dialogs improves learning speed dramatically. Additional experiments, not shown for space, found that ablating the action mask slowed training, agreeing with Williams (2008).

Finally, we conduct a further experiment where we sample 10 training dialogs, then add one to the training set just before RL dialog 0, 100, 200, ... , 900. Results are shown in Figure 4. This shows that SL dialogs can be introduced as RL is in progress – i.e., that it is possible to interleave RL and SL. This is an attractive property for practical systems: if a dialog error is spotted by a developer while RL is in progress, it is natural to add a training dialog to the training set.

7 Conclusion

This paper has introduced Hybrid Code Networks for end-to-end learning of task-oriented dialog

systems. HCNs support a separation of concerns where procedural knowledge and constraints can be expressed in software, and the control flow is learned. Compared to existing end-to-end approaches, HCNs afford more developer control and require less training data, at the expense of a small amount of developer effort.

Results in this paper have explored three different dialog domains. On a public benchmark in the restaurants domain, HCNs exceeded performance of purely learned models. Results in two troubleshooting domains exceeded performance of a commercially deployed rule-based system. Finally, in a name-dialing domain, results from dialog simulation show that HCNs can also be optimized with a mixture of reinforcement and supervised learning.

In future work, we plan to extend HCNs by incorporating lines of existing work, such as integrating the entity extraction step into the neural network (Dhingra et al., 2017), adding richer utterance embeddings (Socher et al., 2013), and supporting text generation (Sordoni et al., 2015). We will also explore using HCNs with automatic speech recognition (ASR) input, for example by forming features from n-grams of the ASR n-best results (Henderson et al., 2014b). Of course, we also plan to deploy the model in a live dialog system. More broadly, HCNs are a general model for stateful control, and we would be interested to explore applications beyond dialog systems – for example, in NLP medical settings or human-robot NL interaction tasks, providing domain constraints are important for safety; and in resource-poor settings, providing domain knowledge can amplify limited data.

A Supplemental Material

A.1 Model implementation details

The RNN was specified using Keras version 0.3.3, with back-end computation in Theano version 0.8.0.dev0 (Theano Development Team, 2016; Chollet, 2015). The Keras model specification is given below. The input variable `obs` includes all features from Figure 1 step 6 except for the previous action (step 18) and the action mask (step 6, top-most vector).

```
# Given:
# obs_size, action_size, nb_hidden

g = Graph()
g.add_input(
  name='obs',
  input_shape=(None, obs_size)
)
g.add_input(
  name='prev_action',
  input_shape=(None, action_size)
)
g.add_input(
  name='avail_actions',
  input_shape=(None, action_size)
)
g.add_node(
  LSTM(
    n_hidden,
    return_sequences=True,
    activation='tanh',
  ),
  name='h1',

no
Oh, sorry about that. Goodbye.

Generating Contrastive Referring Expressions

Martín Villalba and **Christoph Teichmann** and **Alexander Koller**
Department of Language Science and Technology
Saarland University, Germany
{villalba|cteichmann|koller}@coli.uni-saarland.de

Abstract

The referring expressions (REs) produced by a natural language generation (NLG) system can be misunderstood by the hearer, even when they are semantically correct. In an interactive setting, the NLG system can try to recognize such misunderstandings and correct them. We present an algorithm for generating corrective REs that use contrastive focus ("no, the BLUE button") to emphasize the information the hearer most likely misunderstood. We show empirically that these contrastive REs are preferred over REs without contrast marking.

1 Introduction

Interactive natural language generation (NLG) systems face the task of detecting when they have been misunderstood, and reacting appropriately to fix the problem. For instance, even when the system generated a semantically correct referring expression (RE), the user may still misunderstand it, i.e. resolve it to a different object from the one the system intended. In an interactive setting, such as a dialogue system or a pedestrian navigation system, the system can try to detect such misunderstandings – e.g. by predicting what the hearer understood from their behavior (Engonopoulos et al., 2013) – and to produce further utterances which resolve the misunderstanding and get the hearer to identify the intended object after all.

When humans correct their own REs, they routinely employ *contrastive focus* (Rooth, 1992; Krifka, 2008) to clarify the relationship to the original RE. Say that we originally described an object b as "the blue button", but the hearer approaches a button b' which is green, thus providing evidence that they misunderstood the RE to mean b'. In this case, we would like to say "no, the BLUE button", with the contrastive focus realized by an appropriate pitch accent on "BLUE". This utterance alerts the hearer to the fact that they misunderstood the original RE; it reiterates the information from the original RE; and it marks the attribute "blue" as a salient difference between b' and the object the original RE was intended to describe.

In this paper, we describe an algorithm for generating REs with contrastive focus. We start from the modeling assumption that misunderstandings arise because the RE r_s the system uttered was corrupted by a noisy channel into an RE r_u which the user "heard" and then resolved correctly; in the example above, we assume the user literally heard "the green button". We compute this (hypothetical) RE r_u as the RE which refers to b' and has the lowest edit distance from r_s. Based on this, we mark the contrastive words in r_s, i.e. we transform "the blue button" into "the BLUE button". We evaluate our system empirically on REs from the GIVE Challenge (Koller et al., 2010) and the TUNA Challenge (van der Sluis et al., 2007), and show that the contrastive REs generated by our system are preferred over a number of baselines.

The paper is structured as follows. We first review related work in Section 2 and define the problem of generating contrastive REs in Section 3. Section 4 sketches the general architecture for RE generation on which our system is based. In Section 5, we present the corruption model and show how to use it to reconstruct r_u. Section 6 describes how we use this information to generate contrastive markup in r_s, and in Section 7 we evaluate our approach.

2 Related Work

The notion of focus has been extensively studied in the literature on theoretical semantics and prag-

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 678–687
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1063

matics, see e.g. Krifka (2008) and Rooth (1997) for overview papers. Krifka follows Rooth (1992) in taking focus as "indicat(ing) the presence of *alternatives* that are relevant for the interpretation of linguistic expressions"; focus then establishes a contrast between an object and these alternatives. Bornkessel and Schlesewsky (2006) find that corrective focus can even override syntactic requirements, on the basis of "its extraordinarily high communicative saliency". This literature is purely theoretical; we offer an algorithm for automatically generating contrastive focus.

In speech, focus is typically marked through intonation and pitch accents (Levelt, 1993; Pierrehumbert and Hirschberg, 1990; Steube, 2001), while concepts that can be taken for granted are deaccented and/or deleted. Developing systems which realize precise pitch contours for focus in text-to-speech settings is an ongoing research effort. We therefore realize focus in written language in this paper, by capitalizing the focused word. We also experiment with deletion of background words.

There is substantial previous work on interactive systems that detect and respond to misunderstandings. Misu et al. (2014) present an error analysis of an in-car dialogue system which shows that more than half the errors can only be resolved through further clarification dialogues, as opposed to better sensors and/or databases; that is, by improved handling of misunderstandings. Engonopoulos et al. (2013) detect misunderstandings of REs in interactive NLG through the use of a statistical model. Their model also predicts the object to which a misunderstood RE was incorrectly resolved. Moving from misunderstanding detection to error correction, Zarrieß and Schlangen (2016) present an interactive NLG algorithm which is capable of referring in installments, in that it can generate multiple REs that are designed to correct misunderstandings of earlier REs to the same object. The interactive NLG system developed by Akkersdijk et al. (2011) generates both reflective and anticipative feedback based on what a user does and sees. Their error detection and correction strategy distinguishes a fixed set of possible situations where feedback is necessary, and defines custom, hard-coded RE generation sub-strategies for each one. None of these systems generate REs marked for focus.

We are aware of two items of previous work that address the generation of contrastive REs directly. Milosavljevic and Dale (1996) outline strategies for generating clarificatory comparisons in encyclopedic descriptions. Their surface realizer can generate contrastive REs, but the attributes that receive contrastive focus have to be specified by hand. Krahmer and Theune (2002) extend the Incremental Algorithm (Dale and Reiter, 1995) so it can mark attributes as contrastive. This is a fully automatic algorithm for contrastive REs, but it inherits all the limitations of the Incremental Algorithm, such as its reliance on a fixed attribute order. Neither of these two approaches evaluates the quality of the contrastive REs it generates.

Finally, some work has addressed the issue of generating texts that realize the discourse relation *contrast*. For instance, Howcroft et al. (2013) show how to choose contrastive discourse connectives (*but, while,* ...) when generating restaurant descriptions, thus increasing human ratings for naturalness. Unlike their work, the research presented in this paper is not about discourse relations, but about assigning focus in contrastive REs.

3 Interactive NLG

We start by introducing the problem of generating corrective REs in an interactive NLG setting. We use examples from the GIVE Challenge (Koller et al., 2010) throughout the paper; however, the algorithm itself is domain-independent.

GIVE is a shared task in which an NLG system (the instruction giver, IG) must guide a human user (the instruction follower, IF) through a virtual 3D environment. The IF needs to open a safe and steal a trophy by clicking on a number of buttons in the right order without triggering alarms. The job of the NLG system is to generate natural-language instructions which guide the IF to complete this task successfully.

The generation of REs has a central place in the GIVE Challenge because the system frequently needs to identify buttons in the virtual environment to the IF. Figure 1 shows a screenshot of a GIVE game in progress; here b_1 and b_4 are blue buttons, b_2 and b_3 are yellow buttons, and w_1 is a window. If the next button the IF needs to press is b_4 – the *intended object*, o_s – then one good RE for b_4 would be "the blue button below the window", and the system should utter:

(1) Press the blue button below the window.

After uttering this sentence, the system can

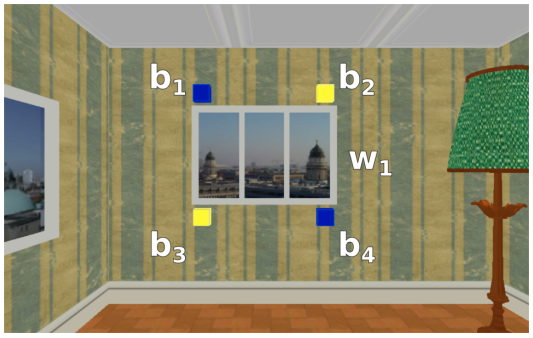

Figure 1: Example scene from the GIVE Challenge.

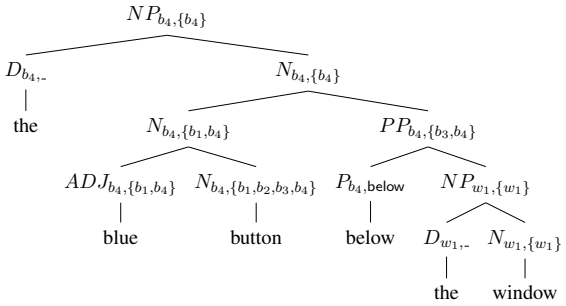

Figure 2: Example syntax tree for an RE for b_4.

track the IF's behavior to see whether the IF has understood the RE correctly. If the wrong button is pressed, or if a model of IF's behavior suggests that they are about to press the wrong button (Engonopoulos et al., 2013), the original RE has been misunderstood. However, the system still gets a second chance, since it can utter a *corrective* RE, with the goal of identifying b_4 to the IF after all. Examples include simply repeating the original RE, or generating a completely new RE from scratch. The system can also explicitly take into account which part of the original RE the IF misunderstood. If it has reason to believe that the IF resolved the RE to b_3, it could say:

(2) No, the BLUE button below the window.

This use of contrastive focus distinguishes the attributes the IF misunderstood (blue) from those that they understood correctly (below the window), and thus makes it easier for the IF to resolve the misunderstanding. In speech, contrastive focus would be realized with a pitch accent; we approximate this accent in written language by capitalizing the focused word. We call an RE that uses contrastive focus to highlight the difference between the misunderstood and the intended object, a *contrastive RE*. The aim of this paper is to present an algorithm for computing contrastive REs.

4 Generating Referring Expressions

While we make no assumptions on how the original RE r_s was generated, our algorithm for reconstructing the corrupted RE r_u requires an RE generation algorithm that can represent all semantically correct REs for a given object compactly in a chart. Here we sketch the RE generation of Engonopoulos and Koller (2014), which satisfies this requirement.

This algorithm assumes a synchronous grammar which relates strings with the sets of objects they refer to. Strings and their referent sets are constructed in parallel from lexicon entries and grammar rules; each grammar rule specifies how the referent set of the parent is determined from those of the children. For the scene in Figure 1, we assume lexicon entries which express, among other things, that the word "blue" denotes the set $\{b_1, b_4\}$ and the word "below" denotes the relation $\{(w_1, b_1), (w_1, b_2), (b_3, w_1), (b_4, w_1)\}$. We combine these lexicons entries using rules such as

$$\text{"N} \rightarrow \text{button() } | \text{button } | \{b_1, b_2, b_3, b_4\}\text{"}$$

which generates the string "button" and associates it with the set of all buttons or

$$\text{"N} \rightarrow \text{N1(N,PP) } | w_1 \bullet w_2 \; | R_1 \cap R_2\text{"}$$

which states that a phrase of type noun can be combined with a prepositional phrase and their denotations will be intersected. Using these rules we can determine that "the window" denotes $\{w_1\}$, that "below the window" can refer to $\{b_3, b_4\}$ and that "blue button below the window" uniquely refers to $\{b_4\}$. The syntax tree in Fig. 2 represents a complete derivation of an RE for $\{b_4\}$.

The algorithm of Engonopoulos and Koller computes a chart which represents the set of all possible REs for a given set of input objects, such as $\{b_4\}$, according to the grammar. This is done by building a chart containing all derivations of the grammar which correspond to the desired set. They represent this chart as a finite tree automaton (Comon et al., 2007). Here we simply write the chart as a Context-Free Grammar. The strings produced by this Context-Free Grammar are then exactly the REs for the intended object. For example, the syntax tree in Fig. 2 is generated by the parse chart for the set $\{b_4\}$. Its nonterminal symbols consist of three parts: a syntactic category

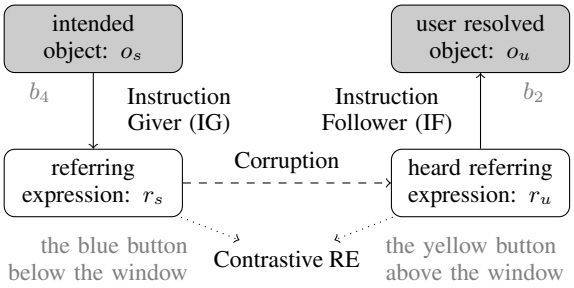

Figure 3: The corruption model.

(given by the synchronous grammar), the referent for which an RE is currently being constructed, and the set of objects to which the entire subtree refers. The grammar may include recursion and therefore allow for an infinite set of possible REs. If it is weighted, one can use the Viterbi algorithm to compute the best RE from the chart.

5 Listener Hypotheses and Edit Distance

5.1 Corruption model

Now let us say that the system has generated and uttered an RE r_s with the intention of referring to the object o_s, but it has then found that the IF has misunderstood the RE and resolved it to another object, o_u (see Fig. 3). We assume for the purposes of this paper that such a misunderstanding arises because r_s was corrupted by a noisy channel when it was transmitted to the IF, and the IF "heard" a different RE, r_u. We further assume that the IF then resolved r_u correctly, i.e. the corruption in the transmission is the only source of misunderstandings.

In reality, there are of course many other reasons why the IF might misunderstand r_s, such as lack of attention, discrepancies in the lexicon or the world model of the IG and IF, and so on. We make a simplifying assumption in order to make the misunderstanding explicit at the level of the RE strings, while still permitting meaningful corrections for a large class of misunderstandings.

An NLG system that builds upon this idea in order to generate a corrective RE has access to the values of o_s, r_s and o_u; but it needs to infer the most likely corrupted RE r_u. To do this, we model the corruption using the edit operations used for the familiar *Levenshtein edit distance* (Mohri, 2003) over the alphabet Σ: S_a, substitution of a word with a symbol $a \in \Sigma$; D, deletion of a word; I_a, insertion of the symbol $a \in \Sigma$; or K, keeping the word. The noisy channel passes over each word in r_s and applies either D, K or one of the S operations to it. It may also apply I operations before or after a word. We call any sequence s of edit operations that could apply to r_s an *edit sequence for* r_s.

An example for an edit sequence which corrupts r_s = "the blue button below the window" into r_u = "the yellow button above the window" is shown in Figure 4. The same r_u could also have been generated by the edit operation sequence $K\, S_{\text{yellow}}\, K\, S_{\text{above}}\, K\, K$, and there is generally a large number of edit sequences that could transform between any two REs. If an edit sequence s maps x to y, we write $\text{apply}(s, x) = y$.

We can now define a probability distribution $P(s \mid r_s)$ over edit sequences s that the noisy channel might apply to the string r_s, as follows:

$$P(s \mid r_s) = \frac{1}{Z} \prod_{s_i \in s} \exp(-c(s_i)),$$

where $c(s_i)$ is a cost for using the edit operation s_i. We set $c(K) = 0$, and for any a in our alphabet we set $c(S_a) = c(I_a) = c(D) = \mathcal{C}$, for some fixed $\mathcal{C} > 0$. Z is a normalizing constant which is independent of s and ensures that the probabilities sum to 1. It is finite for sufficiently high values of $\mathcal{C}$, because no sequence for r_s can ever contain more K, S and D operations than there are words in r_s, and the total weight of sequences generated by adding more and more I operations will converge.

Finally, let L be the set of referring expressions that the IF would resolve to o_u, i.e. the set of candidates for r_u. Then the most probable edit sequence for r_s which generates an $r_u \in L$ is given by

$$\begin{aligned} s^* &= \underset{s\,:\,\text{apply}(s,r_s)\in L}{\arg\max} P(s \mid r_s) \\ &= \arg\min_s \textstyle\sum_{s_i \in s} c(s_i), \end{aligned}$$

i.e. s^* is the edit sequence that maps r_s to an RE in L with minimal cost. We will assume that s^* is the edit sequence that corrupted r_s, i.e. that $r_u = \text{apply}(s^*, r_s)$.

5.2 Finding the most likely corruption

It remains to compute s^*; we will then show in Section 6 how it can be used to generate a corrective RE. Attempting to find s^* by enumeration is impractical, as the set of edit sequences for a given r_s and r_u may be large and the set of possible r_u for a given o_u may be infinite. Instead

r_s	the	blue		button	below	the	window
edit operation sequence	K	D	I_{yellow}	K	S_{above}	K	K
r_u	the		yellow	button	above	the	window

Figure 4: Example edit sequence for a given corruption.

we will use the algorithm from Section 4 to compute a chart for all the possible REs for o_u, represented as a context-free grammar G whose language $L = L(G)$ consists of these REs. We will then intersect it with a finite-state automaton which keeps track of the edit costs, obtaining a second context-free grammar G'. These operations can be performed efficiently, and s^* can be read off of the minimum-cost syntax tree of G'.

Edit automaton. The possible edit sequences for a given r_s can be represented compactly in the form of a weighted finite-state automaton $F(r_s)$ (Mohri, 2003). Each run of the automaton on a string w corresponds to a specific edit sequence that transforms r_s into w, and the sum of transition weights of the run is the cost of that edit sequence. We call $F(r_s)$ the *edit automaton*. It has a state q_i for every position i in r_s; the start state is q_0 and the final state is $q_{|r_s|}$. For each i, it has a "keep" transition from q_i to q_{i+1} that reads the word at position i with cost 0. In addition, there are transitions from q_i to q_{i+1} with cost $\mathcal{C}$ that read any symbol in Σ (for substitution) and ones that read the empty string ϵ (for deletion). Finally, there is a loop with cost $\mathcal{C}$ from each q_i to itself and for any symbol in Σ, implementing insertion.

An example automaton for r_s = "the blue button below the window" is shown in Figure 5. The transitions are written in the form $\langle$word in w : associated cost$\rangle$. Note that every path through the edit transducer corresponds to a specific edit sequence s, and the sum of the costs along the path corresponds to $-\log P(s \mid r_s) - \log Z$.

Combining G and $F(r_s)$. Now we can combine G with $F(r_s)$ to obtain G', by intersecting them using the Bar-Hillel construction (Bar-Hillel et al., 1961; Hopcroft and Ullman, 1979). For the purposes of our presentation we assume that G is in Chomsky Normal Form, i.e. all rules have the form $A \to a$, where a is a word, or $A \to B\ C$, where both symbols on the right hand side are nonterminals. The resulting grammar G' uses nonterminal symbols of the form $N_{b,A,\langle q_i,q_k\rangle}$, where b, A are as in Section 4, and q_i, q_k indicate that the string derived by this nonterminal was generated by editing the substring of r_s from position i to k.

Let $N_{b,A} \to a$ be a production rule of G with a word a on the right-hand side; as explained above, b is the object to which the subtree should refer, and A is the set of objects to which the subtree actually might refer. Let $t = q_i \to \langle a{:}c\rangle q_k$ be a transition in $F(r_s)$, where q, q' are states of $F(r_s)$ and c is the edit cost. From these two, we create a context-free rule $N_{b,A,\langle q_i,q_k\rangle} \to a$ with weight c and add it to G'. If $k = i + 1$, these rules represent K and S operations; if $k = i$, they represent insertions.

Now let $N_{b,A} \to X_{b_1,A_1}\, Y_{b_2,A_2}$ be a binary rule in G, and let q_i, q_j, q_k be states of $F(r_s)$ with $i \le j \le k$. We then add a rule $N_{b,A,\langle q_i,q_k\rangle} \to X_{b_1,A_1,\langle q_i,q_j\rangle}\, Y_{b_2,A_2,\langle q_j,q_k\rangle}$ to G'. These rules are assigned weight 0, as they only combine words according to the grammar structure of G and do not encode any edit operations.

Finally, we deal with deletion. Let $N_{b,A}$ be a nonterminal symbol in G and let q_h, q_i, q_j, q_k be states of $F(r_s)$ with $h \le i \le j \le k$. We then add a rule $N_{b,A,\langle q_h,q_k\rangle} \to N_{b,A,\langle q_i,q_j\rangle}$ to G'. This rule deletes the substrings from positions h to i and j to k from r_s; thus we assign it the cost $((i-h)+(k-j))\mathcal{C}$, i.e. the cost of the corresponding ϵ transitions.

If the start symbol of G is $S_{b,A}$, then the start symbol of G' is $S_{b,A,\langle q_0,q_{|r_s|}\rangle}$. This construction intersects the languages of G and $F(r_s)$, but because $F(r_s)$ accepts all strings over the alphabet, the languages of G' and G will be the same (namely, all REs for o_u). However, the weights in G' are inherited from $F(r_s)$; thus the weight of each RE in $L(G')$ is the edit cost from r_s.

Example. Fig. 6 shows an example tree for the G' we obtain from the automaton in Fig. 5. We can read the string w = "the yellow button above the window" off of the leaves; by construction, this is an RE for o_u. Furthermore, we can reconstruct the edit sequence that maps from r_s to w from the rules of G' that

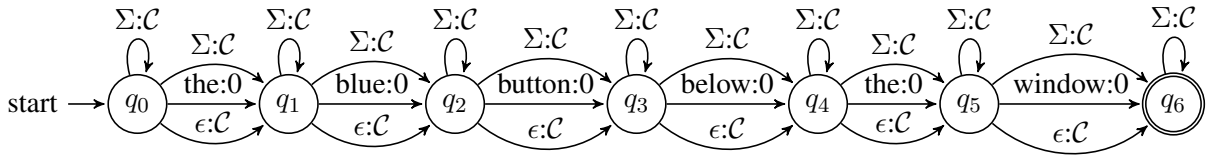

Figure 5: Edit automaton $F(r_s)$ for $r_s =$ "the blue button below the window".

Tree	s	$K\ D\ I_{\text{yellow}}\ K\ S_{\text{above}}\ K\ K$
Emphasis	No, press the BLUE button BELOW the window

Figure 6: A syntax tree described by G', together with its associated edit sequence and contrastive RE.

were used to derive w. We can see that "yellow" was created by an insertion because the two states of $F(r_s)$ in the preterminal symbol just above it are the same. If the two states are different, then the word was either substituted ("above", if the rule had weight $\mathcal{C}$) or kept ("the", if the rule had weight 0). By contrast, unary rules indicate deletions, in that they make "progress" in r_s without adding new words to w.

We can compute the minimal-cost tree of G' using the Viterbi algorithm. Thus, to summarize, we can calculate s^* from the intersection of a context-free grammar G representing the REs to o_u with the automaton $F(r_s)$ representing the edit distance to r_s. From this, we obtain $r_u = \text{apply}(s^*, r_s)$. This is efficient in practice.

6 Generating Contrastive REs

6.1 Contrastive focus

We are now ready to generate a contrastive RE from r_s and s^*. We assign focus to the words in r_s which were changed by the corruption – that is, the ones to which s^* applied Substitute or Delete operations. For instance, the edit sequence in Fig. 6 deleted "blue" and substituted "below" with "above". Thus, we mark these words with focus, and obtain the contrastive RE "the BLUE button BELOW the window". We call this strategy *Emphasis*, and write ${r_s}^E$ for the RE obtained by applying the Emphasis strategy to the RE r_s.

6.2 Shortening

We also investigate a second strategy, which generates more succinct contrastive REs than the *Emphasis* strategy. Most research on RE generation (e.g. Dale and Reiter (1995)) has assumed that hearers should prefer succinct REs, which in particular do not violate the Maxim of Quantity (Grice, 1975). When we utter a contrastive RE, the user has previously heard the RE r_s, so some of the information in ${r_s}^E$ is redundant. Thus we might obtain a more succinct, and possibly better, RE by dropping such redundant information from the RE.

For the grammars we consider here, ${r_s}^E$ often combines an NP and a PP, e.g. "[blue button]$_{NP}$ [below the window]$_{PP}$". If errors occur only in one of these constituents, then it might be sufficient to generate a contrastive RE using only that constituent. We call this strategy *Shortening* and define it as follows.

If all the words that are emphasized in ${r_s}^E$ are in the NP, the Shortening RE is "the" plus the NP, with emphasis as in ${r_s}^E$. So if r_s is "the [blue button] [above the window]" and $s^* = K\ S_{yellow}\ K\ K\ K\ K$, corresponding to a ${r_s}^E$ of "the [BLUE button] [above the window]", then the RE would be "the [BLUE button]".

If all the emphasis in ${r_s}^E$ is in the PP, we use

We wanted our player to select this button:

So we told them: *press the red button to the right of the blue button*.
But they selected this button instead:

Which correction is better for this scene?

- ○ No, press the red **BUTTON** to the right of the **BLUE BUTTON**
- ○ No, press the red button to the **RIGHT** of the blue button

Figure 7: A sample scene from Experiment 1.

We wanted our player to select the person circled in green:

So we told them: *the light haired old man in a suit looking straight*.

But they selected the person circled in red instead.
Which correction is better for this scene?

- ○ No, the light haired old man **IN A SUIT LOOKING STRAIGHT**
- ○ No, the **LIGHT HAIRED OLD** man in a suit looking straight

Figure 8: A sample scene from Experiment 2.

"the one" plus the PP and again capitalize as in ${r_s}^E$. So if we have $s^* = K\,K\,K\,S_{below}\,K\,K$, where ${r_s}^E$ is "the [blue button] [ABOVE the window]", we obtain "the one [ABOVE the window]." If there is no PP or if ${r_s}^E$ emphasizes words in both the NP and the PP, then we just use ${r_s}^E$.

7 Evaluation

To test whether our algorithm for contrastive REs assigns contrastive focus correctly, we evaluated it against several baselines in crowdsourced pairwise comparison overhearer experiments. Like Buß et al. (2010), we opted for an overhearer experiment to focus our evaluation on the effects of contrastive feedback, as opposed to the challenges presented by the navigational and timing aspects of a fully interactive system.

7.1 Domains and stimuli

We created the stimuli for our experiments from two different domains. We performed a first experiment with scenes from the GIVE Challenge, while a second experiment replaced these scenes with stimuli from the "People" domain of the TUNA Reference Corpus (van der Sluis et al., 2007). This corpus consists of photographs of men annotated with nine attributes, such as whether the person has a beard, a tie, or is looking straight. Six of these attributes were included in the corpus to better reflect human RE generation strategies. Many human-generated REs in the corpus are overspecific, in that they contain attributes that are not necessary to make the RE semantically unique.

We chose the GIVE environment in order to test REs referring both to attributes of an object, i.e. color, and to its spatial relation to other visible objects in the scene. The TUNA Corpus was chosen as a more challenging domain, due to the greater number of available properties for each object on a scene.

Each experimental subject was presented with screenshots containing a marked object and an RE. Subjects were told that we had previously referred to the marked object with the given RE, but an (imaginary) player misunderstood this RE and selected a different object, shown in a second screenshot. They were then asked to select which one of two corrections they considered better, where "better" was intentionally left unspecific. Figs. 7 and 8 show examples for each domain. The full set of stimuli is available as supplementary material.

To maintain annotation quality in our crowdsourcing setting, we designed test items with a

clearly incorrect answer, such as REs referring to the wrong target or a nonexistent one. These test items were randomly interspersed with the real stimuli, and only subjects with a perfect score on the test items were taken into account. Experimental subjects were asked to rate up to 12 comparisons, shown in groups of 3 scenes at a time, and were automatically disqualified if they evaluated any individual scene in less than 10 seconds. The order in which the pairs of strategies were shown was randomized, to avoid effects related to the order in which they were presented on screen.

7.2 Experiment 1

Our first experiment tested four strategies against each other. Each experimental subject was presented with two screenshots of 3D scenes with a marked object and an RE (see Fig. 7 for an example). Each subject was shown a total of 12 scenes, selected at random from 16 test scenes. We collected 10 judgments for each possible combination of GIVE scene and pair of strategies, yielding a total of 943 judgements from 142 subjects after removing fake answers.

We compared the *Emphasis* and *Shortening* strategies from Section 6 against two baselines. The *Repeat* strategy simply presented r_s as a "contrastive" RE, without any capitalization. Comparisons to *Repeat* test the hypothesis that subjects prefer explicit contrastive focus. The *Random* strategy randomly capitalized adjectives, adverbs, and/or prepositions that were not capitalized by the *Emphasis* strategy. Comparisons to *Random* verify that any preference for *Emphasis* is not only due to the presence of contrastive focus, but also because our method identifies precisely where that focus should be.

Table 1a shows the results of all pairwise comparisons. For each row strategy $Strat_R$ and each column strategy $Strat_C$, the table value corresponds to

$$\frac{(\#Strat_R \text{ pref. over } Strat_C) - (\#Strat_C \text{ pref. over } Strat_R)}{(\#\text{ tests between } Strat_R \text{ and } Strat_C)}$$

Significance levels are taken from a two-tailed binomial test over the counts of preferences for each strategy. We find a significant preference for the *Emphasis* strategy over all others, providing evidence that our algorithm assigns contrastive focus to the right words in the corrective RE.

While the *Shortening* strategy is numerically preferred over both baselines, the difference is not significant, and it is significantly worse than the *Emphasis* strategy. This is surprising, given our initial assumption that listeners prefer succinct REs. It is possible that a different strategy for shortening contrastive REs would work better; this bears further study.

7.3 Experiment 2

In our second experiment, we paired the *Emphasis*, *Repeat*, and *Random* strategies against each other, this time evaluating each strategy in the TUNA people domain. Due to its poor performance in Experiment 1, which was confirmed in pilot experiments for Experiment 2, the *Shortening* strategy was not included.

The experimental setup for the TUNA domain used 3x4 grids of pictures of people chosen at random from the TUNA Challenge, as shown in Fig. 8. We generated 8 such grids, along with REs ranging from two to five attributes and requiring one or two attributes to establish the correct contrast. The larger visual size of objects in the the TUNA scenes allowed us to mark both o_s and o_u in a single picture without excessive clutter.

The REs for Experiment 2 were designed to only include attributes from the referred objects, but no information about its position in relation to other objects. The benefit is twofold: we avoid taxing our subjects' memory with extremely long REs, and we ensure that the overall length of the second set of REs is comparable to those in the previous experiment.

We obtained 240 judgements from 65 subjects (after removing fake answers). Table 1b shows the results of all pairwise comparisons. We find that even in the presence of a larger number of attributes, our algorithm assigns contrastive focus to the correct words of the RE.

7.4 Discussion

Our experiments confirm that the strategy for computing contrastive REs presented in this paper works in practice. This validates the corruption model, which approximates semantic mismatches between what the speaker said and what the listener understood as differences at the level of words in strings. Obviously, this model is still an approximation, and we will test its limits in future work.

We find that users generally prefer REs with an emphasis over simple repetitions. In the more challenging scenes of the TUNA corpus, users even have a significant preference of Random over

	Repeat	Random	Emphasis	Shortening
Repeat	–	0.041	-0.570***	-0.141
Random	-0.041	–	-0.600***	-0.109
Emphasis	0.570***	0.600***	–	0.376***
Shortening	0.141	0.109	-0.376***	–

(a) Results for Experiment 1

	Repeat	Random	Emphasis
Repeat	–	-0.425***	-0.575***
Random	0.425***	–	-0.425***
Emphasis	0.575***	0.425***	–

(b) Results for Experiment 2

Table 1: Pairwise comparisons between feedback strategies for experiments 1 and 2. A positive value shows preference for the row strategy, significant at *** $p < 0.001$.

Repeat, although this makes no semantic sense. This preference may be due to the fact that emphasizing *anything* at least publically acknowledges the presence of a misunderstanding that requires correction. It will be interesting to explore whether this preference holds up in an interactive setting, rather than an overhearer experiment, where listeners will have to act upon the corrective REs.

The poor performance of the Shortening strategy is a surprising negative result. We would expect a shorter RE to always be preferred, following the Gricean Maxim of Quantity (Grice, 1975). This may because our particular Shortening strategy can be improved, or it may be because listeners interpret the shortened REs not with respect to the original instructions, but rather with respect to a "refreshed" context (as observed, for instance, in Gotzner et al. (2016)). In this case the shortened REs would not be unique with respect to the refreshed, wider context.

8 Conclusion

In this paper, we have presented an algorithm for generating contrastive feedback for a hearer who has misunderstood a referring expression. Our technique is based on modeling likely user misunderstandings and then attempting to give feedback that contrasts with the most probable incorrect understanding. Our experiments show that this technique accurately predicts which words to mark as focused in a contrastive RE.

In future work, we will complement the overhearer experiment presented here with an end-to-end evaluation in an interactive NLG setting. This will allow us to further investigate the quality of the correction strategies and refine the Shortening strategy. It will also give us the opportunity to investigate empirically the limits of the corruption model. Furthermore, we could use this data to refine the costs $c(D), c(I_a)$ etc. for the edit operations, possibly assigning different costs to different edit operations.

Finally, it would be interesting to combine our algorithm with a speech synthesis system. In this way, we will be able to express focus with actual pitch accents, in contrast to the typographic approximation we made here.

Abstract

Even though a linguistics-free sequence to sequence model in neural machine translation (NMT) has certain capability of implicitly learning syntactic information of source sentences, this paper shows that source syntax can be explicitly incorporated into NMT effectively to provide further improvements. Specifically, we linearize parse trees of source sentences to obtain structural label sequences. On the basis, we propose three different sorts of encoders to incorporate source syntax into NMT: 1) *Parallel RNN* encoder that learns word and label annotation vectors parallelly; 2) *Hierarchical RNN* encoder that learns word and label annotation vectors in a two-level hierarchy; and 3) *Mixed RNN* encoder that stitchingly learns word and label annotation vectors over sequences where words and labels are mixed. Experimentation on Chinese-to-English translation demonstrates that all the three proposed syntactic encoders are able to improve translation accuracy. It is interesting to note that the simplest RNN encoder, i.e., *Mixed RNN* encoder yields the best performance with an significant improvement of 1.4 BLEU points. Moreover, an in-depth analysis from several perspectives is provided to reveal how source syntax benefits NMT.

1 Introduction

Recently the sequence to sequence model (seq2seq) in neural machine translation (NMT) has achieved certain success over the state-of-the-art of statistical machine translation (SMT) on various language pairs (Bahdanau et al., 2015; Jean et al., 2015; Luong et al., 2015; Luong and Manning, 2015). However, Shi et al. (2016) show that the seq2seq model still fails to capture a lot of deep structural details, even though it is capable of learning certain implicit source syntax from sentence-aligned parallel corpus. Moreover, it requires an additional parsing-task-specific training mechanism to recover the hidden syntax in NMT. As a result, in the absence of explicit linguistic knowledge, the seq2seq model in NMT tends to produce translations that fail to well respect syntax. In this paper, we show that syntax can be well exploited in NMT explicitly by taking advantage of source-side syntax to improve the translation accuracy.

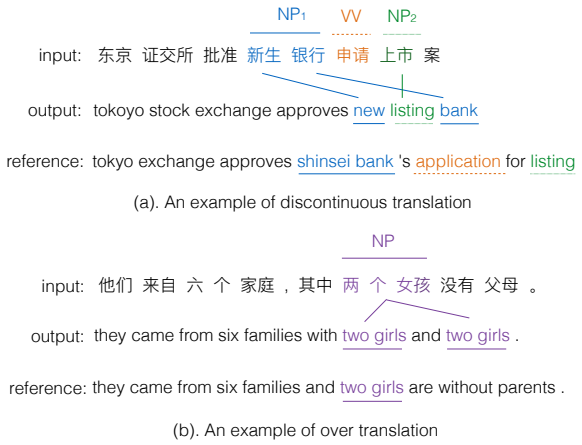

Figure 1: Examples of NMT translation that fail to respect source syntax.

In principle, syntax is a promising avenue for translation modeling. This has been verified by tremendous encouraging studies on syntax-based SMT that substantially improves translation by integrating various kinds of syntactic knowledge (Liu et al., 2006; Marton and Resnik, 2008;

*Work done at Huawei Noah's Ark Lab, HongKong.

Shen et al., 2008; Li et al., 2013). While it is yet to be seen how syntax can benefit NMT effectively, we find that translations of NMT sometimes fail to well respect source syntax. Figure 1 (a) shows a Chinese-to-English translation example of NMT. In this example, the NMT seq2seq model incorrectly translates the Chinese noun phrase (i.e., 新生/*xinsheng* 银行/*yinhang*) into a discontinuous phrase in English (i.e., *new ... bank*) due to the failure of capturing the internal syntactic structure in the input Chinese sentence. Statistics on our development set show that one forth of Chinese noun phrases are translated into discontinuous phrases in English, indicating the substantial disrespect of syntax in NMT translation.[1] Figure 1 (b) shows another example with over translation, where the noun phrase 两/*liang* 个/*ge* 女孩/*nvhai* is translated twice in English. Similar to discontinuous translation, over translation usually happens along with the disrespect of syntax which results in the repeated translation of the same source words in multiple positions of the target sentence.

In this paper we are not aiming at solving any particular issue, either the discontinuous translation or the over translation. Alternatively, we address how to incorporate explicitly the source syntax to improve the NMT translation accuracy with the expectation of alleviating the issues above in general. Specifically, rather than directly assigning each source word with manually designed syntactic labels, as Sennrich and Haddow (2016) do, we linearize a phrase parse tree into a *structural label sequence* and let the model automatically learn useful syntactic information. On the basis, we systematically propose and compare several different approaches to incorporating the label sequence into the seq2seq NMT model. Experimentation on Chinese-to-English translation demonstrates that all proposed approaches are able to improve the translation accuracy.

2 Attention-based NMT

As a background and a baseline, in this section, we briefly describe the NMT model with an attention mechanism by Bahdanau et al. (2015), which mainly consists of an encoder and a decoder, as shown in Figure 2.

Encoder The encoding of a source sentence is formulated using a pair of neural networks, i.e., two recurrent neural networks (denoted *bi-RNN*): one reads an input sequence $x = (x_1, ..., x_m)$ from left to right and outputs a forward sequence of hidden states $(\overrightarrow{h_1}, ..., \overrightarrow{h_m})$, while the other operates from right to left and outputs a backward sequence $(\overleftarrow{h_1}, ..., \overleftarrow{h_m})$. Each source word x_j is represented as h_j (also referred to as word annotation vector): the concatenation of hidden states $\overrightarrow{h_j}$ and $\overleftarrow{h_j}$. Such bi-RNN encodes not only the word itself but also its left and right context, which can provide important evidence for its translation.

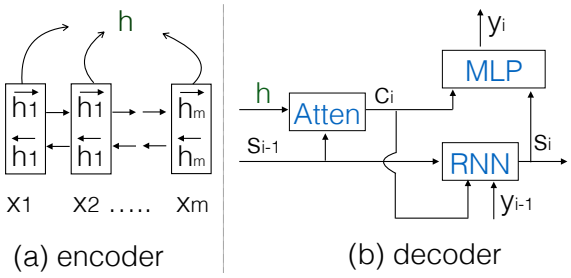

Figure 2: Attention-based NMT model.

Decoder The decoder is also an RNN that predicts a target sequence $y = (y_1, ..., y_n)$. Each target word y_i is predicted via a multi-layer perceptron (MLP) component which is based on a recurrent hidden state s_i, the previous predicted word y_{i-1}, and a source-side context vector c_i. Here, c_i is calculated as a weighted sum over source annotation vectors $(h_1, ..., h_m)$. The weight vector $\alpha_i \in \mathbb{R}^m$ over source annotation vectors is obtained by an attention model, which captures the correspondences between the source and the target languages. The attention weight α_{ij} is computed based on the previous recurrent hidden state s_{i-1} and source annotation vector h_j.

3 NMT with Source Syntax

The conventional NMT models treat a sentence as a sequence of words and ignore external knowledge, failing to effectively capture various kinds of inherent structure of the sentence. To leverage external knowledge, specifically the syntax in the source side, we focus on the parse tree of a sentence and propose three different NMT models that explicitly consider the syntactic structure into encoding. Our purpose is to inform the NMT model the structural context of each word in its corresponding parse tree with the goal that the learned annotation vectors $(h_1, ..., h_m)$ encode not

[1] Manually examining 200 random such discontinuously translated noun phrases, we find that 90% of them should be continuously translated according to the reference translation.

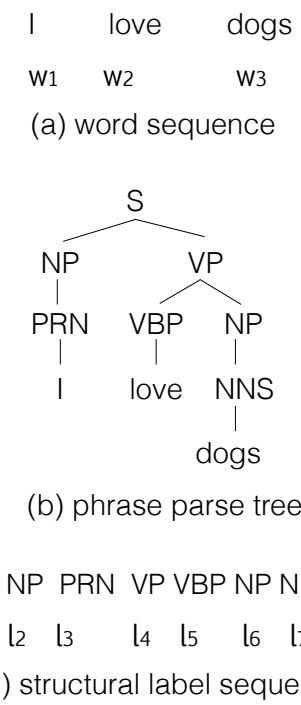

Figure 3: An example of an input sentence (a), its parse tree (b), and the parse tree's sequential form (c).

only the information of words and their surroundings, but also structural context in the parse tree. In the rest of this section, we use English sentences as examples to explain our methods.

3.1 Syntax Representation

To obtain the structural context of a word in its parse tree, ideally the model should not only capture and remember the whole parse tree structure, but also discriminate the contexts of any two different words. However, considering the lack of efficient way to directly model structural information, an alternative way is to linearize the phrase parse tree into a sequence of structural labels and learn the structural context through the sequence. For example, Figure 3(c) shows the structural label sequence of Figure 3(b) in a simple way following a depth-first traversal order. Note that linearizing a parse tree in a depth-first traversal order into a sequence of structural labels has also been widely adopted in recent advances in neural syntactic parsing (Vinyals et al., 2015; Choe and Charniak, 2016), suggesting that the linearized sequence can be viewed as an alternative to its tree structure.[2]

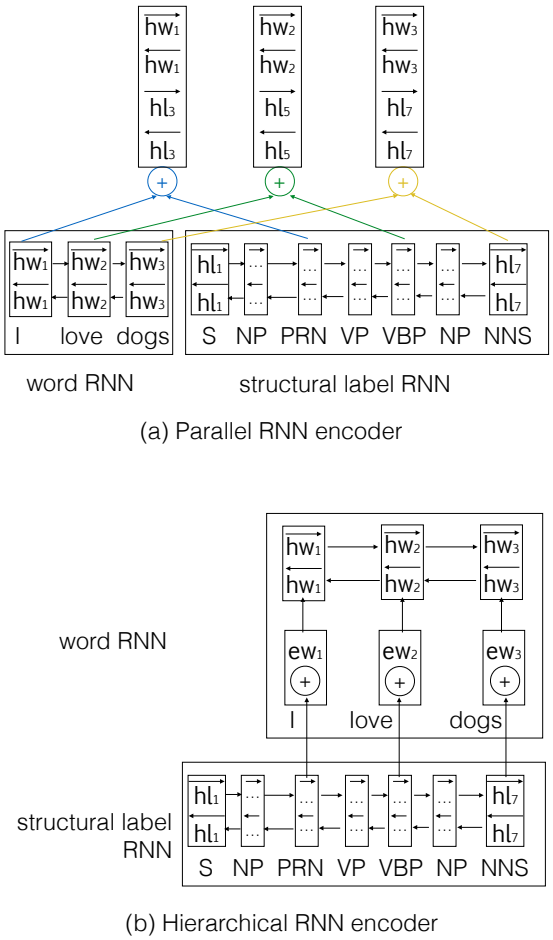

Figure 4: The graphical illustration of the *Parallel RNN* encoder (a) and the *Hierarchical RNN* encoder (b). Here, $\overrightarrow{hw_j}$ and $\overleftarrow{hw_j}$ are the forward and backward hidden states for word w_j, $\overrightarrow{hl_i}$ and $\overleftarrow{hl_i}$ are for structural label l_i, ew_j is the word embedding for word w_j, and $\bigoplus$ is for concatenation operator.

There is no doubt that the structural label sequence is much longer than its word sequence. In order to obtain the structural label annotation vector for w_i in word sequence, we simply look for w_i's part-of-speech (POS) tag in the label sequence and view the tag's annotation vector as w_i's label annotation vector. This is because w_i's POS tag location can also represent w_i's location in the parse tree. For example, in Figure 3, word w_1 in (a) maps to l_3 in (c) since l_3 is the POS tag of w_1. Likewise, w_2 maps to l_5 and w_3 to l_7. That is to say, we use l_3's learned annotation vector as w_1's label annotation vector.

[2]We have also tried to include the ending brackets in the structural label sequence, as what (Vinyals et al., 2015; Choe and Charniak, 2016) do. However, the performance gap is very small by adding the ending brackets or not.

3.2 RNN Encoders with Source Syntax

In the next, we first propose two different encoders to augment word annotation vector with its corresponding label annotation vector, each of which consists of two RNNs [3]: in one encoder, the two RNNs work independently (i.e., *Parallel RNN Encoder*) while in another encoder the two RNNs work in a hierarchical way (i.e., *Hierarchical RNN Encoder*). The difference between the two encoders lies in how the two RNNs interact. Then, we propose the third encoder with a single RNN, which learns word and label annotation vectors stitchingly (i.e., *Mixed RNN Encoder*). Since any of the above three approaches focuses only on the encoder as to generate source annotation vectors along with structural information, we keep the rest part of the NMT models unchanged.

Parallel RNN Encoder Figure 4 (a) illustrates our *Parallel RNN* encoder, which includes two parallel RNNs: i.e., a word RNN and a structural label RNN. On the one hand, the word RNN, as in conventional NMT models, takes a word sequence as input and output a word annotation vector for each word. On the other hand, the structural label RNN takes the structural label sequence of the word sequence as input and obtains a label annotation vector for each label. Besides, we concatenate each word's word annotation vector and its POS tag's label annotation vector as the final annotation vector for the word. For example, the final annotation vector for word *love* in Figure 4 (a) is $[\overrightarrow{hw_2}; \overleftarrow{hw_2}; \overrightarrow{hl_5}; \overleftarrow{hl_5}]$, where the first two subitems $[\overrightarrow{hw_2}; \overleftarrow{hw_2}]$ are the word annotation vector and the rest two subitems $[\overrightarrow{hl_5}; \overleftarrow{hl_5}]$ are its POS tag *VBP*'s label annotation vector.

Hierarchical RNN Encoder Partially inspired by the model architecture of GNMT (Wu et al., 2016) which consists of multiple layers of LSTM RNNs, we propose a two-layer model architecture in which the lower layer is the structural label RNN while the upper layer is the word RNN, as shown in Figure 4 (b). We put the word RNN in the upper layer because each item in the word sequence can map into an item in the structural label sequence, while this does not hold if the order of the two RNNs is reversed. As shown in Figure 4 (b), for example, the POS tag *VBP*'s label annotation vector $[\overrightarrow{hl_5}, \overleftarrow{hl_5}]$ is concatenated with word

[3] Hereafter, we simplify bi-RNN as RNN.

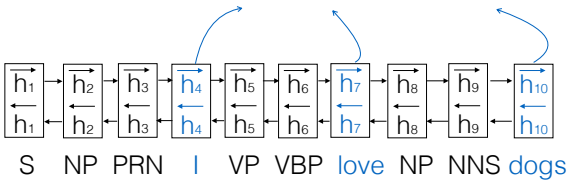

Figure 5: The graphical illustration of the *Mixed RNN* encoder. Here, $\overrightarrow{h_j}$ and $\overleftarrow{h_j}$ are the forward and backward hidden annotation vectors for *j*-th item, which can be either a word or a structural label.

love's word embedding ew_2 to feed as the input to the word RNN.

Mixed RNN Encoder Figure 5 presents our *Mixed RNN* encoder. Similarly, the sequence of input is the linearization of its parse tree (as in Figure 3 (b)) following a depth-first traversal order, but being mixed with both words and structural labels in a stitching way. It shows that the RNN learns annotation vectors for both the words and the structural labels, though only the annotation vectors of words are further fed to decoding (e.g., $([\overrightarrow{h_4}, \overleftarrow{h_4}], [\overrightarrow{h_7}, \overleftarrow{h_7}], [\overrightarrow{h_{10}}, \overleftarrow{h_{10}}])$). Even though the annotation vectors of structural labels are not directly fed forward for decoding, the error signal is back propagated along the word sequence and allows the annotation vectors of structural labels being updated accordingly.

3.3 Comparison of RNN Encoders with Source Syntax

Though all the three encoders model both word sequence and structural label sequence, the differences lie in their respective model architecture with respect to the degree of coupling the two sequences:

- In the *Parallel RNN* encoder, the word RNN and structural label RNN work in a parallel way. That is to say, the error signal back propagated from the word sequence would not affect the structural label RNN, and vice versa. In contrast, in the *Hierarchical RNN* encoder, the error signal back propagated from the word sequence has a direct impact on the structural label annotation vectors, and thus on the structural label embeddings. Finally, the *Mixed RNN* encoder ties the structural label sequence and word sequence together in the closest way. Therefore, the degrees of coupling the word and structural

label sequences in these three encoders are like this: *Mixed RNN* encoder > *Hierarchical RNN* encoder > *Parallel RNN* encoder.

- Figure 4 and Figure 5 suggest that the *Mixed RNN* encoder is the simplest. Moreover, comparing to conventional NMT encoders, the difference lies only in the length of the input sequence. Statistics on our training data reveal that the *Mixed RNN* encoder approximately triples the input sequence length compared to conventional NMT encoders.

4 Experimentation

We have presented our approaches to incorporating the source syntax into NMT encoders. In this section, we evaluate their effectiveness on Chinese-to-English translation.

4.1 Experimental Settings

Our training data for the translation task consists of 1.25M sentence pairs extracted from LDC corpora, with 27.9M Chinese words and 34.5M English words respectively.[4] We choose NIST MT 06 dataset (1664 sentence pairs) as our development set, and NIST MT 02, 03, 04, and 05 datasets (878, 919, 1788 and 1082 sentence pairs, respectively) as our test sets.[5] To get the source syntax for sentences on the source-side, we parse the Chinese sentences with Berkeley Parser [6] (Petrov and Klein, 2007) trained on Chinese TreeBank 7.0 (Xue et al., 2005). We use the case insensitive 4-gram NIST BLEU score (Papineni et al., 2002) for the translation task.

For efficient training of neural networks, we limit the maximum sentence length on both source and target sides to 50. We also limit both the source and target vocabularies to the most frequent 16K words in Chinese and English, covering approximately 95.8% and 98.2% of the two corpora respectively. All the out-of-vocabulary words are mapped to a special token *UNK*. Besides, the word embedding dimension is 620 and the size of a hidden layer is 1000. All the other settings are the same as in Bahdanau et al.(2015).

The inventory of structural labels includes 16 phrase labels and 32 POS tags. In both our *Parallel RNN* encoder and *Hierarchical RNN* encoder, we set the embedding dimension of these labels as 100 and the size of a hidden layer as 100. Besides, the maximum structural label sequence length is set to 100. In our *Mixed RNN* encoder, since we only have one input sequence, we equally treat the structural labels and words (i.e., a structural label is also initialized with 620 dimension embedding). Compared to the baseline NMT model, the only different setting is that we increase the maximum sentence length on source-side from 50 to 150.

We compare our method with two state-of-the-art models of SMT and NMT:

- cdec (Dyer et al., 2010): an open source hierarchical phrase-based SMT system (Chiang, 2007) with default configuration and a 4-gram language model trained on the target portion of the training data.[7]

- RNNSearch: a re-implementation of the attentional NMT system (Bahdanau et al., 2015) with slight changes taken from dl4mt tutorial.[8] For the activation function f of an RNN, RNNSearch uses the gated recurrent unit (GRU) recently proposed by (Cho et al., 2014b). It incorporates dropout (Hinton et al., 2012) on the output layer and improves the attention model by feeding the lastly generated word. We use AdaDelta (Zeiler, 2012) to optimize model parameters in training with the mini-batch size of 80. For translation, a beam search with size 10 is employed.

4.2 Experiment Results

Table 1 shows the translation performances measured in BLEU score. Clearly, all the proposed NMT models with source syntax improve the translation accuracy over all test sets, although there exist considerable differences among different variants.

Parameters The three proposed models introduce new parameters in different ways. As a baseline model, RNNSearch has 60.6M parameters. Due to the infrastructure similarity, the *Parallel RNN* system and the *Hierarchical RNN* system introduce

[4] The corpora include LDC2002E18, LDC2003E07, LDC2003E14, Hansards portion of LDC2004T07, LDC2004T08 and LDC2005T06.

#	System	#Params	Time	MT06	MT02	MT03	MT04	MT05	All
1	cdec	-	-	33.4	34.8	33.0	35.7	32.1	34.2
2	RNNSearch	60.6M	153m	34.0	36.9	33.7	37.0	34.1	35.6
3	Parallel RNN	+1.1M	+9m	34.8†	**37.8**‡	34.2	38.3‡	34.6	36.6‡
4	Hierarchical RNN	+1.2M	+9m	35.2‡	37.2	34.7†	38.7‡	34.7†	36.7‡
5	Mixed RNN	+0	+40m	**35.6**‡	37.7†	**34.9**‡	**38.6**‡	**35.5**‡	**37.0**‡

Table 1: Evaluation of the translation performance. † and ‡: significant over RNNSearch at 0.05/0.01, tested by bootstrap resampling (Koehn, 2004). "+" is the additional number of parameters or training time on the top of the baseline system RNNSearch. Column *Time* indicates the training time in minutes per epoch for different NMT models

the similar size of additional parameters, resulting from the RNN model for structural label sequences (about 0.1M parameters) and catering either the augmented annotation vectors (as shown in Figure 4 (a)) or the augmented word embeddings (as shown in Figure 4 (b)) (the remain parameters). It is not surprising that the *Mixed RNN* system does not require any additional parameters since though the input sequence becomes longer, we keep the vocabulary size unchanged, resulting in no additional parameters.

Speed Introducing the source syntax slightly slows down the training speed. When running on a single GPU GeForce GTX 1080, the baseline model speeds 153 minutes per epoch with 14K updates while the proposed structural label RNNs in both *Parallel RNN* and *Hierarchical RNN* systems only increases the training time by about 6% (thanks to the small size of structural label embeddings and annotation vectors), and the *Mixed RNN* system spends 26% more training time to cater the triple sized input sequence.

Comparison with the baseline NMT model (RNNSearch) While all the three proposed NMT models outperform RNNSearch, the *Parallel RNN* system and the *Hierarchical RNN* system achieve similar accuracy (e.g., 36.6 *v.s.* 36.7). Besides, the *Mixed RNN* system achieves the best accuracy overall test sets with the only exception of NIST MT 02. Over all test sets, it outperforms RNNSearch by 1.4 BLEU points and outperforms the other two improved NMT models by 0.3∼0.4 BLEU points, suggesting the benefits of high degree of coupling the word sequence and the structural label sequence. This is very encouraging since the *Mixed RNN* encoder is the simplest, without introducing new parameters and with only slight additional training time.

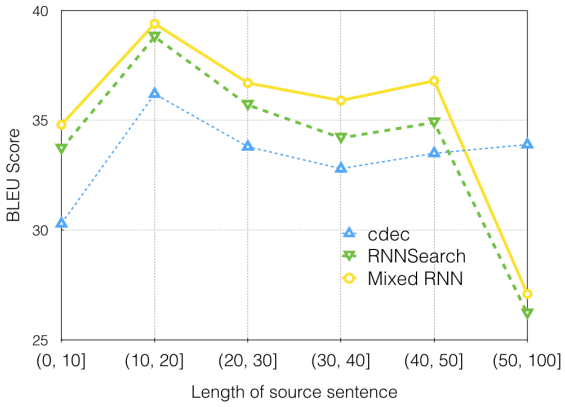

Figure 6: Performance of the generated translations with respect to the lengths of the input sentences.

Comparison with the SMT model (cdec) Table 1 also shows that all NMT systems outperform the SMT system. This is very consistent with other studies on Chinese-to-English translation (Mi et al., 2016; Tu et al., 2017b; Wang et al., 2017).

5 Analysis

As the proposed *Mixed RNN* system achieves the best performance, we further look at the RNNSearch system and the *Mixed RNN* system to explore more on how syntactic information helps in translation.

5.1 Effects on Long Sentences

Following Bahdanau et al. (2015), we group sentences of similar lengths together and compute BLEU scores. Figure 6 presents the BLEU scores over different lengths of input sentences. It shows that *Mixed RNN* system outperforms RNNSearch over sentences with all different lengths. It also shows that the performance drops substantially

System	AER
RNNSearch	50.1
Mixed RNN	47.9

Table 2: Evaluation of alignment quality. The lower the score, the better the alignment quality.

when the length of input sentences increases. This performance trend over the length is consistent with the findings in (Cho et al., 2014a; Tu et al., 2016, 2017a). We also observe that the NMT systems perform surprisingly bad on sentences over 50 in length, especially compared to the performance of SMT system (i.e., cdec). We think that the bad behavior of NMT systems towards long sentences (e.g., length of 50) is due to the following two reasons: (1) the maximum source sentence length limit is set as 50 in training, [9] making the learned models not ready to translate sentences over the maximum length limit; (2) NMT systems tend to stop early for long input sentences.

5.2 Analysis on Word Alignment

Due to the capability of carrying syntactic information in source annotation vectors, we conjecture that our model with source syntax is also beneficial for alignment. To test this hypothesis, we carry out experiments of the word alignment task on the evaluation dataset from Liu and Sun (2015), which contains 900 manually aligned Chinese-English sentence pairs. We force the decoder to output reference translations, as to get automatic alignments between input sentences and their reference translations. To evaluate alignment performance, we report the alignment error rate (AER) (Och and Ney, 2003) in Table 2.

Table 2 shows that source syntax information improves the attention model as expected by maintaining an annotation vector summarizing structural information on each source word.

5.3 Analysis on Phrase Alignment

The above subsection examines the alignment performance at the word level. In this subsection, we turn to phrase alignment analysis by moving from word unit to phrase unit. Given a source phrase *XP*, we use word alignments to examine if the phrase is translated continuously (**Cont.**), or discontinuously (**Dis.**), or if it is not translated at all (**Un.**).

[9] Though the maximum source length limit in *Mixed RNN* system is set to 150, it approximately contains 50 words in maximum.

System	XP	Cont.	Dis.	Un.
RNNSearch	PP	57.3	33.6	9.1
	NP	59.8	25.5	14.7
	CP	47.3	44.6	8.1
	QP	54.0	22.2	23.8
	ALL	58.1	27.1	14.8
Mixed RNN	PP	63.3	27.5	9.2
	NP	63.1	23.1	13.8
	CP	54.5	36.6	8.9
	QP	56.2	19.7	24.1
	ALL	60.4	25.0	14.6

Table 3: Percentages (%) of syntactic phrases in our test sets being translated continuously, discontinuously, or not being translated. Here PP is for prepositional phrase, NP for noun phrase, CP for clause headed by a complementizer, QP for quainter phrase.

There are some phrases, such as noun phrases (NPs), prepositional phrases (PPs) that we usually expect to have a continuous translation. With respect to several such types of phrases, Table 3 shows how these phrases are translated. From the table, we see that translations of RNNSearch system do not respect source syntax very well. For example, in RNNSearch translations, 57.3%, 33.6%, and 9.1% of PPs are translated continuously, discontinuously, and untranslated, respectively. Fortunately, our *Mixed RNN* system is able to have more continuous translation for those phrases. Table 3 also suggests that there is still much room for NMT to show more respect to syntax.

5.4 Analysis on Over Translation

To estimate the over translation generated by NMT, we propose *ratio of over translation (ROT)*:

$$ROT = \frac{\sum_{w_i} t(w_i)}{|w|} \quad (1)$$

where $|w|$ is the number of words in consideration, $t(w_i)$ is the times of over translation for word w_i. Given a word w and its translation $e = e_1 e_2 \dots e_n$, we have:

$$t(w) = |e| - |uniq(e)| \quad (2)$$

where $|e|$ is the number of words in w's translation e, while $|uniq(e)|$ is the number of unique words in e. For example, if a source word 香

System	POS	ROT (%)
RNNSearch	NR	15.7
	CD	7.4
	DT	4.9
	NN	8.0
	ALL	5.5
Mixed RNN	NR	12.3
	CD	5.1
	DT	2.4
	NN	6.8
	ALL	4.5

Table 4: Ratio of over translation (ROT) on test sets. Here NR is for proper noun, CD for cardinal number, DT for determiner, and NN for nouns except proper nouns and temporal nouns.

System	POS	non-UNK	UNK	Un.
RNNSearch	NN	27.2	40.4	32.4
	NR	22.9	58.5	18.6
	VV	34.5	32.9	32.7
	CD	10.7	63.4	25.9
	ALL	27.2	40.4	32.4
Mixed RNN	NN	24.8	41.4	33.8
	NR	17.0	64.5	18.6
	VV	33.6	34.0	32.3
	CD	9.6	68.7	21.7
	ALL	23.9	47.5	28.7

Table 5: Percentages (%) of rare words in our test sets being translated into a *non-UNK* word (**non-UNK**), *UNK* (**UNK**), or if it is not translated at all (**Un.**).

港/xiangkang is translated as *hong kong hong kong*, we say it being over translated *2* times.

Table 4 presents ROT grouped by some typical POS tags. It is not surprising that RNNSearch system has high ROT with respect to POS tags of NR (proper noun) and CD (cardinal number): this is due to the fact that the two POS tags include high percentage of unknown words which tend to be translated multiple times in translation. Words of DT (determiner) are another source of over translation since they are usually translated to multiple *the* in English. It also shows that by introducing source syntax, *Mixed RNN* system alleviates the over translation issue by 18%: ROT drops from 5.5% to 4.5%.

5.5 Analysis on Rare Word Translation

We analyze the translation of source-side rare words that are mapped to a special token *UNK*. Given a rare word *w*, we examine if it is translated into a *non-UNK* word (**non-UNK**), *UNK* (**UNK**), or if it is not translated at all (**Un.**).

Table 5 shows how source-side rare words are translated. The four POS tags listed in the table account for about 90% of all rare words in the test sets. It shows that in *Mixed RNN* system is more likely to translate source-side rare words into *UNK* on the target side. This is reasonable since the source side rare words tends to be translated into rare words in the target side. Moreover, it is hard to obtain its correct non-*UNK* translation when a source-side rare word is replaced as *UNK*.

Note that our approach is compatible with with approaches of open vocabulary. Taking the subword approach (Sennrich et al., 2016) as an example, for a word on the source side which is divided into several subword units, we can synthesize sub-POS nodes that cover these units. For example, if *misunderstand/VB* is divided into units of *mis* and *understand*, we construct substructure *(VB (VB-F mis) (VB-I understand))*.

6 Related Work

While there has been substantial work on linguistically motivated SMT, approaches that leverage syntax for NMT start to shed light very recently. Generally speaking, NMT can provide a flexible mechanism for adding linguistic knowledge, thanks to its strong capability of automatically learning feature representations.

Eriguchi et al. (2016) propose a tree-to-sequence model that learns annotation vectors not only for terminal words, but also for non-terminal nodes. They also allow the attention model to align target words to non-terminal nodes. Our approach is similar to theirs by using source-side phrase parse tree. However, our *Mixed RNN* system, for example, incorporates syntax information by learning annotation vectors of syntactic labels and words stitchingly, but is still a sequence-to-sequence model, with no extra parameters and with less increased training time.

Sennrich and Haddow (2016) define a few linguistically motivated features that are attached to each individual words. Their features include lemmas, subword tags, POS tags, dependency labels, etc. They concatenate feature embeddings with word embeddings and feed the concatenated em-

beddings into the NMT encoder. On the contrast, we do not specify any feature, but let the model implicitly learn useful information from the structural label sequence.

Shi et al. (2016) design a few experiments to investigate if the NMT system without external linguistic input is capable of learning syntactic information on the source-side as a by-product of training. However, their work is not focusing on improving NMT with linguistic input. Moreover, we analyze what syntax is disrespected in translation from several new perspectives.

García-Martínez et al. (2016) generalize NMT outputs as lemmas and morphological factors in order to alleviate the issues of large vocabulary and out-of-vocabulary word translation. The lemmas and corresponding factors are then used to generate final words in target language. Though they use linguistic input on the target side, they are limited to the word level features. Phrase level, or even sentence level linguistic features are harder to obtain for a generation task such as machine translation, since this would require incremental parsing of the hypotheses at test time.

7 Conclusion

In this paper, we have investigated whether and how source syntax can explicitly help NMT to improve its translation accuracy.

To obtain syntactic knowledge, we linearize a parse tree into a structural label sequence and let the model automatically learn useful information through it. Specifically, we have described three different models to capture the syntax knowledge, i.e., *Parallel RNN*, *Hierarchical RNN*, and *Mixed RNN*. Experimentation on Chinese-to-English translation shows that all proposed models yield improvements over a state-of-the-art baseline NMT system. It is also interesting to note that the simplest model (i.e., *Mixed RNN*) achieves the best performance, resulting in obtaining significant improvements of 1.4 BLEU points on NIST MT 02 to 05.

In this paper, we have also analyzed the translation behavior of our improved system against the state-of-the-art NMT baseline system from several perspectives. Our analysis shows that there is still much room for NMT translation to be consistent with source syntax. In our future work, we expect several developments that will shed more light on utilizing source syntax, e.g., designing novel syntactic features (e.g., features showing the syntactic role that a word is playing) for NMT, and employing the source syntax to constrain and guild the attention models.

Abstract

Nowadays a typical Neural Machine Translation (NMT) model generates translations from left to right as a linear sequence, during which latent syntactic structures of the target sentences are not explicitly concerned. Inspired by the success of using syntactic knowledge of target language for improving statistical machine translation, in this paper we propose a novel Sequence-to-Dependency Neural Machine Translation (SD-NMT) method, in which the target word sequence and its corresponding dependency structure are jointly constructed and modeled, and this structure is used as context to facilitate word generations. Experimental results show that the proposed method significantly outperforms state-of-the-art baselines on Chinese-English and Japanese-English translation tasks.

1 Introduction

Recently, Neural Machine Translation (NMT) with the attention-based encoder-decoder framework (Bahdanau et al., 2015) has achieved significant improvements in translation quality of many language pairs (Bahdanau et al., 2015; Luong et al., 2015a; Tu et al., 2016; Wu et al., 2016). In a conventional NMT model, an encoder reads in source sentences of various lengths, and transforms them into sequences of intermediate hidden vector representations. After weighted by attention operations, combined hidden vectors are used by the decoder to generate translations. In most of cases, both encoder and decoder are implemented as recurrent neural networks (RNNs).

Many methods have been proposed to further improve the sequence-to-sequence NMT model since it was first proposed by Sutskever et al. (2014) and Bahdanau et al. (2015). Previous work ranges from addressing the problem of out-of-vocabulary words (Jean et al., 2015), designing attention mechanism (Luong et al., 2015a), to more efficient parameter learning (Shen et al., 2016), using source-side syntactic trees for better encoding (Eriguchi et al., 2016) and so on. All these NMT models employ a sequential recurrent neural network for target generations. Although in theory RNN is able to remember sufficiently long history, we still observe substantial incorrect translations which violate long-distance syntactic constraints. This suggests that it is still very challenging for a linear RNN to learn models that effectively capture many subtle long-range word dependencies. For example, Figure 1 shows an incorrect translation related to the long-distance dependency. The translation fragment in italic is locally fluent around the word *is*, but from a global view the translation is ungrammatical. Actually, this part of translation should be mostly affected by the distant plural noun *foreigners* rather than words *Venezuelan government* nearby.

Fortunately, such long-distance word correspondence can be well addressed and modeled by syntactic dependency trees. In Figure 1, the head word *foreigners* in the partial dependency tree (top dashed box) can provide correct structural context for the next target word, with this information it is more likely to generate the correct word *will* rather than *is*. This structure has been successfully applied to significantly improve the performance of statistical machine translation (Shen et al., 2008). On the NMT side, introducing target syntactic structures could help solve the problem of ungrammatical output because it can bring two advantages over state-of-the-art NMT models:

[*] Contribution during internship at Microsoft Research.

a) syntactic trees can be used to model the grammatical validity of translation candidates; b) partial syntactic structures can be used as additional context to facilitate future target word prediction.

Ref : He added that foreign visitors to Venezuela who criticize the Venezuelan government will face serious consequences and will be deported .

NMT : He also said that foreigners to Venezuela who attack the Venezuelan government *is facing serious consequences*, will be deported .

Figure 1: Dependency trees help the prediction of the next target word. "NMT" refers to the translation result from a conventional NMT model, which fails to capture the long distance word relation denoted by the dashed arrow.

However, it is not trivial to build and leverage syntactic structures on the target side in current NMT framework. Several practical challenges arise:

(1) How to model syntactic structures such as dependency parse trees with recurrent neural network;

(2) How to efficiently perform both target word generation and syntactic structure construction tasks simultaneously in a single neural network;

(3) How to effectively leverage target syntactic context to help target word generation.

To address these issues, we propose and empirically evaluate a novel Sequence-to-Dependency Neural Machine Translation (SD-NMT) model in our paper. An SD-NMT model encodes source inputs with bi-directional RNNs and associates them with target word prediction via attention mechanism as in most NMT models, but it comes with a new decoder which is able to jointly generate target translations and construct their syntactic dependency trees. The key difference from conventional NMT decoders is that we use two RNNs, one for translation generation and the other for dependency parse tree construction, in which incremental parsing is performed with the arc-standard shift-reduce algorithm proposed by Nivre (2004). We will describe in detail how these two RNNs work interactively in Section 3.

We evaluate our method on publicly available data sets with Chinese-English and Japanese-English translation tasks. Experimental results show that our model significantly improves translation accuracy over the conventional NMT and SMT baseline systems.

2 Background

2.1 Neural Machine Translation

As a new paradigm to machine translation, NMT is an end-to-end framework (Sutskever et al., 2014; Bahdanau et al., 2015) which directly models the conditional probability $P(Y|X)$ of target translation $Y = y_1,y_2,...,y_n$ given source sentence $X = x_1,x_2,...,x_m$. An NMT model consists of two parts: an encoder and a decoder. Both of them utilize recurrent neural networks which can be a Gated Recurrent Unit (GRU) (Cho et al., 2014) or a Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) in practice. The encoder bidirectionally encodes a source sentence into a sequence of hidden vectors $H = h_1,h_2,...,h_m$ with a forward RNN and a backward RNN. Then the decoder predicts target words one by one with probability

$$P(Y|X) = \prod_{j=1}^{n} P(y_j|y_{<j}, H) \quad (1)$$

Typically, for the jth target word, the probability $P(y_j|y_{<j}, H)$ is computed as

$$P(y_j|y_{<j}, H) = g(s_j, y_{j-1}, c_j) \quad (2)$$

where g is a nonlinear function that outputs the probability of y_j, and s_j is the RNN hidden state. The context c_j is calculated at each timestamp j based on H by the attention network

$$c_j = \sum_{k=1}^{m} a_{jk} h_k \quad (3)$$

$$a_{jk} = \frac{\exp(e_{jk})}{\sum_{i=1}^{m} \exp(e_{ji})} \quad (4)$$

$$e_{jk} = v_a^T \tanh(W_a s_{j-1} + U_a h_k) \quad (5)$$

where v_a, W_a, U_a are the weight matrices. The attention mechanism is effective to model the correspondences between source and target.

2.2 Dependency Tree Construction

We use a shift-reduce transition-based dependency parser to build the syntactic structure for the target language in our work. Specially, we adopt the arc-standard algorithm (Nivre, 2004) to perform incremental parsing during the translation process. In this algorithm, a stack and a buffer are maintained to store the parsing state over which three kinds of transition actions are applied. Let w_0 and w_1 be two topmost words in the stack, and $\bar{w}$ be the current new word in a sequence of input, three transition actions are described as below.

- Shift(SH) : Push $\bar{w}$ to the stack.
- Left-Reduce(LR(d)) : Link w_0 and w_1 with dependency label d as $w_0 \xrightarrow{d} w_1$, and reduce them to the head w_0.
- Right-Reduce(RR(d)) : Link w_0 and w_1 with dependency label d as $w_0 \xleftarrow{d} w_1$, and reduce them to the head w_1.

During parsing, an specific structure is used to record the dependency relationship between different words of input sentence. The parsing finishes when the stack is empty and all input words are consumed. As each word must be pushed to the stack once and popped off once, the number of actions needed to parse a sentence is always $2n$, where n is the length of the sentence (Nivre, 2004). Because each valid transition action sequence corresponds to a unique dependency tree, a dependency tree can also be equivalently represented by a sequence of transition actions.

3 Sequence-to-Dependency Neural Machine Translation

An SD-NMT model is an extension to the conventional NMT model augmented with syntactic structural information of target translation. Given a source sentence $X = x_1,x_2,..,x_m$, its target translation $Y = y_1,y_2,..,y_n$ and Y's dependency parse tree T, the goal of the extension is to enable us to compute the joint probability $P(Y,T|X)$. As in most structural learning tasks, the full prediction of Y and T is further decomposed into a chain of smaller predictions. For translation Y, it is generated in the left-to-right order as $y_1, y_2, .., y_n$ following the way in a normal sequence-to-sequence model. For Y's parse tree T, instead of directly modeling the tree itself, we predict a parsing action sequence A which can map Y to T. Thus at top level our SD-NMT model can be formulated as

$$\begin{aligned} P(Y,T|X) &= P(Y,A|X) \\ &= P(y_1 y_2..y_n, a_1, a_2..a_l|X) \quad (6) \end{aligned}$$

where $A = a_1,a_2,..,a_j,..,a_l$ [1] with length l ($l = 2n$), $a_j \in \{\text{SH}, \text{RR}(d), \text{LR}(d)\}$[2].

Two recurrent neural networks, Word-RNN and Action-RNN, are used to model generation processes of translation sequence Y and parsing action sequence A respectively. Figure 2 shows an example how translation Y and its parsing actions are predicted step by step.

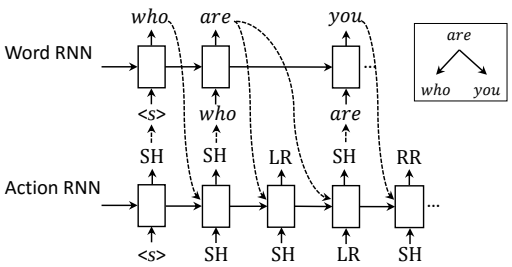

Figure 2: Decoding example of our SD-NMT model for target sentence "who are you" with transition action sequence "SH SH LR SH RR". The ending symbol `EOS` is omitted.

Because the lengths of Word-RNN and Action-RNN are different, they are designed to work in a mutually dependent way: a target word is only allowed to be generated when the SH action is predicted in the action sequence. In this way, we can perform incremental dependency parsing for translation Y and at the same time track the partial parsing status through the translation generation process.

For notational clarity, we introduce a virtual translation sequence $\hat{Y} = \hat{y}_1,\hat{y}_2,..,\hat{y}_j,..,\hat{y}_l$ for Word-RNN which has the same length l with transition action sequence. $\hat{y}_j$ is defined as

$$\hat{y}_j = \begin{cases} y_{v_j} & \delta(\text{SH}, a_j) = 1 \\ y_{v_j - 1} & \delta(\text{SH}, a_j) = 0 \end{cases}$$

where $\delta(\text{SH}, a_j)$ is 1 when $a_j = \text{SH}$, otherwise 0. v_j is the index of Y, computed by $v_j = \sum_{i=1}^{j} \delta(SH, a_i)$. Apparently the mapping from $\hat{Y}$

[1] In the rest of this paper, a_j represents the transition action, rather than the attention weight in Equation 4.

[2] RR(d) refers to a set of RR actions augmented with dependency labels so as to LR(d).

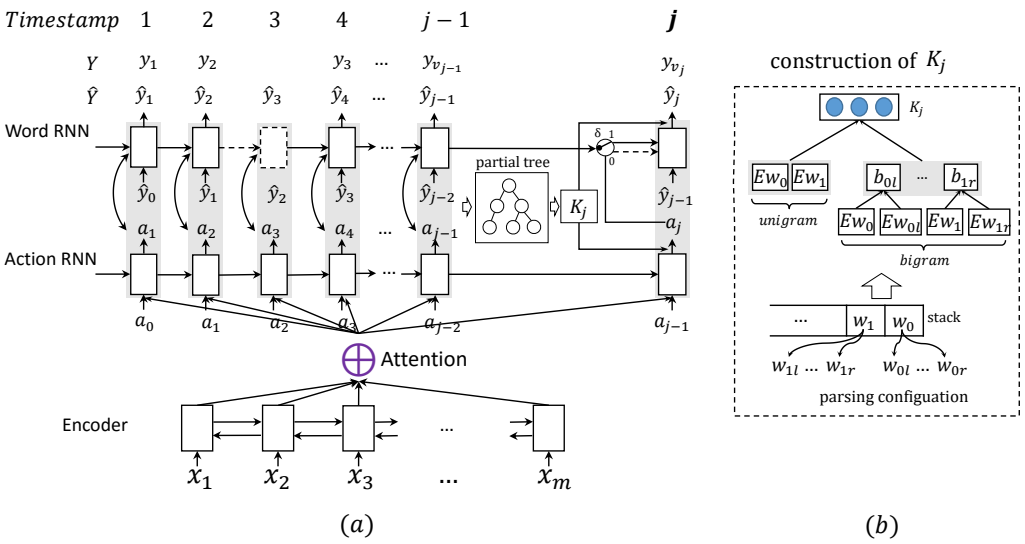

Figure 3: (a) is the overview of SD-NMT model. The dashed arrows mean copying previous recurrent state or word. The two RNNs use the same source context for prediction. $a_j \in \{\text{SH}, \text{RR}(d), \text{LR}(d)\}$. The bidirection arrow refers to the interaction between two RNNs. (b) shows the construction of syntactic context. The gray box means the concatenation of vectors

to Y is deterministic, and Y can be easily derived given $\hat{Y}$ and A.

With the notation of $\hat{Y}$, the sequence probability of Y and A can be written as

$$P(A|X, \hat{Y}_{<l}) = \prod_{j=1}^{l} P(a_j|a_{<j}, X, \hat{Y}_{<j}) \quad (7)$$

$$P(\hat{Y}|X, A_{\leq l}) = \prod_{j=1}^{l} P(\hat{y}_j|\hat{y}_{<j}, X, A_{\leq j})^{\delta(SH, a_j)} \quad (8)$$

where $\hat{Y}_{<j}$ refers to the subsequence $\hat{y}_1, \hat{y}_2, .., \hat{y}_{j-1}$, and $A_{\leq j}$ to $a_1, a_2, .., a_j$. Based on Equation 7 and 8, the overall joint model can be computed as

$$P(Y, T|X) = P(A|X, \hat{Y}_{<l}) \times P(\hat{Y}|X, A_{\leq l}) \quad (9)$$

As we have two RNNs in our model, the termination condition is also different from a conventional NMT model. In decoding, we maintain a stack to track the parsing configuration, and our model terminates once the Word-RNN predicts a special ending symbol `EOS` and all the words in the stack have been reduced.

Figure 3 (a) gives an overview of our SD-NMT model. Due to space limitation, the detailed interconnections between two RNNs are only illustrated at timestamp j. The encoder of our model follows standard bidirectional RNN configuration. At timestamp j during decoding, our model first predicts an action a_j by Action-RNN, then Word-RNN checks the condition gate δ according to a_j. If $a_j = \text{SH}$, the Word-RNN will generate a new state (solid arrow) and predict a new target word y_{v_j}, otherwise it just copies previous state (dashed arrow) to the current state. For example, at timestamp 3, $a_3 \neq \text{SH}$, the state of Word-RNN is copied from its previous one. Meanwhile, $\hat{y}_3 = y_2$ is used as the immediate proceeding word in translation history.

When computing attention scores, we extend Equation 5 by replacing the decoder hidden state with the concatenation of Word-RNN hidden state s and Action-RNN hidden state s' (gray boxes in Figure 3). The new attention score is then updated as

$$e_{jk} = v_a^T \tanh(W_a[s_{j-1}; s'_{j-1}] + U_a h_k) \quad (10)$$

3.1 Syntactic Context for Target Word Prediction

Syntax has been proven useful for sentence generation task (Dyer et al., 2016). We propose to leverage target syntax to help translation generation. In our model, the syntactic context K_j at timestamp j is defined as a vector which is computed by a feed-forward network based on current

parsing configuration of Action-RNN. Denote that w_0 and w_1 are two topmost words in the stack, w_{0l} and w_{1l} are their leftmost modifiers in the partial tree, w_{0r} and w_{1r} their rightmost modifiers respectively. We define two unigram features and four bigram features. The unigram features are w_0 and w_1 which are represented by the word embedding vectors. The bigram features are w_0w_{0l}, w_0w_{0r}, w_1w_{1l} and w_1w_{1r}. Each of them is computed by $b_{hc} = \tanh(W_bEw_h + U_bEw_{hc})$, $h \in \{0,1\}$, $c \in \{l,r\}$. These kinds of feature template have beeb proven effective in dependency parsing task (Zhang and Clark, 2008). Based on these features, the syntactic context vector K_j is computed as

$$K_j = \tanh(W_k[Ew_0; Ew_1] + U_k[b_{0l}; b_{0r}; b_{1l}; b_{1r}]) \quad (11)$$

where W_k, U_k, W_b, U_b are the weight matrices, E stands for the embedding matrix. Figure 2 (b) gives an overview of the construction of K_j. Note that zero vector is used for padding the words which are not available in the partial tree, so that all the K vectors have the same input size in computation.

Adding K_j to Equation 2, the probabilities of transition action and word in Equation 7 and 8 are then updated as

$$P(a_j|a_{<j}, X, \hat{Y}_{<j}) = g(s'_j, a_{j-1}, c_j, K_j) \quad (12)$$
$$P(\hat{y}_j|\hat{y}_{<j}, X, A_{\leq j}) = g(s_j, \hat{y}_{j-1}, c_j, K_j) \quad (13)$$

After each prediction step in Word-RNN and Action-RNN, the syntax context vector K will be updated accordingly. Note that K is not used to calculate the recurrent states s in this work.

3.2 Model Training and Decoding

For SD-NMT model, we use the sum of log-likelihoods of word sequence and action sequence as objective function for training algorithm, so that the joint probability of target translations and their parsing trees can be maximized:

$$J(\theta) = \sum_{(X,Y,A)\in D} \log\ P(A|X, \hat{Y}_{<l}) + \log\ P(\hat{Y}|X, A_{\leq l}) \quad (14)$$

We also use mini-batch for model training. As the target dependency trees are known in the bilingual corpus during training, we pre-compute the partial tree state and syntactic context at each time stamp for each training instance. Thus it is easy for the model to process multiple trees in one batch.

In the decoding process of an SD-NMT model, the score of each search path is the sum of log probabilities of target word sequence and transition action sequence normalized by the sequence length:

$$\text{score} = \frac{1}{l}\sum_{j=1}^{l} \log\ P(a_j|a_{<j}, X, \hat{Y}_{<j}) + \frac{1}{n}\sum_{j=1}^{l} \delta(SH, a_j) \log\ P(\hat{y}_j|\hat{y}_{<j}, X, A_{\leq j}) \quad (15)$$

where n is word sequence length and l is action sequence length.

4 Experiments

The experiments are conducted on the Chinese-English task as well as the Japanese-English translation tasks where the same data set from WAT 2016 ASPEC corpus (Nakazawa et al., 2016) [3] is used for a fair comparison with other work. In addition to evaluate translation performance, we also investigate the quality of dependency parsing as a by-product and the effect of parsing quality against translation quality.

4.1 Setup

In the Chinese-English task, the bilingual training data consists of a set of LDC datasets, [4] which has around 2M sentence pairs. We use NIST2003 as the development set, and the testsets contain NIST2005, NIST2006, NIST2008 and NIST2012. All English words are lowercased.

In the Japanese-English task, we use top 1M sentence pairs from ASPEC Japanese-English corpus. The development data contains 1,790 sentences, and the test data contains 1,812 sentences with single reference per source sentence.

To train SD-NMT model, the target dependency tree references are needed. As there is no golden annotation of parse trees over the target training data, we use pseudo parsing results as the target dependency references, which are got from an in-house developed arc-eager dependency parser based on work in (Zhang and Nivre, 2011).

HPSMT	35.34	33.56	26.06	27.47	30.61
RNNsearch	38.07	38.95	31.61	28.95	34.39
SD-NMT\K	38.83	39.23	31.92	29.72	34.93
SD-NMT	**39.38**	**41.81**	**33.06**	**31.43**	36.42

Table 1: Evaluation results on Chinese-English translation task with BLEU% metric. The "Average" column is the averaged result of all test sets. The numbers in bold indicate statistically significant difference ($p < 0.05$) from baselines.

In the neural network training, the vocabulary size is limited to 30K high frequent words for both source and target languages. All low frequent words are normalized into a special token `unk` and post-processed by following the work in (Luong et al., 2015b). The size of word embedding and transition action embedding is set to 512. The dimensions of the hidden states for all RNNs are set to 1024. All model parameters are initialized randomly with Gaussian distribution (Glorot and Bengio, 2010) and trained on a NVIDIA Tesla K40 GPU. The stochastic gradient descent (SGD) algorithm is used to tune parameters with a learning rate of 1.0. The batch size is set to 96. In the update procedure, Adadelta (Zeiler, 2012) algorithm is used to automatically adapt the learning rate. The beam sizes for both word prediction and transition action prediction are set to 12 in decoding.

The baselines in our experiments are a phrasal system and a neural translation system, denoted by HPSMT and RNNsearch respectively. HPSMT is an in-house implementation of the hierarchical phrase-based model (Chiang, 2005), where a 4-gram language model is trained using the modified Kneser-Ney smoothing (Kneser and Ney, 1995) algorism over the English Gigaword corpus (LDC2009T13) plus the target data from the bilingual corpus. RNNsearch is an in-house implementation of the attention-based neural machine translation model (Bahdanau et al., 2015) using the same parameter settings as our SD-NMT model including word embedding size, hidden vector dimension, beam size, as well as the same mechanism for OOV word processing.

The evaluation results are reported with the case-insensitive IBM BLEU-4 (Papineni et al., 2002). A statistical significance test is performed using the bootstrap resampling method proposed by Koehn (2004) with a 95% confidence level. For Japanese-English task, we use the official evaluation procedure provided by WAT 2016.[5], where both BLEU and RIBES (Isozaki et al., 2010) are used for evaluation.

4.2 Evaluation on Chinese-English Translation

We evaluate our method on the Chinese-English translation task. The evaluation results over all NIST test sets against baselines are listed in Table 1. Generally, RNNsearch outperforms HPSMT by 3.78 BLEU points on average while SD-NMT surpasses RNNsearch 2.03 BLUE point gains on average, which shows that NMT models usually achieve better results than SMT models, and our proposed sequence-to-dependency NMT model performs much better than traditional sequence-to-sequence NMT model.

We also investigate the effect of syntactic knowledge context by excluding its computation in Equation 12 and 13. The alternative model is denoted by SD-NMT\K. According to Table 1, SD-NMT\K outperforms RNNsearch by 0.54 BLEU points but degrades SD-NMT by 1.49 BLEU points on average, which demonstrates that the long distance dependencies captured by the target syntactic knowledge context, such as leftmost/rightmost children together with their dependency relationships, really bring strong positive effects on the prediction of target words.

In addition to translation quality, we compare the perplexity (PPL) changes on the development set in terms of numbers of training mini-batches for RNNsearch and SD-NMT in Figure 4. We can see that the PPL of SD-NMT is initially higher than that of RNNsearch, but decreased to be lower over time. This is mainly because the quality of parse tree is too poor at the beginning which degrades translation quality and leads to higher PPL. After some training iterations, the SD-NMT

SD-NMT	25.93	0.7540	Single-layer SD-NMT model

Table 2: Evaluation results on Japanese-English translation task.

model learns reasonable inferences of parse trees which begins to help target word generation and leads to lower PPL.

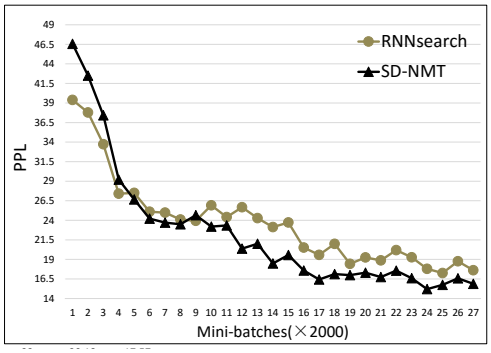

Figure 4: Perplexity (PPL) changes in terms of numbers of training mini-batches.

In our experiments, the time cost of SD-NMT is two times of that for RNNsearch due to a more complicated model structure. But we think it is a worthy trade to pursue high quality translations.

4.3 Evaluation on Japanese-English Translation

In this section, we report results on the Japanese-English translation task. To ensure fair comparisons, we use the same training data and follow the pre-processing steps recommended in WAT 2016[6]. Table 2 shows the comparison results from 8 systems with the evaluation metrics of BLEU and RIBES. The results in the first 3 rows are produced by SMT systems taken from the official WAT 2016. The remaining results are produced by NMT systems, among which the bottom two row results are taken from our in-house NMT systems and others refer to the work in (Cromieres, 2016; Cromieres et al., 2016) that are the competitive NMT results on WAT 2016. According to Table 2, NMT results still outperform SMT results similar to our Chinese-English evaluation results. The SD-NMT model significantly outperforms most other NMT models, which shows that our proposed approach to modeling target dependency tree benefit NMT systems since our RNNsearch baseline achieves comparable performance with the single layer attention-based NMT system in (Cromieres, 2016). Note that our SD-NMT gets comparable results with the 4 single-layer ensemble model in (Cromieres, 2016; Cromieres et al., 2016). We believe SD-NMT can get more improvements with an ensemble of multiple models in future experiments.

[6]http://lotus.kuee.kyoto-u.ac.jp/WAT/baseline/dataPreparationJE.html

4.4 Effect of the Parsing Accuracy upon Translation Quality

The interaction effect between dependency tree conduction and target word generation is investigated in this section. The experiments are conducted on the Chinese-English task over multiple test sets. We evaluate how the quality of dependency trees affect the performance of translation. In the decoding phase of SD-NMT, beam search is applied to the generations of both transition and actions as illustrated in Equation 15. Intuitively, the larger the beam size of action prediction is, the better the dependency tree quality is. We fix the beam size for generating target words to 12, and change the beam size for action prediction to see the difference. Figure 5 shows the evaluation results of all test sets. There is a tendency for BLEU scores to increase with the growth of action prediction beam size. The reason is that the translation quality increases as the quality of dependency tree improves, which shows the construction of dependency trees can boost the generation of target

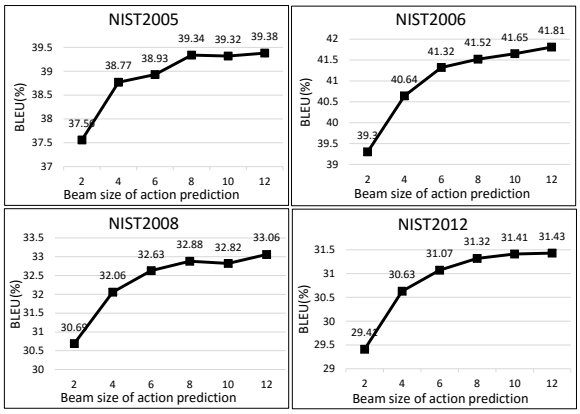

Figure 5: Translation performance against the beam size of action prediction.

words, and vice versa we believe.

4.5 Quality Estimation of Dependency Tree Construction

As a by-product, the quality of dependency trees not only affects the performance of target word generation, but also influences the possible downstream processors or tasks such as text analyses. The direct evaluation of tree quality is not feasible due to the unavailable golden references. So we resort to estimating the consistency between the by-products and the parsing results of our stand-alone dependency parser with state-of-the-art performance. The higher the consistency is, the closer the performance of by-product is to the stand-alone parser. To reduce the influence of ill-formed data as much as possible, we build the evaluation data set by heuristically selecting 360 SD-NMT translation results together with their dependency trees from NIST test sets where both source- and target-side do not contain `unk` and have a length of 20-30. We then take the parsing results of the stand-alone parser for these translations as references to indirectly estimate the quality of by-products. We get a UAS (unlabeled attachment score) of 94.96% and a LAS (labeled attachment score) of 93.92%, which demonstrates that the dependency trees produced by SD-NMT are much similar with the parsing results from the stand-alone parser.

4.6 Translation Example

In this section, we give a case study to explain how our method works. Figure 6 shows a translation example from the NIST testsets. SMT and RNNsearch refer to the translation results from the baselines HPSMT and NMT. For our SD-NMT model, we list both the generated translation and its corresponding dependency tree. We find that the translation of SMT is disfluent and ungrammatical, whereas RNNsearch is better than SMT. Although the translation of RNNsearch is locally fluent around word "have" in the rectangle, both its grammar is incorrect and its meaning is inaccurate from a global view. The word "have" should be in a singular form as its subject is "safety" rather than "workers". For our SD-NMT model, we can see that the translation is much better than baselines and the dependency tree is reasonable. The reason is that after generating the word "workers", the previous subtree in the gray region is transformed to the syntactic context which can guide the generation of the next word as illustrated by the dashed arrow. Thus our model is more likely to generate the correct verb "is" with singular form. In addition, the global structure helps the model correctly identify the inverted sentence pattern of the former translated part and make better choices for the future translation ("only when .. can .." in our translation, "only when .. will .." in the reference), which remains a challenge for conventional NMT model.

5 Related Work

Incorporating linguistic knowledge into machine translation has been extensively studied in Statistic Machine Translation (SMT) (Galley et al., 2006; Shen et al., 2008; Liu et al., 2006). Liu et al. (2006) proposed a tree-to-string alignment template for SMT to leverage source side syntactic information. Shen et al. (2008) proposed a target dependency language model for SMT to employ target-side structured information. These methods show promising improvement for SMT.

Recently, neural machine translation (NMT) has achieved better performance than SMT in many language pairs (Luong et al., 2015a; Zhang et al., 2016; Shen et al., 2016; Wu et al., 2016; Neubig, 2016). In a vanilla NMT model, source and target sentences are treated as sequences where the syntactic knowledge of both sides is neglected. Some effort has been done to incorporate source syntax into NMT. Eriguchi et al. (2016) proposed a tree-to-sequence attentional NMT model where source-side parse tree was used and achieved promising improvement. Intuitively, adding source syntactic information to

[**Source**] 只有 施工 人员 的 安全 得到 了 保证 , 才能 继续 施 工 .
[**Reference**] only when the safety of the workers is guaranteed will they continue with the project .
[**HPSMT**] only safety is assured of construction personnel , to continue construction .
[**RNNsearch**] only when the safety of construction workers *have* been guaranteed *to continue construction* .
[**SD-NMT**] only when the safety of the workers is guaranteed can we continue to work .

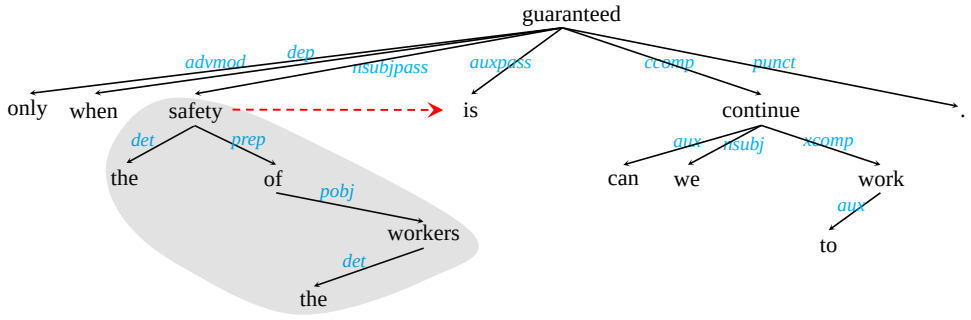

Figure 6: Translation examples of SMT, RNNsearch and our SD-NMT on Chinese-English translation task. The italic words on the arrows are dependency labels. The ending symbol EOS is omitted. RNNsearch fails to capture the long dependency which leads to an ungrammatical result. Whereas with the help of the syntactic tree, our SD-NMT can get a much better translation.

NMT is straightforward, because the source sentence is definitive and easy to attach extra information. However, it is non-trivial to add target syntax as target words are uncertain in decoding process. Up to now, there is few work that attempts to build and leverage target syntactic information for NMT.

There has been work that incorporates syntactic information into NLP tasks with neural networks. Dyer et al. (2016) presented a RNN grammar for parsing and language modeling. They replaced SH with a set of generative actions to generate words under a Stack LSTM framework (Dyer et al., 2015), which achieves promising results for language modeling on the Penn Treebank data. In our work, we propose to involve target syntactic trees into NMT model to jointly learn target translation and dependency parsing where target syntactic context over the parse tree is used to improve the translation quality.

6 Conclusion and Future Work

In this paper, we propose a novel string-to-dependency translation model over NMT. Our model jointly performs target word generation and arc-standard dependency parsing. Experimental results show that our method can boost the two procedures and achieve significant improvements on the translation quality of NMT systems.

In future work, along this research direction, we will try to integrate other prior knowledge, such as semantic information, into NMT systems. In addition, we will apply our method to other sequence-to-sequence tasks, such as text summarization, to verify the effectiveness.

Abstract

How fake news goes viral via social media? How does its propagation pattern differ from real stories? In this paper, we attempt to address the problem of identifying rumors, i.e., fake information, out of microblog posts based on their propagation structure. We firstly model microblog posts diffusion with propagation trees, which provide valuable clues on how an original message is transmitted and developed over time. We then propose a kernel-based method called Propagation Tree Kernel, which captures high-order patterns differentiating different types of rumors by evaluating the similarities between their propagation tree structures. Experimental results on two real-world datasets demonstrate that the proposed kernel-based approach can detect rumors more quickly and accurately than state-of-the-art rumor detection models.

1 Introduction

On November 9th, 2016, Eric Tucker, a grassroots user who had just about 40 followers on Twitter, tweeted his unverified observations about paid protesters being bused to attend anti-Trump demonstration in Austin, Texas. The tweet, which was proved false later, was shared over 16 thousand times on Twitter and 350 thousand times on Facebook within a couple of days, fueling a nation-wide conspiracy theory[1]. The diffusion of the story is illustrated as Figure 1 which gives the key spreading points of the story along the time line. We can see that after the initial post, the tweet was shared or promoted by some influential online communities and users (including Trump himself), resulting in its wide spread.

A widely accepted definition of rumor is "unverified and instrumentally relevant information statements in circulation" (DiFonzo and Bordia, 2007). This unverified information may eventually turn out to be true, or partly or entirely false. In today's ever-connected world, rumors can arise and spread at lightening speed thanks to social media platforms, which could not only be wrong, but be misleading and dangerous to the public society. Therefore, it is crucial to track and debunk such rumors in timely manner.

Journalists and fact-checking websites such as snopes.com have made efforts to track and detect rumors. However, such endeavor is manual, thus prone to poor coverage and low speed. Feature-based methods (Castillo et al., 2011; Yang et al., 2012; Ma et al., 2015) achieved certain success by employing large feature sets crafted from message contents, user profiles and holistic statistics of diffusion patterns (e.g., number of retweets, propagation time, etc.). But such an approach was over simplified as they ignored the dynamics of rumor propagation. Existing studies considering propagation characteristics mainly focused on the temporal features (Kwon et al., 2013, 2017) rather than the structure of propagation.

So, can the propagation structure make any difference for differentiating rumors from non-rumors? Recent studies showed that rumor spreaders are persons who want to get attention and popularity (Sunstein, 2014). However, popular users who get more attention on Twitter (e.g., with more followers) are actually less likely to spread rumor in a sense that the high audience size might hinder a user from participating in propagating unverified information (Kwon et al., 2017). Intuitively, for "successful" rumors being propagated as widely

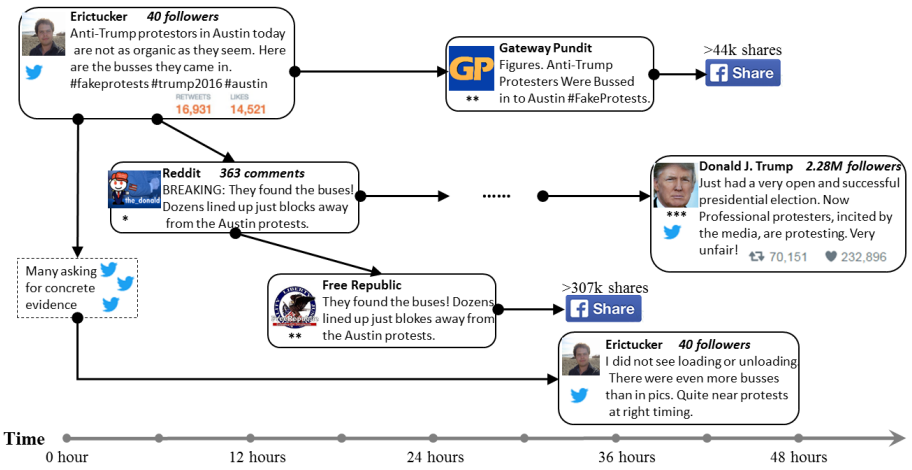

Figure 1: An illustration of how the rumor about "buses used to ship in paid anti-Trump protesters to Austin, Texas" becomes viral, where '*' indicates the level of influence.

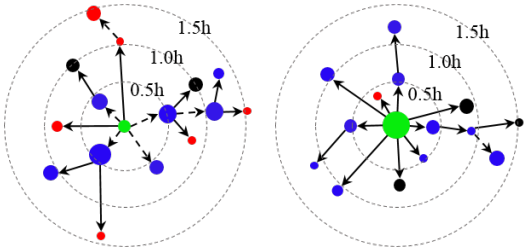
as popular real news, initial spreaders (typically lack of popularity) must attract certain amount of broadcasting power, e.g., attention of influential users or communities that have a lot of audiences joining in promoting the propagation. We refer to this as a constrained mode propagation, relative to the open mode propagation of normal messages that everyone is open to share. Such different modes of propagation may imply some distinct propagation structures between rumors and non-rumors and even among different types of rumors.

Due to the complex nature of information diffusion, explicitly defining discriminant features based on propagation structure is difficult and biased. Figure 2 exemplifies the propagation structures of two Twitter posts, a rumor and a non-rumor, initiated by two users shown as the root nodes (in green color). The information flows here illustrate that the rumorous tweet is first posted by a low-impact user, then some popular users joining in who boost the spreading, but the non-rumorous tweet is initially posted by a popular user and directly spread by many general users; content-based signal like various users' stance (Zhao et al., 2015) and edge-based signal such as relative influence (Kwon et al., 2017) can also suggest the different nature of source tweets. Many of such implicit distinctions throughout message propagation are hard to hand craft specifically using flat summary of statistics as previous work did. In addition, unlike representation learning for plain text, learning for representation of structures such as networks is not well studied in general. Therefore, traditional and latest text-based models (Castillo et al., 2011; Ma et al., 2015, 2016) cannot be applied easily on such complex, dynamic structures.



(a) A rumor (b) A non-rumor

Figure 2: Fragments of the propagation for two source tweets. Node size: denotes the popularity of the user who tweet the post (represented by # of followers); Red, black, blue node: content-wise the user express doubt/denial, support, neutrality in the tweet, respectively; Solid (dotted) edge: information flow from a more (less) popular user to a less (more) popular user; Dashed concentric circles: time stamps.

To capture high-order propagation patterns for rumor detection, we firstly represent the propagation of each source tweet with a propagation tree which is formed by harvesting user's interactions to one another triggered by the source tweet. Then, we propose a kernel-based data-driven method called Propagation Tree Kernel (PTK) to generate relevant features (i.e., subtrees) automatically for estimating the similarity between two propagation trees. Unlike traditional tree kernel (Moschitti, 2006; Zhang et al., 2008) for modeling syntactic structure based on parse tree, our propagation tree consists of nodes corresponding to microblog

posts, each represented as a continuous vector, and edges representing the direction of propagation and providing the context to individual posts. The basic idea is to find and capture the salient substructures in the propagation trees indicative of rumors. We also extend PTK into a context-enriched PTK (cPTK) to enhance the model by considering different propagation paths from source tweet to the roots of subtrees, which capture the context of transmission. Extensive experiments on two real-world Twitter datasets show that the proposed methods outperform state-of-the-art rumor detection models with large margin.

Moreover, most existing approaches regard rumor detection as a binary classification problem, which predicts a candidate hypothesis as rumor or not. Since a rumor often begins as unverified and later turns out to be confirmed as true or false, or remains unverified (Zubiaga et al., 2016), here we consider a set of more practical, finer-grained classes: false rumor, true rumor, unverified rumor, and non-rumor, which becomes an even more challenging problem.

2 Related Work

Tracking misinformation or debunking rumors has been a hot research topic in multiple disciplines (DiFonzo and Bordia, 2007; Morris et al., 2012; Rosnow, 1991). Castillo et al. (2011) studied information credibility on Twitter using a wide range of hand-crafted features. Following that, various features corresponding to message contents, user profiles and statistics of propagation patterns were proposed in many studies (Yang et al., 2012; Wu et al., 2015; Sun et al., 2013; Liu et al., 2015). Zhao et al. (2015) focused on early rumor detection by using regular expressions for finding questing and denying tweets as the key for debunking rumor. All such approaches are over simplistic because they ignore the dynamic propagation patterns given the rich structures of social media data.

Some studies focus on finding temporal patterns for understanding rumor diffusion. Kown et al. (2013; 2017) introduced a time-series fitting model based on the temporal properties of tweet volume. Ma et al. (2015) extended the model using time series to capture the variation of features over time. Friggeri et al. (2014) and Hannak et al. (2014) studied the structure of misinformation cascades by analyzing comments linking to rumor debunking websites. More recently, Ma et al. (2016) used recurrent neural networks to learn the representations of rumor signals from tweet text at different times. Our work will consider temporal, structural and linguistic signals in a unified framework based on propagation tree kernel.

Most previous work formulated the task as classification at event level where an event is comprised of a number of source tweets, each being associated with a group of retweets and replies. Here we focus on classifying a given source tweet regarding a claim which is a finer-grained task. Similar setting was also considered in (Wu et al., 2015; Qazvinian et al., 2011).

Kernel methods are designed to evaluate the similarity between two objects, and tree kernel specifically addresses structured data which has been successfully applied for modeling syntactic information in many natural language tasks such as syntactic parsing (Collins and Duffy, 2001), question-answering (Moschitti, 2006), semantic analysis (Moschitti, 2004), relation extraction (Zhang et al., 2008) and machine translation (Sun et al., 2010). These kernels are not suitable for modeling the social media propagation structures because the nodes are not given as discrete values like part-of-speech tags, but are represented as high dimensional real-valued vectors. Our proposed method is a substantial extension of tree kernel for modeling such structures.

3 Representation of Tweets Propagation

On microblogging platforms, the follower/friend relationship embeds shared interests among the users. Once a user has posted a tweet, all his followers will receive the tweet. Furthermore, Twitter allows a user to retweet or comment another user's post, so that the information could reach beyond the network of the original creator.

We model the propagation of each source tweet as a tree structure $T(r) = \langle V, E \rangle$, where r is the source tweet as well as the root of the tree, V refers to a set of nodes each representing a responsive post (i.e., retweet or reply) of a user at a certain time to the source tweet r which initiates the circulation, and E is a set of directed edges corresponding to the response relation among the nodes in V. If there exists a directed edge from v_i to v_j, it means v_j is a direct response to v_i.

More specifically, each node $v \in V$ is represented as a tuple $v = (u_v, c_v, t_v)$, which provides

the following information: u_v is the creator of the post, c_v represents the text content of the post, and t_v is the time lag between the source tweet r and v. In our case, u_v contains attributes of the user such as # of followers/friends, verification status, # of history posts, etc., c_v is a vector of binary features based on uni-grams and/or bi-grams representing the post's content.

4 Propagation Tree Kernel Modeling

In this section, we describe our rumor detection model based on propagation trees using kernel method called Propagation Tree Kernel (PTK). Our task is, given a propagation tree $T(r)$ of a source tweet r, to predict the label of r.

4.1 Background of Tree Kernel

Before presenting our proposed algorithm, we briefly present the traditional tree kernel, which our PTK model is based on.

Tree kernel was designed to compute the syntactic and semantic similarity between two natural language sentences by implicitly counting the number of common subtrees between their corresponding parse trees. Given a syntactic parse tree, each node with its children is associated with a grammar production rule. Figure 3 illustrates the syntactic parse tree of "cut a tree" and its subtrees. A subtree is defined as any subgraph which has more than one nodes, with the restriction that entire (not partial) rule productions must be included. For example, the fragment [NP [D a]] is excluded because it contains only part of the production NP $\rightarrow$ D N (Collins and Duffy, 2001).

Following Collins and Duffy (2001), given two parse trees T_1 and T_2, the kernel function $K(T_1, T_2)$ is defined as:

$$\sum_{v_i \in V_1} \sum_{v_j \in V_2} \Delta(v_i, v_j) \quad (1)$$

where V_1 and V_2 are the sets of all nodes respectively in T_1 and T_2, and each node is associated with a production rule, and $\Delta(v_i, v_j)$ evaluates the common subtrees rooted at v_i and v_j. $\Delta(v_i, v_j)$ can be computed using the following recursive procedure (Collins and Duffy, 2001):

1) **if** the production rules at v_i and v_j are different, **then** $\Delta(v_i, v_j) = 0$;

2) **else if** the production rules at v_i and v_j are same, and v_i and v_j have only leaf children (i.e., they are pre-terminal symbols), **then** $\Delta(v_i, v_j) = \lambda$;

3) **else** $\Delta(v_i, v_j) = \lambda \prod_{k=1}^{min(nc(v_i), nc(v_j))} (1 + \Delta(ch(v_i, k), ch(v_j, k)))$.

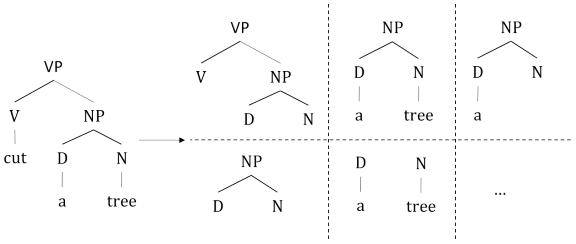


Figure 3: A syntactic parse tree and subtrees.

where $nc(v)$ is the number of children of node v, $ch(v, k)$ is the k-th child of node v, and λ ($0 < \lambda \leq 1$) is a decay factor. $\lambda = 1$ yields the number of common subtrees; $\lambda < 1$ down weighs the contribution of larger subtrees to make the kernel value less variable with respect to subtree size.

4.2 Our PTK Model

To classify propagation trees, we can calculate the similarity between the trees, which is supposed to reflect the distinction of different types of rumors and non-rumors based on structural, linguistic and temporal properties. However, existing tree kernels cannot be readily applied on propagation trees because 1) unlike parse tree where the node is represented by enumerable nominal value (e.g., part-of-speech tag), the propagation tree node is given as a vector of continuous numerical values representing the basic properties of the node; 2) the similarity of two parse trees is based on the count of common subtrees, for which the commonality of subtrees is evaluated by checking if the same production rules and the same children are associated with the nodes in two subtrees being compared, whereas in our context the similarity function should be defined softly since hardly two nodes from different propagation trees are same.

With the representation of propagation tree, we first define a function f to evaluate the similarity between two nodes v_i and v_j (we simplify the node representation for instance $v_i = (u_i, c_i, t_i)$) as the following:

$$f(v_i, v_j) = e^{-t} \left(\alpha \mathcal{E}(u_i, u_j) + (1 - \alpha) \mathcal{J}(c_i, c_j)\right)$$

where $t = |t_i - t_j|$ is the absolute difference between the time lags of v_i and v_j, $\mathcal{E}$ and $\mathcal{J}$ are

user-based similarity and content-based similarity, respectively, and α is the trade-off parameter. The intuition of using exponential function of t to scale down the similarity is to capture the discriminant signals or patterns at the different stages of propagation. For example, a questioning message posted very early may signal a false rumor while the same posted far later from initial post may indicate the rumor is still unverified, despite that the two messages are semantically similar.

The user-based similarity is defined as an Euclidean distance $\mathcal{E}(u_i, u_j) = ||u_i - u_j||_2$, where u_i and u_j are the user vectors of node v_i and v_j and $||\bullet||_2$ is the 2-norm of a vector. Here $\mathcal{E}$ is used to capture the characteristics of users participating in spreading rumors as discriminant signals, throughout the entire stage of propagation.

Contentwise, we use Jaccard coefficient to measure the similarity of post content:

$$\mathcal{J}(c_i, c_j) = \frac{|Ngram(c_i) \cap Ngram(c_j)|}{|Ngram(c_i) \cup Ngram(c_j)|}$$

where c_i and c_j are the sets of content words in two nodes. For n-grams here, we adopt both uni-grams and bi-grams. It can capture cue terms e.g., 'false', 'debunk', 'not true', etc. commonly occurring in rumors but not in non-rumors.

Given two propagation trees $T_1 = \langle V_1, E_1 \rangle$ and $T_2 = \langle V_2, E_2 \rangle$, PTK aims to compute the similarity between T_1 and T_2 iteratively based on enumerating all pairs of most similar subtrees. First, for each node $v_i \in V_1$, we obtain $v_i' \in V_2$, the most similar node of v_i from V_2:

$$v_i' = \arg\max_{v_j \in V_2} f(v_i, v_j)$$

Similarly, for each $v_j \in V_2$, we obtain $v_j' \in V_1$:

$$v_j' = \arg\max_{v_i \in V_1} f(v_i, v_j)$$

Then, the propagation tree kernel $K_P(T_1, T_2)$ is defined as:

$$\sum_{v_i \in V_1} \Lambda(v_i, v_i') + \sum_{v_j \in V_2} \Lambda(v_j', v_j) \qquad (2)$$

where $\Lambda(v, v')$ evaluates the similarity of two subtrees rooted at v and v', which is computed recursively as follows:

1) **if** v or v' are leaf nodes, **then** $\Lambda(v, v') = f(v, v')$;

2) **else** $\Lambda(v, v') = f(v, v') \prod_{k=1}^{min(nc(v), nc(v'))} (1 + \Lambda(ch(v, k), ch(v', k)))$

Note that unlike traditional tree kernel, in PTK the node similarity $f \in [0, 1]$ is used for softly counting similar subtrees instead of common subtrees. Also, λ in tree kernel is not needed as subtree size is not an issue here thanks to node similarity f.

PTK aims to capture discriminant patterns from propagation trees inclusive of user, content and temporal traits, which is inspired by prior analyses on rumors spreading, e.g., user information can be a strong clue in the initial broadcast, content features are important throughout entire propagation periods, and structural and temporal patterns help for longitudinal diffusion (Zubiaga et al., 2016; Kwon et al., 2017).

4.3 Context-Sensitive Extension of PTK

One defect of PTK is that it ignores the clues outside the subtrees, e.g., how the information propagates from source post to the current subtree. Intuitively, propagation paths provide further clue for determining the truthfulness of information since they embed the route and context of how the propagation happens. Therefore, we propose context-sensitive PTK (cPTK) by considering the propagation paths from the root of the tree to the roots of subtrees, which shares similar intuition with the context-sensitive tree kernel (Zhou et al., 2007).

For a propagation tree node $v \in T(r)$, let L_v^r be the length (i.e., # of nodes) of the propagation path from root r to v, and $v[x]$ be the x-th ancestor of v on the path starting from v ($0 \le x < L_v^r, v[0] = v, v[L_v^r - 1] = r$). cPTK evaluates the similarity between two trees $T_1(r_1)$ and $T_2(r_2)$ as follows:

$$\sum_{v_i \in V_1} \sum_{x=0}^{L_{v_i}^{r_1}-1} \Lambda_x(v_i, v_i') + \sum_{v_j \in V_2} \sum_{x=0}^{L_{v_j}^{r_2}-1} \Lambda_x(v_j', v_j) \qquad (3)$$

where $\Lambda_x(v, v')$ measures the similarity of subtrees rooted at $v[x]$ and $v'[x]$ for context-sensitive evaluation, which is computed as follows:

1) **if** $x > 0$, $\Lambda_x(v, v') = f(v[x], v'[x])$, where $v[x]$ and $v'[x]$ are the x-th ancestor nodes of v and v' on the respective propagation path.

2) **else** $\Lambda_x(v, v') = \Lambda(v, v')$, namely PTK.

Clearly, PTK is a special case of cPTK when $x = 0$ (see equation 3). cPTK evaluates the oc-

currence of both context-free (without considering ancestors on propagation paths) and context-sensitive cases.

4.4 Rumor Detection via Kernel Learning

The advantage of kernel-based method is that we can avoid painstakingly engineering the features. This is possible because the kernel function can explore an implicit feature space when calculating the similarity between two objects (Culotta and Sorensen, 2004).

We incorporate the proposed tree kernel functions, i.e., PTK (equation 2) or cPTK (equation 3), into a supervised learning framework, for which we utilize a kernel-based SVM classifier. We treat each tree as an instance, and its similarity values with all training instances as feature space. Therefore, the kernel matrix of training set is $m \times m$ and that of test set is $n \times m$ where m and n are the sizes of training and test sets, respectively.

For our multi-class task, we perform a one-vs-all classification for each label and then assign the one with the highest likelihood among the four, i.e., non-rumor, false rumor, true rumor or unverified rumor. We choose this method due to interpretability of results, similar to recent work on occupational class classification (Preotiuc-Pietro et al., 2015; Lukasik et al., 2015).

5 Experiments and Results

5.1 Data Sets

To our knowledge, there is no public large dataset available for classifying propagation trees, where we need a good number of source tweets, more accurately, the tree roots together with the corresponding propagation structure, to be appropriately annotated with ground truth.

We constructed our datasets based on a couple of reference datasets, namely Twitter15 (Liu et al., 2015) and Twitter16 (Ma et al., 2016). The original datasets were released and used for binary classification of rumor and non-rumor with respect to given events that contain their relevant tweets.

First, we extracted the popular source tweets[2] that are highly retweeted or replied. We then collected all the propagation threads (i.e., retweets and replies) for these source tweets. Because Twitter API cannot retrieve the retweets or replies, we gathered the retweet users for a given tweet from Twrench[3] and crawled the replies through Twitter's web interface.

Table 1: Statistics of the datasets

Statistic	Twitter15	Twitter16
# of users	276,663	173,487
# of source tweets	1,490	818
# of threads	331,612	204,820
# of non-rumors	374	205
# of false rumors	370	205
# of true rumors	372	205
# of unverified rumors	374	203
Avg. time length / tree	1,337 Hours	848 Hours
Avg. # of posts / tree	223	251
Max # of posts / tree	1,768	2,765
Min # of posts / tree	55	81

Finally, we annotated the source tweets by referring to the labels of the events they are from. We first turned the label of each event in Twitter15 and Twitter16 from binary to quaternary according to the veracity tag of the article in rumor debunking websites (e.g., snopes.com, Emergent.info, etc). Then we labeled the source tweets by following these rules: 1) Source tweets from unverified rumor events or non-rumor events are labeled the same as the corresponding event's label; 2) For a source tweet in false rumor event, we flip over the label and assign true to the source tweet if it expresses denial type of stance; otherwise, the label is assigned as false; 3) The analogous flip-over/no-change rule applies to the source tweets from true rumor events.

We make the datasets produced publicly accessible[4]. Table 1 gives statistics on the resulting datasets.

5.2 Experimental Setup

We compare our kernel-based method against the following baselines:

SVM-TS: A linear SVM classification model that uses time-series to model the variation of a set of hand-crafted features (Ma et al., 2015).

DTR: A Decision-Tree-based Ranking method to identify trending rumors (Zhao et al., 2015), which searches for enquiry phrases and clusters disputed factual claims, and ranked the clustered results based on statistical features.

DTC and **SVM-RBF:** The Twitter information credibility model using Decision Tree Classifier (Castillo et al., 2011) and the SVM-based

[2] Though unpopular tweets could be false, we ignore them as they do not draw much attention and are hardly impactful

[3] https://twren.ch

[4] https://www.dropbox.com/s/7ewzdrbelpmrnxu/rumdetect2017.zip?dl=0

model with RBF kernel (Yang et al., 2012), respectively, both using hand-crafted features based on the overall statistics of the posts.

RFC: The Random Forest Classifier proposed by Kwon et al. (2017) using three parameters to fit the temporal properties and an extensive set of hand-crafted features related to the user, linguistic and structure characteristics.

GRU: The RNN-based rumor detection model proposed by Ma et al. (2016) with gated recurrent unit for representation learning of high-level features from relevant posts over time.

BOW: A naive baseline we worked by representing the text in each tree using bag-of-words and building the rumor classifier with linear SVM.

Our models: **PTK** and **cPTK** are our full PTK and cPTK models, respectively; **PTK-** and **cPTK-** are the setting of only using content while ignoring user properties.

We implemented DTC and RFC with Weka[5], SVM models with LibSVM[6] and GRU with Theano[7]. We held out 10% of the trees in each dataset for model tuning, and for the rest of the trees, we performed 3-fold cross-validation. We used accuracy, F_1 measure as evaluation metrics.

5.3 Experimental Results

Table 2 shows that our proposed methods outperform all the baselines on both datasets.

Among all baselines, **GRU** performs the best, which learns the low-dimensional representation of responsive tweets by capturing the textual and temporal information. This indicates the effectiveness of complex signals indicative of rumors beyond cue words or phrases (e.g., "what?", "really?", "not sure", etc.). This also justifies the good performance of **BOW** even though it only uses uni-grams for representation. Although **DTR** uses a set of regular expressions, we found only 19.59% and 22.21% tweets in our datasets containing these expressions. That is why the results of **DTR** are not satisfactory.

SVM-TS and **RFC** are comparable because both of them utilize an extensive set of features especially focusing on temporal traits. But none of the models can directly incorporate structured propagation patterns for deep similarity comparison between propagation trees. **SVM-RBF**, although using a non-linear kernel, is based on traditional hand-crafted features instead of the structural kernel like ours. So, they performed obviously worse than our approach.

Table 2: Rumor detection results (NR: Non-Rumor; FR: False Rumor; TR: True Rumor; UR: Unverified Rumor)

(a) Twitter15 Dataset

Representation learning methods like **GRU** cannot easily utilize complex structural information for learning important features from our networked data. In contrast, our models can capture complex propagation patterns from structured data rich of linguistic, user and temporal signals. Therefore, the superiority of our models is clear: **PTK-** which only uses text is already better than **GRU**, demonstrating the importance of propagation structures. **PTK** that combines text and user yields better results on both datasets, implying that both properties are complementary and **PTK** integrating flat and structured information is obviously more effective.

It is also observed that **cPTK** outperforms **PTK** except for non-rumor class. This suggests the context-sensitive modeling based on **PTK** is effective for different types of rumors, but for non-

Figure 4: Results of rumor early detection

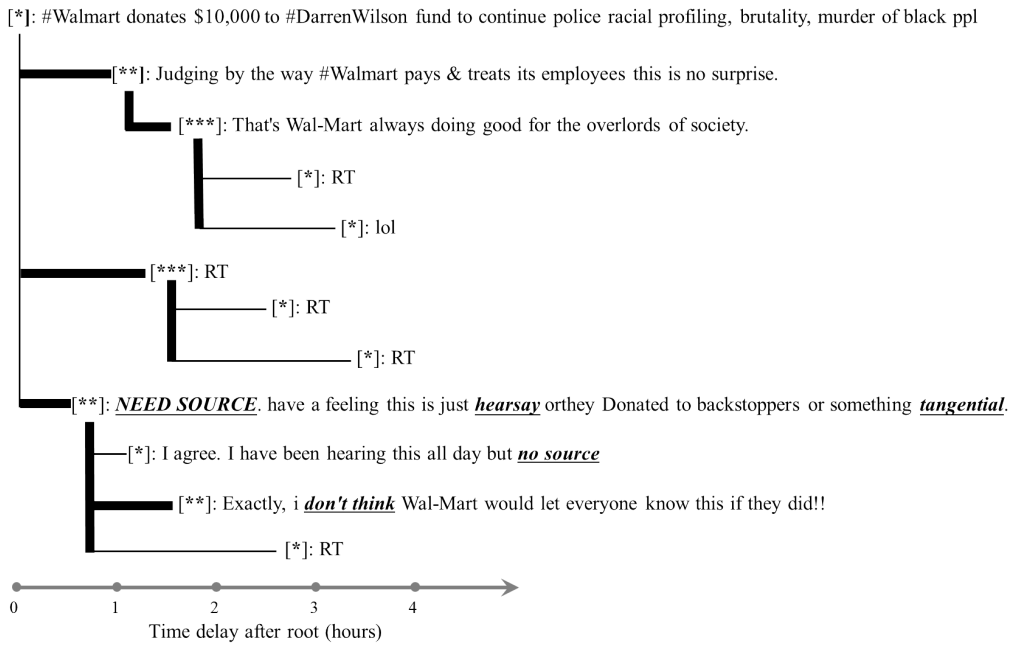

Figure 5: The example subtree of a rumor captured by the algorithm at early stage of propagation

rumors, it seems that considering context of propagation path is not always helpful. This might be due to the generally weak signals originated from node properties on the paths during non-rumor's diffusion since user distribution patterns in non-rumors do not seem as obvious as in rumors. This is not an issue in **cPTK-** since user information is not considered at all. Over all classes, **cPTK** achieves the highest accuracies on both datasets.

Furthermore, we observe that all the baseline methods perform much better on non-rumors than on rumors. This is because the features of existing methods were defined for a binary (rumor vs. non-rumor) classification problem. So, they do not perform well for finer-grained classes. Our approach can differentiate various classes much better by deep, detailed comparison of different patterns based on propagation structure.

5.4 Early Detection Performance

Detecting rumors at an early stage of propagation is very important so that preventive measures could be taken as quickly as possible. In early detection task, all the posts after a detection deadline are invisible during test. The earlier the deadline, the less propagation information can be available.

Figure 4 shows the performances of our **PTK** and **cPTK** models versus **RFC** (the best system based on feature engineering), **GRU** (the best system based on RNN) and **DTR** (an early-detection-

specific algorithm) against various deadlines. In the first few hours, our approach demonstrates superior early detection performance than other models. Particularly, **cPTK** achieve 75% accuracy on Twitter15 and 73% on Twitter16 within 24 hours, that is much faster than other models.

Our analysis shows that rumors typically demonstrate more complex propagation substructures especially at early stage. Figure 5 shows a detected subtree of a false rumor spread in its first few hours, where influential users are somehow captured to boost its propagation and the information flows among the users with an obvious unpopular-to-popular-to-unpopular trend in terms of user popularity, but such pattern was not witnessed in non-rumors in early stage. Many textual signals (underlined) can also be observed in that early period. Our method can learn such structures and patterns naturally, but it is difficult to know and hand-craft them in feature engineering.

6 Conclusion and Future Work

We propose a novel approach for detecting rumors in microblog posts based on kernel learning method using propagation trees. A propagation tree encodes the spread of a hypothesis (i.e., a source tweet) with complex structured patterns and flat information regarding content, user and time associated with the tree nodes. Enlightened by tree kernel techniques, our kernel method learns discriminant clues for identifying rumors of finer-grained levels by directly measuring the similarity among propagation trees via kernel functions. Experiments on two Twitter datasets show that our approach outperforms state-of-the-art baselines with large margin for both general and early rumor detection tasks.

Since kernel-based approach covers more structural information than feature-based methods, it allows kernel to further incorporate information from a high dimensional space for possibly better discrimination. In the future, we will focus on improving the rumor detection task by exploring network representation learning framework. Moreover, we plan to investigate unsupervised models considering massive unlabeled rumorous data from social media.

Abstract

Accurate detection of emotion from natural language has applications ranging from building emotional chatbots to better understanding individuals and their lives. However, progress on emotion detection has been hampered by the absence of large labeled datasets. In this work, we build a very large dataset for fine-grained emotions and develop deep learning models on it. We achieve a new state-of-the-art on 24 fine-grained types of emotions (with an average accuracy of 87.58%). We also extend the task beyond emotion types to model Robert Plutchik's 8 primary emotion dimensions, acquiring a superior accuracy of 95.68%.

1 Introduction

According to the *Oxford English Dictionary*, emotion is defined as "[a] strong feeling deriving from one's circumstances, mood, or relationships with others." [1] This "standard" definition identifies emotions as constructs involving something innate that is often invoked in social interactions and that aids in communicating with others(Hwang and Matsumoto, 2016). It is no exaggeration that humans are emotional beings: Emotions are an integral part of human life, and affect our decision making as well as our mental and physical health. As such, developing emotion detection models is important; they have a wide array of applications, ranging from building nuanced virtual assistants that cater for the emotions of their users to detecting the emotions of social media users in order to understand their mental and/or physical health. However, emotion detection has remained a challenging task, partly due to the limited availability of labeled data and partly due the controversial nature of what emotions themselves are (Aaron C. Weidman and Tracy, 2017).

Recent advances in machine learning for natural language processing (NLP) suggest that, given enough labeled data, there should be an opportunity to build better emotion detection models. Manual labeling of data, however, is costly and so it is desirable to develop labeled emotion data without annotators. While the proliferation of social media has made it possible for us to acquire large datasets with implicit labels in the form of hashtags (Mohammad and Kiritchenko, 2015), such labels are noisy and reliable.

In this work, we seek to enable deep learning by creating a large dataset of fine-grained emotions using Twitter data. More specifically, we harness cues in Twitter data in the form of emotion hashtags as a way to build a labeled emotion dataset that we then exploit using *distant supervision* (Mintz et al., 2009) (the use of hashtags as a surrogate for annotator-generated emotion labels) to build emotion models grounded in psychology. We construct such a dataset and exploit it using powerful deep learning methods to build accurate, high coverage models for emotion prediction. Overall, we make the following contributions: 1) Grounded in psychological theory of emotions, we build a large-scale, high quality dataset of tweets labeled with emotions. Key to this are methods to ensure data quality, 2) we validate the data collection method using human annotations, 3) we develop powerful deep learning models using a gated recurrent network to exploit the data, yielding new state-of-the-art on 24 fine-grained types of emotions, and 4) we extend the task beyond these emotion types to model Plutick's 8 primary emotion dimensions.

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 718–728
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1067

Our emotion modeling relies on *distant supervision* (Read, 2005; Mintz et al., 2009), the approach of using cues in data (e.g., hashtags or emoticons) as a proxy for "ground truth" labels as we explained above. Distant supervision has been investigated by a number of researchers for emotion detection (Tanaka et al., 2005; Mohammad, 2012; Purver and Battersby, 2012; Wang et al., 2012; Pak and Paroubek, 2010; Yang et al., 2007) and for other semantic tasks such as sentiment analysis (Read, 2005; Go et al., 2009) and sarcasm detection (González-Ibánez et al., 2011). In these works, authors successfully use emoticons and/or hashtags as marks to label data after performing varying degrees of data quality assurance. We take a similar approach, using a larger collection of tweets, richer emotion definitions, and stronger filtering for tweet quality.

The remainder of the paper is organized as follows: We first overview related literature in Section 2, describe our data collection in Section 3.1, and the annotation study we performed to validate our distant supervision method in Section 4. We then describe our methods in Section 5, provide results in Section 6, and conclude in Section 8.

2 Related Work

2.1 Computational Treatment of Emotion

The SemEval-2007 Affective Text task (Strapparava and Mihalcea, 2007) [SEM07] focused on classification of emotion and valence (i.e., positive and negative texts) in news headlines. A total of 1,250 headlines were manually labeled with the 6 basic emotions of Ekman (Ekman, 1972) and made available to participants. Similarly, (Aman and Szpakowicz, 2007) describe an emotion annotation task of identifying emotion category, emotion intensity and the words/phrases that indicate emotion in blog post data of 4,090 sentences and a system exploiting the data. Our work differs from both that of SEM07 (Strapparava and Mihalcea, 2007) and (Aman and Szpakowicz, 2007) in that we focus on a different genre (i.e., Twitter) and investigate distant supervision as a way to acquire a significantly larger labeled dataset.

Our work is similar to (Mohammad, 2012; Mohammad and Kiritchenko, 2015), (Wang et al., 2012), and (Volkova and Bachrach, 2016) who use distant supervision to acquire Twitter data with emotion hashtags and report analyses and experiments to validate the utility of this approach. For example, (Mohammad, 2012) shows that by using a simple domain adaptation method to train a classifier on their data they are able to improve both precision and recall on the SemEval-2007 (Strapparava and Mihalcea, 2007) dataset. As the author points out, this is another premise that the self-labeled hashtags acquired from Twitter are consistent, to some degree, with the emotion labels given by the trained human judges who labeled the SemEval-2007 data. As pointed out earlier, (Wang et al., 2012) randomly sample a set of 400 tweets from their data and human-label as relevant/irrelevant, as a way to verify the distant supervision approach with the quality assurance heuristics they employ. The authors found that the precision on a test set is 93.16%, thus confirming the utility of the heuristics. (Wang et al., 2012) provide a number of important observations, as conclusions based on their work. These include that since they are provided by the tweets' writers, the emotion hashtags are more natural and reliable than the emotion labels traditionally assigned by annotators to data by a few annotators. This is the case since in the lab-condition method annotators need to infer the writers emotions from text, which may not be accurate. Additionally, (Volkova and Bachrach, 2016) follow the same distant supervision approach and find correlations of users' emotional tone and the perceived demographics of these users' social networks exploiting the emotion hashtag-labeled data. Our dataset is more than an order of magnitude larger than (Mohammad, 2012) and (Volkova and Bachrach, 2016) and the range of emotions we target is much more fine grained than (Mohammad, 2012; Wang et al., 2012; Volkova and Bachrach, 2016) since we model 24 emotion types, rather than focus on ≤ 7 basic emotions.

(Yan et al., 2016; Yan and Turtle, 2016a,b) develop a dataset of 15,553 tweets labeled with 28 emotion types and so target a fine-grained range as we do. The authors instruct human annotators under lab conditions to assign any emotion they feel is expressed in the data, allowing them to assign more than one emotion to a given tweet. A set of 28 chosen emotions was then decided upon and further annotations were performed using Amazon Mechanical Turk (AMT). The authors cite an agreement of 0.50 Krippendorff's alpha (α) between the lab/expert annotators, and an (α) of 0.28 between experts and AMT workers. EmoTweet-

28 is a useful resource. However, the agreement between annotators is not high and the set of assigned labels do not adhere to a specific theory of emotion. We use a much larger dataset and report an accuracy of the hashtag approach at 90% based on human judgement as reported in Section 4.

2.2 Mood

A number of studies have also been performed to analyze and/or model mood in social media data. (De Choudhury et al., 2012) identify more than 200 moods frequent on Twitter as extracted from psychological literature and filtered by AMT workers. They then collect tweets which have one of the moods in their mood lexicon in the form of a hashtag. To verify the quality of the mood data, the authors run AMT studies where they ask workers whether a tweet displayed the respective mood hashtag or not and find that in 83% of the cases hashtagged moods at the end of posts did capture users' moods, whereas for posts with mood hashtags anywhere in the tweet, only 58% of the cases capture the mood of users. Although they did not build models for mood detection, the annotation studies (De Choudhury et al., 2012) perform further support our specific use of hashtags to label emotions. (Mishne and De Rijke, 2006) collect user-labeled mood from blog post text on LiveJournal and exploit them for predicting the intensity of moods over a time span rather than at the post level. Similarly, (Nguyen, 2010) builds models to infer patterns of moods in a large collection of LiveJournal posts. Some of the moods in these LiveJournal studies (e.g., *hungry*, *cold*), as (De Choudhury et al., 2012) explain, would not fit any psychological theory. Our work is different in that it is situated in psychological theory of emotion.

2.3 Deep Learning for NLP

In spite of the effectiveness of feature engineering for NLP, it is a labor intensive task that also needs domain expertise. More importantly, feature engineering falls short of extracting and organizing all the discriminative information from data (LeCun et al., 2015; Goodfellow et al., 2016). Neural networks (Goodfellow et al., 2016) have emerged as a successful class of methods that has the power of automatically discovering the representations needed for detection or classification and has been successfully applied to multiple NLP tasks. A line of studies in the literature (e.g., (Labutov and Lipson, 2013; Maas et al., 2011; Tang et al., 2014b,a) aim to learn sentiment-specific word embeddings (Bengio et al., 2003; Mikolov et al., 2013) from neighboring text. Another thread of research focuses on learning semantic composition (Mitchell and Lapata, 2010), including extensions to phrases and sentences with recursive neural networks (a class of syntax-tree models) (Socher et al., 2013; Irsoy and Cardie, 2014; Li et al., 2015) and to documents with distributed representations of sentences and paragraphs (Le and Mikolov, 2014; Tang et al., 2015) for modeling sentiment.

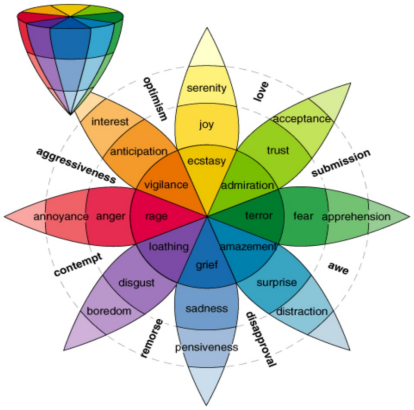
Long-short term memory (LSTM) (Hochreiter and Schmidhuber, 1997) and Gated Recurrent Neural Nets (GRNNs) (Cho et al., 2014; Chung et al., 2015), variations of recurrent neural networks (RNNs), a type of networks suitable for handling time-series data like speech (Graves et al., 2013) or handwriting recognition (Graves, 2012; Graves and Schmidhuber, 2009), have also been used successfully for sentiment analysis (Ren et al., 2016; Liu et al., 2015; Tai et al., 2015; Tang et al., 2015; Zhang et al., 2016). Convolutional neural networks (CNNs) have also been quite successful in NLP, and have been applied to a range of sentence classification tasks, including sentiment analysis (Blunsom et al., 2014; Kim, 2014; Zhang et al., 2015). Other architectures have also been recently proposed (e.g., (Bradbury et al., 2016)). A review of neural network methods for NLP can be found in (Goldberg, 2016).

3 Data

3.1 Collection of a Large-Scale Dataset

To be able to use deep learning for modeling emotion, we needed a large dataset of labeled tweets. Since there is no such human-labeled dataset publicly available, we follow (Mohammad, 2012; Mintz et al., 2009; Purver and Battersby, 2012; González-Ibánez et al., 2011; Wang et al., 2012) in adopting *distant supervision*: We collect tweets with emotion-carrying hashtags as a surrogate for emotion labels. To be able to collect enough tweets to serve our need, we developed a list of hashtags representing each of the 24 emotions proposed by Robert Plutchick (Plutchik, 1980, 1985, 1994). Plutchik (Plutchik, 2001) organizes emotions in a three-dimensional circumplex model analogous to the colors on a color wheel. The cone's vertical dimension represents intensity, and the 3 circle represent degrees of similarity

Figure 1: Plutchik's wheel of emotion.



among the various emotion types. The eight sectors are meant to capture that there are eight primary emotion dimensions arranged as four pairs of opposites. Emotions in the blank spaces are the primary emotion dyads (i.e., emotions that are mixtures of two of the primary emotions). For this work, we exclude the dyads in the exploded model from our treatment. For simplicity, we refer to the circles as `plutchik-1`: with the emotions {*admiration, amazement, ecstasy, grief, loathing, rage, terror, vigilance*}, `plutchik-2`: with the emotions {*joy, trust, fear, surprise, sadness, disgust, anger, anticipation*}, and `plutchik-3`: with the emotions {*acceptance, annoyance, apprehension, boredom, distraction, interest, pensiveness, serenity*}. The wheel is shown in Figure 1.

For each emotion type, we prepared a seed set of hashtags representing the emotion. We used Google synonyms and other online dictionaries and thesauri (e.g., `www.thesaurus.com`) to expand the initial seed set of each emotion. We acquire a total of 665 emotion hashtags across the 24 emotion types. For example, for the *joy* emotion, a subset of the seeds in our expanded set is {*"happy", "happiness", "joy", "joyful", "joyfully", "delighted", "feelingsunny", "blithe", "beatific", "exhilarated", "blissful", "walkingonair", "jubilant"*}. We then used the expanded set to extract tweets with hashtags from the set from a number of massive-scale in-house Twitter datasets. We also used Twitter API to crawl Twitter with hashtags from the expanded set. Using this method, we were able to acquire a dataset of about $1/4$ billion tweets covering an extended time span from July 2009 till January 2017.

3.2 Preprocessing and Quality Assurance

Twitter data are very noisy, not only because of use of non-standard typography (which is less of a problem here) but due to the many duplicate tweets and the fact that tweets often have multiple emotion hashtags. Since these reduce our ability to build accurate models, we need to clean the data and remove duplicates. Starting with $>$ 1/4 billion tweets, we employ a rigorous and strict pipeline. This results in a vastly smaller set of about 1.6 million dependable labeled tweets.

Since our goal is to create non-overlapping categories at the level of a tweet, we first removed all tweets with hashtags belonging to more than one emotion of the 24 emotion categories. Since it was observed (e.g., (Mohammad, 2012; Wang et al., 2012)) and also confirmed by our annotation study as described in Section 4, that hashtags in tweets with URLs are less likely to correlate with a true emotion label, we remove all tweets with URLs from our data. We filter out duplicates using a two-step procedure: 1) we remove all retweets (based on existence of the token "RT" regardless of case) and 2) we use the Python library *pandas* `http://pandas.pydata.org/` "drop_duplicates" method to compare the tweet texts of all the tweets after normalizing character repetitions [all consecutive characters of $>$ 2 to 2] and user mentions (as detected by a string starting with an "@" sign). We then performed a manual inspection of a random sample of 1,000 tweets from the data and found no evidence of any remaining tweet duplicates.

Next, even though the emotion hashtags themselves are exclusively in English, we observe the data do have tweets in languages other than English. This is due to code-switching, but also to the fact that our data dates back to 2009 and Twitter did not allow use of hashtags for several non-English languages until 2012. To filter out non-English, we use the langid (Lui and Baldwin, 2012) (`https://github.com/saffsd/langid.py`) library to assign language tags to the tweets. Since the common wisdom in the literature (e.g., (Mohammad, 2012; Wang et al., 2012)) is to restrict data to hashtags occurring in final position of a tweet, we investigate correlations between a tweet's relevance and emotion hashtag location in Section 4 and test models exclusively on data with hashtags occurring in final position. We also only use tweets con-

taining at least 5 words.

Table 2 shows statistics of the data after applying our cleaning, filtering, language identification, and deduplication pipeline. Since our focus is on English, we only show statistics for tweets tagged with an "en" (for "English") label by langid. Table 2 provides three types of relevant statistics: 1) counts of all tweets, 2) counts of tweets with at least 5 words and the emotion hashtags occurring in the *last quarter* of the tweet text (based on character count), and 3) counts of tweets with at least 5 words and the emotion hashtags occurring as the *final* word in the tweet text. As the last column in Table 2 shows, employing our most strict criterion where an emotion hashtag must occur finally in a tweet of a minimal length 5 words, we acquire a total of 1,608,233 tweets: 205,125 tweets for `plutchik-1`, 790,059 for `plutchik-2`, and 613,049 for `plutchik-3`. 4 Annotation Study

In their work, (Wang et al., 2012) manually label a random sample of 400 tweets extracted with hashtags in a similar way as we acquire our data and find that human annotators agree 93% of the time with the hashtag emotion type if the hashtag occurs as the last word in the tweet. We wanted to validate our use of hashtags in a similar fashion and on a bigger random sample. We had human annotators label a random sample of 5,600 tweets that satisfy our preprocessing pipeline. Manual inspection during annotation resulted in further removing a negligible 16 tweets that were found to have problems. For each of the remaining 5,584 tweets, the annotators assign a binary tag from the set {*relevant, irrelevant*} to indicate whether a tweet carries an emotion category as assigned using our distant supervision method or not. Annotators assigned 61.37% ($n = 3,427$) "relevant" tags and 38.63% ($n = 2,157$) "irrelevant" tags. Our analysis of this manually labeled dataset also supports the findings of (Wang et al., 2012): When we limit position of the emotion hashtag to the end of a tweet, we acquire 90.57% relevant data. We also find that if we relax the constraint on the hashtag position such that we allow the hashtag to occur in the last quarter of a tweet (based on a total tweet character count), we acquire 85.43% relevant tweets. We also find that only 23.20% ($n = 795$ out of $3,427$) of the emotion carrying tweets have the emotion hashtags occurring in final position, whereas 31.75% ($n = 1,088$ out of $3,427$) of the tweets have the emotion hashtags in the last quarter of the tweet string. This shows how enforcing a final hashtag location results in loss of a considerable number of emotion tweets. As shown in Table 2, only $1,608,233$ tweets out of a total of $6,851,955$ tweets ($\% = 23,47$) in our bigger dataset have emotion hashtags occurring in final position. Overall, we agree with (Mohammad, 2012; Wang et al., 2012) that the accuracy acquired by enforcing a strict pipeline and limiting to emotion hashtags to final position is a reasonable measure for warranting good-quality data for training supervised systems, an assumption we have also validated with our empirical findings here.

One advantage of using distant supervision under these conditions for labeling emotion data, as (Wang et al., 2012) also notes, is that the label is assigned by the writer of the tweet himself/herself rather than an annotator who could wrongly decide what category a tweet is. After all, emotion is a fuzzy concept and $> 90\%$ agreement as we

[2] The data can be acquired by emailing the first author. The distribution is in the form of tweet ids and labels, to adhere to Twitter conditions.

report here is higher than the human agreement usually acquired on many NLP tasks. Another advantage of this method is obviously that it enables us to acquire a sufficiently large training set to use deep learning. We now turn to describing our deep learning methods.

5 Methods

For our core modeling, we use *Gated Recurrent Neural Networks (GRNNs)*, a modern variation of *recurrent neural networks (RNNs)*, which we now turn to introduce. For notation, we denote scalars with italic lowercase (e.g., x), vectors with bold lowercase (e.g.,$\mathbf{x}$), and matrices with bold uppercase (e.g.,$\mathbf{W}$).

Recurrent Neural Network A recurrent neural network (RNN) is one type of neural network architecture that is particularly suited for modeling sequential information. At each time step t, an RNN takes an input vector $\mathbf{x}_t \in \mathbb{R}^n$ and a hidden state vector $\mathbf{h}_{t-1} \in \mathbb{R}^m$ and produces the next hidden state $\mathbf{h}_t$ by applying the recursive operation:

$$\mathbf{h}_t = f\left(\mathbf{W}\mathbf{x}_t + \mathbf{U}\mathbf{h}_{t-1} + \mathbf{b}\right) \quad (1)$$

Where the input to hidden matrix $\mathbf{W} \in \mathbb{R}^{mxn}$, the hidden to hidden matrix $\mathbf{U} \in \mathbb{R}^{mxm}$, and the bias vector $\mathbf{b} \in \mathbb{R}^m$ are parameters of an affine transformation and f is an element-wise nonlinearity. While an RNN can in theory summarize all historical information up to time step $\mathbf{h}_t$, in practice it runs into the problem of vanishing/exploding gradients (Bengio et al., 1994; Pascanu et al., 2013) while attempting to learn long-range dependencies.

LSTM Long short-term memory (LSTM) networks (Hochreiter and Schmidhuber, 1997) addresses this exact problem of learning long-term dependencies by augmenting an RNN with a memory cell $\mathbf{c}_t \in \mathbb{R}^n$ at each time step. As such, in addition to the input vector $\mathbf{x}_t$, the hiddent vector $\mathbf{h}_{t-1}$, an LSTM takes a cell state vector $\mathbf{c}_{t-1}$ and produces $\mathbf{h}_t$ and $\mathbf{c}_t$ via the following calculations:

$$\begin{aligned}
\mathbf{i}_t &= \sigma\left(\mathbf{W}^i x_t + \mathbf{U}^i \mathbf{h}_{t-1} + \mathbf{b}^i\right) \\
\mathbf{f}_t &= \sigma\left(\mathbf{W}^f x_t + \mathbf{U}^f \mathbf{h}_{t-1} + \mathbf{b}^f\right) \\
\mathbf{o}_t &= \sigma\left(\mathbf{W}^o x_t + \mathbf{U}^o \mathbf{h}_{t-1} + \mathbf{b}^o\right) \\
\mathbf{g}_t &= \tanh\left(\mathbf{W}^g x_t + \mathbf{U}^g \mathbf{h}_{t-1} + \mathbf{b}^g\right) \\
\mathbf{c}_t &= \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot \mathbf{g}_t \\
\mathbf{h}_t &= \mathbf{o}_t \odot \tanh(\mathbf{c}_t)
\end{aligned} \quad (2)$$

Where $\sigma(\cdot)$ and $\tanh(\cdot)$ are the element-wise sigmoid and hyperbolic tangent functions, $\odot$ the element-wise multiplication operator, and $\mathbf{i}_t$, $\mathbf{f}_t$, $\mathbf{o}_t$ are the *input*, forget, and *output* gates. The $\mathbf{g}_t$ is a new memory cell vector with candidates that could be added to the state. The LSTM parameters $\mathbf{W}_j$, $\mathbf{U}_j$, and $\mathbf{b}_j$ are for $j \in \{i, f, o, g\}$.

GRNNs (Cho et al., 2014; Chung et al., 2015) propose a variation of LSTM with a *reset gate* $\mathbf{r}_t$, an update state $\mathbf{z}_t$, and a new simpler hidden unit $\mathbf{h}_t$, as follows:

$$\begin{aligned}
\mathbf{r}_t &= \sigma\left(\mathbf{W}^r x_t + \mathbf{U}^r \mathbf{h}_{t-1} + \mathbf{b}^r\right) \\
\mathbf{z}_t &= \sigma\left(\mathbf{W}^z x_t + \mathbf{U}^z \mathbf{h}_{t-1} + \mathbf{b}^z\right) \\
\tilde{\mathbf{h}}_t &= \tanh\left(\mathbf{W} x_t + \mathbf{r}_t * \mathbf{U}^{\tilde{h}} \mathbf{h}_{t-1} + \mathbf{b}^{\tilde{h}}\right) \\
\mathbf{h}_t &= \mathbf{z}_t * \mathbf{h}_{t-1} + (1 - \mathbf{z}_t) * \tilde{\mathbf{h}}_t
\end{aligned} \quad (3)$$

The GRNN parameters $\mathbf{W}_j$, $\mathbf{U}_j$, and $\mathbf{b}_j$ are for $j \in \{r, z, \tilde{h}\}$. In this set up, the hidden state is forced to ignore a previous hidden state when the reset gate is close to 0, thus enabling the network to forget or drop irrelevant information. Additionally, the update gate controls how much information carries over from a previous hidden state to the current hidden state (similar to an LSTM memory cell). We use GRNNs as they are simpler and faster than LSTM. For GRNNs, we use Theano (Theano Development Team, 2016).

Online Classifiers We compare the performance of the GRNNs to four online classifiers that are capable of handling the data size: Stochastic Gradient Descent (SGD), Multinomial Naive Bayes (MNB), Perceptron, and the Passive Agressive Classifier (PAC). These classifiers learn online from mini-batches of data. We use mini-batches of 10,000 instances with all the four classifiers. We use the *scikit-learn* implementation of these classifiers (`http://scikit-learn.org`).

Settings We aim to model Plutchik's 24 fine-grained emotions as well as his 8 primary emotion dimensions where each 3 related types of emotion (perceived as varying in intensity) are combined in one dimension. We now turn to describing our experiments experiments.

6 Experiments

6.1 Predicting Fine-Grained Emotions

As explained earlier, Plutchik organizes the 24 emotion types in the 3 main circles that we will refer to as *plutchik-1*, *plutchik-2*, and *plutchik-3*.

Emotion	Qadir (2013)		Roberts (2012)		MD (2015)		Wang (2012)		Volkova (2016)		This work

Table 3: Results in F-score with traditional online classifiers.

We model the set of emotions belonging to each of the 3 circles independently, thus casting each as an 8-way classification task. Inspired by observations from the literature and our own annotation study, we limit our data to tweets of at least 5 words with an emotional hashtag occurring at the end. We then split the data representing each of the 3 circles into 80% training (TRAIN), 10% development (DEV), and 10% testing (TEST). As mentioned above, we run experiments with a range of online, out-of-core classifiers as well as the GRNNs. To train the GRNNs, we optimize the hyper-parameters of the network on a development set as we describe below, choosing a vocabulary size of 80K words (a vocabulary size we also use for the out-of-core classifiers), a word embedding vector of size 300 dimensions learnt directly from the training data, an input maximum length of 30 words, 7 epochs, and the Adam (Kingma and Ba, 2014) optimizer with a learning rate of 0.001. We use 3 dense layers each with $1,000$ units. We use dropout (Hinton et al., 2012) for regularization, with a dropout rate of 0.5. For our loss function, we use categorical cross-entropy. We use a mini-batch (Cotter et al., 2011) size of 128. We found this architecture to work best with almost all the settings and so we fix it across the board for all experiments with GRNNs.

Results with Traditional Classifiers Results with the online classifiers are presented in terms of F-score in Table 3. As the table shows, among this group of classifiers, the Passive Agressive classifier (PAC) acquires the best performance. PAC achieves an overall F-score of 64.86% on `plutchik-1`, 53.30% on `plutchik-2`, and 68.14% on `plutchik-3`, two of which are higher than an arbitrary baseline[3] of 60%.

Results with GRNNs Table 4 presents results with GRNNs, compared with the best results using the traditional classifiers as acquired with PAC. As the table shows, the GRNN models are very successful across all the 3 classification tasks. With GRNNs, we acquire an overall F-scores of: 91.21% on `plutchik-1`, 82.32% on `plutchik-2`, and 87.47% on `plutchik-3`. These results are 26.35%, 29.02%, and 25.37% higher than PAC, respectively.

Negative Results We experiment with aug-

[3]The arbitrary baseline is higher than the majority class in the training data in any of the 3 cases.

Table 4: Results with GRNNs across Plutchik's 24 emotion categories. We compare to best-performing traditional classifier (i.e. Passive Aggressive).

menting training data reported here in two ways: 1) For each emotion type, we concatenate the training data with training data of tweets that are more (or less) intense from the same sector/dimension in the wheel, and 2) for each emotion type, we add tweets where emotion hashtags occur in the last quarter of a tweet (which were originally filtered out from TRAIN). However, we gain no improvements based on either of these methods, thus reflecting the importance of using high-quality training data and the utility of our strict pipeline.

6.2 Predicting 8 Primary Dimensions

We now investigate the task of predicting each of the 8 primary emotion dimensions represented by the sectors of the wheel (where the three degrees of intensity of a given emotion are reduced to a single emotion dimension [e.g., {*ecstasy, joy, serenity*} are reduced to the *joy* dimension]). We concatenate the 80% training data (TRAIN) from each of the 3 circles' data into a single training set (TRAIN-ALL), the 10% DEV to form DEV-ALL, and the 10% TEST to form TEST-ALL. We test a number of hyper-parameters on DEV and find the ones we have identified on the fine-grained prediction to work best and so we adopt them as is with the exception of limiting to only 2 epochs. We believe that with a wider exploration of hyper-parameters, improvements could be possible. As Table 5 shows, we are able to model the 8 dimensions with an overall superior accuracy of 95.68%. As far as we know, this is the first work on modeling these dimensions.

Dimension	**prec**	**rec**	**f-score**
anger	97.40	97.72	97.56
anticipation	91.18	89.95	90.56
disgust	96.20	93.94	95.06
fear	94.97	94.38	94.68

sadness	95.52	95.25	95.39
surprise	94.99	91.62	93.27
trust	96.36	97.58	96.96
All	**95.68**	**95.68**	**95.68**

Table 5: GRNNs results across 8 emotion dimensions. Each dimension represents three different emotions. For example, the *joy* dimension represents *serenity, joy* and *ecstasy*.

Emotion	**Volkova (2016) model**	**This work**
anger	12.38	74.95
disgust	5.71	82.18
fear	11.18	73.74
joy	44.57	90.96
sadness	18.04	73.20
surprise	5.33	85.60
ALL	**26.95**	**80.12**

Table 7: Comparison (in acc) to (Volkova and Bachrach, 2016)'s model.

7 Comparisons to Other Systems

We compare our results on the 8 basic emotions to the published literature. As Table 6 shows, on this subset of emotions, our system is 4.53% (acc) higher than the best published results (Volkova and Bachrach, 2016), facilitated by the fact that we have an order of magnitude more training data. As shown in Table 7, we also apply (Volkova and Bachrach, 2016)'s pre-trained model on our test set of the 6 emotions they predict (which belong to `plutchik-2`), and acquire an overall accuracy of 26.95%, which is significantly lower than our accuracy.

8 Conclusion

In this paper, we built a large, automatically curated dataset for emotion detection using distant supervision and then used GRNNs to model fine-grained emotion, achieving a new state-of-the-art performance. We also extended the classification to 8 primary emotion dimensions situated in psychological theory of emotion.

Abstract

Automatic political preference prediction from social media posts has to date proven successful only in distinguishing between publicly declared liberals and conservatives in the US. This study examines users' political ideology using a seven-point scale which enables us to identify politically moderate and neutral users – groups which are of particular interest to political scientists and pollsters. Using a novel data set with political ideology labels self-reported through surveys, our goal is two-fold: a) to characterize the political groups of users through language use on Twitter; b) to build a fine-grained model that predicts political ideology of unseen users. Our results identify differences in both political leaning and engagement and the extent to which each group tweets using political keywords. Finally, we demonstrate how to improve ideology prediction accuracy by exploiting the relationships between the user groups.

1 Introduction

Social media is used by people to share their opinions and views. Unsurprisingly, an important part of the population shares opinions and news related to politics or causes they support, thus offering strong cues about their political preferences and ideologies. In addition, political membership is also predictable purely from one's interests or demographics — it is much more likely for a religious person to be conservative or for a younger person to lean liberal (Ellis and Stimson, 2012).

User trait prediction from text is based on the assumption that language use reflects a user's demographics, psychological states or preferences. Applications include prediction of age (Rao et al., 2010; Flekova et al., 2016b), gender (Burger et al., 2011; Sap et al., 2014), personality (Schwartz et al., 2013; Preoţiuc-Pietro et al., 2016), socioeconomic status (Preoţiuc-Pietro et al., 2015a,b; Liu et al., 2016c), popularity (Lampos et al., 2014) or location (Cheng et al., 2010).

Research on predicting political orientation has focused on methodological improvements (Pennacchiotti and Popescu, 2011) and used data sets with publicly stated dichotomous political orientation labels due to their easy accessibility (Sylwester and Purver, 2015). However, these data sets are not representative samples of the entire population (Cohen and Ruths, 2013) and do not accurately reflect the variety of political attitudes and engagement (Kam et al., 2007).

For example, we expect users who state their political affiliation in their profile description, tweet with partisan hashtags or appear in public party lists to use social media as a means of popularizing and supporting their political beliefs (BarberASa, 2015). Many users may choose not to publicly post about their political preference for various social goals or perhaps this preference may not be strong or representative enough to be disclosed online. Dichotomous political preference also ignores users who do not have a political ideology. All of these types of users are very important for researchers aiming to understand group preferences, traits or moral values (Lewis and Reiley, 2014; Hersh, 2015).

The most common political ideology spectrum in the US is the conservative – liberal (Ellis and Stimson, 2012). We collect a novel data set of Twitter users mapped to this seven-point spectrum which allows us to:

* Work carried out during a research visit at the University of Pennsylvania

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 729–740
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1068

1. Uncover the differences in language use between ideological groups;
2. Develop a user-level political ideology prediction algorithm that classifies all levels of engagement and leverages the structure in the political ideology spectrum.

First, using a broad range of language features including unigrams, word clusters and emotions, we study the linguistic differences between the two ideologically extreme groups, the two ideologically moderate groups and between both extremes and moderates in order to provide insight into the content they post on Twitter. In addition, we examine the extent to which the ideological groups in our data set post about politics and compare it to a data set obtained similarly to previous work.

In prediction experiments, we show how accurately we can distinguish between opposing ideological groups in various scenarios and that previous binary political orientation prediction has been oversimplified. Then, we measure the extent to which we can predict the two dimensions of political leaning and engagement. Finally, we build an ideology classifier in a multi-task learning setup that leverages the relationships between groups.[1]

2 Related Work

Automatically inferring user traits from their online footprints is a prolific topic of research, enabled by the increasing availability of user generated data and advances in machine learning. Beyond its research oriented goals, user profiling has important industry applications in online marketing, personalization or large-scale audience profiling. To this end, researchers have used a wide range of types of online footprints, including video (Subramanian et al., 2013), audio (Alam and Riccardi, 2014), text (Preoţiuc-Pietro et al., 2015a), profile images (Liu et al., 2016a), social data (Van Der Heide et al., 2012; Hall et al., 2014), social networks (Perozzi and Skiena, 2015; Rout et al., 2013), payment data (Wang et al., 2016) and endorsements (Kosinski et al., 2013).

Political orientation prediction has been studied in two related, albeit crucially different scenarios, as also identified in (Zafar et al., 2016). First, researchers aimed to identify and quantify orientation of words (Monroe et al., 2008), hashtags (Weber et al., 2013) or documents (Iyyer et al., 2014), or to detect bias (Yano et al., 2010) or impartiality (Zafar et al., 2016) at a document level.

Our study belongs to the second category, where political orientation is inferred at a user-level. All previous studies study labeling US conservatives vs. liberals using either text (Rao et al., 2010), social network connections (Zamal et al., 2012), platform-specific features (Conover et al., 2011) or a combination of these (Pennacchiotti and Popescu, 2011; Volkova et al., 2014), with very high reported accuracies of up to 94.9% (Conover et al., 2011).

However, all previous work on predicting user-level political preferences are limited to a binary prediction between liberal/democrat and conservative/republican, disregarding any nuances in political ideology. In addition, as the focus of the studies is more on the methodological or interpretation aspects of the problem, another downside is that the user labels were obtained in simple, albeit biased ways. These include users who explicitly state their political orientation on user lists of party supporters (Zamal et al., 2012; Pennacchiotti and Popescu, 2011), supporting partisan causes (Rao et al., 2010), by following political figures (Volkova et al., 2014) or party accounts (Sylwester and Purver, 2015) or that retweet partisan hashtags (Conover et al., 2011). As also identified in (Cohen and Ruths, 2013) and further confirmed later in this study, these data sets are biased: most people do not clearly state their political preference online – fewer than 5% according to Priante et al. (2016) – and those that state their preference are very likely to be political activists. Cohen and Ruths (2013) demonstrated that predictive accuracy of classifiers is significantly lower when confronted with users that do not explicitly mention their political orientation. Despite this, their study is limited because in their hardest classification task, they use crowdsourced political orientation labels, which may not correspond to reality and suffer from biases (Flekova et al., 2016a; Carpenter et al., 2016). Further, they still only look at predicting binary political orientation. To date, no other research on this topic has taken into account these findings.

3 Data Set

The main data set used in this study consists of 3,938 users recruited through the Qualtrics platform ($\mathcal{D}_1$). Each participant was compensated

[1] Data is available at http://www.preotiuc.ro

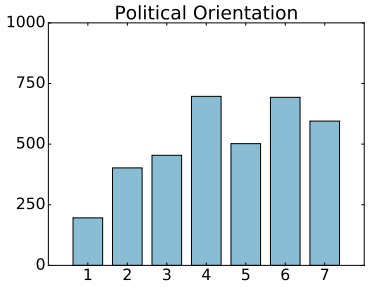

Figure 1: Distribution of political ideology in our data set, from 1 – Very Conservative through 7 – Very Liberal.

with 3 USD for 15 minutes of their time. All participants first answered the same demographic questions (including political ideology), then were directed to one of four sets of psychological questionnaires unrelated to the political ideology question. They were asked to self-report their political ideology on a seven point scale: *Very conservative* (1), *Conservative* (2), *Moderately conservative* (3), *Moderate* (4), *Moderately liberal* (5), *Liberal* (6), *Very liberal* (7). In addition, participants had the option of choosing *Apathetic* and *Other*, which have ambiguous fits on the conservative – liberal spectrum and were removed from our analysis (399 users). We also asked participants to self-report their gender (2322 female, 1205 male, 12 other) and age. Participants were all from the US in order to limit the impact of cultural and political factors. The political ideology distribution in our sample is presented in Figure 1.

We asked users their Twitter handle and downloaded their most recent 3,200 tweets, leading to a total of 4,833,133 tweets. Before adding users to our 3,938 user data set, we performed the following checks to ensure that the Twitter handle was the user's own: 1) *after* compensation, users were if they were truthful in reporting their handle and if not, we removed their data from analysis; 2) we manually examined all handles marked as verified by Twitter or that had over 2000 followers and eliminated them if they were celebrities or corporate/news accounts, as these were unlikely the users who participated in the survey. This study received approval from the Institutional Review Board (IRB) of the University of Pennsylvania.

In addition, to facilitate comparison to previous work, we also use a data set of 13,651 users with overt political orientation ($\mathcal{D}_2$). We selected popular political figures unambiguously associated with US liberal politics (@SenSanders, @JoeBiden, @CoryBooker, @JohnKerry) or US conservative politics (@marcorubio, @tedcruz, @RandPaul, @RealBenCarson). Liberals in our set ($N_l = 7417$) had to follow on Twitter all of the liberal political figures and none of the conservative figures. Likewise, conservative users ($N_c = 6234$) had to follow all of the conservative figures and no liberal figures. We downloaded up to 3,200 of each user's most recent tweets, leading to a total of 25,493,407 tweets. All tweets were downloaded around 10 August 2016.

4 Features

In our analysis, we use a broad range of linguistic features described below.

Unigrams We use the bag-of-words representation to reduce each user's posting history to a normalised frequency distribution over the vocabulary consisting of all words used by at least 10% of the users (6,060 words).

LIWC Traditional psychological studies use a dictionary-based approach to representing text. The most popular method is based on Linguistic Inquiry and Word Count (LIWC) (Pennebaker et al., 2001), and automatically counts word frequencies for 64 different categories manually constructed based on psychological theory. These include different parts-of-speech, topical categories and emotions. Each user is thereby represented as a frequency distribution over these categories.

Word2Vec Topics An alternative to LIWC is to use automatically generated word clusters i.e., groups of words that are semantically and/or syntactically similar. The clusters help reducing the feature space and provides additional interpretability.

To create these groups of words, we use an automatic method that leverages word co-occurrence patterns in large corpora by making use of the distributional hypothesis: similar words tend to co-occur in similar contexts (Harris, 1954). Based on co-occurrence statistics, each word is represented as a low dimensional vector of numbers with words closer in this space being more similar (Deerwester et al., 1990). We use the method from (Preoţiuc-Pietro et al., 2015a) to compute topics using word2vec similarity (Mikolov et al., 2013a,b) and spectral clustering (Shi and Malik, 2000; von Luxburg, 2007) of different sizes (from 30 to 2000). We have tried other alternatives to building clusters: using other word similarities to

generate clusters – such as NPMI (Lampos et al., 2014) or GloVe (Pennington et al., 2014) as proposed in (Preoţiuc-Pietro et al., 2015a) – or using standard topic modelling approached to create soft clusters of words e.g., Latent Dirichlet Allocation (Blei et al., 2003). For brevity, we present experiments with the best performing feature set containing 500 Word2Vec clusters. We aggregate all the words posted in a users' tweets and represent each user as a distribution of the fraction of words belonging to each cluster.

Sentiment & Emotions We hypothesise that different political ideologies differ in the type and amount of emotions the users express through their posts. The most studied model of discrete emotions is the Ekman model (Ekman, 1992; Strapparava and Mihalcea, 2008; Strapparava et al., 2004) which posits the existence of six basic emotions: anger, disgust, fear, joy, sadness and surprise. We automatically quantify these emotions from our Twitter data set using a publicly available crowd-sourcing derived lexicon of words associated with any of the six emotions, as well as general positive and negative sentiment (Mohammad and Turney, 2010, 2013). Using these lexicons, we assign a predicted emotion to each message and then average across all users' posts to obtain user level emotion expression scores.

Political Terms In order to select unigrams pertaining to politics, we assigned the most frequent 12,000 unigrams in our data set to three categories:

- **Political words**: mentions of political terms (234);
- **Political NEs**: mentions of politician proper names out of the political terms (39);
- **Media NEs**: mentions of political media sources and pundits out of the political terms (20).

This coding was initially performed by a research assistant studying political science with good knowledge of US politics and were further filtered and checked by one of the authors.

5 Analysis

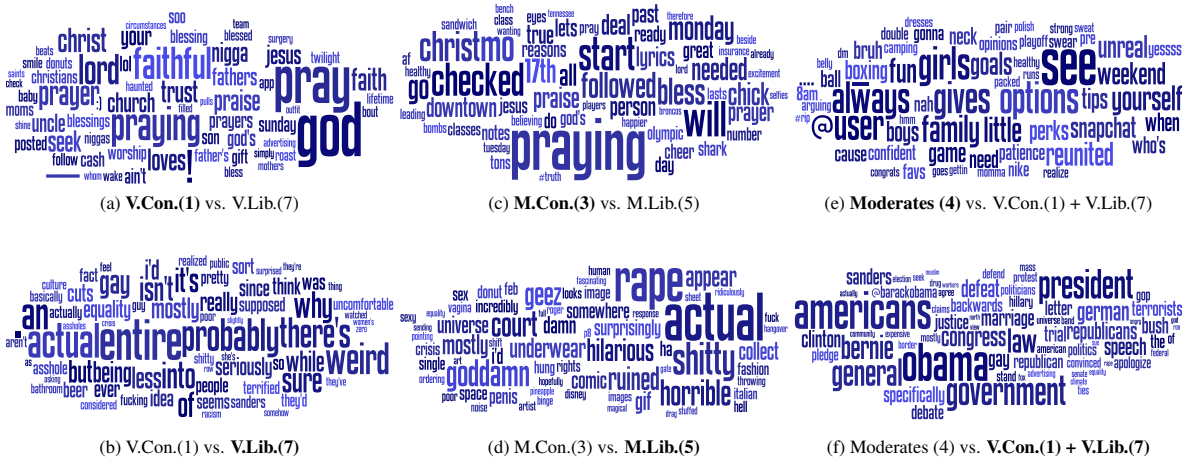
First, we explore the relationships between language use and political ideological groups within each feature set and pairs of opposing user groups. To illustrate differences between ideological groups we compare the two political extremes (Very Conservative – Very Liberal) and the political moderates (Moderate Conservative – Moderate Liberal). We further compare outright moderates with a group combining the two political extremes to study if we can uncover differences in political engagement and extremity, regardless of the conservative–liberal leaning.

We use univariate partial linear correlations with age and gender as co-variates to factor out the influence of basic demographics. For example, in $\mathcal{D}_1$, users who reported themselves as very conservative are older and more likely males ($\mu_{age} = 35.1, \text{pct}_{male} = 44\%$) than the data average ($\mu_{age} = 31.2, \text{pct}_{male} = 35\%$). Additionally, prior to combining the two ideologically extreme groups, we sub-sampled the larger class (Very Liberal) to match the smaller class (Very Conservative) in age and gender. In the later prediction experiments, we do not perform matching, as this represents useful signal for classification (Ellis and Stimson, 2012). Results with unigrams are presented in Figure 2 and with the other features in Table 1. These are selected using standard statistical significance tests.

5.1 Very Conservatives vs. Very Liberals

The comparison between the extreme categories reveals the largest number of significant differences. The unigrams and Word2Vec clusters specific to conservatives are dominated by religion specific terms ('praying', 'god', W2V-485, W2V-018, W2V-099, L-RELIG), confirming a well-documented relationship (Gelman, 2009) and words describing family relationships ('uncle', 'son', L-FAMILY), another conservative value (Lakoff, 1997). The emphasis on religious terms among conservatives is consistent with the claim that many Americans associate 'conservative' with 'religious' (Ellis and Stimson, 2012). Extreme liberals show a tendency to use more adjectives (W2V-075, W2V-110), adverbs (L-ADVERB), conjunctions (L-CONJ) and comparisons (L-COMPARE) which indicate more nuanced and complex posts. Extreme conservatives post tweets higher in all positive emotions than liberals (L-POSEMO, Emot-Joy, Emot-Positive), confirming a previously hypothesised relationship (Napier and Jost, 2008). However, extreme liberals are not associated with posting negative emotions either, only using words that reflect more anxiety (L-ANX), which is related to neuroticism in which the liberals are higher (Gerber et al., 2010).

Political term analysis reveals the partisan terms



(a) **V.Con.(1)** vs. V.Lib.(7)

(c) **M.Con.(3)** vs. M.Lib.(5)

(e) **Moderates (4)** vs. V.Con.(1) + V.Lib.(7)

(b) V.Con.(1) vs. **V.Lib.(7)**

(d) M.Con.(3) vs. **M.Lib.(5)**

(f) Moderates (4) vs. **V.Con.(1) + V.Lib.(7)**

Figure 2: Unigrams with the highest 80 Pearson correlations shown as word clouds in three vertical panels with a binary variable representing the two ideological groups compared. The size of the unigram is scaled by its correlation with the ideological group in bold. The color indexes relative frequency, from light blue (rarely used) to dark blue (frequently used). All correlations are significant at $p < .05$ and controlled for age and gender.

Table 1: Pearson correlations between political ideology groups and text features, split into Word2Vec clusters (W2V), LIWC categories (L), emotions (Emot) and political terms (maximum 5 categories per group). All correlations are significant at $p < .01$, two-tailed t-test and are controlled for age and gender. Words in a category are sorted by frequency in our data set.

employed by both sides. For example, conservatives retweet or mention politicians such as Donald Trump or Ted Cruz, while liberals mention Barack Obama. Extreme conservatives also reference known partisan conservative media sources (@foxnews, @yahoonews) and hashtags (#pjnet,

#tcot), while extreme liberals focus on issues ('gay', 'racism', 'feminism', 'transgender'). This perhaps reflects the desire for conservatives on Twitter to identify like-minded individuals, as extreme conservatives are a minority on the platform. Liberals, by contrast, use the platform to discuss and popularize their causes.

5.2 Moderate Conservatives vs. Moderate Liberals

Comparing the two sides of moderate users reveals a slightly more nuanced view of the two ideologies. While moderate conservatives still make heavy use of religious terms and express positive emotions (Emot-Joy, L-DRIVES), they also use affiliative language (L-AFFILIATION) and plural pronouns (L-WE). Moderate liberals are identified by very different features compared to their more extreme counterparts. Most striking is the use of swear and sex words (L-SEXUAL, L-ANGER, W2V-316), also highlighted by Sylwester and Purver (2015). Two word clusters relating to British culture (W2V-458) and art (W2V-373) reflect that liberals are more inclined towards arts (Dollinger, 2007). Statistically significant political terms are very few compared to the previous comparison, probably due to their lower overall usage, which we further investigate later.

5.3 Moderates vs. Extremists

Our final comparison looks at outright moderates compared to the two extreme groups combined, as we hypothesise the existence of a difference in overall political engagement. Moderates are not characterized by many features besides a topic of casual words (W2V-098), indicating the heterogeneity of this group of users. However, regardless of their orientation, the ideological extremists stand out from moderates. They use words and word clusters related to political actors (W2V-309), issues (W2V-237) and laws (W2V-296, W2V-288). LIWC analysis uncovers differences in article use (L-ARTICLE) or power words (L-POWER) specific of political tweets. The overall sentiment of these users is negative (Emot-Fear, Emot-Disgust, Emot-Sadness, L-DEATH) compared to moderates. This reveals – combined with the finding from the first comparison – that while extreme conservatives are overall more positive than liberals, both groups share negative expression. Political terms are almost all significantly correlated with the extreme ideological groups, confirming the existence of a difference in political engagement which we study in detail next.

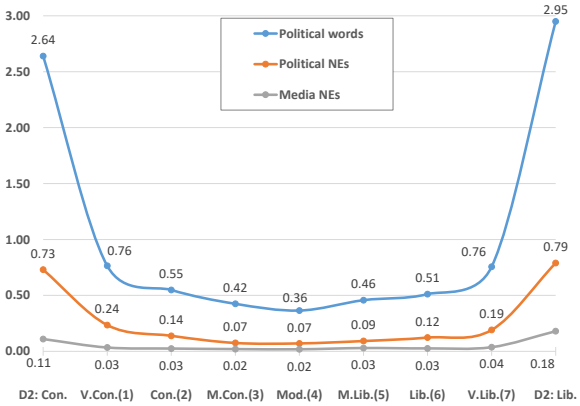

Figure 3: Distribution of political word and entity usage across political categories in % from the total words used. Users from data set $\mathcal{D}_2$ who are following the accounts of the four political figures are prefixed with *D2*. The rest of the categories are from data set $\mathcal{D}_1$.

5.4 Political Terms

Figure 3 presents the use of the three types of political terms across the 7 ideological groups in $\mathcal{D}_1$ and the two political groups from $\mathcal{D}_2$. We notice the following:

- $\mathcal{D}_2$ has a huge skew towards political words, with an average of more than three times more political terms across all three categories than our extreme classes from $\mathcal{D}_1$;
- Within the groups in $\mathcal{D}_1$, we observe an almost perfectly symmetrical U-shape across all three types of political terms, confirming our hypothesis about political engagement;
- The difference between 1–2/6–7 is larger than 2–3/5–6. The extreme liberals and conservatives are disproportionately political, and have the potential to give Twitter's political discussions an unrepresentative, extremist hue (Fiorina, 1999). It is also possible, however, that characterizing one as an extreme liberal or conservative indicates as much about her level of political engagement as it does about her placement on a left-right scale (Converse, 1964; Broockman, 2016).

6 Prediction

In this section we build predictive models of political ideology and compare them to data sets obtained using previous work.

6.1 Cross-Group Prediction

First, we experiment with classifying between conservatives and liberals across various levels of political engagement in $\mathcal{D}_1$ and between the two polarized groups in $\mathcal{D}_2$. We use logistic regression classification to compare three setups in Table 2 with results measured with ROC AUC as the classes are slightly inbalanced:

- 10-fold cross-validation where training is performed on the same task as the testing (principal diagonal);
- A train–test setup where training is performed on one task (presented in rows) and testing is performed on another (presented in columns);
- A domain adaptation setup (results in brackets) where on each of the 10 folds, the 9 training folds (presented in rows) are supplemented with all the data from a different task (presented in columns) using the EasyAdapt algorithm (Daumé III, 2007) as a proof on concept on the effects of using additional distantly supervised data. Data pooling lead to worse results than EasyAdapt.

Each of the three tasks from $\mathcal{D}_1$ have a similar number of training samples, hence we do not expect that data set size has any effects in comparing the results across tasks.

The results with both sets of features show that:

- Prediction performance is much higher for $\mathcal{D}_2$ than for $\mathcal{D}_1$, with the more extreme groups in $\mathcal{D}_1$ being easier to predict than the moderate groups. This confirms that the very high accuracies reported by previous research are an artifact of user label collection and that on regular users, the expected accuracy is much lower (Cohen and Ruths, 2013). We further show that, as the level of political engagement decreases, the classification problem becomes even harder;
- The model trained on $\mathcal{D}_2$ and Word2Vec word clusters performs significantly worse on $\mathcal{D}_1$ tasks even if the training data is over 10 times larger. When using political words, the $\mathcal{D}_2$ trained classifier performs relatively well on all tasks from $\mathcal{D}_1$;
- Overall, using political words as features performs better than Word2Vec clusters in the binary classification tasks;
- Domain adaptation helps in the majority of cases, leading to improvements of up to .03 in AUC (predicting 2v6 supplemented with 3v5 data).

3v5	.727 (.766)	.636 (.670)	.590	.891 (*.976*)
D2	.766 (*.789*)	.677 (*.683*)	**.625** (.613)	**.972**

(b) Political Terms

Table 2: Prediction results of the logistic regression classification in ROC AUC when discriminating between two political groups across different levels of engagement and both data sets. The binary classifier from data set $\mathcal{D}_2$ is represented by *D2*, the rest of the categories are from data set $\mathcal{D}_1$. Results on the principal diagonal represent 10-fold cross-validation results (training in-domain). Results off-diagonal represent training the classifier from the column and testing on the problem indicated in the row (training out-of-domain). Numbers in brackets indicate performance when the training data was added in the 10-fold cross-validation setup using the EasyAdapt algorithm (domain adaptation). Best results without domain adaptation are in bold, while the best results with domain adaptation are in italics.

6.2 Political Leaning and Engagement Prediction

Political leaning (Conservative – Liberal, excluding the Moderate group) can be considered an ordinal variable and the prediction problem framed as one of regression. In addition to the political leaning prediction, based on analysis and previous prediction results, we hypothesize the existence of a separate dimension of political engagement regardless of the partisan side. Thus, we merge users from classes 3–5, 2–6, 1–7 and create a variable with four values, where the lowest value is represented by moderate users (4) and the highest value is represented by either very conservative (1) or very liberal (7) users.

We use a linear regression algorithm with an Elastic Net regularizer (Zou and Hastie, 2005) as implemented in ScikitLearn (Pedregosa et al., 2011). To evaluate our results, we split our data into 10 stratified folds and performed cross-validation on one held-out fold at a time. For all our methods we tune the parameters of our models on a separate validation fold. The overall performance is assessed using Pearson correlation between the set of predicted values and the user-reported score. Results are presented in Table 3.

The same patterns hold when evaluating the results with Root Mean Squared Error (RMSE).

Features	# Feat.	Political Leaning	Political Engagement
Unigrams	6060	.294	.165
LIWC	73	.286	.149
Word2Vec Clusters	500	*.300*	*.169*
Emotions	8	.145	.079
Political Terms	234	.256	*.169*
All (Ensemble)	5	**.369**	**.196**

Table 3: Pearson correlations between the predictions and self-reported ideologies using linear regression with each feature category and a linear combination of their predictions in a 10-fold cross-validation setup. Political leaning is represented on the 1–7 scale removing the moderates (4). Political engagement is a scale ranging from 4 through 3–5 and 2–6 to 1–7.

The results show that both dimensions can be predicted well above chance, with political leaning being easier to predict than engagement. Word2Vec clusters obtain the highest predictive accuracy for political leaning, even though they did not perform as well in the previous classification tasks. For political engagement, political terms and Word2Vec clusters obtain similar predictive accuracy. This result is expected based on the results from Figure 3, which showed how political term usage varies across groups, and how it is especially dependent on political engagement. While political terms are very effective at distinguishing between two opposing political groups, they can not discriminate as well between levels of engagement within the same ideological orientation. Combining all classifiers' predictions in a linear ensemble obtains best results when compared to each individual category.

6.3 Encoding Class Structure

In our previous experiments, we uncovered that certain relationships exist between the seven groups. For example, extreme conservatives and liberals both demonstrate strong political engagement. Therefore, this class structure can be exploited to improve classification performance. To this end, we deploy the sparse graph regularized approach (Argyriou et al., 2007; Zhou et al., 2011) to encode the structure of the seven classes as a graph regularizer in a logistic regression framework.

In particular, we employed a multi-task learning paradigm, where each task is a one-vs-all classification. Multi-task learning (MTL) is a learning paradigm that jointly learns multiple related tasks and can achieve better generalization performance than learning each task individually, especially when presented with insufficient training samples (Liu et al., 2015, 2016b,d). The group structure is encoded into a matrix $\mathbf{R}$ which codes the groups which are considered similar. The objective of the sparse graph regularized multi-task learning problem is:

$$\min_{\mathbf{W},\mathbf{c}} \sum_{t=1}^{\tau} \sum_{i=1}^{N} log(1 + exp(-\mathbf{Y}_{t,i}(\mathbf{W}_{i,t}^T \mathbf{X}_{t,i} + c_t))) + \gamma \|\mathbf{WR}\|_F^2 + \lambda \|\mathbf{W}\|_1,$$

where τ is the number of tasks, $|N|$ the number of samples, $\mathbf{X}$ the feature matrix, $\mathbf{Y}$ the outcome matrix, $\mathbf{W}_{i,t}$ and c_t is the model for task t and $\mathbf{R}$ is the structure matrix.

We define three R matrices: (1) codes that groups with similar political engagement are similar (i.e. 1–7, 2–6, 3–5); (2) codes that groups from each ideological side are similar (i.e. 1–2, 1–3, 2–3, 5–6, 5–7, 6–7); (3) learnt from the data. Results are presented in Table 4. Regular logistic regression performs slightly better than the majority class baseline, which demonstrates that the 7-class classification is a very hard problem although most miss-classifications are within one ideology point. The graph regularization (GR) improves the classification performance over logistic regression (LR) in all cases, with political leaning based matrix (GR–Leaning) obtaining 2% in accuracy higher than the political engagement one (GR–Engagement) and the learnt matrix (GR–Learnt) obtaining best results.

Method	Accuracy
Baseline	19.6%
LR	22.2%
GR–Engagement	24.2%
GR–Leaning	26.2%
GR–Learnt	**27.6%**

Table 4: Experimental results for seven-way classification using multi-task learning (GR–Engagement, GR–Leaning, GR-Learnt) and 500 Word2Vec clusters as features.

7 Conclusions

This study analyzed user-level political ideology through Twitter posts. In contrast to previous work, we made use of a novel data set where fine-grained user political ideology labels are obtained through surveys as opposed to binary self-reports. We showed that users in our data set are far less

likely to post about politics and real-world fine-grained political ideology prediction is harder and more nuanced than previously reported. We analyzed language differences between the ideological groups and uncovered a dimension of political engagement separate from political leaning.

Our work has implications for pollsters or marketers, who are most interested to identify and persuade moderate users. With respect to political conclusions, researchers commonly conceptualize ideology as a single, left-right dimension similar to what we observe in the U.S. Congress (Ansolabehere et al., 2008; Bafumi and Herron, 2010). Our results suggest a different direction: self-reported political extremity is more an indication of political engagement than of ideological self-placement (Abramowitz, 2010). In fact, only self-reported extremists appear to devote much of their Twitter activity to politics at all.

While our study focused solely on text posted by the user, follow-up work can use other modalities such as images or social network analysis to improve prediction performance. In addition, our work on user-level modeling can be integrated with work on message-level political bias to study how this is revealed across users with various levels of engagement. Another direction of future study will look at political ideology prediction in other countries and cultures, where ideology has different or multiple dimensions.

{john1187, jind, dgoldwas}@purdue.edu

Abstract

Framing is a political strategy in which politicians carefully word their statements in order to control public perception of issues. Previous works exploring political framing typically analyze frame usage in longer texts, such as congressional speeches. We present a collection of weakly supervised models which harness collective classification to predict the frames used in political discourse on the microblogging platform, Twitter. Our global probabilistic models show that by combining both lexical features of tweets and network-based behavioral features of Twitter, we are able to increase the average, unsupervised F_1 score by 21.52 points over a lexical baseline alone.

1 Introduction

The importance of understanding political discourse on social media platforms is becoming increasingly clear. In recent U.S. presidential elections, Twitter was widely used by all candidates to promote their agenda, interact with supporters, and attack their opponents. Social interactions on such platforms allow politicians to quickly react to current events and gauge interest in and support for their actions. These dynamic settings emphasize the importance of constructing automated tools for analyzing this content. However, these same dynamics make constructing such tools difficult, as the language used to discuss new events and political agendas continuously changes. Consequently, the rich social interactions on Twitter can be leveraged to help support such analysis by providing alternatives to direct supervision.

In this paper we focus on political framing, a very nuanced political discourse analysis task, on a variety of issues frequently discussed on Twitter. Framing (Entman, 1993; Chong and Druckman, 2007) is employed by politicians to bias the discussion towards their stance by emphasizing specific aspects of the issue. For example, the debate around increasing the minimum wage can be framed as a *quality of life* issue or as an *economic* issue. While the first frame supports increasing minimum wage because it improves workers' lives, the second frame, by conversely emphasizing the costs involved, opposes the increase. Using framing to analyze political discourse has gathered significant interest over the last few years (Tsur et al., 2015; Card et al., 2015; Baumer et al., 2015) as a way to automatically analyze political discourse in congressional speeches and political news articles. Different from previous works which focus on these longer texts or single issues, our dataset includes tweets authored by all members of the U.S. Congress from both parties, dealing with several policy issues (e.g., immigration, ACA, etc.). These tweets were annotated by adapting the annotation guidelines developed by Boydstun et al. (2014) for Twitter.

Twitter issue framing is a challenging multilabel prediction task. Each tweet can be labeled as using one or more frames, out of 17 possibilities, while only providing 140 characters as input to the classifier. The main contribution of this work is to evaluate whether the *social and behavioral information* available on Twitter is sufficient for constructing a reliable classifier for this task. We approach this framing prediction task using a weakly supervised collective classification approach which leverages the dependencies between tweet frame predictions based on the interactions between their authors.

These dependencies are modeled by connecting Twitter users who have social connections or behavioral similarities. Social connections are di-

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 741–752
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1069

rected dependencies that represent the followers of each user as well as retweeting behavior (i.e., user A retweets user B's content). Interestingly, such social connections capture the flow of influence within political parties; however, the number of connections that cross party lines is extremely low. Instead, we rely on capturing behavioral similarity between users to provide this information. For example, users whose Twitter activity peaks at similar times tend to discuss issues in similar ways, providing indicators of their frame usage for those issues. In addition to using social and behavioral information, our approach also incorporates each politician's party affiliation and the frequent phrases (e.g., bigrams and trigrams) used by politicians on Twitter.

These lexical, social, and behavioral features are extracted from tweets via weakly supervised models and then declaratively compiled into a graphical model using Probabilistic Soft Logic (PSL), a recently introduced probabilistic modeling framework.[1] As described in Section 4, PSL specifies high level rules over a relational representation of these features. These rules are then compiled into a graphical model called a hinge-loss Markov random field (Bach et al., 2013), which is used to make the frame prediction. Instead of direct supervision we take a bootstrapping approach by providing a small seed set of keywords adapted from Boydstun et al. (2014), for each frame.

Our experiments show that modeling social and behavioral connections improves F_1 prediction scores in both supervised and unsupervised settings, with double the increase in the latter. We apply our unsupervised model to our entire dataset of tweets to analyze framing patterns over time by both party and individual politicians. Our analysis provides insight into the usage of framing for identification of *aisle-crossing politicians*, i.e., those politicians who vote against their party.

2 Related Work

Issue framing is related to the broader challenges of biased language analysis (Recasens et al., 2013; Choi et al., 2012; Greene and Resnik, 2009) and subjectivity (Wiebe et al., 2004). Several previous works have explored framing in public statements, congressional speeches, and news articles (Fulgoni et al., 2016; Tsur et al., 2015; Card et al., 2015; Baumer et al., 2015). Our approach builds upon the previous work on frame analysis of Boydstun et al. (2014), by adapting and applying their annotation guidelines for Twitter.

In recent years there has been growing interest in analyzing political discourse. Most previous work focuses on opinion mining and stance prediction (Sridhar et al., 2015; Hasan and Ng, 2014; Abu-Jbara et al., 2013; Walker et al., 2012; Abbott et al., 2011; Somasundaran and Wiebe, 2010, 2009). Analyzing political tweets has also attracted considerable interest: a recent SemEval task looked into stance prediction,[2] and more related to our work, Tan et al. (2014) have shown how wording choices can affect message propagation on Twitter. Two recent works look into predicting stance (at user and tweet levels respectively) on Twitter using PSL (Johnson and Goldwasser, 2016; Ebrahimi et al., 2016). Frame classification, however, has a finer granularity than stance classification and describes how someone expresses their view on an issue, not whether they support the issue. Other works focus on identifying and measuring political ideologies (Iyyer et al., 2014; Bamman and Smith, 2015; Sim et al., 2013), policies (Nguyen et al., 2015), and voting patterns (Gerrish and Blei, 2012).

Exploiting social interactions and group structure for prediction has also been explored (Sridhar et al., 2015; Abu-Jbara et al., 2013; West et al., 2014). Works focusing on inferring signed social networks (West et al., 2014), stance classification (Sridhar et al., 2015), social group modeling (Huang et al., 2012), and collective classification using PSL (Bach et al., 2015) are closest to our approach. Unsupervised and weakly supervised models of Twitter data for several various tasks have been suggested, including: profile (Li et al., 2014b) and life event extraction (Li et al., 2014a), conversation modeling (Ritter et al., 2010), and methods for dealing with the unique language used in microblogs (Eisenstein, 2013).

Predicting political affiliation and other characteristics of Twitter users has been explored (Volkova et al., 2015, 2014; Yano et al., 2013; Conover et al., 2011). Others have focused on sentiment analysis (Pla and Hurtado, 2014; Bakliwal et al., 2013), predicting ideology (Djemili et al., 2014), automatic polls

[1] http://psl.cs.umd.edu

[2] http://alt.qcri.org/semeval2016/task6/

based on Twitter sentiment and political forecasting using Twitter (Bermingham and Smeaton, 2011; O'Connor et al., 2010; Tumasjan et al., 2010), as well as distant supervision applications (Marchetti-Bowick and Chambers, 2012).

Several works from political and social science research have studied the role of Twitter and framing in shaping public opinion of certain events, e.g. the Vancouver riots (Burch et al., 2015) and the Egyptian protests (Harlow and Johnson, 2011; Meraz and Papacharissi, 2013). Others have covered framing and sentiment analysis of opponents (Groshek and Al-Rawi, 2013) and network agenda modeling (Vargo et al., 2014) in the 2012 U.S. presidential election. Jang and Hart (2015) studied frames used by the general population specific to global warming. In contrast to these works, we predict the *issue-independent* general frames of tweets, by U.S. politicians, which discuss six different policy issues.

3 Data Collection and Annotation

Data Collection and Preprocessing: We collected 184,914 of the most recent tweets of members of the U.S. Congress (both the House of Representatives and Senate). Using an average of ten keywords per issue, we filtered out tweets not related to the following six issues of interest: (1) limiting or gaining access to abortion, (2) debates concerning the Affordable Care Act (i.e., ACA or Obamacare), (3) the issue of gun rights versus gun control, (4) effects of immigration policies, (5) acts of terrorism, and (6) issues concerning the LGBTQ community. Forty politicians (10 Republicans and 10 Democrats, from both the House and Senate), were chosen randomly for annotation. Table 1 presents the statistics of our congressional tweets dataset, which is available for the community.[3] Appendix A contains more details of our dataset and preprocessing steps.

Data Annotation: Two graduate students were trained in the use of the Policy Frames Codebook developed by Boydstun et al. (2014) for annotating each tweet with a frame. The general aspects of each frame are shown in Table 2. Frames are designed to generalize across issues and overlap of multiple frames is possible. Additionally, the Codebook is typically applied to newspaper articles where discussion of policy can encompass other frames in the text. Consequently, annotators using the Codebook are advised to be careful when assigning Frame 13 to a text.

Based on this guidance and the difficulty of labeling tweets (as discussed in Card et al. (2015)), annotators were instructed to use the following procedure: (1) attempt to assign a primary frame to the tweet if possible, (2) if not possible, assign two frames to the tweet where the first frame is chosen as the more accurate of the two frames, (3) when assigning frames 12 through 17, double check that the tweet cannot be assigned to any other frames. Annotators spent one month labeling the randomly chosen tweets. For all tweets with more than one frame, annotators met to come to a consensus on whether the tweet should have one frame or both. The labeled dataset has an inter-annotator agreement, calculated using Cohen's Kappa statistic, of 73.4%.

Extensions of the Codebook for Twitter Use: The first 14 frames outlined in Table 2 are directly applicable to the tweets of U.S. politicians. In our labeled set, Frame 15 (Other) was never used. Therefore, we drop its analysis from this paper. From our observations, we propose the addition of the 3 frames at the bottom of Table 2 for Twitter analysis: Factual, (Self) Promotion, and Personal Sympathy and Support. Tweets that present a fact, with no detectable political spin or twists, are labeled as having the Factual frame (15). Tweets that discuss a politician's appearances, speeches, statements, or refer to political friends are considered to have the (Self) Promotion frame. Finally, tweets where a politician offers their "thoughts and prayers", condolences, or stands in support of others, are considered to have the Personal frame.

We find that for many tweets, one frame is not enough. This is caused by the compound nature of many tweets, e.g., some tweets are two separate sentences, with each sentence having a different frame or tweets begin with one frame and end with another. A final problem, that may also be relevant to longer text articles, is that of subframes within a larger frame. For example, the tweet *"We must bolster the security of our borders and craft an immigration policy that grows our economy."* has two frames: Security & Defense and Economic. However, both frames could fall under Frame 13 (Policy), if this tweet as a whole was a rebuttal point about an immigration policy. The lack of

[3]The dataset and PSL scripts are available at: http://purduenlp.cs.purdue.edu/projects/twitterframing.

Tweets	By Party		By Issue					
	Rep	Dem	Abortion	ACA	Guns	Immigration	Terrorism	LGBTQ
Entire Dataset	48504	43953	6467	35854	15532	13442	15205	6046
Labeled Subset	894	1156	170	564	543	233	446	183

Table 1: Statistics of Collected Tweets. Rep stands for Republican and Dem for Democrats.

Frame Number, Frame Name, and Brief Description of Frame
1. Economic: *Pertains to the economic impacts of a policy*
2. Capacity & Resources: *Pertains to lack of or availability of resources*
3. Morality & Ethics: *Motivated by religious doctrine, righteousness, sense of responsibility*
4. Fairness & Equality: *Of how laws, punishments, resources, etc. are distributed among groups*
5. Legality, Constitutionality, & Jurisdiction: *Including court cases, restriction and expressions of rights*
6. Crime & Punishment: *Policy violation and consequences*
7. Security & Defense: *Threats or defenses/preemptive actions to protect against threats*
8. Health & Safety: *Includes care access and effectiveness*
9. Quality of Life: *Effects on individual and community life*
10. Cultural Identity: *Culture's norms, trends, customs*
11. Public Sentiment: *Pertains to opinions, polling, and demographics*
12. Political Factors & Implications: *Efforts, stances, filibusters, lobbying, references to other politicians*
13. Policy Description, Prescription, & Evaluation: *Discusses effectiveness of current or proposed policies*
14. External Regulation and Reputation: *Interstate and international relationships of the U.S.*
15. Factual: *Expresses a pure fact, with no detectable political spin*
16. (Self) Promotion: *Promotes another person or the author in some way, e.g. television appearances*
17. Personal Sympathy & Support: *Expresses sympathy, emotional response, or solidarity with others*

Table 2: Frames and Descriptions. The first 14 are Boydstun's frames and the last 3 are our proposed Twitter-specific frames. Boydstun's original Frame 15 (Other) is omitted from this study.

available context for short tweets can make it difficult to determine if a tweet should have one primary frame or is more accurately represented by multiple frames.

4 Global Models of Twitter Language and Activity

Due to the dynamic nature of political discourse on Twitter, our approach is designed to require as little supervision as possible. We implement 6 weakly supervised models which are data-dependent and used to extract and format information from tweets into input for PSL predicates. These predicates are then combined into the probabilistic rules of each model as shown in Table 3. The only sources of supervision these models require includes: unigrams related to the issues, unigrams adapted from the Boydstun et al. (2014) Codebook for frames, and political party of the author of the tweets.

4.1 Global Modeling Using PSL

PSL is a declarative modeling language which can be used to specify weighted, first-order logic rules. These rules are compiled into a hinge-loss Markov random field which defines a probability distribution over possible continuous value assignments to the random variables of the model (Bach et al., 2015).[4] This probability density function is represented as:

$$P(\mathbf{Y} \mid \mathbf{X}) = \frac{1}{Z} \exp\left(-\sum_{r=1}^{M} \lambda_r \phi_r(\mathbf{Y}, \mathbf{X}) \right)$$

where Z is a normalization constant, λ is the weight vector, and

$$\phi_r(\mathbf{Y}, \mathbf{X}) = (\max\{l_r(\mathbf{Y}, \mathbf{X}), 0\})^{\rho_r}$$

is the hinge-loss potential specified by a linear function l_r. The exponent $\rho_r \in 1, 2$ is optional. Each potential represents the instantiation of a rule, which takes the following form:

$$\lambda_1 : P_1(x) \wedge P_2(x, y) \rightarrow P_3(y)$$
$$\lambda_2 : P_1(x) \wedge P_4(x, y) \rightarrow \neg P_3(y)$$

P_1, P_2, P_3, and P_4 are predicates (e.g., political party, issue, frame, and presence of n-grams) and x, y are variables. Each rule has a weight λ which reflects that rule's importance and is learned using the Expectation-Maximization algorithm in our unsupervised experiments. Using concrete constants *a, b* (e.g., tweets and words) which instantiate the variables x, y, model atoms are mapped

[4] Unlike other probabilistic logical models, e.g. MLNs, in which the model's random variables are strictly true or false.

to continuous [0,1] assignments. More important rules (i.e., those with larger weights) are given preference by the model.

4.2 Language Based Models

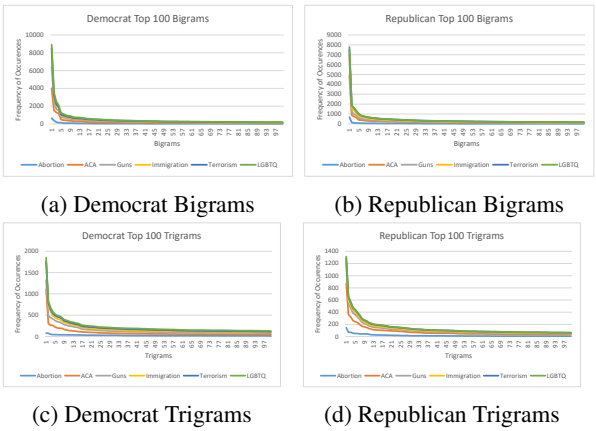
Unigrams: Using the guidelines provided in the Policy Frames Codebook (Boydstun et al., 2014), we adapted a list of expected unigrams for each frame. For example, unigrams that should be related to Frame 12 (Political Factors & Implications) include: filibuster, lobby, Democrats, Republicans. We expect that if a tweet and frame contain a matching unigram, then that frame is likely present in that tweet. The information that tweet T has expected unigram U of frame F is represented with the PSL predicate: UNIGRAM$_F$(T, U). This knowledge is then used as input to PSL Model 1 via the rule: UNIGRAM$_F$(T, U) $\rightarrow$FRAME(T, F) (shown in line 1 of Table 3).

However, not every tweet will have a unigram that matches those in this list. Under the intuition that at least one unigram in a tweet should be *similar* to a unigram in the list, we designed the following *MaxSim* metric to compute the maximum similarity between a word in a tweet and a word from the list of unigrams.

$$\text{MAXSIM(T, F)} = \underset{\text{u}\in F,\text{w}\in T}{\arg\max}\ \text{SIMILARITY(W,U)} \quad (1)$$

T is a tweet, W is each word in T, and U is each unigram in the list of expected unigrams (per frame). SIMILARITY is the computed `word2vec` similarity (using pretrained embeddings) of each word in the tweet with every unigram in the list of unigrams for each frame. The frame F of the maximum scoring unigram is input to the PSL predicate: MAXSIM$_F$(T, F), which indicates that tweet T has the highest similarity to frame F.

Bigrams and Trigrams: In addition to unigrams, we also explored the effects of political party *slogans* on frame prediction. Slogans are common catch phrases or sayings that people typically associate with different U.S. political parties. For example, Republicans are known for using the phrase "repeal and replace" when they discuss the ACA. Similarly, in the 2016 U.S. presidential election, Secretary Hillary Clinton's campaign slogan became "Love Trumps Hate". To visualize slogan usage by parties for different issues, we used the *entire* tweets dataset, including all unlabeled tweets, to extract the top bigrams and trigrams per party for each issue. The histograms in Figure 1 show these distributions for the top 100 bigrams and trigrams. Based on these results, we use the top 20 bigrams (e.g., *women's healthcare* and *immigration reform*) and trigrams (e.g. *prevent gun violence*) as input to PSL predicates BIGRAM$_{IP}$(T, B) and TRIGRAM$_{IP}$(T, TG). These rules represent that tweet T has bigram B or trigram TG from the respective issue I phrase lists of either party P.



(a) Democrat Bigrams (b) Republican Bigrams

(c) Democrat Trigrams (d) Republican Trigrams

Figure 1: Distributions of Bigrams and Trigrams by Party.

4.3 Twitter Behavior Based Models

In addition to language based features of tweets, we also exploit the behavioral and social features of Twitter including similarities between temporal activity and network relationships.

Temporal Similarity: We construct a temporal histogram for each politician which captures their Twitter activity over time. When an event happens politicians are most likely to tweet about that event within hours of its occurrence. Similarly, most politicians tweet about the event most frequently the day of the event and this frequency decreases over time. From these temporal histograms, we observed that the frames used the day of an event were similar and gradually changed over time. For example, once the public is notified of a shooting, politicians respond with Frame 17 to offer sympathy to the victims and their families. Over the next days or weeks, both parties slowly transition to using additional frames, e.g. Democrats use Frame 7 to argue for gun control legislation. To capture this behavior we use the PSL predicate SAMETIME(T1, T2). This indicates that tweet T1 occurs around the same time as tweet

Types of Models	Model Number	Basis of Model	Example of PSL Rules
Language Based	1	Unigrams	Unigram_F(T, U) →Frame(T, F)
	2	Bigrams	Unigram_F(T, U) ∧Bigram_{IP}(T, B) →Frame(T, F)
	3	Trigrams	Unigram_F(T, U) ∧Trigram_{IP}(T, TG) →Frame(T, F)
Behavior Based	4	Temporal Activity	SameTime(T1, T2) ∧Frame(T1, F) →Frame(T2, F)
	5	Retweet Patterns	Retweets(T1, T2) ∧Frame(T1, F) →Frame(T2, F)
	6	Following Network	Follows(T1, T2) ∧Frame(T1, F) →Frame(T2, F)

Table 3: Examples of PSL Model Rules. Each model adds to the rules of the previous model. The full list of rule combinations for each model is available with our dataset.

T2.[5] This information is used in Model 4 via rules such as: SameTime(T1, T2) & Frame(T1, F) →Frame(T2, F), as shown in line 4 of Table 3.

Network Similarity: Finally, we expect that politicians who share ideologies, and thus are likely to frame issues similarly, will retweet and/or follow each other on Twitter. Due to the compound nature of tweets, retweeting with additional comments can add more frames to the original tweet. Additionally, politicians on Twitter are more likely to follow members of their own party or similar non-political entities than those of the opposing party. To capture this network-based behavior we use two PSL predicates: Retweets(T1, T2) and Follows(T1, T2). These predicates indicate that the content of tweet T1 includes a retweet of tweet T2 and that the author of T1 follows the author of T2 on Twitter, respectively. The last two lines of Table 3 show examples of how network similarity is incorporated into PSL rules.

5 Experiments

Evaluation Metrics: Since each tweet can have more than one frame, our prediction task is a multilabel classification task. The precision of a multilabel model is the ratio of how many predicted labels are correct:

$$Precision = \frac{1}{T}\sum_{t=1}^{T}\frac{|Y_t \cap h(x_t)|}{|h(x_t)|} \quad (2)$$

The recall of this model is the ratio of how many of the actual labels were predicted:

$$Recall = \frac{1}{T}\sum_{t=1}^{T}\frac{|Y_t \cap h(x_t)|}{|Y_t|} \quad (3)$$

[5]We conducted experiments with different hour and day limits and found that using a time frame of one hour results in the best accuracy while limiting noise.

In both formulas, T is the number of tweets, Y_t is the true label for tweet *t*, x_t is a tweet example, and $h(x_t)$ are the predicted labels for that tweet. The F_1 score is computed as the harmonic mean of the precision and recall. Additionally, in Tables 4, 5, and 6 the reported average is the micro-weighted average F_1 scores over all frames.

Experimental Settings: We provide an analysis of our PSL models under both supervised and unsupervised settings. In the PSL supervised experiments, we used five-fold cross validation with randomly chosen splits.

Previous works typically use an SVM, with bag-of-words features, which is not used in a multilabel prediction, i.e., each frame is predicted individually. The results of this approach on our dataset are shown in column 2 of Table 4. In this scenario, the SVM tends to prefer the majority class, which results in many incorrect labels. Column 3 shows the results of using an SVM with bag-of-words features to perform multilabel classification. This approach decreases the F_1 score for a majority of frames. Both SVMs also result in F_1 scores of 0 for some frames, further lowering the overall performance. Finally, columns 4 and 5 show the results of using our worst and best PSL models, respectively. PSL Model 1, which uses our adapted unigram features instead of the bag-of-words features for multilabel classification, serves as our baseline to improve upon. Additionally, Model 6 of the supervised, collective network setting represents the best results we can achieve.

We also explore the results of our PSL models in an unsupervised setting because the highly dynamic nature of political discourse on Twitter makes it unrealistic to expect annotated data to generalize to future discussions. The only source of supervision comes from the initial unigrams lists and party information as described in Section 4. The labeled tweets are used for evaluation only. As seen in Table 4, we are able to improve

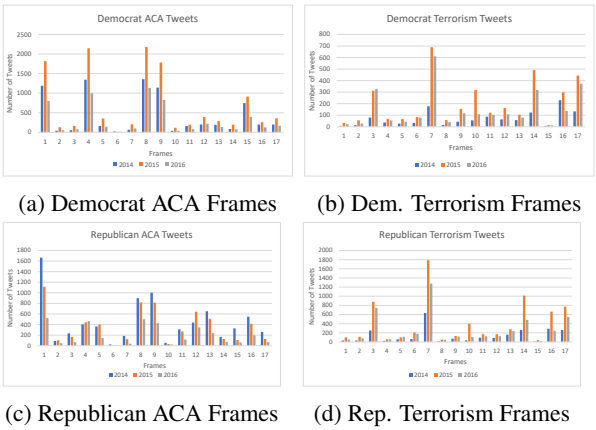
SETTING	SVM INDIV.	SVM MULTI.	PSL M1	PSL M6
SUP.	28.67	18.90	66.02	77.79
UNSUP.	—	—	37.14	58.66

Table 4: Baseline and Skyline Micro-weighted Average F_1 Scores. SVM INDIV. is the SVM trained to predict one frame. SVM MULTI. is the multiclass SVM. PSL M1 is the adapted unigram PSL Model 1. PSL M6 is the collective network.

the best unsupervised model to within an F_1 score of 7.36 points of the unigram baseline of 66.02, and 19.13 points of the best supervised score of 77.79.

Analysis of Supervised Experiments: Table 5 shows the results of our supervised experiments. Here we can see that by adding Twitter behavior (beginning with Model 4), our behavior-based models achieve the best F_1 scores across all frames. Model 4 achieves the highest results on two frames, suggesting retweeting and network follower information do not help improve the prediction score for these frames. Similarly, Model 5 achieves the highest prediction for 5 of the frames, suggesting network follower information cannot further improve the score for these frames. Overall, the Twitter behavior based models are able to outperform language based models alone, including the best performing language model (Model 3) which combines unigrams, bigrams, and trigrams together to collectively infer the correct frames.

Analysis of Unsupervised Experiments: In the unsupervised setting, Model 6, the combination of language and Twitter behavior features achieves the best results on 16 of the 17 issues, as shown in Table 6. There are a few interesting aspects of the unsupervised setting which differ from the supervised setting. Six of the frame predictions do worse in Model 2, which is double that of the supervised version. This is likely due to the presence of overlapping bigrams across frames and issues, e.g., "women's healthcare" could appear in both Frames 4 and 8 and the issues of ACA and abortion. However, all six are able to improve with the addition of trigrams (Model 3), whereas only 1 of 3 frames improves in the supervised setting. This suggests that bigrams may not be as useful as trigrams in an unsupervised setting. Finally, in Model 5, which adds retweet behaviors, we notice that 5 of the frames decrease in F_1 score and 11 of the frames have the same score as the previous model. These results suggest that retweet behaviors are not as useful as the follower network relationships in an unsupervised setting.



(a) Democrat ACA Frames (b) Dem. Terrorism Frames

(c) Republican ACA Frames (d) Rep. Terrorism Frames

Figure 2: Predicted Frames for Tweets from 2014 to 2016 by Party for ACA and Terrorism Issues.

6 Qualitative Analysis

To explore the usefulness of frame identification in political discourse analysis, we apply our best performing model (Model 6) on the *unlabeled* dataset to determine framing patterns over time, both by party and individual. Figure 2 shows the results of our frame analysis for both parties over time for two issues: ACA and terrorism.[6] We compiled the predicted frames for tweets from 2014 to 2016 for each party. Figure 3 presents the results of frame prediction for 2015 tweets of aisle-crossing individual politicians for these two issues.

Party Frames: From Figure 2(a) we can see that Democrats mainly use Frames 1, 4, 8, 9, and 15 to discuss ACA, while Figure 2(c) shows that Republicans predominantly use Frames 1, 8, 9, 12, and 13. Though the parties use similar frames, they are used to express different agendas. For example, Democrats use Frame 8 to indicate the positive effect that the ACA has had in granting more Americans health care access. Republicans, however, use Frame 8 (and Frame 13) to indicate their party's agenda to replace the ACA with access to different options for health care. Additionally, Democrats use the Fairness & Equality Frame (Frame 4) to convey that the ACA gives minority groups a better chance at accessing health care.

[6] Due to space, we omit the other 4 issues. These 2 were chosen because they are among the most frequently discussed issues in our dataset.

Frame Number	Frame	Results of Supervised PSL Model Frame Predictions					
		Model 1	Model 2	Model 3	Model 4	Model 5	Model 6

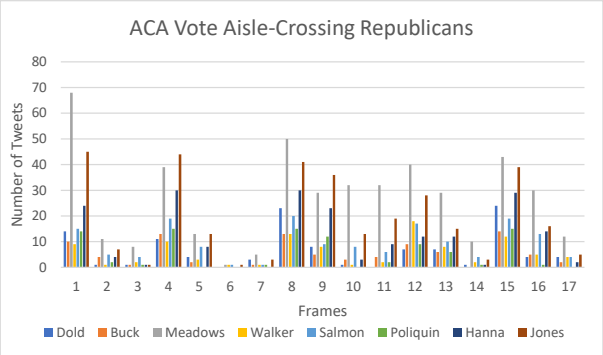
Table 6: F_1 Scores of Unsupervised PSL Models. The highest prediction per frame is marked in bold.

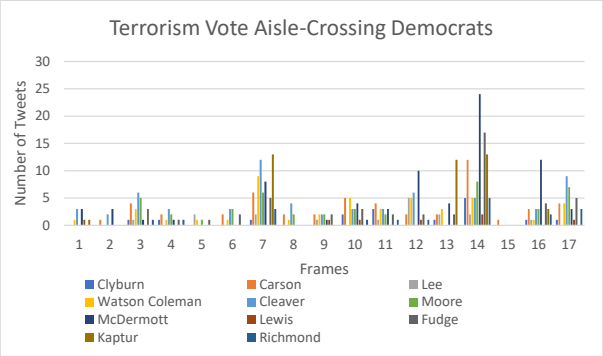
They also use Frame 15 to express statistics about enrollment of Americans under the ACA. Finally, Republicans use Frames 12 and 13 to bring attention to their own party's actions to "repeal and replace" the ACA with different policies.

Figures 2(b) and 2(d) show the party-based framing patterns over time for terrorism related tweets. For this issue both parties use similar frames: 3, 7, 10, 14, 16, and 17, but to express different views. For example, Democrats use Frame 3 to indicate a moral responsibility to fight ISIS. Republicans use Frame 3 to frame terrorists or their attacks as a result of "radical Islam". An interesting pattern to note is seen in Frames 10 and 14 for both parties. In 2015 there is a large increase in the usage of this frame. This seems to indicate that parties possibly adopt new frames *simultaneously or in response to the opposing party*, perhaps in an effort to be in control of the way the message is delivered through that frame.

Individual Frames: In addition to entire party analysis, we were interested in seeing if frames could shed light on the behavior of *aisle-crossing* politicians. These are politicians who do not vote the same as the majority vote of their party (i.e., they vote the same as the opposing party). Identifying such politicians can be useful in governments which are heavily split by party, i.e., governments such as the recent U.S. Congress (2015 to 2017), where politicians tend to vote the same



(a) Aisle-Crossing Republicans on ACA Votes.



(b) Aisle-Crossing Democrats on Terrorism Votes.

Figure 3: Predicted Frames for Tweets of Aisle-Crossing Politicians in 2015.

as the rest of their party members. For this analysis, we collected five 2015 votes from the House of Representatives on both issues and compiled a list of the politicians who voted opposite to their party. The most important descriptor we noticed was that all aisle-crossing politicians *tweet less frequently on the issue* than their fellow party members. This is true for both parties. This behavior could indicate lack of desire to draw attention to one's stance on the particular issue.

Figure 3(a) shows the framing patterns of aisle-crossing Republicans on ACA votes from 2015. Recall from Figure 2 that Democrats mostly use Frames 1, 4, 8, 9, and 15, while Republicans mainly use Frames 1, 8, and 9. In this example, these Republicans are considered aisle-crossing votes because they have voted the same as Democrats on this issue. The most interesting pattern to note here is that these Republicans use the same framing patterns as the Republicans (Frames 1, 8, and 9), but they also use the frames that are *unique to Democrats*: Frames 4 and 15. These latter two frames appear significantly less in the Republican tweets of our entire dataset as well. These results suggest that to predict aisle-crossing Republicans it would be useful to check for usage of typically Democrat-associated frames, especially if those frames are infrequently used by Republicans.

Figure 3(b) shows the predicted frames for aisle-crossing Democrats on terrorism-related votes. We see here that there are very few tweets from these Democrats on this issue and that overall they use the same framing patterns as seen previously: Frames 3, 7, 10, 14, 16, and 17. However, given the small scale of these tweets, we can also consider Frames 12 and 13 to show peaks for this example. This suggests that for aisle-crossing Democrats the use of additional frames not often used by their party for discussing an issue might indicate potentially different voting behaviors.

7 Conclusion

In this paper we present the task of collective classification of Twitter data for framing prediction. We show that by incorporating Twitter behaviors such as similar activity times and similar networks, we can increase F_1 score prediction. We provide an analysis of our approach in both supervised and unsupervised settings, as well as a real world analysis of framing patterns over time. Finally, our global PSL models can be applied to other domains, such as politics in other countries, simply by changing the initial unigram keywords to reflect the politics of those countries.

A Supplementary Material

In this section we provide additional information about our congressional tweets dataset, as well as the lists of keywords and phrases used to filter tweets by issue and the unigrams used to extract information used for the Unigram and MaxSim PSL predicates. It is important to note that during preprocessing capitalization, stop words, URLs, and punctuation have been removed from tweets in our dataset. Additional word lists along with our PSL scripts and dataset are available at: http://purduenlp.cs.purdue.edu/projects/twitterframing.

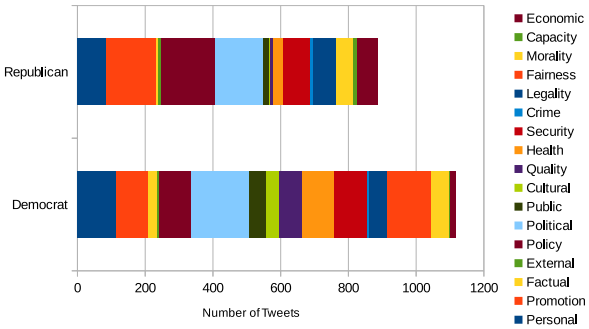

Figure 4: Coverage of Frames by Party.

Dataset Statistics: Figure 4 shows the coverage of the labeled frames by party. From this, general patterns can be observed. For example, Republicans use Frames 12 and 17 more frequently than Democrats, while Democrats tend to use Frames 4, 9, 10, and 11. Table 7 shows the count of each type of frame that appears in each issue in our labeled dataset.

Issue	Frames																
	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17
Abortion	4	7	23	55	40	0	2	32	10	0	4	46	20	0	1	13	8

Table 9: Frame and Corresponding Unigrams Used for Initial Supervision.

Word Lists: Table 8 lists the keywords or phrases used to filter the entire dataset to only tweets related to the six issues studied in this paper. Table 9 lists the unigrams that were designed based on the descriptions for Frames 1 through 14 provided in the Policy Frames Codebook (Boydstun et al., 2014). These unigrams provide the initial supervision for our models as described in Section 4.

A Nested Attention Neural Hybrid Model for Grammatical Error Correction

Abstract

Grammatical error correction (GEC) systems strive to correct both global errors in word order and usage, and local errors in spelling and inflection. Further developing upon recent work on neural machine translation, we propose a new hybrid neural model with nested attention layers for GEC. Experiments show that the new model can effectively correct errors of both types by incorporating word and character-level information, and that the model significantly outperforms previous neural models for GEC as measured on the standard CoNLL-14 benchmark dataset. Further analysis also shows that the superiority of the proposed model can be largely attributed to the use of the nested attention mechanism, which has proven particularly effective in correcting local errors that involve small edits in orthography.

1 Introduction

One of the most successful approaches to grammatical error correction (GEC) is to cast the problem as (monolingual) machine translation (MT), where we translate from possibly ungrammatical English sentences to corrected ones (Brockett et al., 2006; Gao et al., 2010; Junczys-Dowmunt and Grundkiewicz, 2016). Such systems, which are based on phrase-based MT models that are typically trained on large sets of sentence-correction pairs, can correct global errors such as word order and usage and local errors in spelling and inflection. The approach has proven superior to systems based on local classifiers that can only fix focused errors in prepositions, determiners, or inflected forms (Rozovskaya and Roth, 2016).

Recently, neural machine translation (NMT) systems have achieved substantial improvements in translation quality over phrase-based MT systems (Sutskever et al., 2014; Bahdanau et al., 2015). Thus, there is growing interest in applying neural systems to GEC (Yuan and Briscoe, 2016; Xie et al., 2016). In this paper, we significantly extend previous work, and explore new neural models to meet the unique challenges of GEC.

The core component of most NMT systems is a sequence-to-sequence (S2S) model which encodes a sequence of source words into a vector and then generates a sequence of target words from the vector. Unlike the phrase-based MT models, the S2S model can capture long-distance, or even global, word dependencies, which are crucial to correcting global grammatical errors and helping users achieve native speaker fluency (Sakaguchi et al., 2016). Thus, the S2S model is expected to perform better on GEC than phrase-based models. However, as we will show in this paper, to achieve the best performance on GEC, we still need to extend the standard S2S model to address several task-specific challenges, which we will describe below.

First, a GEC model needs to deal with an extremely large vocabulary that consists of a large number of words and their (mis)spelling variations. Second, the GEC model needs to capture structure at different levels of granularity in order to correct errors of different types. For example, while correcting spelling and local grammar errors requires only word-level or sub-word level information, e.g., *violets* → *violates* (spelling) or *violate* → *violates* (verb form), correcting errors in word order or usage requires global semantic relationships among phrases and words.

Standard approaches in neural machine translation, also applied to grammatical error correction by Yuan and Briscoe (2016), address the large vocabulary problem by restricting the vocabulary to a limited number of high-frequency words and re-

*This work was conducted while the third author worked at Microsoft Research.

sorting to standard word translation dictionaries to provide translations for the words that are out of the vocabulary (OOV). However, this approach often fails to take into account the OOVs in context for making correction decisions, and does not generalize well to correcting words that are unseen in the parallel training data. An alternative approach, proposed by Xie et al. (2016), applies a character-level sequence to sequence neural model. Although the model eliminates the OOV issue, it cannot effectively leverage word-level information for GEC, even if it is used together with a separate word-based language model.

Our solution to the challenges mentioned above is a novel, hybrid neural model with nested attention layers that infuse both word-level and character-level information. The architecture of the model is illustrated in Figure 1. The word-level information is used for correcting global grammar and fluency errors while the character-level information is used for correcting local errors in spelling or inflected forms. Contextual information is crucial for GEC. Using the proposed model, by combining embedding vectors and attention at both word and character levels, we model all contextual words, including OOVs, in a unified context vector representation. In particular, as we will discuss in Section 5, the character-level attention layer captures most useful information for correcting local errors that involve small edits in orthography.

Our model differs substantially from the word-level S2S model of Yuan and Briscoe (2016) and the character-level S2S model of Xie et al. (2016) in the way we infuse information at both the word level and the character level. We extend the word-character hybrid model of Luong and Manning (2016), which was originally developed for machine translation, by introducing a character attention layer. This allows the model to learn substitution patterns at both the character level and the word level in an end-to-end fashion, using sentence-correction pairs.

We validate the effectiveness of our model on the CoNLL-14 benchmark dataset (Ng et al., 2014). Results show that the proposed model outperforms all previous neural models for GEC, including the hybrid model of Luong and Manning (2016), which we apply to GEC for the first time. When integrated with a large word-based n-gram language model, our GEC system achieves an $F_{0.5}$ of 45.15 on CoNLL-14, substantially exceeding the previously reported top performance of 40.56 achieved by using a neural model and an external language model (Xie et al., 2016).

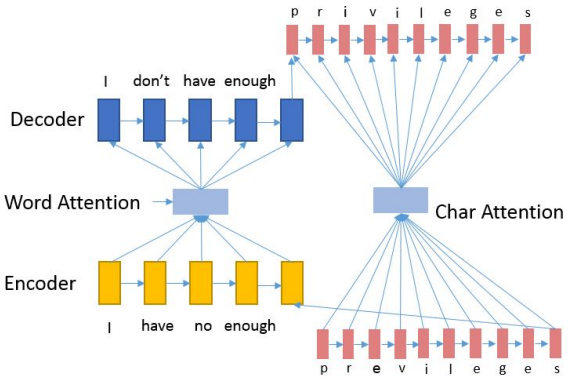

Figure 1: Architecture of Nested Attention Hybrid Model

2 Related Work

A variety of classifier-based and MT-based techniques have been applied to grammatical error correction. The CoNLL-14 shared task overview paper of Ng et al. (2014) provides a comparative evaluation of approaches. Two notable advances after the shared task have been in the areas of combining classifiers and phrase-based MT (Rozovskaya and Roth, 2016) and adapting phrase-based MT to the GEC task (Junczys-Dowmunt and Grundkiewicz, 2016). The latter work has reported the highest performance to date on the task of 49.5 in $F_{0.5}$ score on the CoNLL-14 test set. This method integrates discriminative training toward the task-specific evaluation function, a rich set of features, and multiple large language models. Neural approaches to the task are less explored. We believe that the advances from Junczys-Dowmunt and Grundkiewicz (2016) are complementary to the ones we propose for neural MT, and could be integrated with neural models to achieve even higher performance.

Two prior works explored sequence to sequence neural models for GEC (Xie et al., 2016; Yuan and Briscoe, 2016), while Chollampatt et al. (2016) integrated neural features in a phrase-based system for the task. Neural models were also applied to the related sub-task of grammatical error identification (Schmaltz et al., 2016). Yuan and Briscoe (2016) demonstrated the promise of neural MT for GEC but did not adapt the basic sequence-to-sequence with attention to its unique challenges, falling back to traditional word-alignment models to address vocabulary coverage with a post-processing heuristic. Xie et al. (2016) built a character-level sequence

to sequence model, which achieves open vocabulary and character-level modeling, but has difficulty with global word-level decisions.

The primary focus of our work is integration of character and word-level reasoning in neural models for GEC, to capture global fluency errors and local errors in spelling and closely related morphological variants, while obtaining open vocabulary coverage. This is achieved with the help of character and word-level encoders and decoders with two nested levels of attention. Our model is inspired by advances in sub-word level modeling in neural machine translation. We build mostly on the hybrid model of Luong and Manning (2016) to expand its capability to correct rare words by fine-grained character-level attention. We directly compare our model to the one of Luong and Manning (2016) on the grammar correction task. Alternative methods for MT include modeling of word pieces to achieve open vocabulary (Sennrich et al., 2016), and more recently, fully character-level modeling (Lee et al., 2017). None of these models integrate two nested levels of attention although an empirical evaluation of these approaches for GEC would also be interesting.

3 Nested Attention Hybrid Model

Our model is hybrid, and uses both word-level and character-level representations. It consists of a word-based sequence-to-sequence model as a backbone, and additional character-level encoder, decoder, and attention components, which focus on words that are outside the word-level model's vocabulary.

3.1 Word-based sequence-to-sequence model as backbone

The word-based backbone closely follows the basic neural sequence-to-sequence architecture with attention as proposed by Bahdanau et al. (2015) and applied to grammatical error correction by Yuan and Briscoe (2016). For completeness, we give a sketch here. It uses recurrent neural networks to encode the input sentence and to decode the output sentence.

Given a sequence of embedding vectors, corresponding to a sequence of input words $\mathbf{x}$:

$$\mathbf{x} = (x_1, \ldots, x_T), \tag{1}$$

the encoder creates a corresponding context-specific sequence of hidden state vectors $\mathbf{e}$:

$$\mathbf{e} = (h_1, \ldots, h_T)$$

The hidden state h_t at time t is computed as: $f_t = \text{GRU}_{\text{enc}_f}(f_{t-1}, x_t)$, $b_t = \text{GRU}_{\text{enc}_b}(b_{t+1}, x_t)$, $h_t = [f_t; b_t]$, where $\text{GRU}_{\text{enc}_f}$ and $\text{GRU}_{\text{enc}_b}$ stand for gated recurrent unit functions as described in Cho et al. (2014). We use the symbol GRU with different subscripts to represent GRU functions using different sets of parameters (for example, we used the enc_f and enc_b subscripts to denote the parameters of the forward and backward word-level encoder units.)

The decoder network is also an RNN using GRU units, and defines a sequence of hidden states $\bar{d}_1, \ldots, \bar{d}_S$ used to define the probability of an output sequence $y_1, \ldots, y_S$ as follows:

The context vector c_s at time step s is computed as follows:

$$c_s = \sum_{j=1}^{T} \alpha_{sj} h_j \tag{2}$$

where:

$$\alpha_{sk} = \frac{u_{sk}}{\sum_{j=1}^{T} u_{sj}} \tag{3}$$

$$u_{sk} = \phi_1(d_s)^T \phi_2(h_k) \tag{4}$$

Here ϕ_1 and ϕ_2 denote feedforward linear transformations followed by a $\tanh$ nonlinearity. The next hidden state $\bar{d}_s$ is then defined as:

$$d_s = \text{GRU}_{dec}(\bar{d_{s-1}}, y_{s-1}),$$

$$\bar{d}_s = \text{ReLU}(W[c_s; d_s])$$

where y_{s-1} is the embedding of the output token at time s-1. ReLU indicates rectified linear units (Hahnloser et al., 2000).

The probability of each target word y_s is computed as: $p(y_s|y_{<s}, \mathbf{x}) = \text{softmax}(g(\bar{d}_s))$, where g is a function that maps the decoder state into a vector of size the dimensionality of the target vocabulary.

The model is trained by minimizing the cross-entropy loss, which for a given $(\mathbf{x}, \mathbf{y})$ pair is:

$$Loss(\mathbf{x}, \mathbf{y}) = -\sum_{s=1}^{S} \log p(y_s|y_{<s}, \mathbf{x}) \tag{5}$$

For parallel training data $\mathbb{C}$, the loss is:

$$Loss = -\sum_{(\mathbf{x},\mathbf{y})\in\mathbb{C}} \sum_{s=1}^{S} \log p(y_s|y_{<s}, \mathbf{x})$$

3.2 Hybrid encoder and decoder with two nested levels of attention

The word-level backbone models a limited vocabulary of source and target words, and represents out-of-vocabulary tokens with special UNK symbols. In the standard word-level NMT approach, valuable information is lost for source OOV words and target OOV words are predicted using post-processing heuristics.

Hybrid encoder

Our hybrid architecture overcomes the loss of source information in the word-level backbone by building up compositional representations of the source OOV words using a character-level recurrent neural network with GRU units. These representations are used in place of the special source UNK embeddings in the backbone, and contribute to the contextual encoding of all source tokens.

For example, a three word input sentence where the last term is out-of-vocabulary will be represented as the following vector of embeddings in the word-level model: $\mathbf{x} = (x_1, x_2, x_3)$, where x_3 would be the embedding for the UNK symbol.

The hybrid encoder builds up a word embedding for the third word based on its character sequence: ${x^c}_1, \ldots, {x^c}_M$. The encoder computes a sequence of hidden states $\mathbf{e_c}$ for this character sequence, by a forward character-level GRU network:

$$\mathbf{e_c} = ({h^c}_1, \ldots, {h^c}_M), \tag{6}$$

The last state ${h^c}_M$ is used as an embedding of the unknown word. The sequence of embeddings for our example three-word sequence becomes: $\mathbf{x} = (x_1, x_2, {h^c}_M)$. We use the same dimensionality for word embedding vectors x_i and composed character sequence vectors ${h^c}_M$ to ensure the two ways to define embeddings are compatible. Our hybrid source encoder architecture is similar to the one proposed by Luong and Manning (2016).

Nested attention hybrid decoder

In traditional word-based sequence-to-sequence models special target UNK tokens are used to represent outputs that are outside the target vocabulary. A post-processing UNK-replacement method is then used (Cho et al., 2015; Yuan and Briscoe, 2016) to replace these special tokens with target words. The hybrid model of (Luong and Manning, 2016) uses a jointly trained character-level decoder to generate target words corresponding to UNK tokens, and outperforms the traditional approach in the machine translation task.

However, unlike machine translation, models for grammar correction conduct "translation" in the same language, and often need to apply a small number of local edits to the character sequence of a source word corresponding to the target UNK word. For example, rare but correct words such as entity names need to be copied as is, and local spelling errors or errors in inflection need to be corrected. The architecture of Luong and Manning (2016) does not have direct access to a source character sequence, but only uses a single fixed-dimensionality embedding of source unknown words aggregated with additional contextual information from the source.

To address the needs of the grammatical error correction task, we propose a novel hybrid decoder with two nested levels of attention: word level and character-level. The character-level attention serves to provide the decoder with direct access to the relevant source character sequence.

More specifically, the probability of each target word is defined as follows: For words in the target vocabulary, the probability is defined by the word-level backbone. For words outside the vocabulary, the probability of each token is the probability of UNK according to the backbone, multiplied by the probability of the word's character sequence.

The probability of the target character sequence corresponding to an UNK token at position s in the target is defined using a character-level decoder. As in Luong and Manning (2016), the "separate path" architecture is used to capture the relevant context and define the initial state for the character-level decoder:

$$\hat{d}_s = \text{ReLU}(\hat{W}[c_s; d_s])$$

where $\hat{W}$ are parameters different from W, and $\hat{d}_s$ is not used by the word-level model in predicting the subsequent tokens, but is only used to initialize the character-level decoder.

To be able to attend to the relevant source character sequence when generating the target character sequence, we use the concept of hard attention (Xu et al., 2015), but use an arg-max approximation for inference instead of sampling. A similar approach to represent discrete hidden structure in a variety of architectures is used in Kong et al. (2017).

The source index z_s corresponding to the target

position s is defined according to the word-level attention model:

$$z_s = \arg \max_{k \in 0...T-1} \alpha_{sk}$$

where α_{sk} are the intermediate outputs of the word-level attention model we described in Eq.(3).

The character-level decoder generates a character sequence $\mathbf{y^c} = ({y^c}_1, \ldots, {y^c}_N)$, conditioned on the initial vector $\hat{d}_s$ and the source index z_s. The characters are generated using a hidden state vector ${d^c}_n$ at each time step, via a softmax$(gc({d^c}_n))$, where gc maps the state to the target character vocabulary space.

If the source word x_{z_s} is in the source vocabulary, the model is analogous to the one of Luong and Manning (2016) and does not use character-level attention: the source context is available only in aggregated form to initialize the state of the decoder. The state ${d^c}_n$ for step n in the character-level decoder is defined as follows, where ${\text{GRU}^c}_{\text{dec}}$ are parameters for the gated recurrent cell of this decoder:

$${d^c}_n = \begin{cases} {\text{GRU}^c}_{\text{dec}}(\hat{d}_s, {y^c}_{n-1}) & n = 0 \\ {\text{GRU}^c}_{\text{dec}}({d^c}_{n-1}, {y^c}_{n-1}) & n > 0 \end{cases}$$

In contrast, if the corresponding token in the source x_{z_s} is also an out-of-vocabulary word, we define a second nested level of character attention and use it in the character-level decoder. The character-level attention focuses on individual characters from the source word x_{z_s}. If $\mathbf{e_c}$ are the source character hidden vectors computed as in Eq.(6), the recurrence equations for the character-level decoder with nested attention are:

$$\bar{{d^c}}_n = \text{ReLU}(W_c[{c^c}_n; {d^c}_n])$$

$${d^c}_n = \begin{cases} {\text{GRU}^c}_{\text{decNested}}(\hat{d}_s, {y^c}_{n-1}) & n = 0 \\ {\text{GRU}^c}_{\text{decNested}}(\bar{{d^c}}_{n-1}, {y^c}_{n-1}) & n > 0 \end{cases}$$

where ${c^c}_n$ is the context vector obtained using character-level attention on the sequence $\mathbf{e^c}$ and the last state of the character-level decoder ${d^c}_n$, computed following equations 2, 3 and 4, but using a different set of parameters.

These equations show that the character-level decoder with nested attention can use both the word-level state $\hat{d}_s$, and the character-level context ${c^c}_n$ and hidden state ${d^c}_n$ to perform global and local editing operations.

Since we introduced two architectures for the character-level decoder depending on whether the source word x_{z_s} is OOV, the combined loss function is defined as follows for end-to-end training:

$$Loss_{total} = Loss_w + \alpha Loss_{c1} + \beta Loss_{c2}$$

Here $Loss_w$ is the standard word-level loss in Eq.(5); character level losses $Loss_{c1}$ and $Loss_{c2}$ are losses for target OOV words corresponding to source known and unknown tokens, respectively. α and β are hyper-parameters to balance the loss terms.

As seen, our proposed nested attention hybrid model uses character-level attention only when both a predicted target word and its corresponding source input word are OOV. While the model can be naturally generalized to integrate character-level attention for known words, the original hybrid model proposed by Luong and Manning (2016) does not use any character-level information for known words. Thus for a controlled evaluation of the impact of the addition of character-level attention only, in this paper we limit character-level attention to OOV words, which already use characters as a basis for building their embedding vectors. A thorough investigation of the impact of character-level information in the encoder, attention, and decoder for known words as well is an interesting topic for future research.

Decoding for word-level and hybrid models

Beam-search is used to decode hypotheses according to the word-level backbone model. For the hybrid model architecture, word-level beam search is conducted first; for each target UNK token, character-level beam-search is used to generate a corresponding target word.

4 Experiments

4.1 Dataset and Evaluation

We use standard publicly available datasets for training and evaluation. One data source is the NUS Corpus of Learner English (NUCLE) (Dahlmeier et al., 2013), which is provided as a training set for the CoNLL-13 and CoNLL-14 shared tasks. From the original corpus of size about 60K parallel sentences, we randomly selected close to 5K sentence pairs for use as a validation set, and 45K parallel sentences for use in training. A second data source

	Training	Validation	Development	Test
#Sent pairs	2,608,679	4,771	1,381	1,312

Table 1: Overview of the datasets used.

Source	#Sent pairs
NUCLE	45,422
CLC	1,517,174
lang-8	1,046,083
Total	2,608,679

Table 2: Training data by source.

is the Cambridge Learner Corpus (CLC) (Nicholls, 2003), from which we extracted a substantially larger set of parallel sentences. Finally, we used additional training examples from the Lang-8 Corpus of Learner English v1.0 (Tajiri et al., 2012). As Lang-8 data is crowd-sourced, we used heuristics to filter out noisy examples: we removed sentences longer than 100 words and sentence pairs where the correction was substantially shorter than the input text. Table 2 shows the number of sentence pairs from each source used for training.

We evaluate the performance of the models on the standard sets from the CoNLL-14 shared task (Ng et al., 2014). We report final performance on the CoNLL-14 test set without alternatives, and analyze model performance on the CoNLL-13 development set (Dahlmeier et al., 2013). We use the development and validation sets for model selection. The sizes of all datasets in number of sentences are shown in Table 1. We report performance in $F_{0.5}$-measure, as calculated by the `m2scorer`—the official implementation of the scoring metric in the shared task. [1] Given system outputs and gold-standard edits, `m2scorer` computes the $F_{0.5}$ measure of a set of system edits against a set of gold-standard edits.

4.2 Baseline

We evaluate our model in comparison to the strong baseline of a word-based neural sequence-to-sequence model with attention, with post-processing for handling out-of-vocabulary words (Yuan and Briscoe, 2016); we refer to this model as word NMT+UNK replacement. Like Yuan and Briscoe (2016), we use a traditional word-alignment model (GIZA++) to derive a word-correction lexicon from the parallel training set. However, in decoding, we don't use GIZA++ to find the corresponding source word for each target OOV, but follow Cho et al. (2015), Section 3.3 to use the NMT system's attention weights instead. The target OOV is then replaced by the most likely correction of the source word from the word-correction lexicon, or by the source word itself if there are no available corrections.

[1] `http://www.comp.nus.edu.sg/~nlp/sw/m2scorer.tar.gz`

4.3 Training Details and Results

The embedding size for all word and character-level encoders and decoders is set to 1000, and the hidden unit size is also 1000. To reproduce the model of Yuan and Briscoe (2016), we selected the word vocabulary for the baseline by choosing the 30K most frequent words in the source and target respectively to form the source and target vocabularies. In preliminary experiments for the hybrid models, we found that selecting the same vocabulary of 30K words for the source and target based on combined frequency was better (.003 in $F_{0.5}$) and use that method for vocabulary selection instead. However, there was no gain observed by using such a vocabulary selection method in the baseline. Although the source and target vocabularies in the hybrid models are the same, like in the word-level model, the embedding parameters for source and target words are not shared.

The hyper-parameters for the losses in our models are selected based on the development set and set as follows: $\alpha = \beta = 0.5$. All models are trained with mini-batch size of 128 (batches are shuffled), initial learning rate of 0.0003 and a 0.95 decay ratio if the cost increases in two consecutive 100 iterations. The gradient is rescaled whenever its norm exceeds 10, and dropout is used with a probability of 0.15. Parameters are uniformly initialized in $[-\frac{\sqrt{(3)}}{\sqrt{1000}}, \frac{\sqrt{(3)}}{\sqrt{1000}}]$.

We perform inference on the validation set every 5000 iterations to log word-level cost and character-level costs; we save parameter values for the model every 10000 iterations as well as the end of each epoch. The stopping point for training is selected based on development set $F_{0.5}$ among the top 20 parameter sets with best validation set value of the loss function. Training of the nested attention hybrid model takes approximately five days on a Tesla k40m GPU. The basic hybrid model trains in around four days and the word-level backbone trains in approximately three days.

Table 3 shows the performance of the baseline and our nested attention hybrid model on the development and test sets. In addition to the word-level

Model	Performance	
	Dev	Test
Word NMT + UNK replacement	26.17	38.77
Hybrid model	28.49	40.44
Nested Attention Hybrid Model	**28.61**	**41.53**

Table 3: $F_{0.5}$ results on the CoNLL-13 and CoNLL-14 test sets of main model architectures.

baseline, we include the performance of a hybrid model with a single level of attention, which follows the work of Luong and Manning (2016) for machine translation, and is the first application of a hybrid word/character-level model to grammatical error correction. Based on hyper-parameter selection, the character-level component weight of the loss is $\alpha = 1$ for the basic hybrid model.

As shown in Table 3, our implementation of the word NMT+UNK replacement baseline approaches the performance of the one reported in Yuan and Briscoe (2016) (38.77 versus 39.9). We attribute the difference to differences in the training set and the word-alignment methods used. Our reimplementation serves to provide a controlled experimental evaluation of the impact of hybrid models and nested attention on the GEC task. As seen, our nested attention hybrid model substantially improves upon the baseline, achieving a gain of close to 3 points on the test set. The hybrid word/character model with a single level of attention brings a large improvement as well, showing the importance of character-level information for this task. We delve deeper into the impact of nested attention for the hybrid model in Section 5.

4.4 Integrating a Web-scale Language Model

The value of large language models for grammatical error correction is well known, and such models have been used in classifier and MT-based systems. To establish the potential of such models in word-based neural sequence-to-sequence systems, we integrate a web-scale count-based language model. In particular, we use the modified Kneser-Ney 5-gram language model trained from Common Crawl (Buck et al., 2014), made available for download by Junczys-Dowmunt and Grundkiewicz (2016).

Candidates generated by neural models are reranked using the following linear interpolation of log probabilities: $s_{y|x} = \log P_{NN}(y|x) + \lambda \log P_{LM}(y)$. Here λ is a hyper-parameter that balances the weights of the neural network model and the language model. We tuned λ separately

Model	Performance	
	Dev	Test
Character-based NMT + LM (Xie et al., 2016)		40.56
Word NMT + UNK replacement + LM	31.73	42.82
Hybrid model + LM	33.21	44.99
Nested Attention Hybrid Model + LM	**33.47**	**45.15**

Table 4: $F_{0.5}$ results on the CoNLL-13 and CoNLL-14 test sets of main model architectures, when combined with a large language model.

for each neural model variant, by exploring values in the range $[0.0, 2.0]$ with step size 0.1, and selecting according to development set $F_{0.5}$. The selected values of λ are: 1.6 for word NMT + UNK replacement and 1.0 for the nested attention model.

Table 4 shows the impact of the LM when combined with the neural models implemented in this work. The table also lists the results reported by Xie et al. (2016), for their character-level neural model combined with a large word-level language model. Our best results exceed the ones reported in the prior work by more than 4 points, although we should note that Xie et al. (2016) used a smaller parallel data set for training.

5 Analysis

We analyze the impact of sub-word level information and the two nested levels of attention in more detail by looking at the performance of the models on different segments of the data. In particular, we analyze the performance of the models on sentences containing OOV source words versus ones without OOV words, and corrections to orthographically similar versus dissimilar word forms.

5.1 Performance by Segment: OOV versus Non-OOV

We present a comparative performance analysis of models on the CoNLL-13 development set. First, we divide the set into two segments: OOV and NonOOV, based on whether there is at least one OOV word in the given source input. Table 5 shows that both hybrid architectures substantially outperform the word-level model in both segments of the data. The additional nested character-level attention of our hybrid model brings a sizable improvement over the basic hybrid model in the OOV segment and a small degradation in the non-OOV segment. We should note that in future work character-level attention can be added for non-OOV source words in the nested attention model, which could improve performance on this segment as well.

Model	NonOOV	OOV	Overall
Word NMT + UNK replacement	27.61	21.57	26.17
Hybrid model	**29.36**	25.92	28.49
Nested Attention Hybrid Model	29.00	**27.39**	**28.61**

Table 5: $F_{0.5}$ results on the CoNLL-13 set of main model architectures, on different segments of the set according to whether the input contains OOVs.

source	This greatly **violets** the rights of people .
gold	This greatly **violates** the rights of people .
word NMT + UNK replacement	This greatly **violets** the rights of people .
Nested Attention Hybrid Model	This greatly **violates** the rights of people .

Table 6: An example sentence from the OOV segment where the nested attention hybrid model improves performance.

Table 6 shows an example where the nested attention hybrid model successfully corrects a misspelling resulting in an OOV word on the source, whereas the baseline word-level system simply copies the source word without fixing the error (since this particular error is not observed in the parallel training set).

5.2 Impact of Nested Attention on Different Error Types

To analyze more precisely the impact of the additional character-level attention introduced by our design, we continue to investigate the OOV segment in more detail.

The concept of *edit*, which is also used by the official M2 score metric, is defined as a minimal pair of corresponding sub-strings in a source sentence and a correction. For example, in the sentence fragment pair: "Even though there is a risk of causing **harms** to someone, people still **are prefers** to keep their pets without a leash." → "Even though there is a risk of causing **harm** to someone, people still **prefer** to keep their pets without a leash.", the minimal edits are "harms → harm" and "are prefers → prefer". The $F_{0.5}$ score is computed using weighted precision and recall of the set of a system's edits against one or more sets of reference edits.

For our in-depth analysis, we classify edits in the OOV segment into two types: *small changes* and *large changes*, based on whether the source and target phrase of the edit are orthographically similar or not. More specifically, we say that the target and source phrases are orthographically similar, iff: the character edit distance is at most 2 and the source or target is at most 8 characters long, or $edit\_ratio < 0.25$, where $edit\_ratio = \frac{character\_edit\_distance}{\min(len(src),len(tar))+0.1}$, $len(*)$ denotes number of characters in $*$, and src and tgt denote the pairs in the edit. There are 307 gold edits in the "small changes" portion of the CoNLL-13 OOV segment, and 481 gold edits in the "large changes" portion.

Model	Performance		
	P	R	$F_{0.5}$
Small Changes Portion			
Hybrid model	43.86	16.29	32.77
Nested Attention Hybrid Model	48.25	17.92	36.04
Large Changes Portion			
Hybrid model	32.52	8.32	20.56
Nested Attention Hybrid Model	33.05	8.11	20.46

Table 7: Precision, Recall and $F_{0.5}$ results on CoNLL-13,on the "small changes" and "large changes" portions of the OOV segment.

Our hypothesis is that the additional character-level attention layer is particularly useful to model edits among orthographically similar words. Table 7 contrasts the impact of character-level attention on the two portions of the data. We can see that the gains in the "small changes" portion are indeed quite large, indicating that the fine-grained character-level attention empowers the model to more accurately correct confusions among phrases with high character-level similarity. The impact in the "large changes" portion is slightly positive in precision and slightly negative in recall. Thus most of the benefit of the additional character-level attention stems from improvements in the "small changes" portion.

Table 8 shows an example input which illustrates the precision gain of the nested attention hybrid model. The input sentence has a source OOV word which is correct. The hybrid model introduces an error in this word, because it uses only a single source context vector, aggregating the character-level embedding of the source OOV word together with other source words. The additional character-level attention layer in the nested hybrid model enables the correct copying of this long source OOV word, without employing the heuristic mechanism of the word-level NMT system.

Table 8: An example where the nested attention hybrid model outperforms the non-nested model.

6 Conclusions

We have introduced a novel hybrid neural model with two nested levels of attention: word-level and character-level. The model addresses the unique challenges of the grammatical error correction task and achieves the best reported results on the CoNLL-14 benchmark among fully neural systems. Our nested attention hybrid model deeply combines the strengths of word and character level information in all components of an end-to-end neural model: the encoder, the attention layers, and the decoder. This enables it to correct both global word-level and local character-level errors in a unified way. The new architecture contributes substantial improvement in correction of confusions among rare or orthographically similar words compared to word-level sequence-to-sequence and non-nested hybrid models.

Acknowledgements

We would like to thank the ACL reviewers for their insightful suggestions, Victoria Zayats for her help with reproducing the baseline word-level NMT system and Yu Shi, Daxin Jiang and Michael Zeng for the helpful discussions.

Abstract

Text similarity measures are used in multiple tasks such as plagiarism detection, information ranking and recognition of paraphrases and textual entailment. While recent advances in deep learning highlighted further the relevance of sequential models in natural language generation, existing similarity measures do not fully exploit the sequential nature of language. Examples of such similarity measures include n-grams and skip-grams overlap which rely on distinct slices of the input texts. In this paper we present a novel text similarity measure inspired from a common representation in DNA sequence alignment algorithms. The new measure, called *TextFlow*, represents input text pairs as continuous curves and uses both the actual position of the words and sequence matching to compute the similarity value. Our experiments on eight different datasets show very encouraging results in paraphrase detection, textual entailment recognition and ranking relevance.

1 Background

The number of pages required to print the content of the World Wide Web was estimated to 305 billion in a 2015 article[1]. While a big part of this content consists of visual information such as pictures and videos, texts also continue growing at a very high pace. A recent study shows that the average webpage weights 1,200 KB with plain text accounting for up to 16% of that size[2].

While efficient distribution of textual data and computations are the key to deal with the increasing scale of textual search, similarity measures still play an important role in refining search results to more specific needs such as the recognition of paraphrases and textual entailment, plagiarism detection and fine-grained ranking of information. These tasks are also often performed on dedicated document collections for domain-specific applications where text similarity measures can be directly applied.

Finding relevant approaches to compute text similarity motivated a lot of research in the last decades (Sahami and Heilman, 2006; Hatzivassiloglou et al., 1999), and more recently with deep learning methods (Socher et al., 2011; Yih et al., 2011; Severyn and Moschitti, 2015). However, most of the recent advances focused on designing high performance classification methods, trained and tested for specific tasks and did not offer a standalone similarity measure that could be applied (i) regardless of the application domain and (ii) without requiring training corpora.

For instance, Yih and Meek (2007) presented an approach to improve text similarity measures for web search queries with a length ranging from one word to short sequences of words. The proposed method is tailored to this specific task, and the training models are not expected to perform well on different kinds of data such as sentences, questions or paragraphs. In a more general study, Achananuparp et al. (2008) compared several text similarity measures for paraphrase recognition, textual entailment, and the TREC 9 question variants task. In their experiments the best performance was obtained with a linear combination of semantic and lexical similarities, including a word order similarity proposed in (Li et al., 2006). This word order similarity is computed by constructing first two vectors representing the common words between two given sentences and using their respective positions in the sentences as term

weights. The similarity value is then obtained by subtracting the two vectors and taking the absolute value. While such representation takes into account the actual positions of the words, it does not allow detecting sub-sequence matches and takes into account missing words only by omission.

More generally, existing standalone (or traditional) text similarity measures rely on the intersections between token sets and/or text sizes and frequency, including measures such as the Cosine similarity, Euclidean distance, Levenshtein (Sankoff and Kruskal, 1983), Jaccard (Jain and Dubes, 1988) and Jaro (Jaro, 1989). The sequential nature of natural language is taken into account mostly through word n-grams and skip-grams which capture distinct slices of the analysed texts but do not preserve the order in which they appear.

In this paper, we use intuitions from a common representation in DNA sequence alignment to design a new standalone similarity measure called *TextFlow* (*XF*). The proposed measure uses at the same time the full sequence of input texts in a natural sub-sequence matching approach together with individual token matches and mismatches. Our contributions can be detailed further as follows:

- A novel standalone similarity measure which:
  - exploits the full sequence of words in the compared texts.
  - is asymmetric in a way that allows it to provide the best performance on different tasks (e.g., paraphrase detection, textual entailment and ranking).
  - when required, it can be trained with a small set of parameters controlling the impact of sub-sequence matching, position gaps and unmatched words.
  - provides consistent high performance across tasks and datasets compared to traditional similarity measures.
- A neural network architecture to train *TextFlow* parameters for specific tasks.
- An empirical study on both performance consistency and standard evaluation measures, performed with eight datasets from three different tasks.

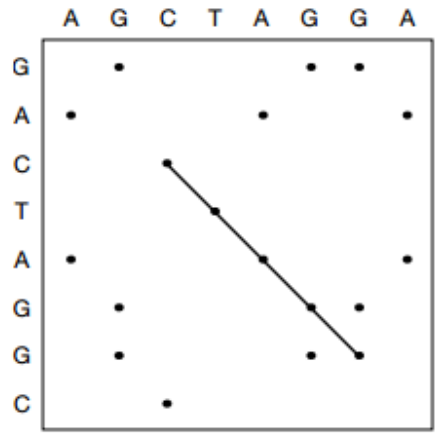

Figure 1: Dot matrix example for 2 DNA sequences (Mount, 2004)

- A new evaluation measure, called *CORE*, used to better show the consistency of a system at high performance using both its rank average and rank variance when compared to competing systems over a set of datasets.

2 The *TextFlow* Similarity

XF is inspired from a dot matrix representation commonly used in pairwise DNA sequence alignment (cf. figure 1). We use a similar dot matrix representation for text pairs and draw a curve oscillating around the diagonal (cf. figure 2). The area under the curve is considered to be the distance between the two text pairs which is then normalized with the matrix surface. For practical computation, we transform this first intuitive representation using the delta of positions as in figure 3. In this setting, the Y axis is the delta of positions of a word occurring in the two texts being compared. If the word does not occur in the target text, the delta is considered to be a maximum reference value (l in figure 2).

The semantics are: the bigger the area under curve is, the lower the similarity between the compared texts. XF values are real numbers in the [0,1] interval, with 1 indicating a perfect match, and 0 indicating that the compared texts do not have any common tokens. With this representation, we are able to take into account all matched words and sub-sequences at the same time. The exact value for the XF similarity between two texts $X = \{x_1, x_2, .., x_n\}$ and $Y = \{y_1, y_2, .., y_m\}$ is therefore computed as:

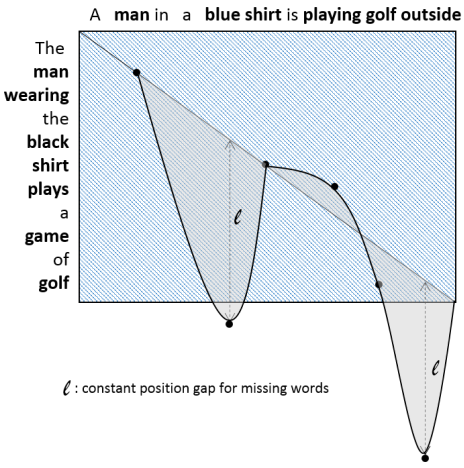

Figure 2: Illustration of *TextFlow* Intuition

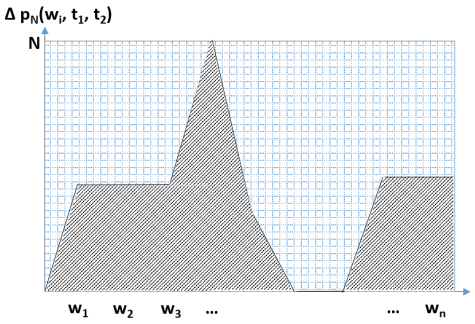

Figure 3: Practical *TextFlow* Computation

$$XF(X,Y) = 1 - \frac{1}{nm}\sum_{i=2}^{n}\frac{1}{S_i}T_{i,i-1}(X,Y) - \frac{1}{nm}\sum_{i=2}^{n}\frac{1}{S_i}R_{i,i-1}(X,Y) \quad (1)$$

With $T_{i,i-1}(X,Y)$ corresponding to the triangular area in the $[i-1,i]$ step (cf. figure 3) and $R_{i,i-1}(X,Y)$ corresponding to the rectangular component. They are expressed as:

$$T_{i,i-1}(X,Y) = \frac{|\Delta P(x_i,X,Y) - \Delta P(x_{i-1},X,Y)|}{2} \quad (2)$$

and:

$$R_{i,i-1}(X,Y) = Min(\Delta P(x_i,X,Y), \Delta P(x_{i-1},X,Y)) \quad (3)$$

With:

- $\Delta P(x_i,X,Y)$ the minimum difference between x_i positions in X and Y. x_i position in X is multiplied by the factor $\frac{|Y|}{|X|}$ for normalization. If $x_i \notin X \cap Y$, $\Delta P(x_i,X,Y)$ is set to the same reference value equal to m, (i.e., the cost of a missing word is set by default to the length of the target text), and:
- S_i is the length of the longest matching sequence between X and Y including the word x_i, if $x_i \in X \cap Y$, or 1 otherwise.

XF computation is performed in $O(nm)$ in the worst case where we have to check all tokens in the target text Y for all tokens in the input text X. XF is an asymmetric similarity measure. Its asymmetric aspect has interesting semantic applications as we show in the example below (cf. figure 2). The minimum value of XF provided the best differentiation between positive and negative text pairs when looking for semantic equivalence (i.e., paraphrases), the maximum value was among the top three for the textual entailment example. We conduct this comparison at a larger scale in the evaluation section.

We add 3 parameters to *XF* in order to represent the importance that should be given to position deltas (Position factor α), missing words (sensitivity factor β), and sub-sequence matching (sequence factor γ), such that:

$$XF_{\alpha,\beta,\gamma}(X,Y) = 1 - \frac{1}{\beta nm}\sum_{i=2}^{n}\frac{\alpha}{S_i^{\gamma}}T_{i,i-1}^{\beta}(X,Y) - \frac{1}{\beta nm}\sum_{i=2}^{n}\frac{\alpha}{S_i^{\gamma}}R_{i,i-1}^{\beta}(X,Y) \quad (4)$$

With:

$$T_{i,i-1}^{\beta}(X,Y) = \frac{|\Delta_\beta P(x_i,X,Y) - \Delta_\beta P(x_{i-1},X,Y)|}{2} \quad (5)$$

$$R_{i,i-1}^{\beta}(X,Y) = Min(\Delta_\beta P(x_i,X,Y), \Delta_\beta P(x_{i-1},X,Y)) \quad (6)$$

and:

- $\Delta_\beta P(x_i,X,Y) = \beta m$, if $x_i \notin X \cap Y$
- $\alpha < \beta$: forces missing words to always cost more than matched words.
- $S_i^{\gamma} = \begin{cases} 1 if S_i = 1 or x_i \notin X \cap Y \\ \gamma\ S_i for S_i > 1 \end{cases}$

The γ factor increases or decreases the impact of sub-sequence matching, α applies to individual token matches whether inside or outside a sequence, and β increases or decreases the impact of

missing tokens as well as the normalization quantity βnm in equation 4 to keep the similarity values in the [0,1] range.

2.1 Parameter Training

By default *XF* has canonical parameters set to 1. However, when needed, α, β, and γ can be learned on training data for a specific task. We designed a neural network to perform this task, with a hidden layer dedicated to compute the exact XF value. To do so we compute, for each input text pair, the coefficients vector that would lead exactly to the XF value when multiplied by the vector $< \frac{\alpha}{\beta}, \frac{\alpha}{\beta\gamma}, 1 >$. Figure 5) presents the training neural network considering several types of sequences (or translations) of the input text pairs (e.g., lemmas, words, synsets).

We use identity as activation function in the dedicated XF layer in order to have a correct comparison with the other similarity measures, including canonical XF where the similarity value is provided in the input layer (cf. figure 6).

3 Evaluation

Datasets. This evaluation was performed on 8 datasets from 3 different classification tasks: Textual Entailment Recognition, Paraphrase Detection, and ranking relevance. The datasets are as follows:

- **RTE 1, 2, and 3**: the first three datasets from the Recognizing Textual Entailment (RTE) challenge (Dagan et al., 2006). Each dataset consists of sentence pairs which are annotated with 2 labels: entailment, and non-entailment. They contain respectively (200, 800), (800, 800), and (800, 800) (train, test) pairs.

- **Guardian**: an RTE dataset collected from 78,696 Guardian articles[5] published from January 2004 onwards and consisting of 32K pairs which we split randomly in 90%/10% training/test sets. Positive examples were collected from the titles and first sentences. Negative examples were collected from the same source by selecting consecutive sentences and random sentences.

- **SNLI**: a recent RTE dataset consisting of 560K training sentence pairs annotated with

[5] https://github.com/daoudclarke/rte-experiment

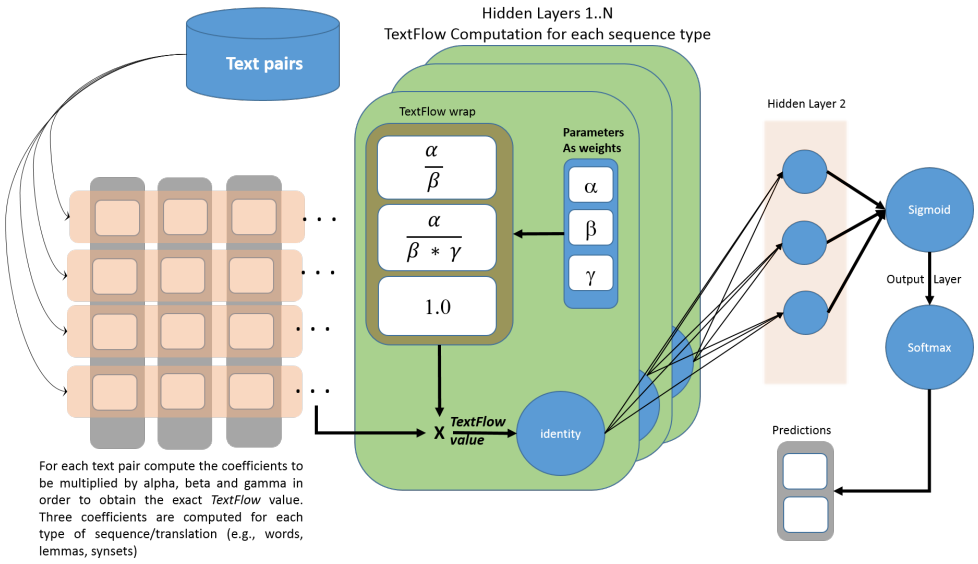

Figure 5: NN architecture **A1** for XF Parameter Training

3 labels: entailment, neutral and contradiction (Bowman et al., 2015). We discarded the contradiction pairs as they do not necessarily represent dissimilar sentences and are therefore a random noise w.r.t. our similarity measure evaluation.

- **MSRP**: the Microsoft Research Paraphrase corpus, consisting of 5,800 sentence pairs annotated with a binary label indicating whether the two sentences are paraphrases or not.

- **Semeval-16-3B**: a dataset of question-question similarity collected from StackOverflow (Nakov et al., 2016). The dataset contains 3,169 training pairs and 700 test pairs. Three labels are considered: "Perfect Match", "Relevant" or "Irrelevant". We combined the first two into the same positive category for our evaluation.

- **Semeval-14-1**: a corpus of Sentences Involving Compositional Knowledge (Marelli et al., 2014) consisting of 10,000 English sentence pairs annotated with both similarity scores and relevance labels.

Features. After a preprocessing step where we removed stopwords, we computed the similarity values using 7 different types of sequences constructed, respectively, with the following value from each token:

- Word (plain text value)
- Lemma
- Part-Of-Speech (POS) tag
- WordNet Synset[6] OR Lemma
- WordNet Synset OR Lemma for Nouns
- WordNet Synset OR Lemma for Verbs
- WordNet Synset OR Lemma for Nouns and Verbs.

In the last 4 types of sequences the lemma is used when there is no corresponding WordNet synset. In a first experiment we compare different aggregation functions on top of XF (minimum, maximum and average) in table 1. We used the LibLinear[7] SVM classifier for this task.

In the second part of the evaluation, we use neural networks to compare the efficiency of XF_c, XF_t and other similarity measures with in the same setting. We use the neural net described in figure 5 for the trained version XF_t and the equivalent architecture presented in figure 6 for all other similarity measures. For canonical XF_c we use by default the best aggregation for the task as observed in table 3.

Table 1: Accuracy evaluation with different aggregations of XF using an SVM classifier.

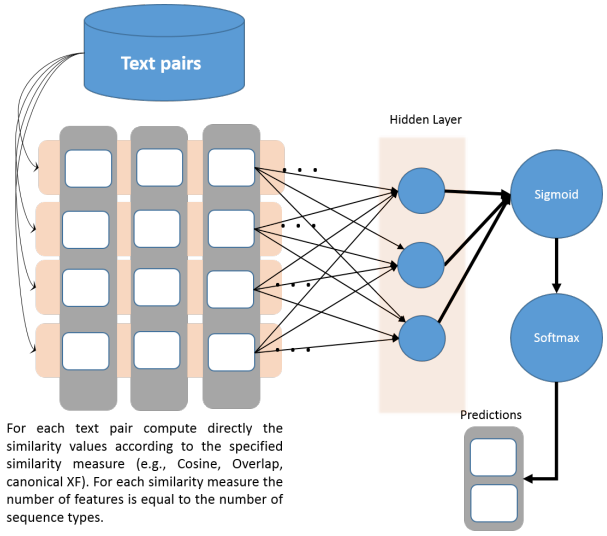

Figure 6: NN Architecture **A2** for the equivalent evaluation of other similarity measures.

Similarity Measures. We considered nine traditional similarity measures included in the Simmetrics distribution[8]: Cosine, Euclidean distance, Word Overlap, Dice coefficient (Dice, 1945), Jaccard(Jain and Dubes, 1988), Damerau, Jaro-Winkler (JW) (Porter et al., 1997), Levenshtein (LEV) (Sankoff and Kruskal, 1983), and Longest Common Subsequence (LCS) (Friedman and Sideli, 1992).

Implementation. XF was implemented in Java as an extension of the Simmetrics package, made available at this address[9]. The neural networks were implemented in Python with TensorFlow[10]. We also share the training sets used for both parameter training and evaluation. The evaluation was performed on a 4-core laptop with 32GB of RAM. The initial parameters for XF_t were chosen with a random function.

Evaluation Measures. We use the standard accuracy values and F1, precision and recall for the positive class (i.e., entailment, paraphrase, and ranking relevance). We also study the relative rank in performance of each similarity measure across all datasets using the average rank, the rank variance and a new evaluation measure called Consistent peRformancE (CORE), computed as follows for a system m, a set of datasets D, a set of systems S, and an evaluation measure $E \in \{F1, Precision, Recall, Accuracy\}$:

$$\underset{D,S,E}{CORE}(m) = \frac{\underset{p \in S}{MIN}\left(\underset{d \in D}{AVG}(R_S(E_d(p)) + V_{d \in D}(R_S(E_d(p)))\right)}{\underset{d \in D}{AVG}\left(R_S(E_d(m))\right) + V_{d \in D}\left(R_S(E_d(m))\right)} \quad (7)$$

With $R_S(E_d(m))$ the rank of m according to the evaluation measure E on dataset d w.r.t. competing systems S. $V_{d \in D}(R_S(E_d(m)))$ is the rank variance of m over datasets. The results in tables 2, 3, and 4 demonstrate the intuition. Basically, $CORE$ tells us how consistent a system/method is in having high performance, relatively to the set of competing systems S. The maximum value of $CORE$ is 1 for the best performing system according to its rank. It also allows quantifying how consistently a system achieves high performance for the remaining systems.

TextFlow outperformed the results obtained with a combination of word order similarity and semantic similarities tested in (Achananuparp et al., 2008), with gaps of +1.0 in F1 and +6.1 accuracy on MSRP and +4.2 F1 and +2.7% accuracy on RTE 3.

4 Discussion

4.1 Canonical *Text Flow*

TF_c had the best average and micro-average accuracy on the 8 classification datasets, with a gap of +0.4 to +6.3 when compared to the state-of-the-art measures. It also reached the best precision average with a gap of +1.8 to +6.3. On the F1 score level XF_c achieved the second best performance with a gap of -1.7, mainly caused by its underperformance in recall, where it had the third best performance with a gap of -6.3 (cf. table 3). On a rank level, XF_c had the best consistent rank for

Table 5: Recall values. The best result is highlighted, the second best is underlined.

accuracy, F1 and precision, and the second best for recall.

4.2 Trained Text Flow

When compared to state-of-the-art measures and to canonical XF, the trained version, XF_t, obtained the best accuracy with a gap ranging from +1.4 to +7.8. XF_t also obtained the second best F1 average with a -1.0 gap, but with clear inconsistencies according to the dataset. XF_t obtained the best precision with a gap ranging from +0.8 to +7.1. XF_t did not perform well on recall with 64.5% micro-average compared to WordOverlap with 72%. Both its recall and F1 performance can be explained by the fact that the measure was trained to optimize accuracy, and not the F1 score for the positive class; which also suggests that the approach could be adapted to F1 optimization if needed.

4.3 Synthesis

Canonical XF was more consistent than trained XF on all dimensions except accuracy, for which XF_t was optimized. We argue that this consistency was made possible through the asymmetry of XF which allowed it to adapt to different kinds of similarities (i.e., equivalence/paraphrase, inference/entailment, and mutual distance/ranking). These results also show that the actual position difference is a relevant factor for text similarity. We explain it mainly by the natural flow of language where the important entities and relations are often expressed first, in contrast with a purely logical-driven approach which has to consider, for instance, that active forms and passive forms are equivalent in meaning. The difference in positions is also not read literally, both because of the higher impact associated to missed words and to the α parameter which allows leveraging their impact in the trained version.

4.4 Additional Experiments

In additional experiments, we compared TF_c and TF_t with the other similarity measures when applied to bi-grams and tri-grams instead of individual tokens. The results were significantly lower on all datasets (between 3 and 10 points loss in accuracy) for both the soa measures and *TextFlow* variants. This result could be explained by the fact that n-grams are too rigid when a sub-sequence varies even slightly, e.g., the insertion of a new word inside a 3-words sequence leads to a tri-gram mismatch and reduces bi-gram overlap from 100% to 50% for the considered sub-sequence. This issue is not encountered with TextFlow as it relies on the token level, and such an insertion will not cancel or reduce significantly the gains from the correct ordering of the words. It must be noted here that not all languages grant the same level of importance to sequences and that additional multilingual tests have to be carried out.

In addition to binary classification output such as textual entailment and paraphrase recognition, text similarity measures can be evaluated more precisely when we consider the correlation of their values for ranking purposes.

We conducted ranking correlation experiments on three test datasets provided at the semantic text similarity task at Semeval 2012, with gold score values for their text pairs. The datasets have 750 sentence pairs each, and are extracted from

the Microsoft Research video descriptions corpus, MSRP and the SMTeuroparl[11]. When compared to the traditional similarity measures, *TextFlow* had the best correlation on the first two datasets with, for instance, 0.54 and 0.46 pearson correlation on the lemmas sequences and the second best on the MSRP extract where the Cosine similarity had the best performance with 0.71 vs 0.68, noting that the Cosine similarity uses word frequencies when the evaluated version of TextFlow did not use word-level weights.

Including word weights is one of the promising perspectives in line with this work as it could be done simply by making the deltas vary according to the weight/importance of the (un)matched word. Also, in such a setting, the impact of a sequence of N words will naturally increase or decrease according to the word weights (cf. figure 3). We conducted a preliminary test using the inverse document frequency of the words as extracted from Wikipedia with Gensim[12], which led to an improvement of up to 2% for most datasets, with performance decreasing slightly on two of them. Other kinds of weights could also be included just as easily, such as contextual word relatedness using embeddings or other semantic relatedness factors such as WordNet distances (Pedersen et al., 2004).

5 Conclusion

We presented a novel standalone similarity measure that takes into account continuous word sequences. An evaluation on eight datasets show promising results for textual entailment recognition, paraphrase detection and ranking. Among the potential extensions of this work are the inclusion of different kinds of weights such as TF-IDF, embedding relatedness and semantic relatedness. We also intend to test other variants around the same concept, including considering the matched words and sequences to have a negative weight to balance further the weight of missing words.

Abstract

Understanding how ideas relate to each other is a fundamental question in many domains, ranging from intellectual history to public communication. Because ideas are naturally embedded in texts, we propose the first framework to systematically characterize the relations between ideas based on their occurrence in a corpus of documents, independent of how these ideas are represented. Combining two statistics—*cooccurrence within documents* and *prevalence correlation over time*—our approach reveals a number of different ways in which ideas can cooperate and compete. For instance, two ideas can closely track each other's prevalence over time, and yet rarely cooccur, almost like a "cold war" scenario. We observe that pairwise cooccurrence and prevalence correlation exhibit different distributions. We further demonstrate that our approach is able to uncover intriguing relations between ideas through in-depth case studies on news articles and research papers.

1 Introduction

Ideas exist in the mind, but are made manifest in language, where they compete with each other for the scarce resource of human attention. Milton (1644) used the "marketplace of ideas" metaphor to argue that the truth will win out when ideas freely compete; Dawkins (1976) similarly likened the evolution of ideas to natural selection of genes. We propose a framework to quantitatively characterize competition and cooperation between ideas in texts, independent of how they might be represented.

By "ideas", we mean any discrete conceptual units that can be identified as being present or absent in a document. In this work, we consider representing ideas using keywords and topics obtained in an unsupervised fashion, but our way of characterizing the *relations* between ideas could be applied to many other types of textual representations, such as frames (Card et al., 2015) and hashtags.

What does it mean for two ideas to compete in texts, quantitatively? Consider, for example, the issue of immigration. There are two strongly competing narratives about the roughly 11 million people[1] who are residing in the United States without permission. One is "illegal aliens", who "steal" jobs and deny opportunities to legal immigrants; the other is "undocumented immigrants", who are already part of the fabric of society and deserve a path to citizenship (Merolla et al., 2013).

Although prior knowledge suggests that these two narratives compete, it is not immediately obvious what measures might reveal this competition in a corpus of writing about immigration. One question is whether or not these two ideas cooccur in the same documents. In the example above, these narratives are used by distinct groups of people with different ideologies. The fact that they don't cooccur is one clue that they may be in competition with each other.

However, cooccurrence is insufficient to express the selection process of ideas, i.e., some ideas fade out over time, while others rise in popularity, analogous to the populations of species in nature. Of the two narratives on immigration, we may expect one to win out at the expense of another as public opinion shifts. Alternatively, we might expect to see these narratives reinforcing each other, as both sides intensify their messaging in response to growing opposition, much like the U.S.S.R. and

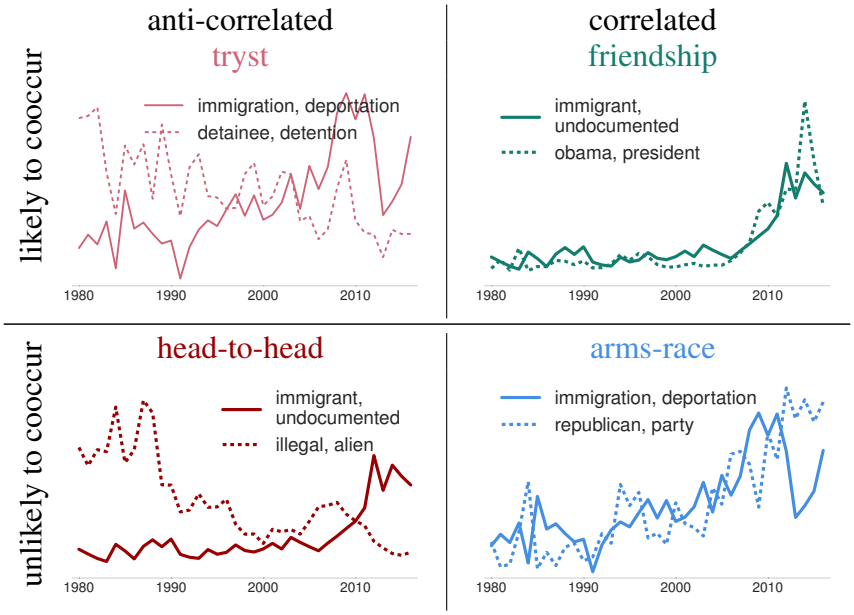

Figure 1: Relations between ideas in the space of cooccurrence and prevalence correlation (prevalence correlation is shown explicitly and cooccurrence is encoded in row captions). We use topics from LDA (Blei et al., 2003) to represent ideas. Each topic is named with a pair of words that are most strongly associated with the topic in LDA. Subplots show examples of relations between topics found in U.S. newspaper articles on immigration from 1980 to 2016, color coded to match the description in text. The y-axis represents the proportion of news articles in a year (in our corpus) that contain the corresponding topic. All examples are among the top 3 strongest relations in each type except ("immigrant, undocumented", "illegal, alien"), which corresponds to the two competing narratives. We explain the formal definition of strength in §2.

the U.S. during the cold war. To capture these possibilities, we use prevalence correlation over time.

Building on these insights, we propose a framework that combines cooccurrence within documents and prevalence correlation over time. This framework gives rise to four possible types of relation that correspond to the four quadrants in Fig. 1. We explain each type using examples from news articles in U.S. newspapers on immigration from 1980 to 2016. Here, we have used LDA to identify ideas in the form of topics, and we denote each idea with a pair of words most strongly associated with the corresponding topic.

Friendship (correlated over time, likely to cooccur). The "immigrant, undocumented" topic tends to cooccur with "obama, president" and both topics have been rising during the period of our dataset, likely because the "undocumented immigrants" narrative was an important part of Obama's framing of the immigration issue (Haynes et al., 2016).

Head-to-head (anti-correlated over time, unlikely to cooccur). "immigrant, undocumented" and "illegal, alien" are in a head-to-head competition: these two topics rarely cooccur, and "immigrant, undocumented" has been growing in prevalence, while the usage of "illegal, alien" in newspapers has been declining. This observation agrees with a report from Pew Research Center (Guskin, 2013).

Tryst (anti-correlated over time, likely to cooccur). The two off-diagonal examples use topics related to law enforcement. Overall, "immigration, deportation" and "detention, jail" often cooccur but "detention, jail" has been declining, while "immigration, deportation" has been rising. This possibly relates to the promises to overhaul the immigration detention system (Kalhan, 2010).[2]

Arms-race (correlated over time, unlikely to cooccur). One of the above law enforcement topics ("immigration, deportation") and a topic on the Republican party ("republican, party") hold an arms-race relation: they are both growing in prevalence over time, but rarely cooccur, perhaps suggesting an underlying common cause.

[2]The tryst relation is the least intuitive, yet is nevertheless observed. The pattern of being anti-correlated yet likely to cooccur is typically found when two ideas exhibit a friendship pattern (cooccurring and correlated), but only briefly, and then diverge.

Note that our terminology describes the relations between ideas in texts, not necessarily between the entities to which the ideas refer. For example, we find that the relation between "Israel" and "Palestine" is "friendship" in news articles on terrorism, based on their prevalence correlation and cooccurrence in that corpus.

We introduce the formal definition of our framework in §2 and apply it to news articles on five issues and research papers from ACL Anthology and NIPS as testbeds. We operationalize ideas using topics (Blei et al., 2003) and keywords (Monroe et al., 2008).

To explore whether the four relation types exist and how strong these relations are, we first examine the marginal and joint distributions of cooccurrence and prevalence correlation (§3). We find that cooccurrence shows a unimodal normal-shaped distribution but prevalence correlation demonstrates more diverse distributions across corpora. As we would expect, there are, in general, more and stronger friendship and head-to-head relations than arms-race and tryst relations.

Second, we demonstrate the effectiveness of our framework through in-depth case studies (§4). We not only validate existing knowledge about some news issues and research areas, but also identify hypotheses that require further investigation. For example, using keywords to represent ideas, a top pair with the tryst relation in news articles on terrorism is "arab" and "islam"; they are likely to cooccur, but "islam" is rising in relative prevalence while "arab" is declining. This suggests a conjecture that the news media have increasingly linked terrorism to a religious group rather than an ethnic group. We also show relations between topics in ACL that center around machine translation.

Our work is a first step towards understanding relations between ideas from text corpora, a complex and important research question. We provide some concluding thoughts in §6.

2 Computational Framework

The aim of our computational framework is to explore *relations* between ideas. We thus assume that the set of relevant ideas has been identified, and those expressed in each document have been tabulated. Our open-source implementation is at `https://github.com/Noahs-ARK/idea_relations/`. In the following, we introduce our formal definitions and datasets.

$$\forall x, y \in \mathcal{I}, \widehat{\mathrm{PMI}}(x,y) = \log \frac{\hat{P}(x,y)}{\hat{P}(x)\hat{P}(y)}$$
$$= C + \log \frac{1+\sum_t \sum_k \mathbf{1}\{x \in d_{t_k}\} \cdot \mathbf{1}\{y \in d_{t_k}\}}{\left(1+\sum_t \sum_k \mathbf{1}\{x \in d_{t_k}\}\right) \cdot \left(1+\sum_t \sum_k \mathbf{1}\{y \in d_{t_k}\}\right)} \quad (1)$$

$$\hat{r}(x,y) = \frac{\sum_t \left(\hat{P}(x|t) - \overline{\hat{P}(x|t)}\right)\left(\hat{P}(y|t) - \overline{\hat{P}(y|t)}\right)}{\sqrt{\sum_t \left(\hat{P}(x|t) - \overline{\hat{P}(x|t)}\right)^2} \sqrt{\sum_t \left(\hat{P}(y|t) - \overline{\hat{P}(y|t)}\right)^2}} \quad (2)$$

Figure 2: Eq. 1 is the empirical pointwise mutual information for two ideas, our measure of cooccurrence of ideas; note that we use add-one smoothing in estimating PMI. Eq. 2 is the Pearson correlation between two ideas' prevalence over time.

2.1 Cooccurrence and Prevalence Correlation

As discussed in the introduction, we focus on two dimensions to quantify relations between ideas:

1. cooccurrence reveals to what extent two ideas tend to occur in the same contexts;

2. similarity between the relative prevalence of ideas over time reveals how two ideas relate in terms of popularity or coverage.

Our input is a collection of documents, each represented by a set of ideas and indexed by time. We denote a *static* set of ideas as $\mathcal{I}$ and a text corpus that consists of these ideas as $C = \{D_1, \ldots, D_T\}$, where $D_t = \{d_{t_1}, \ldots, d_{t_{N_t}}\}$ gives the collection of documents at timestep t, and each document, d_{t_k}, is represented as a subset of ideas in $\mathcal{I}$. Here T is the total number of timesteps, and N_t is the number of documents at timestep t. It follows that the total number of documents $N = \sum_{t=1}^{T} N_t$.

In order to formally capture the two dimensions above, we employ two commonly-used statistics. First, we use empirical pointwise mutual information (PMI) to capture the cooccurrence of ideas within the same document (Church and Hanks, 1990); see Eq. 1 in Fig. 2. Positive $\widehat{\mathrm{PMI}}$ indicates that ideas occur together more frequently than would be expected if they were independent, while negative $\widehat{\mathrm{PMI}}$ indicates the opposite.

Second, we compute the correlation between normalized document frequency of ideas to capture the relation between the relative prevalence of ideas across documents over time; see Eq. 2 in Fig. 2. Positive $\hat{r}$ indicates that two ideas have similar prevalence over time, while negative $\hat{r}$ sug-

gests two anti-correlated ideas (i.e., when one goes up, the other goes down).

The four types of relations in the introduction can now be obtained using $\widehat{\text{PMI}}$ and $\hat{r}$, which capture cooccurrence and prevalence correlation respectively. We further define the *strength* of the relation between two ideas as the absolute value of the product of their $\widehat{\text{PMI}}$ and $\hat{r}$ scores:

$$\forall x, y \in \mathcal{I}, \text{strength}(x, y) = |\widehat{\text{PMI}}(x, y) \times \hat{r}(x, y)|. \quad (3)$$

2.2 Datasets and Representation of Ideas

We use two types of datasets to validate our framework: news articles and research papers. We choose these two domains because competition between ideas has received significant interest in history of science (Kuhn, 1996) and research on framing (Chong and Druckman, 2007; Entman, 1993; Gitlin, 1980; Lakoff, 2014). Furthermore, interesting differences may exist in these two domains as news evolves with external events and scientific research progresses through innovations.

- News articles. We follow the strategy in Card et al. (2015) to obtain news articles from LexisNexis on five issues: abortion, immigration, same-sex marriage, smoking, and terrorism. We search for relevant articles using LexisNexis subject terms in U.S. newspapers from 1980 to 2016. Each of these corpora contains more than 25,000 articles. Please refer to the supplementary material for details.
- Research papers. We consider full texts of papers from two communities: our own ACL community captured by papers from ACL, NAACL, EMNLP, and TACL from 1980 to 2014 (Radev et al., 2009); and the NIPS community from 1987 to 2016.[3] There are 4.8K papers from the ACL community and 6.6K papers from the NIPS community. The processed datasets are available at `https://chenhaot.com/pages/idea-relations.html`.

In order to operationalize ideas in a text corpus, we consider two ways to represent ideas.

- Topics. We extract topics from each document by running LDA (Blei et al., 2003) on each corpus C. In all datasets, we set the number of topics to 50.[4] Formally, $\mathcal{I}$ is the 50 topics learned from the corpus, and each document is represented as the set of topics that are present with greater than 0.01 probability in the topic distribution for that document.
- Keywords. We identify a list of distinguishing keywords for each corpus by comparing its word frequencies to the background frequencies found in other corpora using the informative Dirichlet prior model in Monroe et al. (2008). We set the number of keywords to 100 for all corpora. For news articles, the background corpus for each issue is comprised of all articles from the other four issues. For research papers, we use NIPS as the background corpus for ACL and vice versa to identify what are the core concepts for each of these research areas. Formally, $\mathcal{I}$ is the 100 top distinguishing keywords in the corpus and each document is represented as the set of keywords within $\mathcal{I}$ that are present in the document. Refer to the supplementary material for a list of example keywords in each corpus.

In both procedures, we lemmatize all words and add common bigram phrases to the vocabulary following Mikolov et al. (2013). Note that in our analysis, ideas are only present or absent in a document, and a document can in principle be mapped to any subset of ideas in $\mathcal{I}$. In our experiments 90% of documents are marked as containing between 7 and 14 ideas using topics, 8 and 33 ideas using keywords.

3 Characterizing the Space of Relations

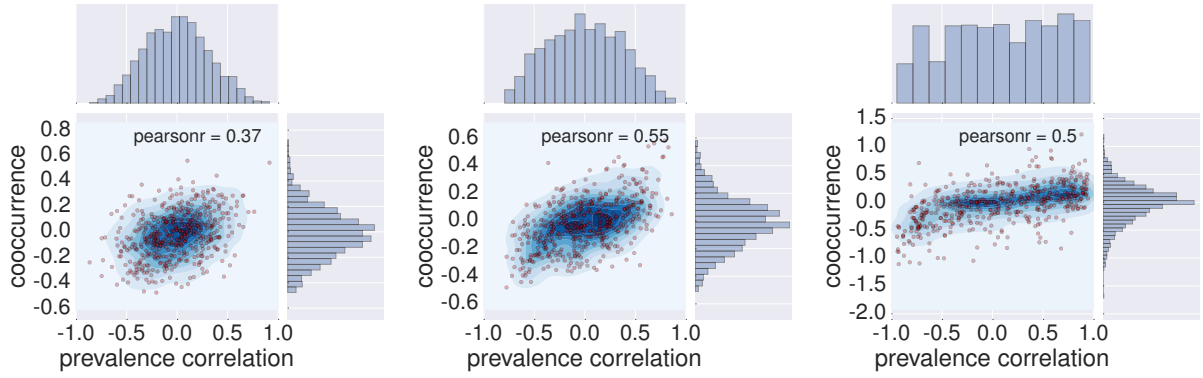
To provide an overview of the four relation types in Fig. 1, we first examine the empirical distributions of the two statistics of interest across pairs of ideas. In most exploratory studies, however, we are most interested in pairs that exemplify each type of relation, i.e., the most extreme points in each quadrant. We thus look at these pairs in each corpus to observe how the four types differ in salience across datasets.

3.1 Empirical Distribution Properties

To the best of our knowledge, the distributions of pairwise cooccurrence and prevalence correlation have not been examined in previous literature. We thus first investigate the marginal distributions of cooccurrence and prevalence correlation and then

[3] `http://papers.nips.cc/`.

[4] We chose 50 topics based on past experience, though this could be tuned for particular applications. Recall that our framework is to analyze *relations* between ideas, so this choice is not essential in this work.



(a) Terrorism topics (b) Immigration topics (c) ACL topics

Figure 3: Overall distributions of cooccurrence and prevalence correlation. In the main plot, each point represents a pair of ideas: color density shows the kernel density estimation of the joint distribution (Scott, 2015). The plots along the axes show the marginal distribution of the corresponding dimension. In each plot, we give the Pearson correlation, and all Pearson correlations' p-values are less than 10^{-40}. In these plots, we use topics to represent ideas.

their joint distribution. Fig. 3 shows three examples: two from news articles and one from research papers. We will also focus our case studies on these three corpora in §4. The corresponding plots for keywords have been relegated to supplementary material due to space limitations.

Cooccurrence tends to be unimodal but not normal. In all of our datasets, pairwise cooccurrence ($\widehat{\text{PMI}}$) presents a unimodal distribution that somewhat resembles a normal distribution, but it is rarely precisely normal. We cannot reject the hypothesis that it is unimodal for any dataset (using topics or keywords) using the dip test (Hartigan and Hartigan, 1985), though D'Agostino's K^2 test (D'Agostino et al., 1990) rejects normality in almost all cases.

Prevalence correlation exhibits diverse distributions. Pairwise prevalence correlation follows different distributions in news articles compared to research papers: they are unimodal in news articles, but not in ACL or NIPS. The dip test only rejects the unimodality hypothesis in NIPS. None follow normal distributions based on D'Agostino's K^2 test.

Cooccurrence is positively correlated with prevalence correlation. In all of our datasets, cooccurrence is positively correlated with prevalence correlation whether we use topics or keywords to represent ideas, although the Pearson correlation coefficients vary. This suggests that there are more friendship and head-to-head relations than tryst and arms-race relations. Based on the results of kernel density estimation, we also observe that this correlation is often loose, e.g., in ACL topics, cooccurrence spreads widely at each mode of prevalence correlation.

3.2 Relative Strength of Extreme Pairs

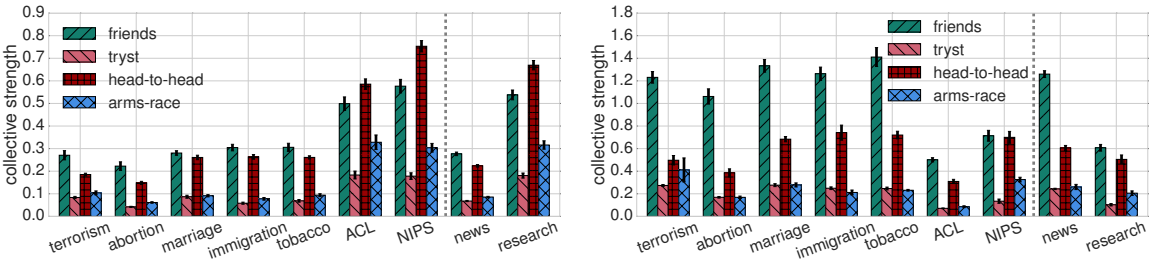
We are interested in how our framework can identify intriguing relations between ideas. These potentially interesting pairs likely correspond to the extreme points in each quadrant instead of the ones around the origin, where PMI and prevalence correlation are both close to zero. Here we compare the relative strength of extreme pairs in each dataset. We will discuss how these extreme pairs confirm existing knowledge and suggest new hypotheses via case studies in §4.

For each relation type, we average the strengths of the 25 pairs with the strongest relations in that type, with strength defined in Eq. 3. This heuristic (henceforth *collective strength*) allows us to collectively compare the strengths of the most prominent friendship, tryst, arms-race, and head-to-head relations. The results are not sensitive to the choice of 25.

Fig. 4 shows the collective strength of the four types in all of our datasets. The most common ordering is:

$$\text{friendship} > \text{head-to-head} > \text{arms-race} > \text{tryst}.$$

The fact that friendship and head-to-head relations are strong is consistent with the positive correlation between cooccurrence and prevalence correlation. In news, friendship is the strongest relation type, but head-to-head is the strongest in ACL topics and NIPS topics. This suggests, unsurprisingly, that there are stronger head-to-head competitions



(a) Topics

(b) Keywords

Figure 4: Collective strength of the four relation types in each dataset (*news* is the average of the news corpora and *research* is for ACL and NIPS). Fig. 4a uses topics to represent ideas, while Fig. 4b uses keywords to represent ideas. Each bar presents the average strength of the top 25 pairs in a relation type in the corresponding dataset. Error bars represent standard errors calculated in the usual way, but note that since the top 25 pairs are not random samples, they cannot be interpreted in the usual way.

(i.e., one idea takes over another) between ideas in scientific research than in news. We also see that topics show greater strength in our scientific article collections, while keywords dominate in news, especially in friendship. We conjecture that terms in scientific literature are often overloaded (e.g., a *tree* could be a parse tree or a decision tree), necessitating some abstraction when representing ideas. In contrast, news stories are more self-contained and seek to employ consistent usage.

4 Exploratory Studies

We present case studies based on strongly related pairs of ideas in the four types of relation. Throughout this section, "rank" refers to the rank of the relation strength between a pair of ideas in its corresponding relation type.

4.1 International Relations in Terrorism

Following a decade of declining violence in the 90s, the events of September 11, 2001 precipitated a dramatic increase in concern about terrorism, and a major shift in how it was framed (Kern et al., 2003). As a showcase, we consider a topic which encompasses much of the U.S. government's response to terrorism: "federal, state".[5] We observe two topics engaging in an "arms race" with this one: "afghanistan, taliban" and "pakistan, india". These correspond to two geopolitical regions closely linked to the U.S. government's concern with terrorism, and both were sites of U.S. military action during the period of our dataset. Events abroad and the U.S. government's responses follow the arms-race pattern, each holding increasing

[5]As in §1, we summarize each topic using a pair of strongly associated words, instead of assigning a name.

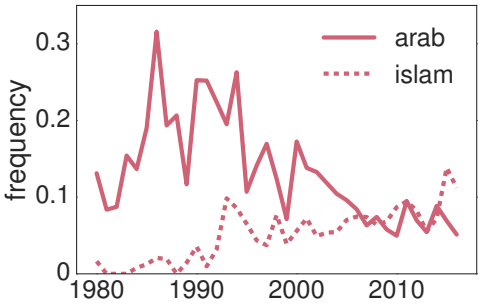


Figure 6: Tryst relation between arab and islam using keywords to represent ideas (#2 in tryst): these two words tend to cooccur but are anti-correlated in prevalence over time. In particular, islam was rarely used in coverage of terrorism in the 1980s.

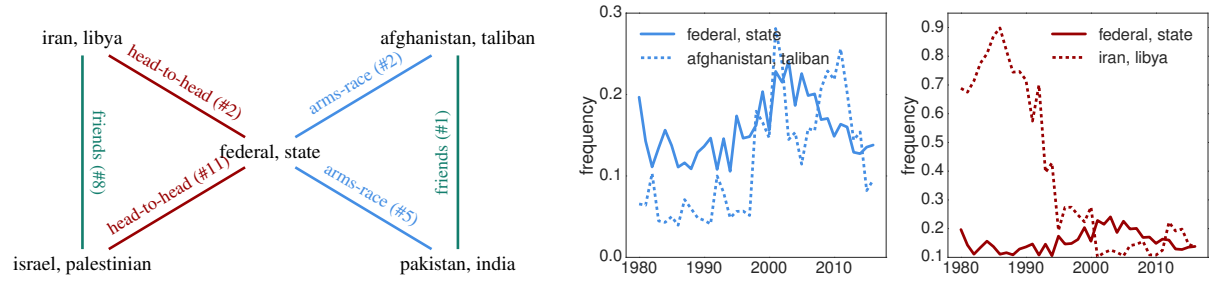
attention with the other, likely because they share the same underlying cause.

We also observe two head-to-head rivals to the "federal, state" topic: "iran, libya" and "israel, palestinian". While these topics correspond to regions that are hotly debated in the U.S., their coverage in news tends not to correlate temporally with the U.S. government's responses to terrorism, at least during the time period of our corpus. Discussion of these regions was more prevalent in the 80s and 90s, with declining media coverage since then (Kern et al., 2003).

The relations between these topics are consistent with structural balance theory (Cartwright and Harary, 1956; Heider, 1946), which suggests that the enemy of an enemy is a friend. The "afghanistan, taliban" topic has the strongest friendship relation with the "pakistan, india" topic, i.e., they are likely to cooccur and are positively correlated in prevalence. Similarly, the "iran, libya" topic is a close "friend" with the "israel, palestinian" topic (ranked 8th in friendship).



(a) Relations between a United States topic and international topics.

(b) ("federal, state", "afghanistan, taliban")

(c) ("federal, state", "iran, libya")

Figure 5: Fig. 5a shows the relations between the "federal, state" topic and four international topics. Edge colors indicate relation types and the number in an edge label presents the ranking of its strength in the corresponding relation type. Fig. 5b and Fig. 5c represent concrete examples in Fig. 5a: "federal, state" and "afghanistan, taliban" follow similar trends, although "afghanistan, taliban" fluctuates over time due to significant events such as the September 11 attacks in 2001 and the death of Bin Laden in 2011; while "iran, lybia" is negatively correlated with "federal, state". In fact, more than 70% of terrorism news in the 80s contained the "iran, lybia" topic.

When using keywords to represent ideas, we observe similar relations between the term homeland security and terms related to the above foreign countries. In addition, we highlight an interesting but unexpected tryst relation between arab and islam (Fig. 6). It is not surprising that these two words tend to cooccur in the same news articles, but the usage of islam in the news is increasing while arab is declining. The increasing prevalence of islam and decreasing prevalence of arab over this time period can also be seen, for example, using Google's n-gram viewer, but it of course provides no information about cooccurrence.

This trend has not been previously noted to the best of our knowledge, although an article in the *Huffington Post* called for news editors to distinguish Muslim from Arab.[6] Our observation suggests a conjecture that the news media have increasingly linked terrorism to a religious group rather than an ethnic group, perhaps in part due to the tie between the events of 9/11 and Afghanistan, which is not an Arab or Arabic-speaking country. We leave it to further investigation to confirm or reject this hypothesis.

To further demonstrate the effectiveness of our approach, we compare a pair's rank using only cooccurrence or prevalence correlation with its rank in our framework. Table 1 shows the results for three pairs above. If we had looked at only cooccurrence or prevalence correlation, we would probably have missed these interesting pairs.

[6] http://www.huffingtonpost.com/haroon-moghul/even-the-new-york-times-d_b_766658.html

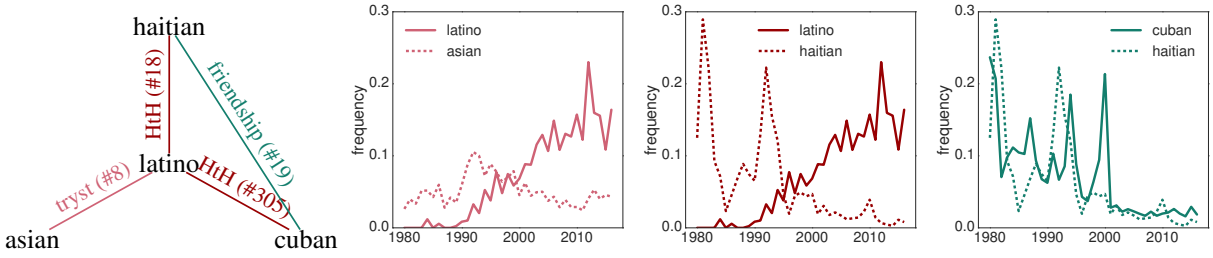
	PMI	Corr
"federal, state", "afghanistan, taliban" (#2 in arms-race)	43	99
"federal, state", "iran, lybia" (#2 in head-to-head)	36	56
arab, islam (#2 in tryst)	106	1,494

Table 1: Ranks of pairs by using the absolute value of only cooccurrence or prevalence correlation.

4.2 Ethnicity Keywords in Immigration

In addition to results on topics in §1, we observe unexpected patterns about ethnicity keywords in immigration news. Our observation starts with a top tryst relation between latino and asian. Although these words are likely to cooccur, their prevalence trajectories differ, with the discussion of Asian immigrants in the 1990s giving way to a focus on the word latino from 2000 onward. Possible theories to explain this observation include that undocumented immigrants are generally perceived as a Latino issue, or that Latino voters are increasingly influential in U.S. elections.

Furthermore, latino holds head-to-head relations with two subgroups of Latin American immigrants: haitian and cuban. In particular, the strength of the relation with haitian is ranked #18 in head-to-head relations. Meanwhile, haitian and cuban have a friendship relation, which is again consistent with structural balance theory. The decreasing prevalence of haitian and cuban perhaps speaks to the shifting geographical focus of recent immigration to the U.S., and issues of the Latino pan-ethnicity. In fact, a majority of Latinos prefer to identify with their national origin relative to the



(a) Relations graph. (b) (latino, asian) (c) (latino, haitian) (d) (cuban, haitian)

Figure 7: Relations between ethnicity keywords in immigration news (HtH for head-to-head): latino holds a tryst relation with asian and head-to-head relations with two subgroups from Latin America, haitian and cuban. We do not show the relations between asian and haitian, cuban, because their strength is close to 0.

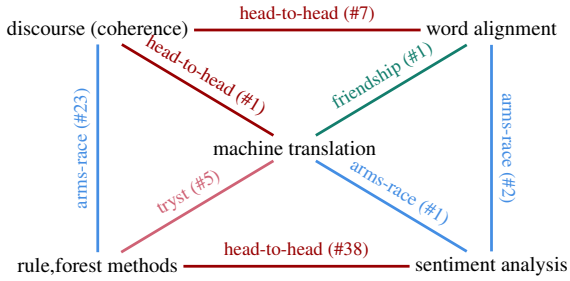


Figure 8: Top relations between the topics in ACL Anthology. The top 10 words for the rule, forest methods topic are *rule, grammar, derivation, span, algorithm, forest, parsing, figure, set, string*.

pan-ethnic terms (Taylor et al., 2012). However, we should also note that much of this coverage relates to a set of specific refugee crises, temporarily elevating the political importance of these nations in the U.S. Nevertheless, the underlying social and political reasons behind these head-to-head relations are worth further investigation.

4.3 Relations between Topics in ACL

Finally, we analyze relations between topics in the ACL Anthology. It turns out that "machine translation" is at a central position among top ranked relations in all the four types (Fig. 8).[7] It is part of the strongest relation in all four types except tryst (ranked #5).

The full relation graph presents further patterns. Friendship demonstrates transitivity: both "machine translation" and "word alignment" have similar relations with other topics. But such transitivity does not hold for tryst: although the prevalence of "rule, forest methods" is anti-correlated with both "machine translation" and "sentiment analysis", "sentiment analysis" seldom cooccurs with "rule, forest methods" because "sentiment analysis" is seldom built on parsing algorithms. Similarly, "rule, forest methods" and "discourse (coherence)" hold an arms-race relation: they do not tend to cooccur and both decline in relative prevalence as "machine translation" rises.

The prevalence of each of these ideas in comparison to machine translation is shown in in Fig. 9, which reveals additional detail.

5 Related Work

We present two strands of related studies in addition to what we have discussed.

Trends in ideas. Most studies have so far examined the trends of ideas individually (Michel et al., 2011; Hall et al., 2008; Rule et al., 2015). For instance, Hall et al. (2008) present various trends in our own computational linguistics community, including the rise of statistical machine translation. More recently, rhetorical framing has been used to predict these sorts of patterns (Prabhakaran et al., 2016). An exception is that Shi et al. (2010) use prevalence correlation to analyze lag relations between topics in publications and research grants. Anecdotally, Grudin (2009) observes a "head-to-head" relation between artificial intelligence and human-computer interaction in research funding. However, to our knowledge, our work is the first study to systematically characterize relations *between* ideas.

Representation of ideas. In addition to topics and keywords, studies have also sought to operationalize the "memes" metaphor using quotes and text reuse in the media (Leskovec et al., 2009; Niculae et al., 2015; Smith et al., 2013; Wei et al., 2013). In topic modeling literature, Blei and Lafferty (2006) also point out that topics do not cooccur independently and explicitly model the cooccurrence within documents.

[7] In the ranking, we filtered a topic where the top words are *ion, ing, system, process, language, one, input, natural language, processing, grammar*. For the purposes of this corpus, this is effectively a stopword topic.

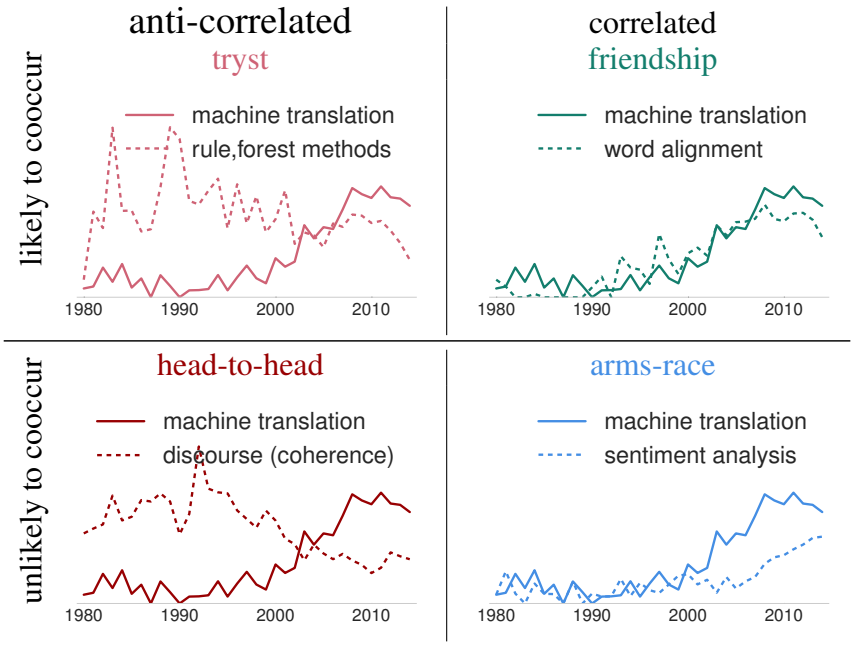

Figure 9: Relations between topics in ACL Anthology in the space of cooccurrence and prevalence correlation (prevalence correlation is shown explicitly and cooccurrence is encoded in row captions), color coded to match the text. The y-axis represents the relative proportion of papers in a year that contain the corresponding topic. The top 10 words for the rule, forest methods topic are *rule, grammar, derivation, span, algorithm, forest, parsing, figure, set, string*.

6 Concluding Discussion

We proposed a method to characterize relations between ideas in texts through the lens of cooccurrence within documents and prevalence correlation over time. For the first time, we observe that the distribution of pairwise cooccurrence is unimodal, while the distribution of pairwise prevalence correlation is not always unimodal, and show that they are positively correlated. This combination suggests four types of relations between ideas, and these four types are all found to varying extents in our experiments.

We illustrate our computational method by exploratory studies on news corpora and scientific research papers. We not only confirm existing knowledge but also suggest hypotheses around the usage of arab and islam in terrorism and latino and asian in immigration.

It is important to note that the relations found using our approach depend on the nature of the representation of ideas and the source of texts. For instance, we cannot expect relations found in news articles to reflect shifts in public opinion if news articles do not effectively track public opinion.

Our method is entirely observational. It remains as a further stage of analysis to understand the underlying reasons that lead to these relations between ideas. In scientific research, for example, it could simply be the progress of science, i.e., newer ideas overtake older ones deemed less valuable at a given time; on the other hand, history suggests that it is not always the correct ideas that are most expressed, and many other factors may be important. Similarly, in news coverage, underlying sociological and political situations have significant impact on which ideas are presented, and how.

There are many potential directions to improve our method to account for complex relations between ideas. For instance, we assume that both ideas and relations are statically grounded in keywords or topics. In reality, ideas and relations both evolve over time: a tryst relation might appear as friendship if we focus on a narrower time period. Similarly, new ideas show up and even the same idea may change over time and be represented by different words.

Polish evaluation dataset for compositional distributional semantics models

Alina Wróblewska **Katarzyna Krasnowska-Kieraś**
Institute of Computer Science, Polish Academy of Sciences
alina@ipipan.waw.pl kasia.krasnowska@gmail.com

Abstract

The paper presents a procedure of building an evaluation dataset[1]. for the validation of compositional distributional semantics models estimated for languages other than English. The procedure generally builds on steps designed to assemble the SICK corpus, which contains pairs of English sentences annotated for semantic relatedness and entailment, because we aim at building a comparable dataset. However, the implementation of particular building steps significantly differs from the original SICK design assumptions, which is caused by both lack of necessary extraneous resources for an investigated language and the need for language-specific transformation rules. The designed procedure is verified on Polish, a fusional language with a relatively free word order, and contributes to building a Polish evaluation dataset. The resource consists of 10K sentence pairs which are human-annotated for semantic relatedness and entailment. The dataset may be used for the evaluation of compositional distributional semantics models of Polish.

1 Introduction and related work

1.1 Distributional semantics

The basic idea of distributional semantics, i.e. determining the meaning of a word based on its co-occurrence with other words, is derived from the empiricists – Harris (1954) and Firth (1957). John R. Firth drew attention to the context-dependent nature of meaning especially with his famous maxim "You shall know a word by the company it keeps" (Firth, 1957, p. 11).

Nowadays, distributional semantics models are estimated with various methods, e.g. word embedding techniques (Bengio et al., 2003, 2006; Mikolov et al., 2013). To ascertain the purport of a word, e.g. *bath*, you can use the context of other words that surround it. If we assume that the meaning of this word expressed by its lexical context is associated with a distributional vector, the distance between distributional vectors of two semantically similar words, e.g *bath* and *shower*, should be smaller than between vectors representing semantically distinct words, e.g. *bath* and *tree*.

1.2 Compositional distributional semantics

Based on empirical observations that distributional vectors encode certain aspects of word meaning, it is expected that similar aspects of the meaning of phrases and sentences can also be represented with vectors obtained via composition of distributional word vectors. The idea of semantic composition is not new. It is well known as the *principle of compositionality*:[2] "The meaning of a compound expression is a function of the meaning of its parts and of the way they are syntactically combined." (Janssen, 2012, p. 19).

Modelling the meaning of textual units larger than words using compositional and distributional information is the main subject of compositional distributional semantics (Mitchell and Lapata, 2010; Baroni and Zamparelli, 2010; Grefenstette and Sadrzadeh, 2011; Socher et al., 2012, to name a few studies). The fundamental principles of compositional distributional semantics, henceforth referred to as CDS, are mainly propagated with papers written on the topic. Apart from the papers, it was the SemEval-2014 Shared Task 1

[1] The dataset is obtainable at: http://zil.ipipan.waw.pl/Scwad/CDSCorpus

[2] As the principle of compositionality is attributed to Gottlob Frege, it is often called *Frege's principle*.

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 784–792
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1073

(Marelli et al., 2014) that essentially contributed to the expansion of CDS and increased an interest in this domain. The goal of the task was to evaluate CDS models of English in terms of semantic relatedness and entailment on proper sentences from the SICK corpus.

1.3 The SICK corpus

The SICK corpus (Bentivogli et al., 2014) consists of 10K pairs of English sentences containing multiple lexical, syntactic, and semantic phenomena. It builds on two external data sources – the 8K ImageFlickr dataset (Rashtchian et al., 2010) and SemEval-2012 Semantic Textual Similarity dataset (Agirre et al., 2012). Each sentence pair is human-annotated for relatedness in meaning and entailment.

The relatedness score corresponds to the degree of semantic relatedness between two sentences and is calculated as the average of ten human ratings collected for this sentence pair on the 5-point Likert scale. This score indicates the extent to which the meanings of two sentences are related.

The entailment relation between two sentences, in turn, is labelled with *entailment*, *contradiction*, or *neutral*. According to the SICK guidelines, the label assigned by the majority of human annotators is selected as the valid entailment label.

1.4 Motivation and organisation of the paper

Studying approaches to various natural language processing (henceforth NLP) problems, we have observed that the availability of language resources (e.g. training or testing data) stimulates the development of NLP tools and the estimation of NLP models. English is undoubtedly the most prominent in this regard and English resources are the most numerous. Therefore, NLP methods are mostly designed for English and tested on English data, even if there is no guarantee that they are universal. In order to verify whether an NLP algorithm is adequate, it is not enough to evaluate it solely for English. It is also valuable to have high-quality resources for languages typologically different to English. Hence, we aim at building datasets for the evaluation of CDS models in languages other than English, which are often underresourced. We strongly believe that the availability of test data will encourage development of CDS models in these languages and allow to better test the universality of CDS methods.

We start with a high-quality dataset for Polish, which is a completely different language than English in at least two dimensions. First, it is a rather under-resourced language in contrast to the resource-rich English. Second, it is a fusional language with a relatively free word order in contrast to the isolated English with a relatively fixed word order. If some heuristics is tested on e.g. Polish, the evaluation results can be approximately generalised to other Slavic languages. We hope the Slavic NLP community will be interested in designing and evaluating methods of semantic modelling for Slavic languages.

The procedure of building an evaluation dataset for validating compositional distributional semantics models of Polish generally builds on steps designed to assemble the SICK corpus (described in Section 1.3) because we aim at building an evaluation dataset which is comparable to the SICK corpus. However, the implementation of particular building steps significantly differs from the original SICK design assumptions, which is caused by both lack of necessary extraneous resources for Polish (see Section 2.1) and the need for Polish-specific transformation rules (see Section 2.2). Furthermore, the rules of arranging sentences into pairs (see Section 2.3) are defined anew taking into account the characteristic of data and bidirectional entailment annotations, since an entailment relation between two sentences must not be symmetric. Even if our assumptions of annotating sentence pairs coincide with the SICK principles to a certain extent (see Section 3.1), the annotation process differs from the SICK procedure, in particular by introducing an element of human verification of correctness of automatically transformed sentences (see Section 3.2) and some additional post-corrections (see Section 3.3). Finally, a summary of the dataset is provided in Section 4.1 and the dataset evaluation is given in Section 4.2.

2 Procedure of collecting data

2.1 Selection and description of images

The first step of building the SICK corpus consisted in the random selection of English sentence pairs from existing datasets (Rashtchian et al., 2010; Agirre et al., 2012). Since we are not aware of accessibility of analogous resources for Polish, we have to select images first and then describe the selected images.

Images are selected from the 8K ImageFlickr

dataset (Rashtchian et al., 2010). At first we wanted to take only these images the descriptions of which were selected for the SICK corpus. However, a cursory check shows that these images are quite homogeneous, with a predominant number of dogs depictions. Therefore, we independently extract 1K images and split them into 46 thematic groups (e.g. *children*, *musical instruments*, *motorbikes*, *football*, *dogs*). The numbers of images within individual thematic groups vary from 6 images in the *volleyball* and *telephoning* groups to 94 images in the *various people* group. The second largest groups are *children* and *dogs* with 50 images each.

The chosen images are given to two authors who independently of each other formulate their descriptions based on a short instruction. The authors are instructed to write one single sentence (with a sentence predicate) describing the action in a displayed image. They should not describe an imaginable context or an interpretation of what may lie behind the scene in the picture. If some details in the picture are not obvious, they should not be described either. Furthermore, the authors should avoid multiword expressions, such as idioms, metaphors, and named entities, because those are not compositional linguistic phenomena. Finally, descriptions should contain Polish diacritics and proper punctuation.

2.2 Transformation of descriptions

The second step of building the SICK corpus consisted in pre-processing extracted sentences, i.e. normalisation and expansion (Bentivogli et al., 2014, p. 3–4). Since the authors of Polish descriptions are asked to follow the guidelines (presented in Section 2.1), the normalisation step is not essential for our data. The expansion step, in turn, is implemented and the sentences provided by the authors are lexically and syntactically transformed in order to obtain derivative sentences with similar, contrastive, or neutral meanings. The following transformations are implemented:

1. *dropping conjunction* concerns sentences with coordinated predicates sharing a subject, e.g. *Rowerzysta odpoczywa i obserwuje morze.* (Eng. ‘A cyclist is resting and watching the sea.’). The finite form of one of the coordinated predicates is transformed into:
    - an active adjectival participle, e.g. *Odpoczywający rowerzysta obserwuje morze.* (Eng. ‘A resting cyclist is watching the sea.’) or *Obserwujący morze rowerzysta odpoczywa.* (Eng. ‘A cyclist, who is watching the sea, is resting.’),
    - a contemporary adverbial participle, e.g. *Rowerzysta, odpoczywając, obserwuje morze.* (Eng. ‘A cyclist is watching the sea, while resting.’) or *Rowerzysta odpoczywa, obserwując morze.* (Eng. ‘A cyclist is resting, while watching the sea.’).
2. *removing conjunct in adjuncts*, i.e. the deletion of one of coordinated elements of an adjunct, e.g. *Mały, ale zwinny kot miauczy.* (Eng. ‘A small but agile cat miaows.’) can be changed into either *Mały kot miauczy.* (Eng. ‘A small cat miaows.’) or *Zwinny kot miauczy.* (Eng. ‘An agile cat miaows.’).
3. *passivisation*, e.g. *Człowiek ujeżdża byka.* (Eng. ‘A man is breaking a bull in.’) can be transformed into *Byk jest ujeżdżany przez człowieka.* (Eng. ‘A bull is being broken in by a man.’).
4. *removing adjuncts*, e.g. *Dwa białe króliki siedzą na trawie.* (Eng. ‘Two small rabbits are sitting on the grass.’) can be changed into *Króliki siedzą.* (Eng. ‘The rabbits are sitting.’).
5. *swapping relative clause for participles*, i.e. a relative clause swaps with a participle (and vice versa), e.g. *Kobieta przytula psa, którego trzyma na smyczy.* (Eng. ‘A woman hugs a dog which she keeps on a leash.’). The relative clause is interchanged for a participle construction, e.g. *Kobieta przytula trzymanego na smyczy psa.* (Eng. ‘A woman hugs a dog kept on a leash.’).
6. *negation*, e.g. *Mężczyźni w turbanach na głowach siedzą na słoniach.* (Eng. ‘Men in turbans on their heads are sitting on elephants.’) can be transformed into *Nikt nie siedzi na słoniach.* (Eng. ‘Nobody is sitting on elephants.’), *Żadni mężczyźni w turbanach na głowach nie siedzą na słoniach.* (Eng. ‘No men in turbans on their heads are sitting on elephants.’), and *Mężczyźni w turbanach na głowach nie siedzą na słoniach.* (Eng. ‘Men in turbans on their heads are not sitting on elephants.’).

7. *constrained mixing of dependents from various sentences*, e.g. *Dwoje dzieci siedzi na wielbłądach w pobliżu wysokich gór.* (Eng. 'Two children are sitting on camels near high mountains.') can be changed into *Dwoje dzieci siedzi przy zastawionym stole w pobliżu wysokich gór.* (Eng. 'Two children are sitting at the table laid with food near high mountains.').

The first five transformations are designed to produce sentences with a similar meaning, the sixth transformation outputs sentences with a contradictory meaning, and the seventh transformation should generate sentences with a neutral (or unrelated) meaning. All transformations are performed on the dependency structures of input sentences (Wróblewska, 2014).

Some of the transformations are very productive (e.g. mixing dependents). Other, in turn, are sparsely represented in the output (e.g. dropping conjunction). The number of transformed sentences randomly selected to build the dataset is in the second column of Table 1.

transformation	**selected**	
dropping conjunction	139	2.0%
removing conjunct in adjunct	485	6.9%
passivisation	893	12.8%
removing adjuncts	1013	14.5%
swapping rc↔ptcp	1291	18.4%
negation	1304	18.6%
mixing dependents	1878	26.8%

Table 1: Numbers of transformed sentences selected for annotation.

2.3 Data ensemble

The final step of building the SICK corpus consisted in arranging normalised and expanded sentences into pairs. Since our data diverges from SICK data, the process of arranging Polish sentences into pairs also differs from pairing in the SICK corpus. The general idea behind the pair-ensembling procedure was to introduce sentence pairs with different levels of relatedness into the dataset. Apart from pairs connecting two sentences originally written by humans (as described in Section 2.1), there are also pairs in which an original sentence is connected with a transformed sentence. For each of the 1K images, the following 10 pairs are constructed (for A being the set of all sentences originally written by the first author, B being the set of all sentences originally written by the second author, $\mathbf{a} \in A$ and $\mathbf{b} \in B$ being the original descriptions of the picture):

1. $(\mathbf{a}, \mathbf{b})$
2. $(\mathbf{a}, \mathbf{a}_1)$, where $\mathbf{a}_1 \in t(\mathbf{a})$, and $t(\mathbf{a})$ is the set of all transformations of the sentence $\mathbf{a}$
3. $(\mathbf{b}, \mathbf{b}_1)$, where $\mathbf{b}_1 \in t(\mathbf{b})$
4. $(\mathbf{a}, \mathbf{b}_2)$, where $\mathbf{b}_2 \in t(\mathbf{b})$
5. $(\mathbf{b}, \mathbf{a}_2)$, where $\mathbf{a}_2 \in t(\mathbf{a})$
6. $(\mathbf{a}, \mathbf{a}_3)$, where $\mathbf{a}_3 \in t(\mathbf{a}'), \mathbf{a}' \in A, \mathcal{T}(\mathbf{a}') = \mathcal{T}(\mathbf{a}), \mathbf{a}' \neq \mathbf{a}$, for $\mathcal{T}(\mathbf{a})$ being the thematic group[3] of $\mathbf{a}$
7. $(\mathbf{b}, \mathbf{b}_3)$, where $\mathbf{b}_3 \in t(\mathbf{b}'), \mathbf{b}' \in B, \mathcal{T}(\mathbf{b}') = \mathcal{T}(\mathbf{b}), \mathbf{b}' \neq \mathbf{b}$
8. $(\mathbf{a}, \mathbf{a}_4)$, where $\mathbf{a}_4 \in A, \mathcal{T}(\mathbf{a_4}) \neq \mathcal{T}(\mathbf{a})$[4]
9. $(\mathbf{b}, \mathbf{b}_4)$, where $\mathbf{b_4} \in B, \mathcal{T}(\mathbf{b_4}) \neq \mathcal{T}(\mathbf{b})$
10. $(\mathbf{a}, \mathbf{a}_5)$, where $\mathbf{a}_5 \in t(\mathbf{a}), \mathbf{a}_5 \neq \mathbf{a}_1$ for 50% images, $(\mathbf{b}, \mathbf{b}_5)$ (analogously) for other 50%.[5]

For each sentence pair $(\mathbf{a}, \mathbf{b})$ created according to this procedure, its reverse $(\mathbf{b}, \mathbf{a})$ is also included in our corpus. As a result, the working set consists of 20K sentence pairs.

3 Corpus annotation

3.1 Annotation assumptions

The degree of semantic relatedness between two sentences is calculated as the average of all human ratings on the Likert scale with the range from 0 to 5. Since we do not want to excessively influence

[3]The thematic group of a sentence $\mathbf{a}$ corresponds to the thematic group of an image being the source of $\mathbf{a}$ (as described in Section 2.1).

[4]The pairs $(\mathbf{a}, \mathbf{a}_4)$ of the same authors' descriptions of two images from different thematic groups are expected to be unrelated. The same applies to $(\mathbf{b}, \mathbf{b}_4)$.

[5]A repetition of point 2 with a restriction that a different pair is created (pairs of very related sentences are expected). We alternate between authors A and B to obtain equal author proportions in the final ensemble of pairs.

the annotations, the guidelines given to annotators are mainly example-based:[6]

- 5 (very related): *Kot siedzi na płocie.* (Eng. 'A cat is sitting on the fence.') vs. *Na płocie jest duży kot.* (Eng. 'There is a large cat on the fence.'),

- 1–4 (more or less related):
  Kot siedzi na płocie. (Eng. 'A cat is sitting on the fence.') vs. *Kot nie siedzi na płocie.* (Eng. 'A cat is not sitting on the fence.');
  Kot siedzi na płocie. (Eng. 'A cat is sitting on the fence.') vs. *Właściciel dał kotu chrupki.* (Eng. 'The owner gave kibble to his cat.');
  Kot siedzi na płocie. (Eng. 'A cat is sitting on the fence.') vs. *Kot miauczy pod płotem.* (Eng. 'A cat miaows by the fence.').

- 0 (unrelated): *Kot siedzi na płocie.* (Eng. 'A cat is sitting on the fence.') vs. *Zaczął padać deszcz.* (Eng. 'It started to rain.').

Apart from these examples, there is a note in the annotation guidelines indicating that the degree of semantic relatedness is not equivalent to the degree of semantic similarity. Semantic similarity is only a special case of semantic relatedness, semantic relatedness is thus a more general term than the other one.

Polish entailment labels correspond directly to the SICK labels (i.e. *entailment*, *contradiction*, *neutral*). The entailment label assigned by the majority of human judges is selected as the gold label. The entailment labels are defined as follows:

- **a wynika z b** (**b** entails **a**) – if a situation or an event described by sentence **b** occurs, it is recognised that a situation or an event described by **a** occurs as well, i.e. **a** and **b** refer to the same event or the same situation,

- **a jest zaprzeczeniem b** (**a** is the negation of **b**) – if a situation or an event described by **b** occurs, it is recognised that a situation or an event described by **a** may not occur at the same time,

- **a jest neutralne wobec b** (**a** is neutral to **b**) – the truth of a situation described by **a** cannot be determined on the basis of **b**.

3.2 Annotation procedure

Similar to the SICK corpus, each Polish sentence pair is human-annotated for semantic relatedness and entailment by 3 human judges experienced in Polish linguistics.[7] Since for each annotated pair $(\mathbf{a}, \mathbf{b})$, its reverse $(\mathbf{b}, \mathbf{a})$ is also subject to annotation, the entailment relation is in practice determined 'in both directions' for 10K sentence pairs. For the task of relatedness annotation, the order of sentences within pairs seems to be irrelevant, we can thus assume to obtain 6 relatedness scores for 10K unique pairs.

Since the transformation process is fully automatic and to a certain extent based on imperfect dependency parsing, we cannot ignore errors in the transformed sentences. In order to avoid annotating erroneous sentences, the annotation process is divided into two stages:

1. a sentence pair is sent to a judge with the *leader* role, who is expected to edit and to correct the transformed sentence from this pair before annotation, if necessary,

2. the verified and possibly enhanced sentence pair is sent to the other two judges, who can only annotate it.

The *leader* judges should correct incomprehensible and ungrammatical sentences with a minimal number of necessary changes. Unusual sentences which could be accepted by Polish speakers should not be modified. Moreover, the modified sentence may not be identical with the other sentence in the pair. The classification and statistics of distinct corrections made by the *leader* judges are provided in Table 2.

A strict classification of error types is quite hard to provide because some sentences contain more than one error. We thus order the error types from the most serious errors (i.e. 'sense' errors) to the redundant corrections (i.e. 'other' type). If a sentence contains several errors, it is qualified for the higher order error type.

In the case of sentences with 'sense' errors, the need for correction is uncontroversial and

[6] We realise that the boundary between semantic perception of a sentence by various speakers is fuzzy (it depends on speakers' education, origin, age, etc.). It was thus our well-thought-out decision to draw only general annotation frames and to enable annotators to rely on their feel for language.

[7] Our annotators have relatively strong linguistic background. Five of them have PhD in linguistics, five are PhD students, one is a graduate, and one is an undergraduate.

error type	# of errors	% of errors
sense	171	12.3
semantic	407	29.2
grammatical	243	17.4
word order	141	10.1
punctuation	366	26.2
other	68	4.9

Table 2: Classification and statistics of corrections.

arises from an internal logical contradiction.[8] The sentences with 'semantic' changes are syntactically correct, but deemed unacceptable by the *leader* annotators from the semantic or pragmatic point of view.[9] The 'grammatical' errors mostly concern missing agreement.[10] The majority of 'word order' corrections are unnecessary, but we found some examples which can be classified as actual word or phrase order errors.[11] The correction of punctuation consists in adding or deleting a comma.[12] The sentences in the 'other' group, in turn, could as well have been left unchanged because they are proper Polish sentences, but were apparently considered odd by the *leader* annotators.

[8] An example of 'sense' error: the sentence *Chłopak w zielonej bluzie i czapce zjeżdża na rolkach* ***na leżąco***. (Eng. 'A boy in a green sweatshirt and a cap roller-skates downhill **in a lying position**.') is corrected into *Chłopak w zielonej bluzie i czapce zjeżdża na rolkach.* (Eng. 'A boy in a green sweatshirt and a cap roller-skates downhill.').

[9] An example of 'semantic' correction: the sentence *Dziewczyna trzyma w* ***pysku*** *patyk.* (Eng. 'A girl holds a stick in her **muzzle**.') is corrected into *Dziewczyna trzyma w* ***ustach*** *patyk.* (Eng. 'A girl holds a stick in her **mouth**.').

[10] An example of 'grammatical' error: the sentence *Grupa*$_{\mathbf{sg}.nom}$ *uśmiechających się ludzi* ***tańczą***$_{pl}$. (Eng. *'A group of smiling people are dancing.') is corrected into *Grupa*$_{\mathbf{sg}.nom}$ *uśmiechających się ludzi* ***tańczy***$_{sg}$. (Eng. 'A group of smiling people is dancing.').

[11] An example of word order error: the sentence *Samochód, który jest uszkodzony,* ***koloru białego*** *stoi na lawecie dużego auta.* (lit. 'A car that is damaged, **of the white color** stands on the trailer of a large car.', Eng. 'A **white** car that is damaged is standing on the trailer of a large car.') is corrected into *Samochód* ***koloru białego****, który jest uszkodzony, stoi na lawecie dużego auta.*

[12] An example of punctuation correction: the wrong comma in the sentence *Nad brzegiem wody, stoją dwaj mężczyźni z wędkami.* (lit. 'On the water's edge, two men are standing with rods.'; Eng. 'Two men with rods are standing on the water's edge.') should be deleted, i.e. *Nad brzegiem wody stoją dwaj mężczyźni z wędkami.*

3.3 Impromptu post-corrections

During the annotation process it came out that sentences accepted by some human annotators are unacceptable for other annotators. We thus decided to garner annotators' comments and suggestions for improving sentences. After validation of these suggestions by an experienced linguist, it turns out that most of these proposals concern punctuation errors (e.g. missing comma) and typos in 312 distinct sentences. These errors are fixed directly in the corpus because they should not impact the annotations of sentence pairs. The other suggestions concern more significant changes in 29 distinct sentences (mostly minor grammatical or semantic problems overlooked by the *leader* annotators). The annotations of pairs with modified sentences are resent to the annotators so that they can verify and update them.

4 Corpus summary and evaluation

4.1 Corpus statistics

Tables 3 and 4 summarise the annotations of the resulting 10K sentence pairs corpus. Table 3 aggregates the occurrences of 6 possible relatedness scores, calculated as the mean of all 6 individual annotations, rounded to an integer.

relatedness	# of pairs
0	1978
1	1428
2	1082
3	2159
4	2387
5	966

Table 3: Final relatedness scores rounded to integers (total: 10K pairs).

Table 4 shows the number of the particular entailment labels in the corpus. Since each sentence pair is annotated for entailment in both directions, the final entailment label is actually a pair of two labels:

- *entailment+neutral* points to 'one-way' entailment,
- *contradiction+neutral* points to 'one-way' contradiction,
- *entailment+entailment*, *contradiction+contradiction*, and *neutral+neutral* point to equivalence.

While the actual corpus labels are ordered in the sense that there is a difference between e.g. *entailment+neutral* and *neutral+entailment* (the entailment occurs in different directions), we treat all labels as unordered for the purpose of this summary (e.g. *entailment+neutral* covers *neutral+entailment* as well, representing the same type of relation between two sentences).

entailment	**# of pairs**
neutral+neutral	6483
entailment+neutral	1748
entailment+entailment	933
contradiction+contradiction	721
contradiction+neutral	115

Table 4: Final entailment labels (total: 10K pairs).

4.2 Inter-annotator agreement

The standard measure of inter-annotator agreement in various natural language labelling tasks is Cohen's kappa (Cohen, 1960). However, this coefficient is designed to measure agreement between two annotators only. Since there are three annotators of each pair of ordered sentences, we decided to apply Fleiss' kappa[13] (Fleiss, 1971) designed for measuring agreement between multiple raters who give categorical ratings to a fixed number of items. An additional advantage of this measure is that different items can be rated by different human judges, which doesn't impact measurement. The normalised Fleiss' measure of inter-annotator agreement is:

$$\kappa = \frac{\bar{P} - \bar{P}_e}{1 - \bar{P}_e}$$

where the quantity $\bar{P} - \bar{P}_e$ measures the degree of agreement actually attained in excess of chance, while "[t]he quantity $1 - \bar{P}_e$ measures the degree of agreement attainable over and above what would be predicted by chance" (Fleiss, 1971, p. 379).

We recognise Fleiss' kappa as particularly useful for measuring inter-annotator agreement with respect to entailment labelling in our evaluation dataset. First, there are more than two raters. Second, entailment labels are categorically. Measured with Fleiss' kappa, there is an inter-annotator agreement of $\kappa = 0.734$ for entailment labels in Polish evaluation dataset, which is quite satisfactory as for a semantic labelling task.

Relative to semantic relatedness, the distinction in meaning of two sentences made by human judges is often very subtle. This is also reflected in the inter-annotator agreement scores measured with Fleiss' kappa. Inter-annotator agreement measured for six semantic relatedness groups corresponding to points on the Likert scale is quite low: $\kappa = 0.337$. If we measure inter-annotator agreement for three classes corresponding to the three relatedness groups from the annotation guidelines (see Section 3.1), i.e. <0>, <1, 2, 3, 4>, and <5>, the Fleiss' score is significantly higher: $\kappa = 0.543$. Hence, we conclude that Fleiss' kappa is not a reliable measure of inter-annotator agreement in relation to relatedness scores. Therefore, we decided to use Krippendorff's α instead.

Krippendorff's α (Krippendorff, 1980, 2013) is a coefficient appropriate for measuring the inter-annotator agreement of a dataset which is annotated with multiple judges and characterised by different magnitudes of disagreement and missing values. Krippendorff proposes distance metrics suitable for various scales: binary, nominal, interval, ordinal, and ratio. In ordinal measurement[14] the attributes can be rank-ordered, but distances between them do not have any meaning. Measured with Krippendorff's ordinal α, there is an inter-annotator agreement of $\alpha = 0.780$ for relatedness scores in the Polish evaluation dataset, which is quite satisfactory as well. Hence, we conclude that our dataset is a reliable resource for the purpose of evaluating compositional distributional semantics model of Polish.

5 Conclusions

The goal of this paper is to present the procedure of building a Polish evaluation dataset for the validation of compositional distributional semantics models. As we aim at building an evalua-

[13] As Fleiss' kappa is actually the generalisation of Scott's π (Scott, 1955), it is sometimes referred to as Fleiss' *multi-*π, cf. Artstein and Poesio (2008).

[14] Nominal measurement is useless for measuring agreement between relatedness scores ($\alpha = 0.340$ is the identical value as Fleiss' kappa, since all disagreements are considered equal). We also test interval measurement, in which the distance between the attributes does have meaning and an average of an interval variable is computed. The interval score measured for relatedness annotations is quite high $\alpha = 0.785$, but we doubt whether the distance between relatedness scores is meaningful in this case.

tion dataset which is comparable to the SICK corpus, the general assumptions of our procedure correspond to the design principles of the SICK corpus. However, the procedure of building the SICK corpus cannot be adapted without modifications. First, the Polish seed-sentences have to be written based on the images which are selected from 8K ImageFlickr dataset and split into thematic groups, since usable datasets are not publicly available. Second, since the process of transforming sentences seems to be language-specific, the linguistic transformation rules appropriate for Polish have to be defined from scratch. Third, the process of arranging Polish sentences into pairs is defined anew taking into account the data characteristic and bidirectional entailment annotations. The discrepancies relative to the SICK procedure also concern the annotation process itself. Since an entailment relation between two sentences must not be symmetric, each sentence pair is annotated for entailment in both directions. Furthermore, we introduce an element of human verification of correctness of automatically transformed sentences and some additional post-corrections.

The presented procedure of building a dataset was tested on Polish. However, it is very likely that the annotation framework will work for other Slavic languages (e.g. Czech with an excellent dependency parser).

The presented procedure results in building the Polish test corpus of relatively high quality, confirmed by the inter-annotator agreement coefficients of $\kappa = 0.734$ (measured with Fleiss' kappa) for entailment labels and of $\alpha = 0.780$ (measured with Krippendorff's ordinal alpha) for relatedness scores.

Acknowledgments

We would like to thank the reliable and tenacious annotators of our dataset: Alicja Dziedzic-Rawska, Bożena Itoya, Magdalena Król, Anna Latusek, Justyna Małek, Małgorzata Michalik, Agnieszka Norwa, Małgorzata Szajbel-Keck, Alicja Walichnowska, Konrad Zieliński, and some other. The research presented in this paper was supported by SONATA 8 grant no 2014/15/D/HS2/03486 from the National Science Centre Poland.

Abstract

Until now, error type performance for Grammatical Error Correction (GEC) systems could only be measured in terms of recall because system output is not annotated. To overcome this problem, we introduce ERRANT, a grammatical ERRor ANnotation Toolkit designed to automatically extract edits from parallel original and corrected sentences and classify them according to a new, dataset-agnostic, rule-based framework. This not only facilitates error type evaluation at different levels of granularity, but can also be used to reduce annotator workload and standardise existing GEC datasets. Human experts rated the automatic edits as "Good" or "Acceptable" in at least 95% of cases, so we applied ERRANT to the system output of the CoNLL-2014 shared task to carry out a detailed error type analysis for the first time.

1 Introduction

Grammatical Error Correction (GEC) systems are often only evaluated in terms of overall performance because system hypotheses are not annotated. This can be misleading however, and a system that performs poorly overall may in fact outperform others at specific error types. This is significant because a robust *specialised* system is actually more desirable than a mediocre *general* system. Without an error type analysis however, this information is completely unknown.

The main aim of this paper is hence to rectify this situation and provide a method by which parallel error correction data can be automatically annotated with error type information. This not only facilitates error type evaluation, but can also be used to provide detailed error type feedback to non-native learners. Given that different corpora are also annotated according to different standards, we also attempted to standardise existing datasets under a common error type framework.

Our approach consists of two main steps. First, we automatically extract the edits between parallel original and corrected sentences by means of a linguistically-enhanced alignment algorithm (Felice et al., 2016) and second, we classify them according to a new, rule-based framework that relies solely on dataset-agnostic information such as lemma and part-of-speech. We demonstrate the value of our approach, which we call the ERRor ANnotation Toolkit (ERRANT)[1], by carrying out a detailed error type analysis of each system in the CoNLL-2014 shared task on grammatical error correction (Ng et al., 2014).

It is worth mentioning that despite an increased interest in GEC evaluation in recent years (Dahlmeier and Ng, 2012; Felice and Briscoe, 2015; Bryant and Ng, 2015; Napoles et al., 2015; Grundkiewicz et al., 2015; Sakaguchi et al., 2016), ERRANT is the only toolkit currently capable of producing error types scores.

2 Edit Extraction

The first stage of automatic annotation is *edit extraction*. Specifically, given an original and corrected sentence pair, we need to determine the start and end boundaries of any edits. This is fundamentally an alignment problem:

We	took	a	**guide**	tour	**on**		**center**	**city**	.
We	took	a	**guided**	tour	**of**	**the**	**city**	**center**	.

Table 1: A sample alignment between an original and corrected sentence (Felice et al., 2016).

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 793–805
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1074

The first attempt at automatic edit extraction was made by Swanson and Yamangil (2012), who simply used the Levenshtein distance to align parallel original and corrected sentences. As the Levenshtein distance only aligns individual tokens however, they also merged all adjacent non-matches in an effort to capture multi-token edits. Xue and Hwa (2014) subsequently improved on Swanson and Yamangil's work by training a maximum entropy classifier to predict whether edits should be merged or not.

Most recently, Felice et al. (2016) proposed a new method of edit extraction using a linguistically-enhanced alignment algorithm supported by a set of merging rules. More specifically, they incorporated various linguistic information, such as part-of-speech and lemma, into the cost function of the Damerau-Levenshtein[2] algorithm to make it more likely that tokens with similar linguistic properties aligned. This approach ultimately proved most effective at approximating human edits in several datasets (80-85% F_1), and so we use it in the present study.

3 Automatic Error Typing

Having extracted the edits, the next step is to assign them error types. While Swanson and Yamangil (2012) did this by means of maximum entropy classifiers, one disadvantage of this approach is that such classifiers are biased towards their particular training corpora. For example, a classifier trained on the First Certificate in English (FCE) corpus (Yannakoudakis et al., 2011) is unlikely to perform as well on the National University of Singapore Corpus of Learner English (NUCLE) (Dahlmeier and Ng, 2012) or vice versa, because both corpora have been annotated according to different standards (cf. Xue and Hwa (2014)). Instead, a dataset-agnostic error type classifier is much more desirable.

3.1 A Rule-Based Error Type Framework

To solve this problem, we took inspiration from Swanson and Yamangil's (2012) observation that most error types are based on part-of-speech (POS) categories, and wrote a rule to classify an edit based only on its automatic POS tags. We then added another rule to similarly differentiate between Missing, Unnecessary and Replacement errors depending on whether tokens were inserted, deleted or substituted. Finally, we extended our approach to classify errors that are not well-characterised by POS, such as Spelling or Word Order, and ultimately assigned all error types based solely on automatically-obtained, objective properties of the data.

In total, we wrote roughly 50 rules. While many of them are very straightforward, significant attention was paid to discriminating between different kinds of verb errors. For example, despite all having the same correction, the following sentences contain different types of common learner errors:

(a) He IS asleep now. [*IS* → *is*]: orthography

(b) He iss asleep now. [*iss* → *is*]: spelling

(c) He has asleep now. [*has* → *is*]: verb

(d) He being asleep now. [*being* → *is*]: form

(e) He was asleep now. [*was* → *is*]: tense

(f) He are asleep now. [*are* → *is*]: SVA

To handle these cases, we hence wrote the following ordered rules:

1. Are the lower case forms of both sides of the edit the same? (a)
2. Is the original token a real word? (b)
3. Do both sides of the edit have the same lemma? (c)
4. Is one side of the edit a gerund (VBG) or participle (VBN)? (d)
5. Is one side of the edit in the past tense (VBD)? (e)
6. Is one side of the edit in the 3rd person present tense (VBZ)? (f)

While the final three rules could certainly be reordered, we informally found the above sequence performed best during development. It is also worth mentioning that this is a somewhat simplified example and that there are additional rules to discriminate between auxiliary verbs, main verbs and multi verb expressions. Nevertheless, the above case exemplifies our approach, and a more complete description of all rules is provided with the software.

[2]Damerau-Levenshtein is an extension of Levenshtein that also handles transpositions; e.g. AB→BA

Code	Meaning	Description / Example
ADJ	Adjective	*big → wide*
ADJ:FORM	Adjective Form	Comparative or superlative adjective errors. *goodest → best, bigger → biggest, more easy → easier*
ADV	Adverb	*speedily → quickly*
CONJ	Conjunction	*and → but*
CONTR	Contraction	*n't → not*
DET	Determiner	*the → a*
MORPH	Morphology	Tokens have the same lemma but nothing else in common. *quick (adj) → quickly (adv)*
NOUN	Noun	*person → people*
NOUN:INFL	Noun Inflection	Count-mass noun errors. *informations → information*
NOUN:NUM	Noun Number	*cat → cats*
NOUN:POSS	Noun Possessive	*friends → friend's*
ORTH	Orthography	Case and/or whitespace errors. *Bestfriend → best friend*
OTHER	Other	Errors that do not fall into any other category (e.g. paraphrasing). *at his best → well, job → professional*
PART	Particle	*(look) in → (look) at*
PREP	Preposition	*of → at*
PRON	Pronoun	*ours → ourselves*
PUNCT	Punctuation	*! → .*
SPELL	Spelling	*genectic → genetic, color → colour*
UNK	Unknown	The annotator detected an error but was unable to correct it.
VERB	Verb	*ambulate → walk*
VERB:FORM	Verb Form	Infinitives (with or without "to"), gerunds (-ing) and participles. *to eat → eating, dancing → danced*
VERB:INFL	Verb Inflection	Misapplication of tense morphology. *getted → got, fliped → flipped*
VERB:SVA	Subject-Verb Agreement	*(He) have → (He) has*
VERB:TENSE	Verb Tense	Includes inflectional and periphrastic tense, modal verbs and passivization. *eats → ate, eats → has eaten, eats → can eat, eats → was eaten*
WO	Word Order	*only can → can only*

Table 2: The list of 25 main error categories in our new framework with examples and explanations.

3.2 A Dataset-Agnostic Classifier

One of the key strengths of a rule-based approach is that by being dependent only on automatic mark-up information, our classifier is entirely dataset independent and does not require labelled training data. This is in contrast with machine learning approaches which not only learn dataset specific biases, but also presuppose the existence of sufficient quantities of training data.

A second significant advantage of our approach is that it is also always possible to determine precisely why an edit was assigned a particular error category. In contrast, human and machine learning classification decisions are often much less transparent.

Finally, by being fully deterministic, our approach bypasses bias effects altogether and should hence be more consistent.

3.3 Automatic Markup

The prerequisites for our rule-based classifier are that each token in both the original and corrected sentence is POS tagged, lemmatized, stemmed and dependency parsed. We use spaCy[3] v1.7.3 for all but the stemming, which is performed by the Lancaster Stemmer in NLTK.[4] Since fine-grained POS tags are often too detailed for the purposes of error evaluation, we also map spaCy's Penn Treebank style tags to the coarser set of Universal Dependency tags.[5] We use the latest Hunspell GB-large word list[6] to help classify non-word errors. The marked-up tokens in an edit span are then input to the classifier and an error type is returned.

3.4 Error Categories

The complete list of 25 error types in our new framework is shown in Table 2. Note that most of them can be prefixed with 'M:', 'R:' or 'U:', depending on whether they describe a Missing, Replacement, or Unnecessary edit, to enable

[3] https://spacy.io/

[4] http://www.nltk.org/

[5] http://universaldependencies.org/tagset-conversion/en-penn-uposf.html

[6] https://sourceforge.net/projects/wordlist/files/speller/2017.01.22/

evaluation at different levels of granularity (see Appendix A for all valid combinations). This means we can choose to evaluate, for example, only *replacement* errors (anything prefixed by 'R:'), only *noun* errors (anything suffixed with 'NOUN') or only *replacement noun* errors ('R:NOUN'). This flexibility allows us to make more detailed observations about different aspects of system performance.

One caveat concerning error scheme design is that it is always possible to add new categories for increasingly detailed error types; for instance, we currently label [*could* → *should*] a tense error, when it might otherwise be considered a modal error. The reason we do not call it a modal error, however, is because it would then become less clear how to handle other cases such as [*can* → *should*] and [*has eaten* → *should eat*], which might be considered a more complex combination of modal and tense error. As it is impractical to create new categories and rules to differentiate between such narrow distinctions however, our final framework aims to be a compromise between informativeness and practicality.

3.5 Classifier Evaluation

As our new error scheme is based solely on automatically obtained properties of the data, there are no gold standard labels against which to evaluate classifier performance. For this reason, we instead carried out a small-scale manual evaluation, where we simply asked 5 GEC researchers to rate the appropriateness of the predicted error types for 200 randomly chosen edits in context (100 from FCE-test and 100 from CoNLL-2014) as "Good", "Acceptable" or "Bad". "Good' meant the chosen type was the most appropriate for the given edit, "Acceptable" meant the chosen type was appropriate, but probably not optimum, while "Bad" meant the chosen type was not appropriate for the edit. Raters were warned that the edit boundaries had been determined automatically and hence might be unusual, but that they should focus on the appropriateness of the error type regardless of whether they agreed with the boundary or not.

It is worth stating that the main purpose of this evaluation was not to evaluate the specific strengths and weaknesses of the classifier, but rather ascertain how well humans believed the predicted error types characterised each edit. GEC is known to be a highly subjective task (Bryant and Ng, 2015) and so we were more interested in overall judgements than specific disagreements.

Rater	Good	Acceptable	Bad
1	92.0%	4.0%	4.0%
2	89.5%	6.5%	4.0%
3	83.0%	13.0%	4.0%
4	84.5%	11.0%	4.5%
5	82.5%	15.5%	2.0%
OVERALL	**86.3%**	**10.0%**	**3.7%**

Table 3: The percent distribution for how each expert rated the appropriateness of the predicted error types. E.g. Rater 3 considered 83% of all predicted types to be "Good".

The results from this evaluation are shown in Table 3. Significantly, all 5 raters considered at least 95% of the predicted error types to be either "Good" or "Acceptable", despite the degree of noise introduced by automatic edit extraction. Furthermore, whenever raters judged an edit as "Bad", this could usually be traced back to a POS or parse error; e.g. [*ring* → *rings*] might be considered a NOUN:NUM or VERB:SVA error depending on whether the POS tagger considered both sides of the edit nouns or verbs. Inter-annotator agreement was also good at 0.724 κ_{free} (Randolph, 2005).

In contrast, although incomparable on account of the different metric and error scheme, the best results using machine learning were between 50-70% F_1 (Felice et al., 2016). Ultimately however, we believe the high scores awarded by the raters validates the efficacy of our rule-based approach.

4 Error Type Scoring

Having described how to automatically annotate parallel sentences with ERRANT, we now also have a method to annotate system hypotheses; this is the first step towards an error type evaluation. Since no scorer is currently capable of calculating error type performance however (Dahlmeier and Ng, 2012; Felice and Briscoe, 2015; Napoles et al., 2015), we instead built our own.

Fortunately, one benefit of explicitly annotating system hypotheses is that it makes evaluation much more straightforward. In particular, for each sentence, we only need to compare the edits in the hypothesis against the edits in each respective reference and measure the overlap. Any edit with the same span and correction in both files is hence a

true positive (TP), while unmatched edits in the hypothesis and references are false positives (FP) and false negatives (FN) respectively. These results can then be grouped by error type for the purposes of error type evaluation.

Finally, it is worth noting that this scorer is much simpler than other scorers in GEC which typically incorporate edit extraction or alignment directly into their algorithms. Our approach, on the other hand, treats edit extraction and evaluation as separate tasks.

4.1 Gold Reference vs. Auto Reference

Before evaluating an automatically annotated hypothesis against its reference, we must also address another mismatch: namely that hypothesis edits must be extracted and classified automatically, while reference edits are typically extracted and classified manually using a different framework. Since evaluation is now reduced to a straightforward comparison between two files however, it is especially important that the hypothesis and references are both processed in the same way. For instance, a hypothesis edit [*have eating* → *has eaten*] will not match the reference edits [*have* → *has*] and [*eating* → *eaten*] because the former is one edit while the latter is two edits, even though they equate to the same thing.

To solve this problem, we can reprocess the references in the same way as the hypotheses. In other words, we can apply ERRANT to the references such that each reference edit is subject to the same automatic extraction and classification criteria as each hypothesis edit. While it may seem unorthodox to discard gold reference information in favour of automatic reference information, this is necessary to minimise the difference between hypothesis and reference edits and also standardise error type annotations.

To show that automatic references are feasible alternatives to gold references, we evaluated each team in the CoNLL-2014 shared task using both types of reference with the M^2 scorer (Dahlmeier and Ng, 2012), the *de facto* standard of GEC evaluation, and our own scorer. Table 4 hence shows that there is little difference between the overall scores for each team, and we formally validated this hypothesis for precision, recall and $F_{0.5}$ by means of bootstrap significance testing (Efron and Tibshirani, 1993). Ultimately, we found no statistically significant difference between automatic and gold references (1,000 iterations, $p > .05$) which leads us to conclude that our automatic references are qualitatively as good as human references.

	M^2 Scorer		Our Scorer	
Team	**Gold**	**Auto**	**Gold**	**Auto**
AMU	35.01	35.05	31.95	32.25
CAMB	37.33	37.34	33.39	34.01

SJTU	15.19	15.22	14.85	14.89
UFC	7.84	7.89	7.84	7.89
UMC	25.37	25.45	23.08	23.52

Table 4: Overall scores for each team in CoNLL-2014 using gold and auto references with both the M^2 scorer and our simpler edit comparison approach. All scores are in terms of $F_{0.5}$.

4.2 Comparison with the M^2 Scorer

Despite using the same metric, Table 4 also shows that the M^2 scorer tends to produce slightly higher $F_{0.5}$ scores than our own. This initially led us to believe that our scorer was underestimating performance, but we subsequently found that instead the M^2 scorer tends to overestimate performance (cf. Felice and Briscoe (2015) and Napoles et al. (2015)).

In particular, given a choice between matching [*have eating* → *has eaten*] from Annotator 1 or [*have* → *has*] and [*eating* → *eaten*] from Annotator 2, the M^2 scorer will always choose Annotator 2 because two true positives (TP) are worth more than one. Similarly, whenever the scorer encounters two false positives (FP) within a certain distance of each other,[7] it merges them and treats them as one false positive; e.g. [*is a cat* → *are a cats*] is selected over [*is* → *are*] and [*cat* → *cats*] even though these edits are best handled separately. In other words, the M^2 scorer exploits its dynamic edit boundary prediction to artificially maximise true positives and minimise false positives and hence produce slightly inflated scores.

[7] The distance is controlled by the *max_unchanged_words* parameter which is set to 2 by default.

5 CoNLL-2014 Shared Task Analysis

To demonstrate the value of ERRANT, we applied it to the data produced in the CoNLL-2014 shared task (Ng et al., 2014). Specifically, we automatically annotated all the system hypotheses and official reference files.[8] Although ERRANT can be applied to any dataset of parallel sentences, we chose to evaluate on CoNLL-2014 because it represents the largest collection of publicly available GEC system output. For more information about the systems in CoNLL-2014, we refer the reader to the shared task paper.

5.1 Edit Operation

In our first category experiment, we simply investigated the performance of each system in terms of Missing, Replacement and Unnecessary edits. The results are shown in Table 5 with additional information in Appendix B, Table 10.

The most surprising result is that five teams (AMU, IPN, PKU, RAC, UFC) failed to correct any unnecessary token errors at all. This is noteworthy because unnecessary token errors account for roughly 25% of all errors in the CoNLL-2014 test data and so failing to address them significantly limits a system's maximum performance. While the reason for this is clear in some cases, e.g. UFC's rule-based system was never designed to tackle unnecessary tokens (Gupta, 2014), it is less clear in others, e.g. there is no obvious reason why AMU's SMT system failed to learn when to delete tokens (Junczys-Dowmunt and Grundkiewicz, 2014). AMU's result is especially remarkable given that their system still came 3rd overall despite this limitation.

In contrast, CUUI's classifier approach (Rozovskaya et al., 2014) was the most successful at correcting not only unnecessary token errors, but also replacement token errors, while CAMB's hybrid MT approach (Felice et al., 2014) significantly outperformed all others in terms of missing token errors. It would hence make sense to combine these two approaches, and indeed recent research has shown this improves overall performance (Rozovskaya and Roth, 2016).

5.2 General Error Types

Table 6 shows precision, recall and $F_{0.5}$ for each of the error types in our proposed framework for each team in CoNLL-2014. As some error types are more common than others, we also provide the TP, FP and FN counts used to make this table in Appendix B, Table 11.

Overall, CAMB was the most successful team in terms of error types, achieving the highest F-score in 10 (out of 24) error categories, followed by AMU, who scored highest in 6 categories. All but 3 teams (IITB, IPN and POST) achieved the best score in at least 1 category, which suggests that different approaches to GEC complement different error types. Only CAMB attempted to correct at least 1 error from every category.

Other interesting observations we can make from this table include:

Table 6: Precision, recall and $F_{0.5}$ for each team and error type. A dash indicates the team's system did not attempt to correct the given error type (TP+FP = 0). The highest F-score for each type is highlighted.

	CAMB		
Type	**P**	**R**	**$F_{0.5}$**
M:DET	43.20	51.77	44.68
R:DET	19.33	35.37	21.26
U:DET	43.75	39.90	42.92
DET	36.16	43.03	37.35

	CUUI		
Type	**P**	**R**	**$F_{0.5}$**
M:DET	23.86	45.00	26.34
R:DET	27.03	24.39	26.46
U:DET	36.19	66.37	39.81
DET	30.92	51.91	33.64

Table 7: Detailed breakdown of Determiner errors for two teams.

- Despite the prevalence of spell checkers nowadays, many teams did not seem to employ them; this would have been an easy way to boost overall performance.
- Although several teams built specialised classifiers for DET and PREP errors, CAMB's hybrid MT approach still outperformed them. This might be because the classifiers were trained using a different error type framework however.
- CUUI's classifiers significantly outperformed all other approaches at ORTH and VERB:FORM errors. This suggests classifiers are well-suited to these error types.
- Although UFC's rule-based approach was the best at VERB:SVA errors, CUUI's classifier was not very far behind.
- Only AMU managed to correct any CONJ errors.
- Content word errors (i.e. ADJ, ADV, NOUN and VERB) were unsurprisingly very difficult for all teams.

5.3 Detailed Error Types

In addition to analysing general error types, the modular design of our framework also allows us to evaluate error type performance at an even greater level of detail. For example, Table 7 shows the breakdown of Determiner errors for two teams using different approaches in terms of edit operation. Note that this is a representative example of detailed error type performance, as an analysis of all error type combinations for all teams would take up too much space.

Team	**P**	**R**	**$F_{0.5}$**
AMU	16.90	5.33	11.79
CAMB	27.22	17.06	24.32
CUUI	15.69	3.67	9.48
IITB	28.57	0.94	4.15
IPN	3.33	0.47	1.51
NTHU	0.00	0.00	0.00
PKU	25.00	1.40	5.73
POST	12.77	2.82	7.48
RAC	2.96	2.82	2.93
SJTU	10.00	0.47	1.99
UFC	-	-	-
UMC	19.82	9.82	16.47

Table 8: Each team's performance at correcting multi-token edits; i.e. there are at least two tokens on one side of the edit.

While CAMB's hybrid MT approach achieved a higher score than CUUI's classifier overall, our more detailed evaluation reveals that CUUI actually outperformed CAMB at Replacement Determiner errors. We also learn that CAMB scored twice as highly on M:DET and U:DET than it did on R:DET and that CUUI's significantly higher U:DET recall was offset by a lower precision. Ultimately, this shows that even though one approach might be better than another overall, different approaches may still have complementary strengths.

5.4 Multi Token Errors

Another benefit of explicitly annotating all hypothesis edits is that edit spans become fixed; this means we can evaluate system performance in terms of edit size. Table 8 hence shows the overall performance for each team at correcting multi-token edits, where a multi-token edit is an edit that has at least two tokens on either side. In the CoNLL-2014 test set, there are roughly 220 such edits (about 10% of all edits).

In general, teams did not do well at multi-token edits. In fact only three teams achieved scores greater than 10% $F_{0.5}$ and all of them used MT (AMU, CAMB, UMC). This is significant because recent work has suggested that the main goal of GEC should be to produce fluent-sounding, rather than just grammatical sentences, even though this often requires complex multi-token edits (Sakaguchi et al., 2016). If no system is particularly adept at correcting multi-token errors however, robust fluency correction will likely require more sophisticated methods than are currently available.

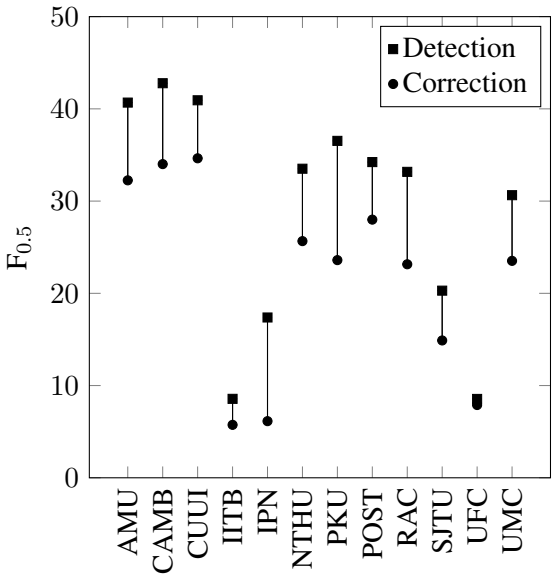

Figure 1: The difference between detection and correction scores for each team overall.

5.5 Detection vs. Correction

Another important aspect of GEC that is seldom reported in the literature is that of error detection; i.e. the extent to which a system can identify erroneous tokens in text. This can be calculated by comparing the edit overlap between the hypothesis and reference files *regardless of the proposed correction* in a manner similar to Recognition evaluation in the HOO shared tasks for GEC (Dale and Kilgarriff, 2011).

Figure 1 hence shows how each team's score for detection differed in relation to their score for correction. While CAMB scored highest for detection overall, it is interesting to note that CUUI ultimately performed slightly better than CAMB at correction. This suggests CUUI was more successful at correcting the errors they detected than CAMB. In contrast, IPN and PKU are notable for detecting significantly more errors than they were able to correct. Nevertheless, a system's ability to detect errors, even if it is unable to correct them, is still likely to be valuable information to a learner (Rei and Yannakoudakis, 2016).

Finally, although we do not do so here, our scorer is also capable of providing a detailed error type breakdown for detection.

6 Conclusion

In this paper, we described ERRANT, a grammatical ERRor ANnotation Toolkit designed to automatically annotate parallel error correction data with explicit edit spans and error type information. ERRANT can be used to not only facilitate a detailed error type evaluation in GEC, but also to standardise existing error correction corpora and reduce annotator workload. We release ERRANT with this paper.

Our approach makes use of previous work to align sentences based on linguistic intuition and then introduces a new rule-based framework to classify edits. This framework is entirely dataset independent, and relies only on automatically obtained information such as POS tags and lemmas. A small-scale evaluation of our classifier found that each rater considered >95% of the predicted error types as either "Good" (85%) or "Acceptable" (10%).

We demonstrated the value of ERRANT by carrying out a detailed evaluation of system error type performance for all teams in the CoNLL-2014 shared task on Grammatical Error Correction. We found that different systems had different strengths and weaknesses which we hope researchers can exploit to further improve general performance.

Abstract

Knowing the quality of reading comprehension (RC) datasets is important for the development of natural-language understanding systems. In this study, two classes of metrics were adopted for evaluating RC datasets: prerequisite skills and readability. We applied these classes to six existing datasets, including MCTest and SQuAD, and highlighted the characteristics of the datasets according to each metric and the correlation between the two classes. Our dataset analysis suggests that the readability of RC datasets does not directly affect the question difficulty and that it is possible to create an RC dataset that is easy to read but difficult to answer.

1 Introduction

A major goal of natural language processing (NLP) is to develop agents that can understand natural language. Such an ability can be tested with a reading comprehension (RC) task that requires the agent to read open-domain documents and answer questions about them. Constructing systems with RC competence is challenging because RC comprises multiple processes including parsing, understanding cohesion, and inference with linguistic and general knowledge.

Clarifying what a system achieves is important in the development of RC systems. To achieve robust improvement, systems should be measured according to a variety of metrics beyond simple accuracy. However, a current problem is that most RC datasets are presented only with superficial categories, such as question types (e.g., what, where, and who) and answer types (e.g., numeric, location, and person). In addition, Chen et al. (2016) noted that some questions in datasets may not be suited to the testing of RC systems. In such situations, it is difficult to obtain an accurate assessment of the RC system.

ID: SQuAD, United_Methodist_Church
Context: The United Methodist Church (UMC) practices infant and adult baptism. Baptized Members are those who have been baptized as an infant or child, but who have not subsequently professed their own faith.
Question: What are members who have been baptized as an infant or child but who have not subsequently professed their own faith?
Answer: Baptized Members

ID: MCTest, mc160.dev.8
Context: Sara wanted to play on a baseball team. She had never tried to swing a bat and hit a baseball before. Her Dad gave her a bat and together they went to the park to practice.
Question: Why was Sara practicing?
Answer: She wanted to play on a team

Figure 1: Examples of RC questions from SQuAD (Rajpurkar et al., 2016) and MCTest (Richardson et al., 2013) (the Contexts are excerpts).

Norvig (1989) argued that questions that are easy for humans to answer often turn out to be difficult for machines. For example, consider the two RC questions in Figure 1. The first example is from SQuAD (Rajpurkar et al., 2016), although the document is taken from a Wikipedia article and was therefore written for adults. The question is answerable simply by noticing one sentence, without needing to fully understand the content of the text. On the other hand, consider the second example from MCTest (Richardson et al., 2013), which was written for children and is easy to read. Here, answering the question involves gathering information from multiple sentences and utilizing a combination of several skills, such as understanding causal relations (*Sara wanted...* $\rightarrow$ *they went to...*), coreference resolution (*Sara* and *Her Dad* = *they*), and complementing ellipsis (*baseball team* = *team*). These two examples show that the readability of the text does not necessarily correlate with the difficulty of answering questions about it.

Furthermore, the accompanying categories of existing RC datasets cannot help with the analysis of this issue.

In this study, our goal is to investigate how these two types of difficulty, namely "answering questions" and "reading text," are correlated in RC. Corresponding to each type, we formalize two classes of evaluation metrics, *prerequisite skills* and *readability*, and analyze existing RC datasets. Our intention is to provide the basis of an evaluation methodology of RC systems to help their robust development.

Our two classes of metrics are inspired by the analysis in McNamara and Magliano (2009) of human text comprehension in psychology. They considered two aspects of text comprehension, namely "strategic/skilled comprehension" and "text ease of processing."

Our first class defines metrics for "strategic/skilled comprehension," namely the difficulty of comprehending the context when answering questions. We adopted the set of prerequisite skills that Sugawara et al. (2017) proposed for the fine-grained analysis of RC capability. Their study also presented an important observation of the relation between the difficulty of an RC task and prerequisite skills: the more skills that are required to answer a question, the more difficult is the question. Based on this observation, in this work, we assume that the number of skills required to answer a question is a reasonable indication of the difficulty of the question. This is because each skill corresponds to one of the functions of an NLP system, which has to be capable of that functionality.

Our second class defines metrics for "text ease of processing," namely the difficulty of reading the text. We regard it as readability of the text in terms of syntactic and lexical complexity. From among readability studies in NLP, we adopt a wide range of linguistic features proposed by Vajjala and Meurers (2012), which can be used for texts with no available annotations.

The contributions of this paper are as follows.

1. We adopt two classes of evaluation metrics to show the qualitative features of RC datasets. Through analyses of RC datasets, we demonstrate that there is only a weak correlation between the difficulty of questions and the readability of context texts in RC datasets.

2. We revise a previous classification of prerequisite skills for RC. Specifically, skills of knowledge reasoning are organized by using insights of entailment phenomena in NLP and human text comprehension in psychology.

3. We annotate six existing RC datasets, compared to the two datasets considered in Sugawara and Aizawa (2016), with our organized metrics being used in the comparison. We have made the results publicly available[1] and report on the characteristics of the datasets and the differences between them.

We should note that, in this study, RC datasets with different task formulations were annotated with prerequisite skills under the same conditions. Annotators first saw a context, a question, and its answer. They selected the sentences required to provide the answer, and then annotated them with appropriate prerequisite skills. That is, the datasets were annotated from the point of view of whether the context entailed the hypothesis constructed from the pair of the question and answer. This means that our methodology cannot quantify the systems' competence in searching the context for necessary sentences and answer candidates. In other words, our methodology can be only used to evaluate the competence of understanding RC questions as *contextual entailments*.

The remainder of this paper is divided into the following sections. First, we discuss related work in Section 2. Next, we specify our two classes of metrics in Section 3. In Section 4, we annotate existing RC datasets with the prerequisite skills. Section 5 gives the results of our dataset analysis and Section 6 discusses their implications. Section 7 presents our conclusions.

2 Related Work

2.1 Reading Comprehension Datasets

In this section, we present a short history of RC datasets. To our knowledge, Hirschman et al. (1999) were the first to use NLP methods for RC. Their dataset comprised reading materials for grades 3–6 with simple 5W (*wh*-) questions. Subsequent investigations into questions of natural language understanding focused on other formulations, such as question answering (Yang et al., 2015; Wang et al., 2007; Voorhees et al., 1999) and

[1] http://www-al.nii.ac.jp/rc_dataset_analysis

textual entailment (Bentivogli et al., 2010; Sammons et al., 2010; Dagan et al., 2006). One of the RC tasks of the time was QA4MRE (Sutcliffe et al., 2013). The highest accuracy achieved for this task was 59% and the size of the dataset was very limited: there were only 224 gold-standard questions, which is insufficient for machine learning methods.

This means that an important issue for designing RC datasets is their scalability. Richardson et al. (2013) presented MCTest, which is an open-domain narrative dataset for gauging comprehension at a child's level. This dataset was created by crowdsourcing and was based on a scalable methodology. Since then, additional large-scale datasets have been proposed with the development of machine learning methods in NLP. For example, the CNN/Daily Mail dataset (Hermann et al., 2015) and CBTest (Hill et al., 2016) have approximately 1.4M and 688K passages, respectively. These context texts and questions were automatically curated and generated from large corpora. However, Chen et al. (2016) indicated that approximately 25% of the questions in the CNN/Daily Mail dataset are either unsolvable or nonsensical. This dataset-quality issue highlights the demand for more stable and robust sourcing methods.

Several additional RC datasets were presented in the last half of 2016, involving large documents and sensible queries that were guaranteed by crowdsourcing or other human testing. They were intended to provide large and high-quality content for machine learning models. Nonetheless, as shown in the examples of Figure 1, they were not offered with metrics that could evaluate NLP systems adequately with respect to the difficulty of questions and the surface features of texts.

2.2 Reading Comprehension in Psychology

In psychology, there is a rich tradition of research on human text comprehension. The construction–integration (C–I) model (Kintsch, 1988) is one of the most basic and influential theories. This model assumes a connectional and computational architecture for text comprehension. It assumes that comprehension is the processing of information based on the following two steps.[2]

1. *Construction:* read sentences or clauses as inputs; form and elaborate concepts and propositions corresponding to the inputs.
2. *Integration:* associate the contents to understand them consistently (e.g., coreference, discourse, and coherence).

During these steps, three levels of representation are constructed (van Dijk and Kintsch, 1983): the *surface code* (i.e., wording and syntax), the *textbase* (i.e., text propositions with cohesion), and the *situation model* (i.e., mental representation). Based on these assumptions, McNamara and Magliano (2009) proposed two aspects of text comprehension, namely "strategic/skilled comprehension" and "text ease of processing." We adopted these assumptions as the basis of our two classes of evaluation metrics (Section 3).

In an alternative approach, Kintsch (1993) proposed two dichotomies for the classification of human inferences, including the knowledge-based inference assumed in the C–I model. The first dichotomy is between inferences that are *automatic* and those that are *controlled*. However, Graesser et al. (1994) indicated that this distinction is ambiguous, because there is a continuum between the two states that depends on individuals. Therefore, this dichotomy is unsuited to empirical evaluation, which is our focus. The second dichotomy is between inferences that are *retrieved* and those that are *generated*. *Retrieved* means that the information used for inference is retrieved entirely from the context. In contrast, when inferences are *generated*, the reader uses external knowledge that goes beyond the context.

A similar distinction was proposed by McNamara and Magliano (2009), namely that between *bridging* and *elaboration*. A bridging inference connects current information to other information that has been encountered previously. Elaboration connects current information to external knowledge that is not included in the context. We use these two types of inference in the classification of knowledge reasoning.

3 Evaluation Metrics for Datasets

Following the depiction of text comprehension by McNamara and Magliano (2009), we adopted two classes for the evaluation of RC datasets: *prerequisite skills* and *readability*.

For the prerequisite skills class (Section 3.1), we refined RC skills that were proposed by Sugawara et al. (2017) and Sugawara and Aizawa (2016). However, a problem in these studies is that their categorization of knowledge reasoning

[2]Note that this is a very simplified overview.

was provisional and with a weak theoretical background.

Therefore, in this study, we reorganized the category of knowledge reasoning in terms of textual entailment in NLP and human text comprehension in psychology. In research on textual entailment, several methodologies have been proposed for the precise analysis of entailment phenomena (Dagan et al., 2013; LoBue and Yates, 2011). In psychology research, as described in Section 2.2, McNamara and Magliano (2009) proposed a similar distinction for inferences: *bridging* versus *elaboration*. We utilized these insights in developing a comprehensive but not overly specific classification of knowledge reasoning.

Our prerequisite skills class includes the *textbase* and *situation model* (van Dijk and Kintsch, 1983). In our terminology, this means understanding each fact and associating multiple facts in a text, such as the relations of events, characters, or the topic of a story. The skills also involve knowledge reasoning, which is divided into several metrics according to the distinctions of human inferences. This point is discussed by Kintsch (1993) and McNamara and Magliano (2009). It also accords with the classification of entailment phenomena by Dagan et al. (2013) and LoBue and Yates (2011).

Readability metrics (Section 3.2) are quantitative measures used to assess the difficulty of reading, with respect to vocabulary and the complexity of texts. In this study, they measure the competence in understanding the first basic representation of a text, called the *surface code* (van Dijk and Kintsch, 1983).

3.1 Prerequisite Skills

Based on the 10 RC skills in Sugawara et al. (2017), we identified 13 prerequisite skills, which are presented below. (We use * and † to indicate skills that have been modified/elaborated from the original definition or have been newly introduced in this study, respectively.)

1. Object tracking*: jointly tracking or grasping of multiple objects, including sets or memberships (Clark, 1975). This skill is a version of the *list/enumeration* used in the original classification, renamed to emphasize its scope with respect to multiple objects.

2. Mathematical reasoning*: we merged statistical and quantitative reasoning with mathematical reasoning. This skill is a renamed version of *mathematical operations*.

3. Coreference resolution*: this skill has a small modification to include an anaphora (Dagan et al., 2013). It is similar to *direct reference* (Clark, 1975).

4. Logical reasoning*: we identified this skill as the understanding of predicate logic, e.g., conditionals, quantifiers, negation, and transitivity. Note that this skill, together with *mathematical reasoning*, is intended to align with the offline skills described by Graesser et al. (1994).

5. Analogy*: understanding of metaphors including metonymy and synecdoche (see LoBue and Yates (2011) for examples of synecdoche.)

6. Causal relation: understanding of causality that is represented by explicit expressions such as "why," "because," and "the reason for" (only if they exist).

7. Spatiotemporal relation: understanding of spatial and/or temporal relationships between multiple entities, events, and states.

In addition, we propose the following four categories by refining the "commonsense reasoning" category proposed originally in Sugawara et al. (2017).

8. Ellipsis†: recognizing implicit/omitted information (argument, predicate, quantifier, time, or place). This skill is inspired by Dagan et al. (2013) and the discussion in Sugawara et al. (2017).

9. Bridging†: inference supported by grammatical and lexical knowledge (e.g., synonymy, hypernymy, thematic role, part of events, idioms, and apposition). This skill is inspired by the concept of *indirect reference* in the literature (Clark, 1975). Note that we exclude *direct reference* because it is covered by *coreference resolution* (pronominalization) and *elaboration* (epithets).

10. Elaboration†: inference using known facts, general knowledge (e.g., kinship, exchange, typical event sequence, and naming), and implicit relations (e.g., noun compounds and possessives) (see Dagan et al. (2013) for details). *Bridging* and *elaboration* are distinguished by the knowledge used in inferences being grammatical/lexical or general/commonsense, respectively.

11. Meta-knowledge†: using knowledge that includes a reader, writer, or text genre (e.g., narratives and expository documents) from meta-viewpoints (e.g., *Who are the principal characters of the story?* or *What is the main subject of*

this article?). Although this skill can be regarded as part of *elaboration*, we defined it as an independent skill because this knowledge is specific to RC. We were motivated by the discussion in Smith et al. (2015).

Whereas the above 11 skills involve multiple items, the final pair of skills involve only a single sentence.

12. Schematic clause relation: understanding of complex sentences that have coordination or subordination, including relative clauses.

13. Punctuation*: understanding of punctuation marks (e.g., parenthesis, dash, quotation, colon, or semicolon). This skill is a renamed version of *special sentence structure*. Concerning the original definition, we regarded "scheme" in figures of speech as ambiguous and excluded it. We defined *ellipsis* as a independent skill, and apposition was merged into *bridging*. Similarly, understanding of constructions was merged into the idioms in *bridging*.

Note that we did not construct this classification to be dependent on particular RC systems in NLP. This was because our methodology is intended to be general and applicable to many kinds of architectures. For example, we did not consider the dichotomy between *automatic* and *controlled* inferences because the usage of knowledge is not necessarily the same for all RC systems.

3.2 Readability Metrics

In this study, we evaluated the readability of texts based on metrics in NLP. Several studies have examined readability in various applications, such as second-language learning (Razon and Barnden, 2015) and text simplification (Aluisio et al., 2010), and from various aspects, such as development measures in second-language acquisition (Vajjala and Meurers, 2012) and discourse relations (Pitler and Nenkova, 2008).

Of these, we adopted the classification of linguistic features proposed by Vajjala and Meurers (2012). This was because they presented a comparison of a wide range of linguistic features focusing on second-language acquisition and their method can be applied to plain text.[3]

We list the readability metrics in Table 1, which were reported by Vajjala and Meurers (2012) as the top 10 features that affect human readability. To classify these metrics, we can identify three classes: lexical features (*NumChar*, *NumSyll*, *AWL*, *AdvVar*, and *ModVar*), syntactic features (*MLS*, *CoOrd*, *DC/C*, and *CN/C*), and traditional features (*Coleman*). We applied these metrics only to sentences that needed to be read in answering questions.

- Ave. no. of characters per word (*NumChar*)
- Ave. no. of syllables per word (*NumSyll*)
- Ave. sentence length in words (*MLS*)
- Proportion of words in AWL (*AWL*)
- Modifier variation (*ModVar*)
- No. of coordinate phrases per sentence (*CoOrd*)
- Coleman–Liau index (*Coleman*)
- Dependent clause-to-clause ratio (*DC/C*)
- Complex nominals per clause (*CN/C*)
- Adverb variation (*AdvVar*)

Table 1: Readability metrics. *AWL* refers to the Academic Word List.[4]

However, because these metrics were proposed for human readability, they do not necessarily correlate with those used in RC systems. Therefore, in any system analysis, ideally we would have to consult a variety of features.

4 Annotation of Reading Comprehension Datasets

We annotated six existing RC datasets with the prerequisite skills. We explain the annotation procedure in Section 4.1 and the annotated RC datasets in Section 4.2.

4.1 Annotation Procedure

We prepared annotation guidelines according to Sugawara et al. (2017). The guidelines include the definitions and examples of the skills and annotation instructions.

Four annotators were asked to simulate the process of answering questions in RC datasets, using only the prerequisite skills, and to annotate questions with one or more skills required in answering. For each task in the datasets, the annotators saw simultaneously the context, question, and its answer. When a dataset contained multiple-choice questions, we showed all candidate answers and labeled the correct one with an asterisk. The an-

[3]The classification in Pitler and Nenkova (2008) is more suited to measuring text quality. However, we could not use their results because we could not use discourse annotations.

[4]http://en.wikipedia.org/wiki/Academic_Word_List

RC dataset	Genre	Query sourcing	Task formulation
QA4MRE (2013)	Technical documents	Handcrafted by experts	Multiple choice
MCTest (2013)	Narratives by crowd workers	Crowdsourced	Multiple choice
SQuAD (2016)	Wikipedia articles	Crowdsourced	Text span selection
Who-did-What (2016)	News articles	Automated	Cloze
MS MARCO (2016)	Segmented web pages	Search engine queries	Description
NewsQA (2016)	News articles	Crowdsourced	Text span selection

Table 2: Analyzed RC datasets, their genres, query sourcing methods, and task formulations.

notators then selected the sentences that needed to be read to be able to answer the question and decided on the set of prerequisite skills required.

The annotators were allowed to select *nonsense* for unsolvable or unanswerable questions (e.g., the "coreference error" and "ambiguous" questions described in Chen et al. (2016)) to distinguish them from any solvable questions that required no skills.

4.2 Datasets

As summarized in Table 2, the annotation was performed on six existing RC datasets: QA4MRE (Sutcliffe et al., 2013), MCTest (Richardson et al., 2013), SQuAD (Rajpurkar et al., 2016), Who-did-What (Onishi et al., 2016), MS MARCO (Nguyen et al., 2016), and NewsQA (Trischler et al., 2016). We selected these datasets to enable coverage of a variety of genres, query sourcing methods, and task formulations. From each dataset, we randomly selected 100 questions. This number was considered sufficient for the degree of analysis of RC datasets performed by Chen et al. (2016). The questions were sampled from the gold-standard dataset of QA4MRE and the development sets of the other RC datasets. (We explain the method of choosing questions for the annotation in Appendix A.)

For a variety of reasons, there were other datasets we did not annotate in this study. CNN/Daily Mail (Hermann et al., 2015) is anonymized and contains errors, according to Chen et al. (2016), making it unsuitable for annotation. We considered CBTest (Hill et al., 2016) to be devised as language-modeling tasks rather than RC-related tasks. LAMBADA (Paperno et al., 2016) texts are formatted for machine reading, with all tokens in lower case, which would seem to disallow inferences based on proper nouns and render them unsuitable for human reading and annotation.

Table 4: Frequencies (%) of the number of required prerequisite skills for the RC datasets.

5 Results of the Dataset Analysis

We now present the results of evaluating the RC datasets according to the two classes of metrics. In the annotation of prerequisite skills, the inter-annotator agreement was 90.1% for 62 randomly sampled questions. The evaluation was performed with respect to the following four aspects: (i) frequencies of prerequisite skills required for each RC dataset; (ii) number of prerequisite skills required per question; (iii) readability metrics for each RC dataset; and (iv) correlation between readability metrics and the number of required prerequisite skills.

(i) Frequencies of prerequisite skills (see Table 3): QA4MRE had the highest scores for frequencies among the datasets. This seems to reflect

Metrics	QA4MRE	MCTest	SQuAD	WDW	MARCO	NewsQA
NumChar	5.026	3.892	**5.378**	4.988	5.016	5.017

F–K	14.953	3.607	14.678	**15.304**	12.065	12.624
Words	**1545.7**	174.1	130.4	253.7	70.7	638.4

Table 5: Results of readability metrics for the RC datasets. *F–K* is the Flesch–Kincaid grade level (Kincaid et al., 1975). *Words* is the average word count of the context for each question.

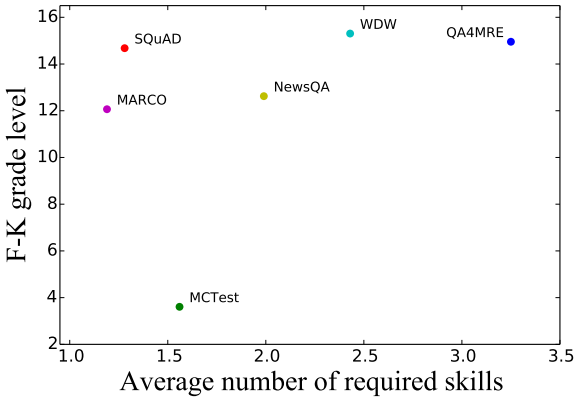

Figure 2: Flesch–Kincaid grade levels and average number of required prerequisite skills for the RC datasets.

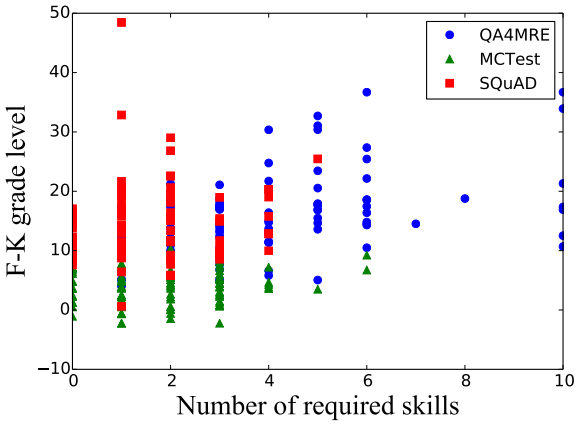

Figure 3: Flesch–Kincaid grade levels and number of required prerequisite skills for all questions in the selected RC datasets.

the fact that QA4MRE involves technical documents that contain a wide range of knowledge, multiple clauses, and punctuation. Moreover, the questions are devised by experts.

MCTest achieved a high score for several skills (best for *causal relation* and *meta-knowledge* and second-best for *coreference resolution* and *spatiotemporal relation*), but a low score for *punctuation*. These scores seem to be because the MCTest dataset consists of narratives.

Another dataset that achieved notable scores is Who-did-What. This dataset achieved the highest score for *ellipsis*. This is because the questions of Who-did-What are automatically generated from articles not used as context. This methodology tends to avoid textual overlap between a question and its context, thereby requiring frequently the skills of *ellipsis*, *bridging*, and *elaboration*.

With regard to *nonsense*, MS MARCO and Who-did-What received relatively high scores. This appears to have been caused by the automated sourcing methods, which may generate a separation between the contents of the context and question (i.e., web segments and a search query in MS MARCO, and a context article and question article in Who-did-What). In contrast, NewsQA had no nonsense questions. Although this result was affected by our filtering (described in Appendix A), it is important to note that the NewsQA dataset includes annotations of meta-information whether or not a question makes sense (*is_question_bad*).

(ii) Number of required prerequisite skills (see Table 4): QA4MRE had the highest score. On average, each question required 3.25 skills. There were few questions in QA4MRE that required zero or one skill, whereas such questions were contained more frequently in other datasets. Table 4 also indicates that more than 90% of the MS MARCO questions required fewer than three skills according to the annotation.

(iii) Readability metrics for each dataset (see Table 5): SQuAD and QA4MRE achieved the highest scores for most metrics. This reflects the fact that Wikipedia articles and technical documents usually require a high-grade level of understanding. In contrast, MCTest had the lowest scores, with its dataset consisting of narratives for children.

(iv) Correlation between numbers of required prerequisite skills and readability metrics (see Figures 2 and 3, and Table 6): our main interest was in the correlation between prerequisite skills and readability. To investigate this, we examined the relation between the number of required prerequisite skills and readability metrics.

Metrics	r	p	Metrics	r	p
NumChar	0.068	0.095	CoOrd	0.166	0.000
NumSyll	0.057	0.161	Coleman	0.140	0.001
MLS	0.416	0.000	DC/C	0.188	0.000
AWL	0.114	0.005	CN/C	0.131	0.001
ModVar	0.025	0.545	AdvVar	0.026	0.515
F–K	0.343	0.000	Words	0.355	0.000

Table 6: Pearson's correlation coefficients (r) with the p-values (p) for the readability metrics and number of required prerequisite skills for all questions in the RC datasets.

We used the Flesch–Kincaid grade level (Kincaid et al., 1975) as an intuitive reference for readability. This value represents the typical number of years of education required to understand texts based on counts of syllables, words, and sentences.

Figures 2 and 3 show the relation between two values for each dataset and for each question, respectively. Figure 2 shows the trends of the datasets. QA4MRE was relatively difficult both to read and to answer, whereas SQuAD was difficult to read but easy to answer. For further investigation, we selected three datasets (QA4MRE, MCTest, and SQuAD) and plotted all of their questions in Figure 3. Three separate domains can be seen.

Table 6 presents Pearson's correlation coefficients between the number of required prerequisite skills and each readability metric for all questions in the RC datasets. Although there are weak correlations, from 0.025 to 0.416, these results demonstrate that there is not necessarily a strong correlation between the two values. This leads to the following two insights. First, the readability of RC datasets does not directly affect the difficulty of their questions. That is, RC datasets that are difficult to read are not necessarily difficult to answer. Second, it is possible to create difficult questions from the context that are easy to read. MCTest is a good example. The context texts in the MCTest dataset are easy to read, but the difficulty of its questions compares to that for the other datasets.

To summarize our results in terms of each RC dataset, we can make the following observations.

- **QA4MRE** is difficult both to read and to answer among the datasets analyzed. This would seem to follow its questions being devised by experts.
- **MCTest** is a good example of an RC dataset that is easy to read but difficult to answer. We presume that this is because the corpus genre (i.e., narrative) reflects the trend in required skills for the questions.
- **SQuAD** is difficult to read, along with QA4MRE, but relatively easy to answer compared with the other datasets.
- **Who-did-What** performs well in terms of its query-sourcing method. Although its questions are created automatically, they are sophisticated in terms of knowledge reasoning. However, the automated sourcing method must be improved to exclude nonsense questions.
- **MS MARCO** is a relatively easy dataset in terms of prerequisite skills. However, one problem is that the dataset contained nonsense questions.
- **NewsQA** is advantageous in that it provides meta-information on the reliability of the questions. Such information enabled us to avoid using nonsense questions, as for the training of machine learning models.

6 Discussion

In this section, we discuss several issues regarding the construction of RC datasets and the development of RC systems using our methodology.

How to utilize the two classes of metrics for system development: one possible scenario for developing an RC system is that it is first built to solve an easy-to-read and easy-to-answer dataset. The next step would be to improve the system so that it can solve an easy-to-read but difficult-to-answer dataset (or its converse). Finally, only after it can solve such datasets should the system be applied to difficult-to-read and difficult-to-answer datasets. The metrics of this study may be useful in preparing appropriate datasets for each step by measuring their properties. The datasets can then be ordered according to the grades of the metrics and applied to each step of the development, as in curriculum learning (Bengio et al., 2009) and transfer learning (Pan and Yang, 2010).

Corpus genre: attention should be paid to the genre of the corpus used to construct a dataset. Expository documents such as news articles tend to require factorial understanding. Most existing RC datasets use such texts because of their availability. On the other hand, narrative texts may have a

closer correspondence to our everyday experience, involving the emotions and intentions of characters (Graesser et al., 1994). To build agents that work in the real world, RC datasets may have to be constructed from narratives.

Question type: in contrast to factorial understanding, comprehensive understanding of natural language texts needs a better grasp of *global* coherence (e.g., the main point or moral of the text, the goal of a story, or the intention of characters) from the broad context (Graesser et al., 1994). Most questions in current use require only *local* coherence (e.g., referential relations and thematic roles) within a narrow context. An example of a question based on global coherence would be to give a summary of the text, as used in Hermann et al. (2015). It could be generated automatically by techniques of abstractive text summarization (Rush et al., 2015; Ganesan et al., 2010).

Annotation issues: we found questions for which there were disagreements regarding *non-sense* decisions. For example, some questions can be solved by external knowledge without even seeing their context. Therefore, we should clarify what constitutes a "solvable" or "reasonable" question for RC. In addition, annotators reported that the prerequisite skills did not easily treat questions whose answer was "none of the above" in QA4MRE. We considered these "no answer" questions difficult, in that systems have to decide not to select any of the candidate answers, and our methodology failed to specify them.

Competence in selecting necessary sentences: as mentioned in Section 1, our methodology cannot evaluate competence in selecting sentences that need to be read to answer questions. In a brief analysis, we further investigated sentences in the context of the datasets that were selected in the annotation. Analyses were performed in two ways. For each question, we counted the number of required sentences and their distance apart.[4] The first row of Table 7 gives the average number of required sentences per question for each RC dataset. Although the scores are reasonably close, MCTest required multiple sentences to be read most frequently. The second row gives the average distance apart of the required sentences. QA4MRE required the longest distance because readers had to look for clues in the long context texts. In contrast, SQuAD and MS MARCO had lower scores. Most of their questions seemed to be answered by reading only a single sentence. Of course, the scores for distances will depend on the length of the context texts.

Sentence	QA4MRE	MCTest	SQuAD	WDW	MARCO	NewsQA
Number	1.120	**1.180**	1.040	1.110	1.080	1.170
Distance	**1.880**	0.930	0.090	0.730	0.280	0.540

Table 7: Average number and distance apart of sentences that need to be read to answer a question in the RC datasets.

Metrics of RC for machines: our underlying assumption in this study is that, in the development of interactive agents such as dialogue systems, it is important to make the systems behave in a human-like way. This has also become a distinguishing feature of recent RC task design, and one that has never been explicitly considered in conventional NLP tasks. To date, the difference between human and machine RC has not attracted much research attention. We believe that our human-based evaluation metrics and analysis will help researchers to develop a method for the step-by-step construction of better RC datasets and improved RC systems.

7 Conclusion

In this study, we adopted evaluation metrics that comprise two classes, namely refined *prerequisite skills* and *readability*, for analyzing the quality of RC datasets. We applied these classes to six existing datasets and highlighted their characteristics according to each metric. Our dataset analysis suggests that the readability of RC datasets does not directly affect the difficulty of the questions and that it is possible to create an RC dataset that is easy to read but difficult to answer. In future work, we plan to use the analysis from the present study in constructing a system that can be applied to multiple datasets.

Acknowledgments

We would like to thank anonymous reviewers for their insightful comments. This work was supported by JSPS KAKENHI Grant Numbers 15H02754 and 16K16120.

[4]The distance of sentences was calculated as follows. If a question required only one sentence to be read, its distance was zero. If a question required two adjacent sentences to be read, its distance was one. If a question required more than two sentences to be read, its distance was the sum of the distances of any two sentences.

A Sampling Methods for Questions

In this appendix, we explain the method of choosing questions for annotation.

QA4MRE (Sutcliffe et al., 2013): the gold-standard dataset comprised four different topics and four documents for each topic. We randomly selected 100 main and auxiliary questions so that at least one question for each document was included.

MCTest (Richardson et al., 2013): this dataset comprised two sets: MC160 and MC500. Their development sets had 80 tasks in total, with each containing context texts and four questions. We randomly chose 25 tasks (100 questions) from the development sets.

SQuAD (Rajpurkar et al., 2016): this dataset included Wikipedia articles involving various topics, with the articles being divided into paragraphs. We randomly chose 100 paragraphs from 15 articles and used only one question from each paragraph for the annotation.

Who-did-What (WDW) (Onishi et al., 2016): this dataset was constructed from the English Gigaword newswire corpus (v5). Its questions were automatically created using a different article from that used for context. In addition, questions that could be solved by a simple baseline method were excluded from the dataset.

MS MARCO (MARCO) (Nguyen et al., 2016): each task in this dataset comprised several segments, one question, and its answer. We randomly chose 100 tasks (100 questions) and only used segments whose attribute was *is_selected* = 1 as context.

NewsQA (Trischler et al., 2016): we randomly chose questions that satisfied the following conditions: *is_answer_absent* = 0, *is_question_bad* = 0, and *validated_answers* do not include *bad_question* or *none*.

A Minimal Span-Based Neural Constituency Parser

Abstract

In this work, we present a minimal neural model for constituency parsing based on independent scoring of labels and spans. We show that this model is not only compatible with classical dynamic programming techniques, but also admits a novel greedy top-down inference algorithm based on recursive partitioning of the input. We demonstrate empirically that both prediction schemes are competitive with recent work, and when combined with basic extensions to the scoring model are capable of achieving state-of-the-art single-model performance on the Penn Treebank (91.79 F1) and strong performance on the French Treebank (82.23 F1).

1 Introduction

This paper presents a minimal but surprisingly effective span-based neural model for constituency parsing. Recent years have seen a great deal of interest in parsing architectures that make use of recurrent neural network (RNN) representations of input sentences (Vinyals et al., 2015). Despite evidence that linear RNN decoders are implicitly able to respect some nontrivial well-formedness constraints on structured outputs (Graves, 2013), researchers have consistently found that the best performance is achieved by systems that explicitly require the decoder to generate well-formed tree structures (Chen and Manning, 2014).

There are two general approaches to ensuring this structural consistency. The most common is to encode the output as a sequence of operations within a transition system which constructs trees incrementally. This transforms the parsing problem back into a sequence-to-sequence problem, while making it easy to force the decoder to take only actions guaranteed to produce well-formed outputs. However, transition-based models do not admit fast dynamic programs and require careful feature engineering to support exact search-based inference (Thang et al., 2015). Moreover, models with recurrent state require complex training procedures to benefit from anything other than greedy decoding (Wiseman and Rush, 2016).

An alternative line of work focuses on *chart parsers*, which use log-linear or neural scoring potentials to parameterize a tree-structured dynamic program for maximization or marginalization (Finkel et al., 2008; Durrett and Klein, 2015). These models enjoy a number of appealing formal properties, including support for exact inference and structured loss functions. However, previous chart-based approaches have required considerable scaffolding beyond a simple well-formedness potential, e.g. pre-specification of a complete context-free grammar for generating output structures and initial pruning of the output space with a weaker model (Hall et al., 2014). Additionally, we are unaware of any recent chart-based models that achieve results competitive with the best transition-based models.

In this work, we present an extremely simple chart-based neural parser based on independent scoring of labels and spans, and show how this model can be adapted to support a greedy top-down decoding procedure. Our goal is to preserve the basic algorithmic properties of span-oriented (rather than transition-oriented) parse representations, while exploring the extent to which neural representational machinery can replace the additional structure required by existing chart parsers. On the Penn Treebank, our approach outperforms a number of recent models for chart-based and transition-based parsing—including the state-of-the-art models of Cross and Huang (2016) and Liu and Zhang (2016)—achieving an F1 score of 91.79. We additionally obtain a strong F1 score of 82.23 on the French Treebank.

2 Model

A constituency tree can be regarded as a collection of labeled spans over a sentence. Taking this view as a guiding principle, we propose a model with two components, one which assigns scores to span labels and one which assigns scores directly to span existence. The former is used to determine the labeling of the output, and the latter provides its structure.

At the core of both of these components is the issue of span representation. Given that a span's correct label and its quality as a constituent depend heavily on the context in which it appears, we naturally turn to recurrent neural networks as a starting point, since they have previously been shown to capture contextual information suitable for use in a variety of natural language applications (Bahdanau et al., 2014; Wang et al., 2015)

In particular, we run a bidirectional LSTM over the input to obtain context-sensitive forward and backward encodings for each position i, denoted by $\mathbf{f}_i$ and $\mathbf{b}_i$, respectively. Our representation of the span (i, j) is then the concatenatation the vector differences $\mathbf{f}_j - \mathbf{f}_i$ and $\mathbf{b}_i - \mathbf{b}_j$. This corresponds to a bidirectional version of the LSTM-Minus features first proposed by Wang and Chang (2016).

On top of this base, our label and span scoring functions are implemented as one-layer feedforward networks, taking as input the concatenated span difference and producing as output either a vector of label scores or a single span score. More formally, letting $\mathbf{s}_{ij}$ denote the vector representation of span (i, j), we define

$$s_{\text{labels}}(i, j) = \mathbf{V}_\ell g(\mathbf{W}_\ell \mathbf{s}_{ij} + \mathbf{b}_\ell),$$
$$s_{\text{span}}(i, j) = \mathbf{v}_s^\top g(\mathbf{W}_s \mathbf{s}_{ij} + \mathbf{b}_s),$$

where g denotes an elementwise nonlinearity. For notational convenience, we also let the score of an individual label ℓ be denoted by

$$s_{\text{label}}(i, j, \ell) = [s_{\text{labels}}(i, j)]_\ell,$$

where the right-hand side is the corresponding element of the label score vector.

One potential issue is the existence of unary chains, corresponding to nested labeled spans with the same endpoints. We take the common approach of treating these as additional atomic labels alongside all elementary nonterminals. To accommodate n-ary trees, our inventory additionally includes a special empty label $\varnothing$ used for spans that are not themselves full constituents but arise during the course of implicit binarization.

Our model shares several features in common with that of Cross and Huang (2016). In particular, our representation of spans and the form of our label scoring function were directly inspired by their work, as were our handling of unary chains and our use of an empty label. However, our approach differs in its treatment of structural decisions, and consequently, the inference algorithms we describe below diverge significantly from their transition-based framework.

3 Chart Parsing

Our basic model is compatible with traditional chart-based dynamic programming. Representing a constituency tree T by its labeled spans,

$$T := \{(\ell_t, (i_t, j_t)) : t = 1, \ldots, |T|\},$$

we define the score of a tree to be the sum of its constituent label and span scores,

$$s_{\text{tree}}(T) = \sum_{(\ell,(i,j))\in T} \left[s_{\text{label}}(i, j, \ell) + s_{\text{span}}(i, j)\right].$$

To find the tree with the highest score for a given sentence, we use a modified CKY recursion. As with classical chart parsing, the running time of our procedure is $O(n^3)$ for a sentence of length n.

3.1 Dynamic Program for Inference

The base case is a span $(i, i + 1)$ consisting of a single word. Since every valid tree must include all singleton spans, possibly with an empty label, we need not consider the span score in this case and perform only a single maximization over the choice of label:

$$s_{\text{best}}(i, i + 1) = \max_\ell \left[s_{\text{label}}(i, i + 1, \ell)\right].$$

For a general span (i, j), we define the score of the split (i, k, j) as the sum of its subspan scores,

$$s_{\text{split}}(i, k, j) = s_{\text{span}}(i, k) + s_{\text{span}}(k, j). \quad (1)$$

For convenience, we also define an augmented split score incorporating the scores of the corresponding subtrees,

$$\tilde{s}_{\text{split}}(i, k, j) = s_{\text{split}}(i, k, j) + s_{\text{best}}(i, k) + s_{\text{best}}(k, j).$$

Using these quantities, we can then write the general joint label and split decision as

$$s_{\text{best}}(i,j) = \max_{\ell,k} \left[s_{\text{label}}(i,j,\ell) + \tilde{s}_{\text{split}}(i,k,j) \right]. \tag{2}$$

Because our model assigns independent scores to labels and spans, this maximization decomposes into two disjoint subproblems, greatly reducing the size of the state space:

$$s_{\text{best}}(i,j) = \max_{\ell} \left[s_{\text{label}}(i,j,\ell) \right] + \max_{k} \left[\tilde{s}_{\text{split}}(i,k,j) \right].$$

We also note that the span scores $s_{\text{span}}(i,j)$ for each span (i,j) in the sentence can be computed once at the beginning of the procedure and shared across different subproblems with common left or right endpoints, allowing for a quadratic rather than cubic number of span score computations.

3.2 Margin Training

Training the model under this inference scheme is accomplished using a margin-based approach. When presented with an example sentence and its corresponding parse tree T^*, we compute the best prediction under the current model using the above dynamic program,

$$\widehat{T} = \operatorname*{argmax}_{T} \left[s_{\text{tree}}(T) \right].$$

If $\widehat{T} = T^*$, then our prediction was correct and no changes need to be made. Otherwise, we incur a hinge penalty of the form

$$\max\left(0,\ 1 - s_{\text{tree}}(T^*) + s_{\text{tree}}(\widehat{T})\right)$$

to encourage the model to keep a margin of at least 1 between the gold tree and the best alternative. The loss to be minimized is then the sum of penalties across all training examples.

Prior work has found that it can be beneficial in a variety of applications to incorporate a structured loss function into this margin objective, replacing the hinge penalty above with one of the form

$$\max\left(0,\ \Delta(\widehat{T}, T^*) - s_{\text{tree}}(T^*) + s_{\text{tree}}(\widehat{T})\right)$$

for a loss function Δ that measures the similarity between the prediction $\widehat{T}$ and the reference T^*. Here we take Δ to be a Hamming loss on labeled spans. To incorporate this loss into the training objective, we modify the dynamic program of Section 3.1 to support loss-augmented decoding (Taskar et al., 2005). Since the label decisions are isolated from the structural decisions, it suffices to replace every occurrence of the label scoring function $s_{\text{label}}(i,j,\ell)$ by

$$s_{\text{label}}(i,j,\ell) + \mathbf{1}(\ell \neq \ell^*_{ij}),$$

where ℓ^*_{ij} is the label of span (i,j) in the gold tree T^*. This has the effect of requiring larger margins between the gold tree and predictions that contain more mistakes, offering a greater degree of robustness and better generalization.

4 Top-Down Parsing

While we have so far motivated our model from the perspective of classical chart parsing, it also allows for a novel inference algorithm in which trees are constructed greedily from the top down. At a high level, given a span, we independently assign it a label and pick a split point, then repeat this process for the left and right subspans; the recursion bottoms out with length-one spans that can no longer be split. Figure 1 gives an illustration of the process, which we describe in more detail below.

The base case is again a singleton span $(i, i+1)$, and follows the same form as the base case for the chart parser. In particular, we select the label $\widehat{\ell}$ that satisfies

$$\widehat{\ell} = \operatorname*{argmax}_{\ell} \left[s_{\text{label}}(i, i+1, \ell) \right],$$

omitting span scores from consideration since singleton spans cannot be split.

To construct a tree over a general span (i,j), we aim to solve the maximization problem

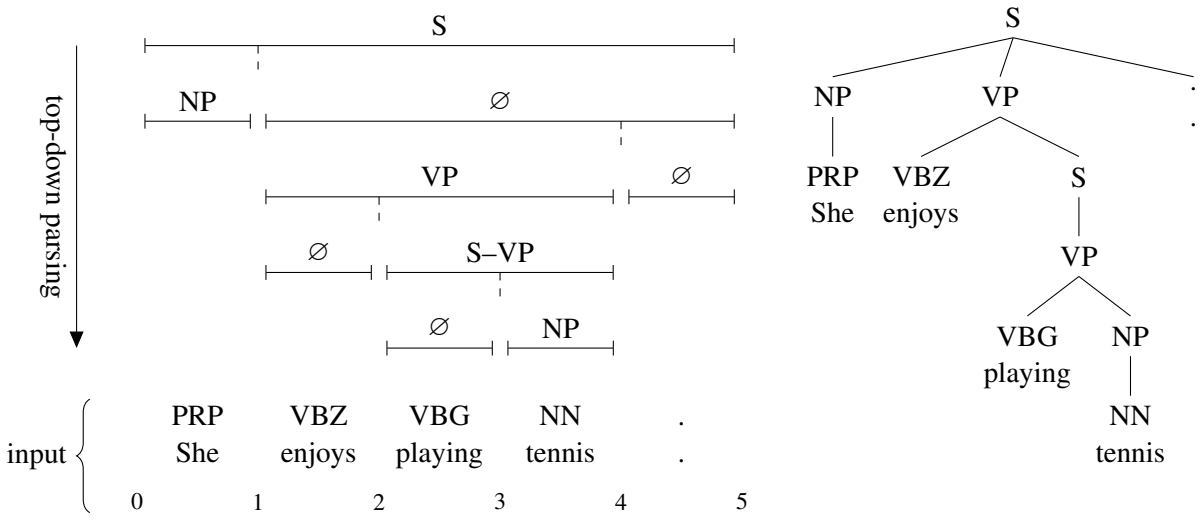
$$(\widehat{\ell}, \widehat{k}) = \operatorname*{argmax}_{\ell,k} \left[s_{\text{label}}(i,j,\ell) + s_{\text{split}}(i,k,j) \right],$$

where $s_{\text{split}}(i,k,j)$ is defined as in Equation (1). The independence of our label and span scoring functions again yields the decomposed form

$$\begin{aligned} \widehat{\ell} &= \operatorname*{argmax}_{\ell} \left[s_{\text{label}}(i,j,\ell) \right], \\ \widehat{k} &= \operatorname*{argmax}_{k} \left[s_{\text{split}}(i,k,j) \right], \end{aligned} \tag{3}$$

leading to a significant reduction in the size of the state space.

To generate a tree for the whole sentence, we call this procedure on the full sentence span $(0,n)$ and return the result. As there are $O(n)$ spans each



(a) Execution of the top-down parsing algorithm.

(b) Output parse tree.

Figure 1: An execution of our top-down parsing algorithm (a) and the resulting parse tree (b) for the sentence "She enjoys playing tennis." Part-of-speech tags, shown here together with the words, are predicted externally and are included as part of the input to our system. Beginning with the full sentence span $(0, 5)$, the label S and the split point 1 are predicted, and recursive calls are made on the child spans $(0, 1)$ and $(1, 5)$. The left child span $(0, 1)$ is assigned the label NP, and with no further splits to make, recursion terminates on this branch. The right child span $(1, 5)$ is assigned the empty label $\varnothing$, indicating that it does not represent a constituent in the tree. A split point of 4 is selected, and further recursive calls are made on the grandchild spans $(1, 4)$ and $(4, 5)$. This process of labeling and splitting continues until every branch of recursion bottoms out in singleton spans, at which point the full parse tree can be returned. Note that the unary chain S–VP is produced in a single labeling step.

requiring one label evaluation and at most $n - 1$ split point evaluations, the running time of the procedure is $O(n^2)$.

The algorithm outlined here bears a strong resemblance to the chart parsing dynamic program discussed in Section 3, but differs in one key aspect. When performing inference from the bottom up, we have already computed the scores of all of the subtrees below the current span, and we can take this knowledge into consideration when selecting a split point. In contrast, when producing a tree from the top down, we can only select a split point based on top-level evaluations of span quality, without knowing anything about the subtrees that will be generated below them. This difference is manifested in the augmented split score $\tilde{s}_{\text{split}}$ used in the definition of s_{best} in Equation (2), where the scores of the subtrees associated with a split point are included in the chart recursion but necessarily excluded from the top-down recursion.

While this apparent deficiency may be a cause for concern, we demonstrate the surprising empirical result in Section 6 that there is no loss in performance when moving from the globally-optimal chart parser to the greedy top-down procedure.

4.1 Margin Training

As with the chart parsing formulation, we also use a margin-based method for learning under the top-down model. However, rather than requiring separation between the scores of full trees, we instead enforce a local margin at every decision point.

For a span (i, j) occurring in the gold tree, let ℓ^* and k^* represent the correct label and split point, and let $\widehat{\ell}$ and $\widehat{k}$ be the predictions made by computing the maximizations in Equation (3). If $\widehat{\ell} \neq \ell^*$, meaning the prediction is incorrect, we incur a hinge penalty of the form

$$\max\left(0, 1 - s_{\text{label}}(i, j, \ell^*) + s_{\text{label}}(i, j, \widehat{\ell})\right).$$

Similarly, if $\widehat{k} \neq k^*$, we incur a hinge penalty of the form

$$\max\left(0, 1 - s_{\text{split}}(i, k^*, j) + s_{\text{split}}(i, \widehat{k}, j)\right).$$

To obtain the loss for a given training example, we trace out the actions corresponding to the gold tree and accumulate the above penalties over all decision points. As before, the total loss to be minimized is the sum of losses across all training examples.

Loss augmentation is also beneficial for the local decisions made by the top-down model, and can be implemented in a manner akin to the one discussed in Section 3.2.

4.2 Training with Exploration

The hinge penalties given above are only defined for spans (i, j) that appear in the example tree. The model must therefore be constrained at training time to follow decisions that exactly reproduce the gold tree, since supervision cannot be provided otherwise. As a result, the model is never exposed to its mistakes, which can lead to a lack of calibration and poor performance at test time.

To circumvent this issue, a *dynamic oracle* can be defined to inform the model about correct behavior even after it has deviated from the gold tree. Cross and Huang (2016) propose such an oracle for a related transition-based parsing system, and prove its optimality for the F1 metric on labeled spans. We adapt their result here to obtain a dynamic oracle for the present model with similar guarantees.

The oracle for labeling decisions carries over without modification: the correct label for a span is the label assigned to that span if it is part of the gold tree, or the empty label $\varnothing$ otherwise.

For split point decisions, the oracle can be broken down into two cases. If a span (i, j) appears as a constituent in the gold tree T, we let $b(i, j)$ denote the collection of its interior boundary points. For example, if the constituent over $(1, 7)$ has children spanning $(1, 3)$, $(3, 6)$, and $(6, 7)$, then we would have the two interior boundary points, $b(1, 7) = \{3, 6\}$. The oracle for a span appearing in the gold tree is then precisely the output of this function. Otherwise, for spans (i, j) not corresponding to gold constituents, we must instead identify the smallest enclosing gold constituent:

$$(i^*, j^*) = \min\{(i', j') \in T : i' \leq i < j \leq j'\},$$

where the minimum is taken with respect to the partial ordering induced by span length. The output of the oracle is then the set of interior boundary points of this enclosing span that also lie inside the original, $\{k \in b(i^*, j^*) : i < k < j\}$. The proof of correctness is similar to the proof in Cross and Huang (2016); we refer to the Dynamic Oracle section in their paper for a more detailed discussion.

As presented, the dynamic oracle for split point decisions returns a collection of one or more splits rather than a single correct answer. Any of these is a valid choice, with different splits corresponding to different binarizations of the original n-ary tree. We choose to use the leftmost split point for consistency in our implementation, but remark that the oracle split with the highest score could also be chosen at training time to allow for additional flexibility.

Having defined the dynamic oracle for our system, we note that training with exploration can be implemented by a single modification to the procedure described in Section 4.1. Local penalties are accumulated as before, but instead of tracing out the decisions required to produce the gold tree, we instead follow the decisions predicted by the model. In this way, supervision is provided at states within the prediction procedure that are more likely to arise at test time when greedy inference is performed.

5 Scoring and Loss Alternatives

The model presented in Section 2 is designed to be as simple as possible. However, there are many variations of the label and span scoring functions that could be explored; we discuss some of the options here.

5.1 Top-Middle-Bottom Label Scoring

Our basic model treats the empty label, elementary nonterminals, and unary chains each as atomic units, obscuring similarities between unary chains and their component nonterminals or between different unary chains with common prefixes or suffixes. To address this lack of structure, we consider an alternative scoring scheme in which labels are predicted in three parts: a top nonterminal, a middle unary chain, and a bottom nonterminal (each of which is possibly empty).[1] This not only allows for parameter sharing across labels with common subcomponents, but also has the added benefit of allowing the model to produce novel unary chains at test time.

[1] In more detail, $\varnothing$ decomposes as $(\varnothing, \varnothing, \varnothing)$, X decomposes as $(X, \varnothing, \varnothing)$, X–Y decomposes as $(X, \varnothing, Y)$, and X–Z_1–$\cdots$–Z_k–Y decomposes as $(X, Z_1$–$\cdots$–$Z_k, Y)$.

More precisely, we introduce the decomposition

$$s_{\text{label}}(i, j, (\ell_t, \ell_m, \ell_b)) = s_{\text{top}}(i, j, \ell_t) + s_{\text{middle}}(i, j, \ell_m) + s_{\text{bottom}}(i, j, \ell_b),$$

where s_{top}, s_{middle}, and s_{bottom} are independent one-layer feedforward networks of the same form as s_{label} that output vectors of scores for all label tops, label middle chains, and label bottoms encountered in the training corpus, respectively. The best label for a span (i, j) is then computed by solving the maximization problem

$$\max_{\ell_t, \ell_m, \ell_b} \left[s_{\text{label}}(i, j, (\ell_t, \ell_m, \ell_b)) \right],$$

which decomposes into three independent subproblems corresponding to the three label components. The final label is obtained by concatenating ℓ_t, ℓ_m, and ℓ_b, with empty components being omitted from the concatenation.

5.2 Left and Right Span Scoring

The basic model uses the same span scoring function s_{span} to assign a score to the left and right subspans of a given span. One simple extension is to replace this by a pair of distinct left and right feedforward networks of the same form, giving the decomposition

$$s_{\text{split}}(i, k, j) = s_{\text{left}}(i, k) + s_{\text{right}}(k, j).$$

5.3 Span Concatenation Scoring

Since span scores are only used to score splits in our model, we also consider directly scoring a split by feeding the concatenation of the span representations of the left and right subspans through a single feedforward network, giving

$$s_{\text{split}}(i, k, j) = \mathbf{v}_s^\top g\left(\mathbf{W}_s[\mathbf{s}_{ik}; \mathbf{s}_{kj}] + \mathbf{b}_s\right).$$

This is similar to the structural scoring function used by Cross and Huang (2016), although whereas they additionally include features for the outside spans $(0, i)$ and (j, n) in their concatenation, we omit these from our implementation, finding that they do not improve performance.

5.4 Deep Biaffine Span Scoring

Inspired by the success of deep biaffine scoring in recent work by Dozat and Manning (2016) for dependency parsing, we also consider a split scoring function of a similar form for our model. Specifically, we let $\mathbf{h}_{ik} = f_{\text{left}}(\mathbf{s}_{ik})$ and $\mathbf{h}_{kj} = f_{\text{right}}(\mathbf{s}_{kj})$ be deep left and right span representations obtained by passing the child vectors through corresponding left and right feedforward networks. We then define the biaffine split scoring function

$$s_{\text{split}}(i, k, j) = \mathbf{h}_{ik}^\top \mathbf{W}_s \mathbf{h}_{kj} + \mathbf{v}_{\text{left}}^\top \mathbf{h}_{ik} + \mathbf{v}_{\text{right}}^\top \mathbf{h}_{kj},$$

which consists of the sum of a bilinear form between the two hidden representations together with two inner products.

5.5 Structured Label Loss

The three-way label scoring scheme described in Section 5.1 offers one path towards the incorporation of label structure into the model. We additionally consider a structured Hamming loss on labels. More specifically, given two labels ℓ_1 and ℓ_2 consisting of zero or more nonterminals, we define the loss as $|\ell_1 \setminus \ell_2| + |\ell_2 \setminus \ell_1|$, treating each label as a multiset of nonterminals. This structured loss can be incorporated into the training process using the methods described in Sections 3.2 and 4.1.

6 Experiments

We first describe the general setup used for our experiments. We use the Penn Treebank (Marcus et al., 1993) for our English experiments, with standard splits of sections 2-21 for training, section 22 for development, and section 23 for testing. We use the French Treebank from the SPMRL 2014 shared task (Seddah et al., 2014) with its provided splits for our French experiments. No token preprocessing is performed, and only a single <UNK> token is used for unknown words at test time. The inputs to our system are concatenations of 100-dimensional word embeddings and 50-dimensional part-of-speech embeddings. In the case of the French Treebank, we also include 50-dimensional embeddings of each morphological tag. We use automatically predicted tags for training and testing, obtaining predicted part-of-speech tags for the Penn Treebank using the Stanford tagger (Toutanova et al., 2003) with 10-way jackknifing, and using the provided predicted part-of-speech and morphological tags for the French Treebank. Words are replaced by <UNK> with probability $1/(1+\text{freq}(w))$ during training, where $\text{freq}(w)$ is the frequency of w in the training data.

We use a two-layer bidirectional LSTM for our base span features. Dropout with a ratio selected from $\{0.2, 0.3, 0.4\}$ is applied to all non-recurrent

Table 1: Development F1 scores on the Penn Treebank. Each table corresponds to a particular choice of label loss (either the basic 0-1 loss or the structured Hamming label loss of Section 5.5) and labeling scheme (either the basic atomic scheme or the top-middle-bottom labeling scheme of Section 5.1). The columns within each table correspond to different split scoring schemes: basic minimal scoring, the left-right scoring of Section 5.2, the concatenation scoring of Section 5.3, and the deep biaffine scoring of Section 5.4.

connections of the LSTM, including its inputs and outputs. We tie the hidden dimension of the LSTM and all feedforward networks, selecting a size from $\{150, 200, 250\}$. All parameters (including word and tag embeddings) are randomly initialized using Glorot initialization (Glorot and Bengio, 2010), and are tuned on development set performance. We use the Adam optimizer (Kingma and Ba, 2014) with its default settings for optimization, with a batch size of 10. Our system is implemented in C++ using the DyNet neural network library (Neubig et al., 2017).

We begin by training the minimal version of our proposed chart and top-down parsers on the Penn Treebank. Out of the box, we obtain test F1 scores of 91.69 for the chart parser and 91.58 for the top-down parser. The higher of these matches the recent state-of-the-art score of 91.7 reported by Liu and Zhang (2016), demonstrating that our simple neural parsing system is already capable of achieving strong results.

Building on this, we explore the effects of different split scoring functions when using either the basic 0-1 label loss or the structured label loss discussed in Section 5.5. Our results are presented in Tables 1a and 1b.

We observe that regardless of the label loss, the minimal and deep biaffine split scoring schemes perform a notch below the left-right and concatenation scoring schemes. That the minimal scoring scheme performs worse than the left-right scheme is unsurprising, since the latter is a strict generalization of the former. It is evident, however, that joint scoring of left and right subspans is not required for strong results—in fact, the left-right scheme which scores child subspans in isolation slightly outperforms the concatenation scheme in all but one case, and is stronger than the deep biaffine scoring function across the board.

Comparing results across the choice of label loss, however, we find that fewer trends are apparent. The scores obtained by training with a 0-1 loss are all within 0.1 of those obtained using a structured Hamming loss, being slightly higher in four out of eight cases and slightly lower in the other half. This leads us to conclude that the more elementary approach is sufficient when selecting atomic labels from a fixed inventory.

We also perform the same set of experiments under the setting where the top-middle-bottom label scoring function described in Section 5.1 is used in place of an atomic label scoring function. These results are shown in Tables 1c and 1d.

A priori, we might expect that exposing additional structure would allow the model to make better predictions, but on the whole we find that the scores in this set of experiments are worse than those in the previous set. Trends similar to before hold across the different choices of scoring functions, though in this case the minimal setting has scores closer to those of the left-right setting, even exceeding its performance in the case of a chart parser with a 0-1 label loss.

Our final test results are given in Table 2, along with the results of other recent single-model parsers trained without external parse data. We

Final Parsing Results on Penn Treebank

Parser	LR	LP	F1
Durrett and Klein (2015)	–	–	91.1
Vinyals et al. (2015)	–	–	88.3
Dyer et al. (2016)	–	–	89.8
Cross and Huang (2016)	90.5	92.1	91.3
Liu and Zhang (2016)	91.3	92.1	91.7
Best Chart Parser	90.63	92.98	91.79
Best Top-Down Parser	90.35	93.23	91.77

Table 2: Comparison of final test F1 scores on the Penn Treebank. Here we only include scores from single-model parsers trained without external parse data.

Final Parsing Results on French Treebank

Parser	LR	LP	F1
Björkelund et al. (2014)	–	–	82.53
Durrett and Klein (2015)	–	–	81.25
Cross and Huang (2016)	81.90	84.77	83.11
Best Chart Parser	80.26	84.12	82.14
Best Top-Down Parser	79.60	85.05	82.23

Table 3: Comparison of final test F1 scores on the French Treebank.

achieve a new state-of-the-art F1 score of 91.79 with our best model. Interestingly, we observe that our parsers have a noticeably higher gap between precision and recall than do other top parsers, likely owing to the structured label loss which penalizes mismatching nonterminals more heavily than it does a nonterminal and empty label mismatch. In addition, there is little difference between the best top-down model and the best chart model, indicating that global normalization is not required to achieve strong results. Processing one sentence at a time on a `c4.4xlarge` Amazon EC2 instance, our best chart and top-down parsers operate at speeds of 20.3 sentences per second and 75.5 sentences per second, respectively, as measured on the test set.

We additionally train parsers on the French Treebank using the same settings from our English experiments, selecting the best model of each type based on development performance. We list our test results along with those of several other recent papers in Table 3. Although we fall short of the scores obtained by Cross and Huang (2016), we achieve competitive performance relative to the neural CRF parser of Durrett and Klein (2015).

7 Related Work

Many early successful approaches to constituency parsing focused on rich modeling of correlations in the *output space*, typically by engineering proabilistic context-free grammars with state spaces enriched to capture long-distance dependencies and lexical phenomena (Collins, 2003; Klein and Manning, 2003; Petrov and Klein, 2007). By contrast, the approach we have described here continues a recent line of work on direct modeling of correlations in the *input space*, by using rich feature representations to parameterize local potentials that interact with a comparatively unconstrained structured decoder. As noted in the introduction, this class of feature-based tree scoring functions can be implemented with either a linear transition system (Chen and Manning, 2014) or a global decoder (Finkel et al., 2008). Kiperwasser and Goldberg (2016) describe an approach closely related to ours but targeted at dependency formalisms, and which easily accommodates both sparse log-linear scoring models (Hall et al., 2014) and deep neural potentials (Henderson, 2004; Ballesteros et al., 2016).

The best-performing constituency parsers in the last two years have largely been transition-based rather than global; examples include the models of Dyer et al. (2016), Cross and Huang (2016) and Liu and Zhang (2016). The present work takes many of the insights developed in these models (e.g. the recurrent representation of spans (Kiperwasser and Goldberg, 2016), and the use of a dynamic oracle and exploration policy during training (Goldberg and Nivre, 2013)) and extends these insights to span-oriented models, which support a wider range of decoding procedures. Our approach differs from other recent chart-based neural models (e.g. Durrett and Klein (2015)) in the use of a recurrent input representation, structured loss function, and comparatively simple parameterization of the scoring function. In addition to the globally optimal decoding procedures for which these models were designed, and in contrast to the left-to-right decoder typically employed by transition-based models, our model admits an additional greedy top-to-bottom inference procedure.

8 Conclusion

We have presented a minimal span-oriented parser that uses a recurrent input representation to score

trees with a sum of independent potentials on their constituent spans and labels. Our model supports both exact chart-based decoding and a novel top-down inference procedure. Both approaches achieve state-of-the-art performance on the Penn Treebank, and our best model achieves competitive performance on the French Treebank. Our experiments show that many of the key insights from recent neural transition-based approaches to parsing can be easily ported to the chart parsing setting, resulting in a pair of extremely simple models that nonetheless achieve excellent performance.

Abstract

We model a dependency graph as a book, a particular kind of topological space, for semantic dependency parsing. The spine of the book is made up of a sequence of words, and each page contains a subset of noncrossing arcs. To build a semantic graph for a given sentence, we design new Maximum Subgraph algorithms to generate noncrossing graphs on each page, and a Lagrangian Relaxation-based algorithm to combine pages into a book. Experiments demonstrate the effectiveness of the book embedding framework across a wide range of conditions. Our parser obtains comparable results with a state-of-the-art transition-based parser.

1 Introduction

Dependency analysis provides a lightweight and effective way to encode syntactic and semantic information of natural language sentences. One of its branches, syntactic dependency parsing (Kübler et al., 2009) has been an extremely active research area, with high-performance parsers being built and applied for practical use of NLP. Semantic dependency parsing, however, has only been addressed in the literature recently (Oepen et al., 2014, 2015; Du et al., 2015; Zhang et al., 2016; Cao et al., 2017).

Semantic dependency parsing employs a graph-structured semantic representation. On the one hand, it is flexible enough to provide analysis for various semantic phenomena (Ivanova et al., 2012). This very flexibility, on the other hand, brings along new challenges for designing parsing algorithms. For graph-based parsing, no previously defined Maximum Subgraph algorithm has simultaneously a high coverage and a polynomial complexity to low degrees. For transition-based parsing, no principled decoding algorithms, e.g. dynamic programming (DP), has been developed for existing transition systems.

In this paper, we borrow the idea of book embedding from graph theory, and propose a novel framework to build parsers for flexible dependency representations. In graph theory, a *book* is a kind of topological space that consists of a spine and a collection of one or more half-planes. In our "book model" of semantic dependency graph, the spine is made up of a sequence of words, and each half-plane contains a subset of dependency arcs. In particular, the arcs on each page compose a noncrossing dependency graph, a.k.a. planar graph. Though a dependency graph in general is very flexible, its subgraph on each page is rather regular. Under the new perspective, semantic dependency parsing can be cast as a two-step task: Each page is first analyzed separately, and then all the pages are bound coherently.

Our work is motivated by the extant low-degree polynomial time algorithm for first-order Maximum Subgraph parsing for noncrossing dependency graphs (Kuhlmann and Jonsson, 2015). We enhance existing work with new exact second- and approximate higher-order algorithms. Our algorithms facilitate building with high accuracy the partial semantic dependency graphs on each page. To produce a full semantic analysis, we also need to integrate partial graphs on all pages into one coherent book. To this end, we formulate the problem as a combinatorial optimization problem, and propose a Lagrangian Relaxation-based algorithm for solutions.

We implement a practical parser in the new framework with a statistical disambiguation model. We evaluate this parser on four data sets: those used in SemEval 2014 Task 8 (Oepen et al., 2014), and the dependency graphs extracted from

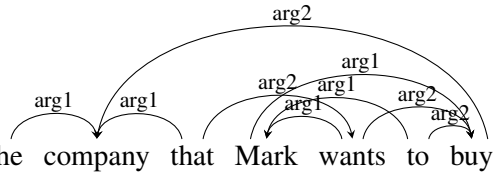

Figure 1: A fragment of a semantic dependency graph.

CCGbank (Hockenmaier and Steedman, 2007). On all data sets, we find that our higher-order parsing models are more accurate than the first-order baseline. Experiments also demonstrate the effectiveness of our page binding algorithm. Our new parser can be taken as a graph-based parser extended for more general dependency graphs. It parallels the state-of-the-art transition-based system of Zhang et al. (2016) in performance.

The implementation of our parser is available at `http://www.icst.pku.edu.cn/lcwm/grass`.

2 Background

2.1 Semantic Dependency Graphs

A dependency graph $G = (V, A)$ is a labeled directed graph for a sentence $s = w_1, \ldots, w_n$. The vertex set V consists of n vertices, each of which corresponds to a word and is indexed by an integer. The arc set A represents the labeled dependency relations of the particular analysis G. Specifically, an arc, viz. $a_{(i,j,l)}$, represents a dependency relation l from head w_i to dependent w_j.

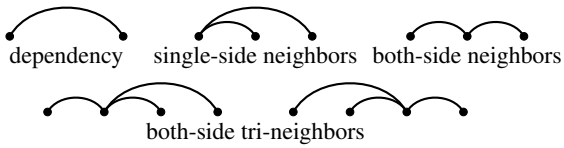
Semantic dependency parsing is the task of mapping a natural language sentence into a formal meaning representation in the form of a dependency graph. Figure 1 shows a graph fragment of a noun phrase. This semantic graph is grounded on Combinatory Categorial Grammar (CCG; Steedman, 2000), and can be taken as a proxy for predicate–argument structure. The graph includes most semantically relevant non-anaphoric local (e.g. from "wants" to "Mark") and long-distance (e.g. from "buy" to "company") dependencies.

2.2 Maximum Subgraph Parsing

Usually, syntactic dependency analysis employs *tree*-shaped representations. Dependency parsing, thus, can be formulated as the search for a maximum spanning tree (MST) of an arc-weighted graph. For semantic dependency parsing, where the target representations are not necessarily trees, Kuhlmann and Jonsson (2015) proposed to generalize the MST model to other types of subgraphs. In general, dependency parsing is formulated as the search for Maximum Subgraph for graph class $\mathcal{G}$: Given a graph $G = (V, A)$, find a subset $A' \subseteq A$ with maximum total weight such that the induced subgraph $G' = (V, A')$ belongs to $\mathcal{G}$. Formally, we have the following optimization problem:

$$G'(s) = \arg \max_{H \in \mathcal{G}(s,G)} \sum_{p \in H} \textsc{ScorePart}(s, p)$$

Here, $\mathcal{G}(s, G)$ is the set of all graphs that belong to $\mathcal{G}$ and are compatible with s and G. For parsing, G is usually a complete graph. $\textsc{ScorePart}(s, p)$ evaluates the event that a small subgraph p of a candidate graph H is good. We define the *order* of a part according to the number of dependencies it contains, in analogy with tree parsing in terminology. Previous work only discussed the first-order case for Maximum Subgraph parsing (Kuhlmann and Jonsson, 2015). In this paper, we are also interested in higher-order parsing, with a special focus on factorizations utilizing the following parts:



If $\mathcal{G}$ is the set of projective trees or non-crossing graphs the first-order Maximum Subgraph problem can be solved in cubic-time (Eisner, 1996; Kuhlmann and Jonsson, 2015). Unfortunately, these two graph classes are not expressive enough to encode semantic dependency graphs. Moreover, this problem for several well-motivated graph classes, including acyclic or 2-planar graphs, is NP-hard, even if one only considers first-order factorization. The lack of appropriate decoding algorithms results in one major challenge for semantic dependency parsing.

2.3 Book Embedding

This section introduces the basic idea about book embedding from a graph theoretical point of view.

Definition 1. *A book is a kind of topological space that consists of a line, called the spine, together with a collection of one or more half-planes, called the pages, each having the spine as its boundary.*

Definition 2. *A book embedding of a finite graph G onto a book B satisfies the following conditions.*

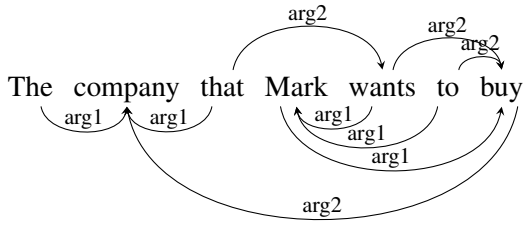


Figure 2: Book embedding for the graph in Figure 1. Arcs are assigned to two pages.

1. *Every vertex of G is depicted as a point on the spine of B.*
2. *Every edge of G is depicted as a curve that lies within a single page of B.*
3. *Every page of B does not have any edge crossings.*

A book embedding separates a graph into several subgraphs, each of which contains all vertices, but only a subset of arcs that are not crossed with each other. This kind of graph is named noncrossing dependency graph by Kuhlmann and Jonsson (2015) and planar by Titov et al. (2009), Gómez-Rodríguez and Nivre (2010) and many others.

We can formalize a semantic dependency graph as a *book*. Take the graph in Figure 1 for example. We can separate the edges into two sets and take each set as a single page, as shown in Figure 2.

Empirically, a semantic dependency graph is sparse enough that it can be that it can be usually embedded onto a very *thin* book. To measure the thickness, we can use pagenumber that is defined as follows.

Definition 3. *The book pagenumber of G is the minimum number of pages required for a book embedding of G.*

We look into the pagenumber of graphs on four linguistic graph banks (as defined in Section 5). These corpora are also used for training and evaluating our data-driven parsers. The pagenumbers are calculated using sentences in the training sets. Table 1 lists the percentages of complete graphs that can be accounted with books of different thickness. The percentages of noncrossing graphs, i.e. graphs that have pagenumber 1, vary between 48.23% and 78.26%. The practical usefulness of the algorithms for computing maximum noncrossing graphs will be limited by the relatively low coverage.

The class of graphs with pagenumber no more than two has a considerably satisfactory coverage.

PN	DM	PAS	CCD	PSD
1	69.83%	60.07%	48.23%	78.26%
2	29.85%	39.46%	49.86%	20.12%
3	0.31%	0.46%	1.71%	1.39%
4	0	0.02%	0.18%	0.21%
5	0	0	0.02%	0.02%
6	0	0	0	0.01%

Table 1: Coverage in terms of complete graphs with respect to different pagenumbers ("PN" for short). "DM," "PAS," "CCD" and "PSD" are short for DeepBank, Enju HPSGBank, CCGBank and Prague Dependency Treebank.

It can account for more than 98% of the graphs and sometimes close to 100% in each data set. Unfortunately, the power of Maximum Subgraph parsing is limited given that finding the maximum acyclic subgraph when pagenumber is at most k is NP-hard for $k \geq 2$ (Kuhlmann and Jonsson, 2015). As an alternative, we propose to model a semantic graph as a book, in which the spine is made up of a sequence of words, and each half-plane contains a subset of dependency arcs. To build a semantic graph for a given sentence, we design new parsing algorithms to generate noncrossing graphs on each page (Section 3), and a Lagrangian Relaxation-based algorithm to integrate pages into a book (Section 4).

3 Maximum Subgraph for Noncrossing Graphs

We introduce several DP algorithms for calculating the maximum noncrossing dependency graphs. Each algorithm visits all the spans from bottom to top, finding the best combination of smaller structures to form a new structure, according to the scores of first- or higher-order features. For sake of conciseness, we focus on undirected graphs and treat direction of linguistic dependencies as edge labels[1]. We will use $e_{(i,j,l)}(i < j)$ or simply $e_{(i,j)}$ to indicate an edge in either direction

[1] The *single-head* property does not hold. We currently do not consider other constraints of directions. So prediction of the direction of one edge does not affect prediction of other edges as well as their directions. The directions can be assigned *locally*, and our parser builds directed rather than undirected graphs in this way. Undirected graphs are only used to conveniently illustrate our algorithms. All experimental results in Section 5 consider directed dependencies in a standard way. We use the official evaluation tool provided by SDP2014 shared task. The numberic results reported in this paper are directly comparable to results in other papers.

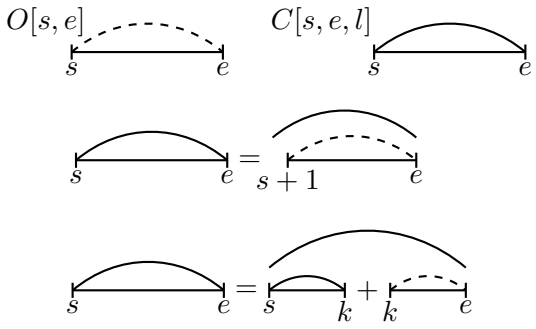

Figure 3: The sub-problems of first-order factorization and the decomposition for $C[s, e, l]$.

between i and j.

For sake of formal concision, we introduce the algorithm of which the goal is to calculate the maximum score of a subgraph. Extracting corresponding optimal graphs can be done in a number of ways. For example, we can maintain an auxiliary arc table which is populated parallel to the procedure of obtaining maximum scores. We define two score functions: (1) $\mathrm{s}_{\mathrm{fst}}(s, e, l)$ assigns a score to an individual edge $e_{(s,e,l)}$ and (2) $\mathrm{s}_{\mathrm{scd}}(s, e_1, e_2, l_1, l_2)$ assigns a score to a pair of neighboring edges $e_{(s,e_1,l_1)}$ and $e_{(s,e_2,l_2)}$.

3.1 First-Order Factorization

Given a sentence, we define two DP tables, namely $O[s, e]$ and $C[s, e, l]$ which represents the value of the highest scoring noncrossing graphs that spans sequences of words of a sentence. The two tables are related to two sub-problems, as graphically shown in Figure 3. The following is their explaination.

Open $O[s, e]$ is intended to represent the highest weighted subgraph spanning w_s to w_e. The subgraphs related to $O[s, e]$ may or may not contain $e_{(s,e)}$.

Closed $C[s, e, l]$ represents the highest weighted subgraph spanning w_s to w_e too. But the subgraphs related to $C[s, e, l]$ must contain $e_{(s,e,l)}$.

$O[s, e]$ can be obtained by one of the following combinations:

- $C[s, e, l](l \in L)$, if there is an edge between s and e with label l.
- $C[s, k, l] + O[k, e](l \in L, s < k < e)$, if $e_{(s,e)}$ does not exist and there is an edge with label l between s and some node in this span. k is the farthest node linked to s.
- $O[s + 1, e]$, if $e_{(s,e)}$ does not exist and there is no edge to its right in this span.

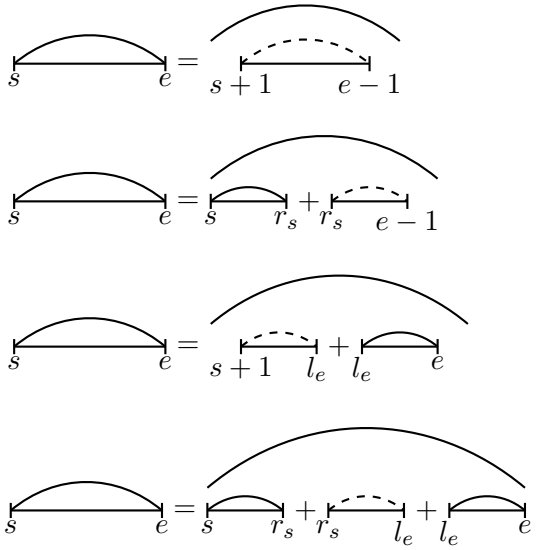

Figure 4: The decomposition for $C[s, e, l]$ in exact single-side second-order factorization.

$C[s, e, l]$ can be obtained by one of the following combinations:

- $O[s + 1, e] + \mathrm{s}_{\mathrm{fst}}(s, e, l)$, if s has no edge to its right;
- $C[s, k, l'] + O[k, e] + \mathrm{s}_{\mathrm{fst}}(s, e, l)(l' \in L, s < k < e)$, if there is an edge from s to some node in the span.

For each edge, there are two directions for the edge, we encode the directions into the label l, and treat it as undirected edge. We need to search for a best split and a best label for every span, so the time complexity of the algorithm is $O(n^3|L|)$ where n is the length of the sentence and L is the set of labels.

3.2 Second-Order Single Side Factorization

We propose a new algorithm concerning single-side second-order factorization. The DP tables, as well as the decomposition for the open problem, are the same as in the first order factorization. The decomposition of $C[s, e, l]$ is very different. In order to score second-order features from adjacent edges in the same side, which is similar to *sibling* features for tree parsing (McDonald and Pereira,

2006), we need to find the rightmost node adjacent to s, denoted as r_s, and the leftmost node adjacent to e, denoted as l_e, and here we have $s < r_s \leq l_e < e$. And, sometimes, we split $C[s, e, l]$ into three parts to capture the neighbor factors on both endpoints. In summary, $C[s, e, l]$ can be obtained by one of the following combination (as graphically shown in Figure 4):

- $O[s + 1, e - 1] + \mathrm{s}_{\mathrm{fst}}(s, e, l) + \mathrm{s}_{\mathrm{scd}}(s, nil, e, nil, l) + \mathrm{s}_{\mathrm{scd}}(e, nil, s, nil, l)$, if there is no edge from s/e to any node in the span.
- $C[s, r_s, l'] + O[r_s, e - 1] + \mathrm{s}_{\mathrm{fst}}(s, e, l) + \mathrm{s}_{\mathrm{scd}}(s, r_s, e, l', l) + \mathrm{s}_{\mathrm{scd}}(e, nil, s, nil, l)$ $(s < r_s < e)$, if there is no edge from e to any node in the span.
- $O[s + 1, l_e] + C[l_e, e, l'] + \mathrm{s}_{\mathrm{fst}}(s, e, l) + \mathrm{s}_{\mathrm{scd}}(e, l_e, s, l', l) + \mathrm{s}_{\mathrm{scd}}(s, nil, e, nil, l)$ $(s < l_e < e)$, if there is no edge from s to any node in the span.
- $C[s, r_s, l'] + O[r_s, l_e] + C[l_e, e, l''] + \mathrm{s}_{\mathrm{fst}}(s, e, l) + \mathrm{s}_{\mathrm{scd}}(s, r_s, e, l', l) + \mathrm{s}_{\mathrm{scd}}(e, l_e, s, l'', l)$ $(s < r_s \leq l_e < e)$, otherwise.

For the last combination, we need to search for two best separating words, namely s_r and l_e, and two best labels, namely l' and l', so the time complexity of this second-order algorithm is $O(n^4|L|^2)$.

3.3 Generalized Higher-Order Parsing

Both of the above two algorithms are exact decoding algorithms. Solutions allow for exact decoding with higher-order features typically at a high cost in terms of efficiency. A trade-off between rich features and exact decoding benefit tree parsing (McDonald and Nivre, 2011). In particular, Zhang and McDonald (2012) proposed a generalized higher-order model that abandons exact search in graph-based parsing in favor of freedom in feature scope. They kept intact Eisner's algorithm for first-order parsing problems, while enhanced the scoring function in an approximate way by introducing higher-order features.

We borrow Zhang and McDonald's idea and develop a generalized parsing model for noncrossing dependency representations. The sub-problems and their decomposition are much like the first-order algorithm. The difference is that we expand

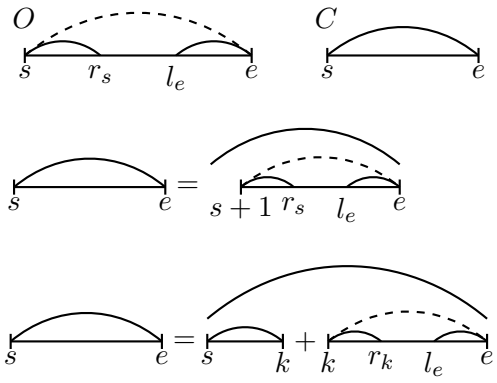

Figure 5: Sub-problems of generalized higher-order factorization and some of the combinations.

the signature of each structure to include all the larger context required to compute higher-order features. For example, we can record the leftmost and the rightmost edges in the open structure to get the tri-neighbor features. The time complexity is thus always $O(n^3B^2)$, no matter how complicatedly higher-order features are incorporated.

We focus on five factors introduced in Section 2.2. Still consider single-side second-order factorization. We keep the closed structure the same but modify the open one to $O[s, e; r_s, l_e, l_{s,r_s}, l_{l_e,e}]$. During parsing, we only record the top-B combinations of label concerning $e_{(s,e)}$ and related r_s, l_e, l_{s,r_s} and $l_{l_e,e}$. The split of a structure is similar to the first-order algorithm, shown in Figure 5. Note that r_s may be e and l_e may be s. In this way, we know exactly whether or not there is an edge from s to e in a refined open structure. This is different from the intuition of the design of the open structure when we consider first-order factorization.

4 Finding and Binding Pages

Statistics presented in Table 1 indicate that the coverage of noncrossing dependency graphs is relatively low. If we treat semantic dependency parsing as Maximum Subgraph parsing, the practical usefulness of the algorithms introduced above is rather limited accordingly. To deal with this problem, we model a semantic graph as a book, and view semantic dependency parsing as finding a book with coherent optimal pages. Given the considerably high coverage of pagenumber at most 2, we only consider 2-page books.

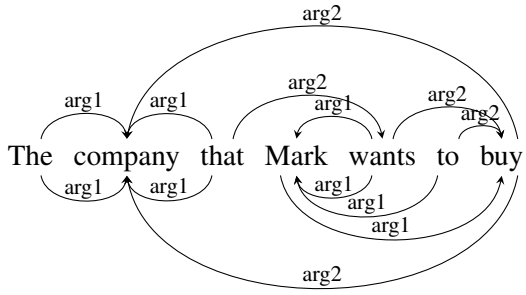

Figure 6: Every non-crossing arc is repeatedly assigned to every page.

4.1 Finding Pages via Coloring

In general, finding the pagenumber of a graph is NP-hard (Gómez-Rodríguez and Nivre, 2010). However, it is easy to figure out that the problem is solvable if the pagenumber is at most 2. Fortunately, a semantic dependency graph is not so dense that it can be usually embedded onto a very *thin* book with only 2 pages. For a structured prediction problem, the structural information of the output produced by a parser is very important. The density of semantic dependency graphs therefore results in a defect: The output's structural information is limited because only a half of arcs on average are included in one page. To enrich the structural information, we put into each page the arcs that do not cross with any other arcs. See Figure 6 for example.

We utilize an algorithm based on coloring to decompose a graph $G = (V, A)$ into two noncrossing subgraphs $G_A = (V, A_B)$ and $G_B = (V, A_B)$. A detailed description is included in the supplementary note. The key idea of our algorithm is to color each crossing arc in two colors using depth-first search. When we color an arc e_x, we examine all arcs crossing with e_x. If one of them, say e_y, has not been examined and can be colored in the other color (no crossing arc of e_y has the same color with e_y), we color e_y and then recursively process e_y. Otherwise, e_y is marked as a bad arc and dropped from both A_A and A_B. After coloring all the crossing arcs, we add every arc in different color to different subgraphs. Specially, all noncrossing arcs are assigned to both A_A and A_B.

4.2 Binding Pages via Lagrangian Relaxation

Applying the above algorithm, we can obtain two corpora to train two noncrossing dependency parsing models. In other words, we can learn two score functions f_A and f_B to score noncrossing dependency graphs. Given the trained models and a sentence, we can find two optimal noncrossing graphs, i.e. find the solutions for $\arg\max_{\boldsymbol{g}} f_A(\boldsymbol{g})$ and $\arg\max_{\boldsymbol{g}} f_B(\boldsymbol{g})$, respectively.

We can put all the arcs contained in $\boldsymbol{g}_A = \arg\max_{\boldsymbol{g}} f_A(\boldsymbol{g})$ and $\boldsymbol{g}_B = \arg\max_{\boldsymbol{g}} f_B(\boldsymbol{g})$ together as our parse for the sentence. This naive combination always gives a graph with a recall much higher than the precision. The problem is that a naive combination does not take the agreements of the graphs on the two pages into consideration, and thus loses some information. To combine the two pages in a principled way, we must do *joint* decoding to find two graphs $\boldsymbol{g}_A$ and $\boldsymbol{g}_B$ to maximize the score $f_A(\boldsymbol{g}_A) + f_B(\boldsymbol{g}_B)$, under the following constraints.

$$\boldsymbol{g}_A(i,j) \leq \sum_{\text{cross}((i,j),(i',j'))} \boldsymbol{g}_B(i',j') + \boldsymbol{g}_B(i,j)$$
$$\boldsymbol{g}_B(i,j) \leq \sum_{\text{cross}((i,j),(i',j'))} \boldsymbol{g}_A(i',j') + \boldsymbol{g}_A(i,j)$$
$$\forall i, j$$

The functionality of *cross* is to figure out whether $e_{(i,j)}$ and $e_{(i',j')}$ cross. The meaning of the first constraint is: When there is an arc $e_{(i,j)}$ in the first graph, $e_{(i,j)}$ is also in the second graph, or there is an arc $e_{(i',j')}$ in the second graph which cross with $e_{(i,j)}$. So is the second one. All constraints are linear and can be written in a simplified way as,

$$A\boldsymbol{g}_A + B\boldsymbol{g}_B \leq \mathbf{0}$$

where A and B are matrices that can be constructed by checking all possible crossing arc pairs. In summary, we have the following constrained optimization problem,

$$\begin{array}{ll} \text{min.} & -f_A(\boldsymbol{g}_A) - f_B(\boldsymbol{g}_B) \\ \text{s.t.} & \boldsymbol{g}_A, \boldsymbol{g}_B \text{ are noncrossing graphs} \\ & A\boldsymbol{g}_A + B\boldsymbol{g}_B \leq \mathbf{0} \end{array}$$

The Lagrangian of the optimization problem is

$$\begin{aligned} &\mathcal{L}(\boldsymbol{g}_A, \boldsymbol{g}_B; u) \\ &\quad = -f_g(\boldsymbol{g}_A) - f_t(\boldsymbol{g}_B) + u^\top (A\boldsymbol{g}_A + B\boldsymbol{g}_B) \end{aligned}$$

where u is the Lagrangian multiplier. Then the dual is

$$\begin{aligned} \mathcal{L}(u) &= \min_{\boldsymbol{g}_A, \boldsymbol{g}_B} \mathcal{L}(\boldsymbol{g}_A, \boldsymbol{g}_B; u) \\ &= \max_{\boldsymbol{g}_A} (f_g(\boldsymbol{g}_A) - u^\top A\boldsymbol{g}_A) \\ &\quad + \max_{\boldsymbol{g}_B} (f_y(\boldsymbol{g}_B) - u^\top B\boldsymbol{g}_B) \end{aligned}$$

BINDTWOPAGES($\boldsymbol{g}_A, \boldsymbol{g}_B$)
1 $u^{(0)} \leftarrow 0$
2 **for** $k \leftarrow 0..T$ **do**
3 $\quad \boldsymbol{g}_A \leftarrow \arg\max_{\boldsymbol{g}} f_A(\boldsymbol{g}) - u^{(k)\top} A\boldsymbol{g}$
4 $\quad \boldsymbol{g}_B \leftarrow \arg\max_{\boldsymbol{g}} f_B(\boldsymbol{g}) - u^{(k)\top} B\boldsymbol{g}$
5 $\quad$ **if** $A\boldsymbol{g}_A + B\boldsymbol{g}_B \leq \mathbf{0}$ **then**
6 $\quad\quad$ **return** $\boldsymbol{g}_A, \boldsymbol{g}_B$
7 $\quad$ **else**
8 $\quad\quad u^{(k+1)} \leftarrow u^{(k)} + \alpha^{(k)}(A\boldsymbol{g}_A + B\boldsymbol{g}_B)$
9 **return** $\boldsymbol{g}_A, \boldsymbol{g}_B$

Figure 7: The page binding algorithm.

We instead try to find the solution for $\max_u \mathcal{L}(u)$. By using a subgradient method to calculate $\max_u \mathcal{L}(u)$, we have an algorithm for joint decoding (see Figure 7). $\mathcal{L}(u)$ is divided into two optimization problems which can be decoded easily. Each sub-problem is still a parsing problem for noncrossing graphs. Only the scores of factors are modified (see Line 3 and 4). Specifically, to modify the first order weights of edges, we take a subtraction of $u^\top A$ in the first model and a substraction of $u^\top B$ in the second one. In each iteration, after obtaining two new parsing results, we check whether the constraints are satisfied. If the answer is "yes," we stop and return the merged graph. Otherwise, we update u in a way to increase $\mathcal{L}(u)$ (see Line 8).

5 Experiments

5.1 Data Sets

To evaluate the effectiveness of book embedding in practice, we conduct experiments on unlabeled parsing using four corpora: CCGBank (Hockenmaier and Steedman, 2007), DeepBank (Flickinger et al., 2012), Enju HPSGBank (EnjuBank; Miyao et al., 2004) and Prague Dependency TreeBank (PCEDT; Hajic et al., 2012), We use "standard" training, validation, and test splits to facilitate comparisons. Following previous experimental setup for CCG parsing, we use section 02-21 as training data, section 00 as the development data, and section 23 for testing. The other three data sets are from SemEval 2014 Task 8 (Oepen et al., 2014), and the data splitting policy follows the shared task. All the four data sets are publicly available from LDC (Oepen et al., 2016).

Experiments for CCG analysis were performed using automatically assigned POS-tags generated by a symbol-refined HMM tagger (Huang et al., 2010). For the other three data sets we use POS-tags provided by the shared task. We also use features extracted from trees. We consider two types of trees: (1) syntactic trees provided as a companion analysis by the shared task and CCGBank, (2) pseudo trees (Zhang et al., 2016) automatically extracted from semantic dependency annotations. We utilize the Mate parser (Bohnet, 2010) to generate pseudo trees for all data sets and also syntactic trees for CCG analysis, and use the companion syntactic analysis provided by the shared task for the other three data sets.

5.2 Statistical Disambiguation

Our parsing algorithms can be applied to scores originated from any source, but in our experiments we chose to use the framework of global linear models, deriving our scores as:

$$\text{SCOREPART}(s, p) = \mathbf{w}^\top \phi(s, p)$$

ϕ is a feature-vector mapping and $\mathbf{w}$ is a parameter vector. p may refer to a single arc, a pair of neighboring arcs, or a general tuple of arcs, according to the definition of a parsing model. For details we refer to the source code. We chose the averaged structured perceptron (Collins, 2002) for parameter estimation.

5.3 Results of Practical Parsing

We evaluate five decoding algorithms:

M1 first-order exact algorithm,

M2 second-order exact algorithm with single-side factorization,

M3 second-order approximate algorithm[2] with single-side factorization,

M4 second-order approximate algorithm with single- and both-side factorization,

M5 third-order approximate algorithm with single- and both-side factorization.

5.3.1 Effectiveness of Higher-Order Features

Table 2 lists the accuracy of Maximum Subgraph parsing. The output of our parser was evaluated against each dependency in the corpus. We report unlabeled precision (UP), recall (UR) and f-score (UF). We can see that the first-order model obtains a considerably good precision, with rich features.

[2]The beam size is set to 4 for all approximate algorithms.

Table 2: Parsing accuracy evaluated on the development sets. "MS" is short for Maximum Subgraph parsing. "NC" and "LR" are short for naive combination and Lagrangian Relaxation.

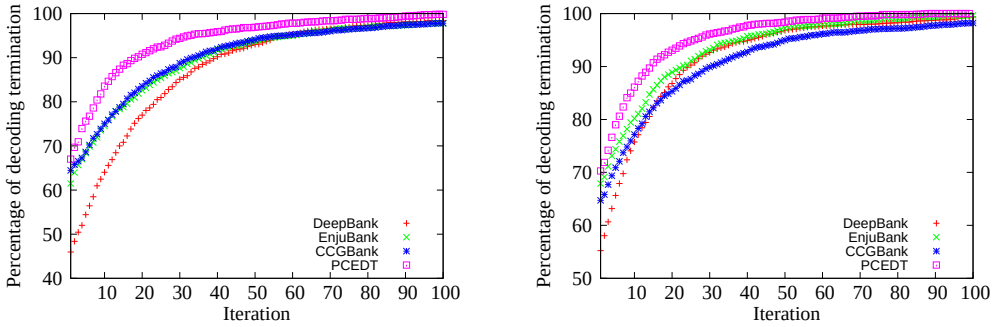

Figure 8: The termination rate of page binding. The left and right diagrams show the results obtained when applying syntactic and pseudo tree features respectively.

But due to the low coverage of the noncrossing dependency graphs, a set of dependencies can not be built. This property has a great impact on recall. Furthermore, we can see that the introduction of higher-order features improves parsing substantially for all data sets, as expected. When pseudo trees are utilized, the improvement is marginal. We think the reason is that we have already included many higher-order features at the stage of pseudo tree parsing.

5.3.2 Effectiveness of Approximate Parsing

Perhaps surprisingly approximate parsing with single-side second order features and cube pruning is even slightly better than exact parsing. This result demonstrates the effectiveness of generalized dependency parsing. Further including third-order features does not improve parsing accuracy.

5.3.3 Effectiveness of Page Binding

When arcs are assigned to two sets, we can separately train two parsers for producing two types of noncrossing dependency graphs. These two parsers can be integrated using a naive merger or a LR-based merger. Table 2 also shows the accuracy obtained by the second-order model M4. The effectivenss of the Lagrangian Relaxation-based algorithm for binding pages is confirmed.

5.3.4 Termination Rate of Page Binding

Figure 8 presents the termination rate with respective to the number of iterations. Here we apply M4 with syntax and pseudo tree features. In practice the Lagrangian Relaxation-based algorithm finds solutions in a few iterations for a majority of sentences. This suggests that even though the joint decoding is an iterative procedure, satisfactory efficiency is still available.

Table 3: Parsing accuracy evaluated on the test sets.

5.4 Comparison with Other Parsers

We show the parsing results on the test data together with some relevant results from related work. We compare our parser with two other systems: (1) ZDSW (Zhang et al., 2016) is a transition-based system that obtains state-of-the-art accuracy; we present the results of their best single parsing model; (2) Peking (Du et al., 2014) is the best-performing system in the shared task; it is a hybrid system that integrate more than ten submodels to achieve high accuracy. Our parser can be taken as a graph-based parser. It reaches state-of-the-art performance produced by the transition-based system. On DeepBank and EnjuBank, the accuracy of our parser is equivalent to ZDSW, while on CCGBank, our parser is significantly better.

There is still a gap between our single parsing model and Peking hybrid model. For a majority of NLP tasks, e.g. parsing (Surdeanu and Manning, 2010), semantic role labeling (Koomen et al., 2005), hybrid systems that combines complementary strength of heterogeneous models perform better. But good individual system is the cornerstone of hybrid systems. Better design of single system almost always benefits system ensemble.

6 Conclusion

We propose a new data-driven parsing framework, namely book embedding, for semantic dependency analysis, viz. mapping from natural language sentences to bilexical semantic dependency graphs. Our work includes two contributions:

1. new algorithms for maximum noncrossing dependency parsing.

2. a Lagrangian Relaxation based algorithm to combine noncrossing dependency subgraphs.

Experiments demonstrate the effectiveness of the book embedding framework across a wide range of conditions. Our graph-based parser obtains state-of-the-art accuracy.

Abstract

Neural word segmentation research has benefited from large-scale raw texts by leveraging them for pretraining character and word embeddings. On the other hand, statistical segmentation research has exploited richer sources of external information, such as punctuation, automatic segmentation and POS. We investigate the effectiveness of a range of external training sources for neural word segmentation by building a modular segmentation model, pretraining the most important submodule using rich external sources. Results show that such pretraining significantly improves the model, leading to accuracies competitive to the best methods on six benchmarks.

1 Introduction

There has been a recent shift of research attention in the word segmentation literature from statistical methods to deep learning (Zheng et al., 2013; Pei et al., 2014; Morita et al., 2015; Chen et al., 2015b; Cai and Zhao, 2016; Zhang et al., 2016b). Neural network models have been exploited due to their strength in *non-sparse representation learning* and *non-linear power* in feature combination, which have led to advances in many NLP tasks. So far, neural word segmentors have given comparable accuracies to the best statictical models.

With respect to *non-sparse representation*, character embeddings have been exploited as a foundation of neural word segmentors. They serve to reduce sparsity of character ngrams, allowing, for example, "猫(cat) 躺(lie) 在(in) 墙角(corner)" to be connected with "狗(dog) 蹲(sit) 在(in) 墙角(corner)" (Zheng et al., 2013), which is infeasible by using sparse one-hot character features. In addition to character embeddings, distributed representations of character bigrams (Mansur et al., 2013; Pei et al., 2014) and words (Morita et al., 2015; Zhang et al., 2016b) have also been shown to improve segmentation accuracies.

With respect to *non-linear modeling power*, various network structures have been exploited to represent contexts for segmentation disambiguation, including multi-layer perceptrons on five-character windows (Zheng et al., 2013; Mansur et al., 2013; Pei et al., 2014; Chen et al., 2015a), as well as LSTMs on characters (Chen et al., 2015b; Xu and Sun, 2016) and words (Morita et al., 2015; Cai and Zhao, 2016; Zhang et al., 2016b). For structured learning and inference, CRF has been used for character sequence labelling models (Pei et al., 2014; Chen et al., 2015b) and structural beam search has been used for word-based segmentors (Cai and Zhao, 2016; Zhang et al., 2016b).

Previous research has shown that segmentation accuracies can be improved by pretraining character and word embeddings over large Chinese texts, which is consistent with findings on other NLP tasks, such as parsing (Andor et al., 2016). Pretraining can be regarded as one way of leveraging external resources to improve accuracies, which is practically highly useful and has become a standard practice in neural NLP. On the other hand, statistical segmentation research has exploited raw texts for semi-supervised learning, by collecting clues from raw texts more thoroughly such as mutual information and punctuation (Li and Sun, 2009; Sun and Xu, 2011), and making use of self-predictions (Wang et al., 2011; Liu and Zhang, 2012). It has also utilised heterogenous annotations such as POS (Ng and Low, 2004; Zhang and Clark, 2008) and segmentation under different

Table 1: A transition based word segmentation example.

standards (Jiang et al., 2009). To our knowledge, such rich external information has not been systematically investigated for neural segmentation.

We fill this gap by investigating rich external pretraining for neural segmentation. Following Cai and Zhao (2016) and Zhang et al. (2016b), we adopt a globally optimised beam-search framework for neural structured prediction (Andor et al., 2016; Zhou et al., 2015; Wiseman and Rush, 2016), which allows word information to be modelled explicitly. Different from previous work, we make our model conceptually simple and modular, so that the most important sub module, namely a five-character window context, can be pretrained using external data. We adopt a multi-task learning strategy (Collobert et al., 2011), casting each external source of information as a auxiliary classification task, sharing a five-character window network. After pretraining, the character window network is used to initialize the corresponding module in our segmentor.

Results on 6 different benchmarks show that our method outperforms the best statistical and neural segmentation models consistently, giving the best reported results on 5 datasets in different domains and genres. Our implementation is based on *LibN3L*[1] (Zhang et al., 2016a). Code and models can be downloaded from `http://gitHub.com/jiesutd/RichWordSegmentor`

2 Related Work

Work on *statistical* word segmentation dates back to the 1990s (Sproat et al., 1996). State-of-the-art approaches include *character* sequence labeling models (Xue et al., 2003) using CRFs (Peng et al., 2004; Zhao et al., 2006) and max-margin structured models leveraging *word* features (Zhang and Clark, 2007; Sun et al., 2009; Sun, 2010). Semi-supervised methods have been applied to both character-based and word-based models, exploring external training data for better segmentation (Sun and Xu, 2011; Wang et al., 2011; Liu and Zhang, 2012; Zhang et al., 2013). Our work belongs to recent *neural* word segmentation.

To our knowledge, there has been no work in the literature systematically investigating rich external resources for neural word segmentation training. Closest in spirit to our work, Sun and Xu (2011) empirically studied the use of various external resources for enhancing a statistical segmentor, including character mutual information, access variety information, punctuation and other statistical information. Their baseline is similar to ours in the sense that both character and word contexts are considered. On the other hand, their model is statistical while ours is neural. Consequently, they integrate external knowledge as features, while we integrate it by shared network parameters. Our results show a similar degree of error reduction compared to theirs by using external data.

Our model inherits from previous findings on context representations, such as character windows (Mansur et al., 2013; Pei et al., 2014; Chen et al., 2015a) and LSTMs (Chen et al., 2015b; Xu and Sun, 2016). Similar to Zhang et al. (2016b) and Cai and Zhao (2016), we use word context on top of character context. However, words play a relatively less important role in our model, and we find that word LSTM, which has been used by all previous neural segmentation work, is unnecessary for our model. Our model is conceptually simpler and more modularised compared with

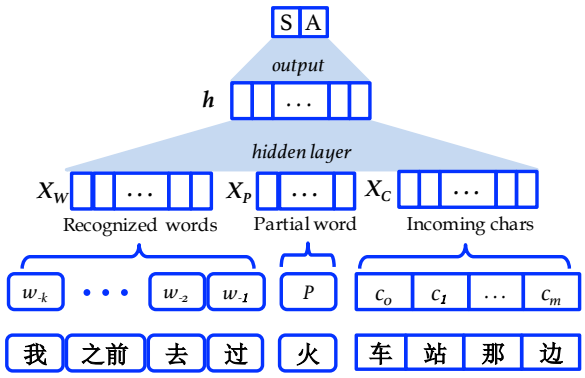

Figure 1: Overall model.

Zhang et al. (2016b) and Cai and Zhao (2016), allowing a central sub module, namely a five-character context window, to be pretrained.

3 Model

Our segmentor works incrementally from left to right, as the example shown in Table 1. At each step, the state consists of a sequence of words that have been fully recognized, denoted as $W = [w_{-k}, w_{-k+1}, ..., w_{-1}]$, a current partially recognized word P, and a sequence of next incoming characters, denoted as $C = [c_0, c_1, ..., c_m]$, as shown in Figure 1. Given an input sentence, W and P are initialized to $[\,]$ and ϕ, respectively, and C contains all the input characters. At each step, a decision is made on c_0, either appending it as a part of P, or seperating it as the beginning of a new word. The incremental process repeats until C is empty and P is null again ($C = [\,]$, $P = \phi$). Formally, the process can be regarded as a state-transition process, where a state is a tuple $S = \langle W, P, C\rangle$, and the transition actions include SEP (*seperate*) and APP (*append*), as shown by the deduction system in Figure 2[2].

In the figure, V denotes the score of a state, given by a neural network model. The score of the initial state (i.e. axiom) is 0, and the score of a non-axiom state is the sum of scores of all incremental decisions resulting in the state. Similar to Zhang et al. (2016b) and Cai and Zhao (2016), our model is a global structural model, using the overall score to disambiguate states, which correspond to sequences of inter-dependent transition actions.

Different from previous work, the structure of

$$\text{Axiom:}\quad S = \langle [\,], \phi, C\rangle,\ V = 0$$
$$\text{Goal:}\quad S = \langle W, \phi, [\,]\rangle,\ V = V_{final}$$

$$\text{SEP:}\quad \frac{S = \langle W, P, c_0|C\rangle,\ V}{S' = \langle W|P, c_0, C\rangle,\ V' = V + Score(S, \text{SEP})}$$

$$\text{APP:}\quad \frac{S = \langle W, P, c_0|C\rangle,\ V}{S' = \langle W, P \oplus c_0, C\rangle,\ V' = V + Score(S, \text{APP})}$$

Figure 2: Deduction system, where $\oplus$ denotes string concatenation.

our scoring network is shown in Figure 1. It consists of three main layers. On the bottom is a *representation layer*, which derives dense representations X_W, X_P and X_C for W, P and C, respectively. We compare various distributed representations and neural network structures for learning X_W, X_P and X_C, detailed in Section 3.1. On top of the representation layer, we use a *hidden layer* to merge X_W, X_P and X_C into a single vector

$$h = tanh(W_{hW} \cdot X_W + W_{hP} \cdot X_P + W_{hC} \cdot X_C + b_h) \quad (1)$$

The hidden feature vector h is used to represent the state $S = \langle W, P, C\rangle$, for calculating the scores of the next action. In particular, a linear *output layer* with two nodes is employed:

$$o = W_o \cdot h + b_o \quad (2)$$

The first and second node of o represent the scores of SEP and APP given S, namely $Score(S, \text{SEP})$, $Score(S, \text{APP})$ respectively.

3.1 Representation Learning

Characters. We investigate two different approaches to encode incoming characters, namely a *window approach* and an *LSTM approach*. For the former, we follow prior methods (Xue et al., 2003; Pei et al., 2014), using five-character window $[c_{-2}, c_{-1}, c_0, c_1, c_2]$ to represent incoming characters. Shown in Figure 3, a multi-layer perceptron (MLP) is employed to derive a five-character window vector D_C from single-character vector representations $V_{c_{-2}}, V_{c_{-1}}, V_{c_0}, V_{c_1}, V_{c_2}$.

$$D_C = MLP([V_{c_{-2}}; V_{c_{-1}}; V_{c_0}; V_{c_1}; V_{c_2}]) \quad (3)$$

For the latter, we follow recent work (Chen et al., 2015b; Zhang et al., 2016b), using a bi-directional LSTM to encode input character sequence.[3] In particular, the bi-directional LSTM

[2] An end of sentence symbol $\langle/s\rangle$ is added to the input so that the last partial word can be put onto W as a full word before segmentation finishes.

[3] The LSTM variation with coupled input and forget gate but without peephole connections is applied (Gers and Schmidhuber, 2000)

hidden vector $[\overleftarrow{h_C}(c_0); \overrightarrow{h_C}(c_0)]$ of the next incoming character c_0 is used to represent the coming characters $[c_0, c_1, ...]$ given a state. Intuitively, a five-character window provides a local context from which the meaning of the middle character can be better disambiguated. LSTM, on the other hand, captures larger contexts, which can contain more useful clues for dismbiguation but also irrelevant information. It is therefore interesting to investigate a combination of their strengths, by first deriving a locally-disambiguated version of c_0, and then feed it to LSTM for a globally disambiguated representation.

Now with regard to the single-character vector representation $V_{c_i} (i \in [-2, 2])$, we follow previous work and consider both character embedding $e^c(c_i)$ and character-bigram embedding $e^b(c_i, c_{i+1})$, investigating the effect of each on the accuracies. When both $e^c(c_i)$ and $e^b(c_i, c_{i+1})$ are utilized, the concatenated vector is taken as V_{c_i}.

Partial Word. We take a very simple approach to representing the partial word P, by using the embedding vectors of its first and last characters, as well as the embedding of its length. Length embeddings are randomly initialized and then tuned in model training. X_P has relatively less influence on the empirical segmentation accuracies.

$$X_P = [e^c(P[0]); e^c(P[-1]); e^l(\text{LEN}(P))] \quad (4)$$

Word. Similar to the character case, we investigate two different approaches to encoding incoming characters, namely a *window approach* and an *LSTM approach*. For the former, we follow prior methods (Zhang and Clark, 2007; Sun, 2010), using the two-word window $[w_{-2}, w_{-1}]$ to represent recognized words. A hidden layer is employed to derive a two-word vector X_W from single word embeddings $e^w(w_{-2})$ and $e^w(w_{-1})$.

$$X_W = tanh(W_w[e^w(w_{-2}); e^w(w_{-1})] + b_w) \quad (5)$$

For the latter, we follow Zhang et al. (2016b) and Cai and Zhao (2016), using an uni-directional LSTM on words that have been recognized.

3.2 Pretraining

Neural network models for NLP benefit from pretraining of word/character embeddings, learning distributed sementic information from large raw texts for reducing sparsity. The three basic elements in our neural segmentor, namely characters, character bigrams and words, can all be pretrained

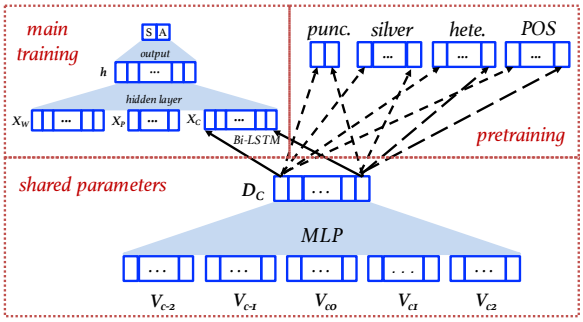

Figure 3: Shared character representation.

over large unsegmented data. We pretrain the five-character window network in Figure 3 as an unit, learning the MLP parameter together with character and bigram embeddings. We consider four types of commonly explored external data to this end, all of which have been studied for statistical word segmentation, but not for neural network segmentors.

Raw Text. Although raw texts do not contain explicit word boundary information, statistics such as mutual information between consecutive characters can be useful features for guiding segmentation (Sun and Xu, 2011). For neural segmentation, these distributional statistics can be implicitly learned by pretraining character embeddings. We therefore consider a more explicit clue for pretraining our character window network, namely punctuations (Li and Sun, 2009).

Punctuation can serve as a type of explicit markup (Spitkovsky et al., 2010), indicating that the two characters on its left and right belong to two different words. We leverage this source of information by extracting character five-grams excluding punctuation from raw sentences, using them as inputs to classify whether there is punctuation before middle character. Denoting the resulting five character window as $[c_{-2}, c_{-1}, c_0, c_1, c_2]$, the MLP in Figure 3 is used to derive its representation D_C, which is then fed to a softmax layer for binary classification:

$$P(punc) = softmax(W_{punc} \cdot D_C + b_{punc}) \quad (6)$$

Here $P(punc)$ indicates the probability of a punctuation mark existing before c_0. Standard back-propagation training of the MLP in Figure 3 can be done jointly with the training of W_{punc} and b_{punc}. After such training, the embedding V_{ci} and MLP values can be used to initialize the corresponding parameters for D_C in the main segmentor, before

its training.

Automatically Segmented Text. Large texts automatically segmented by a baseline segmentor can be used for self-training (Liu and Zhang, 2012) or deriving statistical features (Wang et al., 2011). We adopt a simple strategy, taking automatically segmented text as silver data to pretrain the five-character window network. Given $[c_{-2}, c_{-1}, c_0, c_1.c_2]$, D_C is derived using the MLP in Figure 3, and then used to classify the segmentation of c_0 into B(begining)/M(middle)/E(end)/S(single character word) labels.

$$P(silver) = softmax(W_{silv} \cdot D_C + b_{silv}) \quad (7)$$

Here W_{silv} and b_{silv} are model parameters. Training can be done in the same way as training with punctuation.

Heterogenous Training Data. Multiple segmentation corpora exist for Chinese, with different segmentation granularities. There has been investigation on leveraging two corpora under different annotation standards to improve statistical segmentation (Jiang et al., 2009). We try to utilize heterogenous treebanks by taking an external treebank as labeled data, training a B/M/E/S classifier for the character windows network.

$$P(hete) = softmax(W_{hete} \cdot D_C + b_{hete}) \quad (8)$$

POS Data. Previous research has shown that POS information is closely related to segmentation (Ng and Low, 2004; Zhang and Clark, 2008). We verify the utility of POS information for our segmentor by pretraining a classifier that predicts the POS on each character, according to the character window representation D_C. In particular, given $[c_{-2}, c_{-1}, c_0, c_1, c_2]$, the POS of the word that c_0 belongs to is used as the output.

$$P(pos) = softmax(W_{pos} \cdot D_C + b_{pos}) \quad (9)$$

Multitask Learning. While each type of external training data can offer one source of segmentation information, different external data can be complimentary to each other. We aim to inject all sources of information into the character window representation D_C by using it as a shared representation for different classification tasks. Neural model have been shown capable of doing multi-task learning via parameter sharing (Collobert et al., 2011). Shown in Figure 3, in our case, the output layer for each task is independent, but the hidden layer D_C and all layers below D_C are shared.

For training with all sources above, we randomly sample sentences from the Punc./Auto-seg/Heter./POS sources with the ratio of 10/1/1/1, for each sentence in punctuation corpus we take only 2 characters (character before and after the punctuation) as input instances.

Algorithm 1: Training

UPDATE(y^i, $\hat{y}$,Θ)
return

4 Decoding and Training

To train the main segmentor, we adopt the global transition-based learning and beam-search strategy of Zhang and Clark (2011). For decoding, standard beam search is used, where the *B* best partial output hypotheses at each step are maintained in an *agenda*. Initially, the agenda contains only the start state. At each step, all hypotheses in the agenda are expanded, by applying all possible actions and *B* highest scored resulting hypotheses are used as the agenda for the next step.

For training, the same decoding process is applied to each training example (x^i, y^i). At step j, if the gold-standard sequence of transition actions y^i_j falls out of the agenda, max-margin update is performed by taking the current best hypothesis $\hat{y}_j$ in the beam as a negative example, and y^i_j as

Paramater	Value	Paramater	Value
α	0.01	$size(e^c)$	50
λ	10^{-8}	$size(e^b)$	50
p	0.2	$size(e^w)$	50
η	0.2	$size(e^l)$	20
MLP layer	2	$size(X_C)$	150
beam B	8	$size(X_P)$	50
$size(h)$	200	$size(X_W)$	100

Table 2: Hyper-parameter values.

a positive example. The loss function is

$$l(\hat{y}_j, y^i_j) = max((score(\hat{y}_j) + \eta \cdot \delta(\hat{y}_j, y^i_j) - score(y^i_j)), 0), \quad (10)$$

where $\delta(\hat{y}_j, y^i_j)$ is the number of incorrect local decisions in $\hat{y}_j$, and η controls the score margin.

The strategy above is *early-update* (Collins and Roark, 2004). On the other hand, if the gold-standard hypothesis does not fall out of the agenda until the full sentence has been segmented, a final update is made between the highest scored hypothesis $\hat{y}$ (non-gold standard) in the agenda and the gold-standard y^i, using exactly the same loss function. Pseudocode for the online learning algorithm is shown in Algorithm 1.

We use *Adagrad* (Duchi et al., 2011) to optimize model parameters, with an initial learning rate α. $L2$ regularization and dropout (Srivastava et al., 2014) on input are used to reduce overfitting, with a $L2$ weight λ and a dropout rate p. All the parameters in our model are randomly initialized to a value $(-r, r)$, where $r = \sqrt{\frac{6.0}{fan_{in}+fan_{out}}}$ (Bengio, 2012). We fine-tune character and character bigram embeddings, but not word embeddings, according to Zhang et al. (2016b).

5 Experiments

5.1 Experimental Settings

Data. We use Chinese Treebank 6.0 (CTB6) (Xue et al., 2005) as our main dataset. Training, development and test set splits follow previous work (Zhang et al., 2014). In order to verify the robustness of our model, we additionally use SIGHAN 2005 bake-off (Emerson, 2005) and NLPCC 2016 shared task for Weibo segmentation (Qiu et al., 2016) as test datasets, where the standard splits are used. For pretraining embedding of words, characters and character bigrams, we use Chinese Gigaword (simplified Chinese sections)[4], automatically segmented using ZPar 0.6 off-the-shelf (Zhang and Clark, 2007), the statictics of which are shown in Table 3.

	Source	#Chars	#Words	#Sents
Raw data	Gigaword	116.5m	–	–
Auto seg	Gigaword	398.2m	238.6m	12.04m
Hete.	People's Daily	10.14m	6.17m	104k
POS	People's Daily	10.14m	6.17m	104k

Table 3: Statistics of external data.

For pretraining character representations, we extract punctuation classification data from the Gigaword corpus, and use the word-based ZPar and a standard character-based CRF model (Tseng et al., 2005) to obtain automatic segmentation results. We compare pretraining using ZPar results only and using results that both segmentors agree on. For heterogenous segmentation corpus and POS data, we use a People's Daily corpus of 5 months[5]. Statistics are listed in Table 3.

Evaluation. The standard word precision, recall and F1 measure (Emerson, 2005) are used to evaluate segmentation performances.

Hyper-parameter Values. We adopt commonly used values for most hyperparameters, but tuned the sizes of hidden layers on the development set. The values are summarized in Table 2.

5.2 Development Experiments

We perform development experiments to verify the usefulness of various context representations, network configurations and different pretraining methods, respectively.

5.2.1 Context Representations

The influence of character and word context representations are empirically studied by varying the network structures for X_C and X_W in Figure 1, respectively. All the experiments in this section are performed using a beam size of 8.

Character Context. We fix the word representation X_W to a 2-word window and compare different character context representations. The results are shown in Table 4, where "no char" represents our model without X_C, "5-char window" represents a five-character window context, "char LSTM" represents character LSTM context and

[4]https://catalog.ldc.upenn.edu/LDC2011T13
[5]http://www.icl.pku.edu.cn/icl_res

Character	P	R	F
No char	82.19	87.20	84.62
5-char window	95.33	95.50	95.41
char LSTM	95.21	95.82	95.51
5-char window+LSTM	95.77	95.95	**95.86**
-char emb	95.20	95.19	95.20
-bichar emb	93.87	94.67	94.27

Table 4: Influence of character contexts.

Word	P	R	F
No word	95.50	95.83	95.66
1-word window	95.70	95.85	95.78
2-word window	95.77	95.95	**95.86**
3-word window	95.80	95.85	95.83
word LSTM	95.71	95.97	95.84
2-word window+LSTM	95.74	95.95	95.84

Table 5: Influence of word contexts.

"5-char window + LSTM" represents a combination, detailed in Section 3.1. "-char emb" and "-bichar emb" represent the combined window and LSTM context without character and character-bigram information, respectively.

As can be seen from the table, without character information, the F-score is 84.62%, demonstrating the necessity of character contexts. Using window and LSTM representations, the F-scores increase to 95.41% and 95.51%, respectively. A combination of the two lead to further improvement, showing that local and global character contexts are indeed complementary, as hypothesized in Section 3.1. Finally, by removing character and character-bigram embeddings, the F-score decreases to 95.20% and 94.27%, respectively, which suggests that character bigrams are more useful compared to character unigrams. This is likely because they contain more distinct tokens and hence offer a larger parameter space.

Word Context. The influence of various word contexts are shown in Table 5. Without using word information, our segmentor gives an F-score of 95.66% on the development data. Using a context of only w_{-1} (1-word window), the F-measure increases to 95.78%. This shows that word contexts are far less important in our model compared to character contexts, and also compared to word contexts in previous word-based segmentors (Zhang et al., 2016b; Cai and Zhao, 2016). This is likely due to the difference in our neural network structures, and that we fine-tune both character and character bigram embeddings, which significantly enlarges the adjustable parameter space as compared with Zhang et al. (2016b). The fact that word contexts can contribute relatively less than characters in a word is also not surprising in the sense that word-based neural segmentors do not outperform the best character-based models by large margins. Given that character context is what we pretrain, our model relies more heavily on them.

With both w_{-2} and w_{-1} being used for the context, the F-score further increases to 95.86%, showing that a 2-word window is useful by offering more contextual information. On the other hand, when w_{-3} is also considered, the F-score does not improve further. This is consistent with previous findings of statistical word segmentation (Zhang and Clark, 2007), which adopt a 2-word context. Interestingly, using a word LSTM does not bring further improvements, even when it is combined with a window context. This suggests that global word contexts may not offer crucial additional information compared with local word contexts. Intuitively, words are significantly less polysemous compared with characters, and hence can serve as effective contexts even if used locally, to supplement a more crucial character context.

5.2.2 Stuctured Learning and Inference

We verify the effectiveness of structured learning and inference by measuring the influence of beam size on the baseline segmentor. Figure 4 shows the F-scores against different numbers of training iterations with beam size 1,2,4,8 and 16, respectively. When the beam size is 1, the inference is local and greedy. As the size of the beam increases, more global structural ambiguities can be resolved since learning is designed to guide search. A contrast between beam sizes 1 and 2 demonstrates the usefulness of structured learning and inference. As the beam size increases, the gain by doubling the beam size decreases. We choose a beam size of 8 for the remaining experiments for a tradeoff between speed and accuracy.

5.2.3 Pretraining Results

Table 6 shows the effectiveness of rich pretraining of D_c on the development set. In particular, by using punctuation information, the F-score increases from 95.86% to 96.25%, with a relative error reduction of 9.4%. This is consistent with

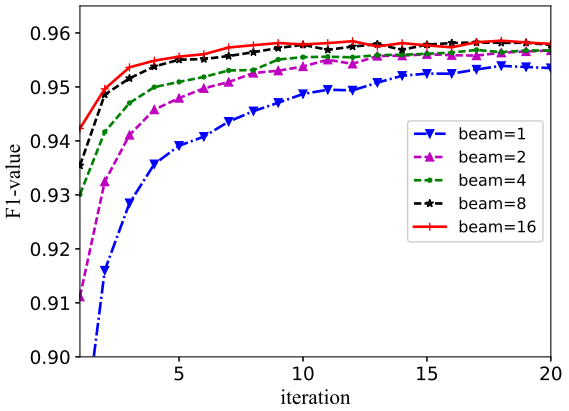

Figure 4: F1 measure against the training epoch.

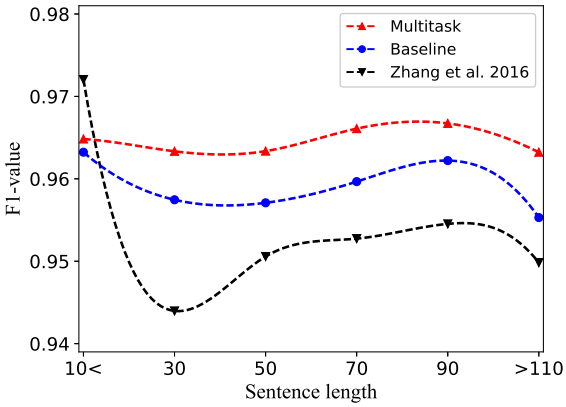

Figure 5: F1 measure against the sentence length.

Pretrain	P	R	F	ER%
Baseline	95.77	95.95	95.86	0

Table 6: Influence of pretraining.

the observation of Sun and Xu (2011), who show that punctuation is more effective compared with mutual information and access variety as semi-supervised data for a statistical word segmentation model. With automatically-segmented data[6], heterogenous segmentation and POS information, the F-score increases to 96.26%, 96.27% and 96.22%, respectively, showing the relevance of all information sources to neural segmentation, which is consistent with observations made for statistical word segmentation (Jiang et al., 2009; Wang et al., 2011; Zhang et al., 2013). Finally, by integrating all above information via multi-task learning, the F-score is further improved to 96.48%, with a 15.0% relative error reduction.

5.2.4 Comparision with Zhang et al. (2016b)

Both our model and Zhang et al. (2016b) use global learning and beam search, but our network is different. Zhang et al. (2016b) utilizes the action history with LSTM encoder, while we use partial word rather than action information. Besides, the character and character bigram embeddings are fine-tuned in our model while Zhang et al. (2016b) set the embeddings fixed during training.

[6]By using ZPar alone, the auto-segmented result is 96.02%, less than using results by matching ZPar and the CRF segmentor outputs.

We study the F-measure distribution with respect to sentence length on our baseline model, multi-task pretraining model and Zhang et al. (2016b). In particular, we cluster the sentences in the development dataset into 6 categories based on their length and evaluate their F1-values, respectively. As shown in Figure 5, the models give different error distributions, with our models being more robust to the sentence length compared with Zhang et al. (2016b). Their model is better on very short sentences, but worse on all other cases. This shows the relative advantages of our model.

5.3 Final Results

Our final results on CTB6 are shown in Table 7, which lists the results of several current state-of-the-art methods. Without multitask pretraining, our model gives an F-score of 95.44%, which is higher than the neural segmentor of Zhang et al. (2016b), which gives the best accuracies among pure neural segments on this dataset. By using multitask pretraining, the result increases to 96.21%, with a relative error reduction of 16.9%. In comparison, Sun and Xu (2011) investigated heterogenous semi-supervised learning on a state-of-the-art *statistical* model, obtaining a relative error reduction of 13.8%. Our findings show that external data can be as useful for *neural* segmentation as for statistical segmentation.

Our final results compare favourably to the best statistical models, including those using semi-supervised learning (Sun and Xu, 2011; Wang et al., 2011), and those leveraging joint POS and syntactic information (Zhang et al., 2014). In addition, it also outperforms the best neural models, in particular Zhang et al. (2016b)*, which is a hybrid neural and statistical model, integrating man-

ual discrete features into their word-based neural model. We achieve the best reported F-score on this dataset. To our knowledge, this is the first time a pure neural network model outperforms all existing methods on this dataset, allowing the use of external data [7]. We also evaluate our model pretrained only on punctuation and auto-segmented data, which do not include additional manual labels. The results on CTB test data show the accuracy of 95.8% and 95.7%, respectivley, which are comparable with those statistical semi-supervised methods (Sun and Xu, 2011; Wang et al., 2011). They are also among the top performance methods in Table 7. Compared with discrete semi-supervised methods (Sun and Xu, 2011; Wang et al., 2011), our semi-supervised model is free from hand-crafted features.

In addition to CTB6, which has been the most commonly adopted by recent segmentation research, we additionally evaluate our results on the SIGHAN 2005 bakeoff and Weibo datasets, to examine cross domain robustness. Different state-of-the-art methods for which results are recorded on these datasets are listed in Table 8. Most neural models reported results only on the PKU [8] and MSR datasets of the bakeoff test sets, which are in simplified Chinese. The AS and CityU corpora are in traditional Chinese, sourced from Taiwan and Hong Kong corpora, respectively. We map them into simplified Chinese before segmentation. The Weibo corpus is in a yet different genre, being social media text. Xia et al. (2016) achieved the best results on this dataset by using a statistical model with features learned using external lexicons, the CTB7 corpus and the People Daily corpus. Similar to Table 7, our method gives the best accuracies on all corpora except for MSR, where it underperforms the hybrid model of Zhang et al. (2016b) by 0.2%. To our knowledge, we are the first to report results for a neural segmentor on more than 3 datasets, with competitive results consistently. It verifies that knowledge learned from a certain set of resources can be used to enhance cross-domain robustness in training a neural segmentor for different datasets, which is of practical importance.

6 Conclusion

We investigated rich external resources for enhancing neural word segmentation, by building a globally optimised beam-search model that leverages both character and word contexts. Taking each type of external resource as an auxiliary classification task, we use neural multi-task learning to pre-train a set of shared parameters for character contexts. Results show that rich pretraining leads to 15.4% relative error reduction, and our model gives results highly competitive to the best systems on six different benchmarks.

Acknowledgments

We thank the anonymous reviewers for their insightful comments and the support of NSFC 61572245. We would like to thank Meishan Zhang for his insightful discussion and assisting coding. Yue Zhang is the corresponding author.

[7] We did not investigate the use of lexicons (Chen et al., 2015a,b) in our research, since lexicons might cover different OOV in the training and test data, and hence directly affecting the accuracies, which makes it relatively difficult to compare different methods fairly unless a single lexicon is used for all methods, as observed by Cai and Zhao (2016).

[8] We notice that both PKU dataset and our heterogenous data are based on the news of People's Daily. While the heterogenous data only collect news from Febuary 1998 to June 1998, it does not contain the sentences in the dev and test datasets of PKU.

Abstract

In this paper, we propose a new method for calculating the output layer in neural machine translation systems. The method is based on predicting a binary code for each word and can reduce computation time/memory requirements of the output layer to be logarithmic in vocabulary size in the best case. In addition, we also introduce two advanced approaches to improve the robustness of the proposed model: using error-correcting codes and combining softmax and binary codes. Experiments on two English ↔ Japanese bidirectional translation tasks show proposed models achieve BLEU scores that approach the softmax, while reducing memory usage to the order of less than 1/10 and improving decoding speed on CPUs by x5 to x10.

1 Introduction

When handling broad or open domains, machine translation systems usually have to handle a large vocabulary as their inputs and outputs. This is particularly a problem in neural machine translation (NMT) models (Sutskever et al., 2014), such as the attention-based models (Bahdanau et al., 2014; Luong et al., 2015) shown in Figure 1. In these models, the output layer is required to generate a specific word from an internal vector, and a large vocabulary size tends to require a large amount of computation to predict each of the candidate word probabilities.

Because this is a significant problem for neural language and translation models, there are a number of methods proposed to resolve this problem, which we detail in Section 2.2. However, none of these previous methods simultaneously satisfies the following desiderata, all of which, we argue, are desirable for practical use in NMT systems:

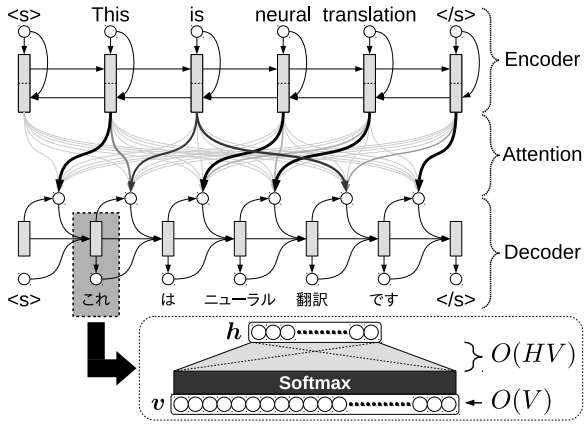

Figure 1: Encoder-decoder-attention NMT model and computation amount of the output layer.

Memory efficiency: The method should not require large memory to store the parameters and calculated vectors to maintain scalability in resource-constrained environments.

Time efficiency: The method should be able to train the parameters efficiently, and possible to perform decoding efficiently with choosing the candidate words from the full probability distribution. In particular, the method should be performed fast on general CPUs to suppress physical costs of computational resources for actual production systems.

Compatibility with parallel computation: It should be easy for the method to be mini-batched and optimized to run efficiently on GPUs, which are essential for training large NMT models.

In this paper, we propose a method that satisfies all of these conditions: requires significantly less memory, fast, and is easy to implement mini-batched on GPUs. The method works by not predicting a softmax over the entire output vocab-

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 850–860
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1079

ulary, but instead by encoding each vocabulary word as a vector of binary variables, then independently predicting the bits of this binary representation. In order to represent a vocabulary size of 2^n, the binary representation need only be at least n bits long, and thus the amount of computation and size of parameters required to select an output word is only $O(\log V)$ in the size of the vocabulary V, a great reduction from the standard linear increase of $O(V)$ seen in the original softmax.

While this idea is simple and intuitive, we found that it alone was not enough to achieve competitive accuracy with real NMT models. Thus we make two improvements: First, we propose a hybrid model, where the high frequency words are predicted by a standard softmax, and low frequency words are predicted by the proposed binary codes separately. Second, we propose the use of convolutional error correcting codes with Viterbi decoding (Viterbi, 1967), which add redundancy to the binary representation, and even in the face of localized mistakes in the calculation of the representation, are able to recover the correct word.

In experiments on two translation tasks, we find that the proposed hybrid method with error correction is able to achieve results that are competitive with standard softmax-based models while reducing the output layer to a fraction of its original size.

2 Problem Description and Prior Work

2.1 Formulation and Standard Softmax

Most of current NMT models use *one-hot representations* to represent the words in the output vocabulary – each word w is represented by a unique sparse vector $\boldsymbol{e}_{\mathrm{id}(w)} \in \mathbb{R}^V$, in which only one element at the position corresponding to the word ID $\mathrm{id}(w) \in \{x \in \mathbb{N} \mid 1 \leq x \leq V\}$ is 1, while others are 0. V represents the vocabulary size of the target language. NMT models optimize network parameters by treating the one-hot representation $\boldsymbol{e}_{\mathrm{id}(w)}$ as the true probability distribution, and minimizing the cross entropy between it and the softmax probability $\boldsymbol{v}$:

$$
\begin{aligned}
L_{\mathcal{H}}(\boldsymbol{v}, \mathrm{id}(w)) &:= \mathcal{H}(\boldsymbol{e}_{\mathrm{id}(w)}, \boldsymbol{v}), && (1)\\
&= \log \operatorname{sum} \exp \boldsymbol{u} - u_{\mathrm{id}(w)}, && (2)\\
\boldsymbol{v} &:= \exp \boldsymbol{u} / \operatorname{sum} \exp \boldsymbol{u}, && (3)\\
\boldsymbol{u} &:= W_{hu}\boldsymbol{h} + \boldsymbol{\beta}_u, && (4)
\end{aligned}
$$

where $\operatorname{sum} \boldsymbol{x}$ represents the sum of all elements in $\boldsymbol{x}$, x_i represents the i-th element of $\boldsymbol{x}$, $W_{hu} \in \mathbb{R}^{V \times H}$ and $\boldsymbol{\beta}_u \in \mathbb{R}^V$ are trainable parameters and H is the total size of hidden layers directly connected to the output layer.

According to Equation (4), this model clearly requires time/space computation in proportion to $O(HV)$, and the actual load of the computation of the output layer is directly affected by the size of vocabulary V, which is typically set around tens of thousands (Sutskever et al., 2014).

2.2 Prior Work on Suppressing Complexity of NMT Models

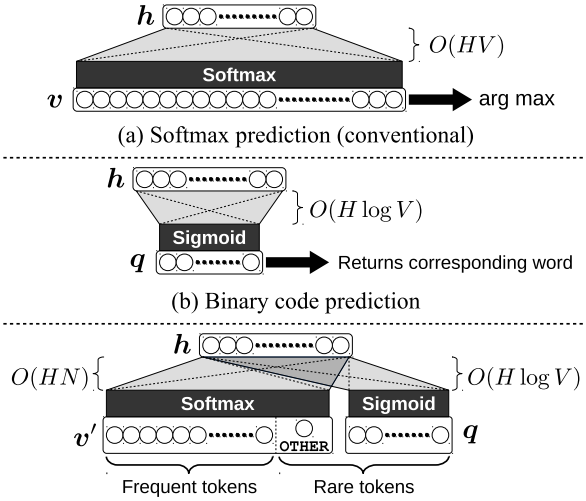
Several previous works have proposed methods to reduce computation in the output layer. The *hierarchical softmax* (Morin and Bengio, 2005) predicts each word based on binary decision and reduces computation time to $O(H \log V)$. However, this method still requires $O(HV)$ space for the parameters, and requires calculation much more complicated than the standard softmax, particularly at test time.

The *differentiated softmax* (Chen et al., 2016) divides words into clusters, and predicts words using separate part of the hidden layer for each word clusters. This method make the conversion matrix of the output layer sparser than a fully-connected softmax, and can reduce time/space computation amount by ignoring zero part of the matrix. However, this method restricts the usage of hidden layer, and the size of the matrix is still in proportion to V.

Sampling-based approximations (Mnih and Teh, 2012; Mikolov et al., 2013) to the denominator of the softmax have also been proposed to reduce calculation at training. However, these methods are basically not able to be applied at test time, still require heavy computation like the standard softmax.

Vocabulary selection approaches (Mi et al., 2016; L'Hostis et al., 2016) can also reduce the vocabulary size at testing, but these methods abandon full search over the target space and the quality of picked vocabularies directly affects the translation quality.

Other methods using characters (Ling et al., 2015) or subwords (Sennrich et al., 2016; Chitnis and DeNero, 2015) can be applied to suppress the vocabulary size, but these methods also make for longer sequences, and thus are not a direct solution to problems of computational efficiency.



(a) Softmax prediction (conventional)

(b) Binary code prediction

(c) Hybrid prediction (softmax & binary code)

Figure 2: Designs of output layers.

3 Binary Code Prediction Models

3.1 Representing Words using Bit Arrays

Figure 2(a) shows the conventional softmax prediction, and Figure 2(b) shows the binary code prediction model proposed in this study. Unlike the conventional softmax, the proposed method predicts each output word indirectly using dense bit arrays that correspond to each word. Let $\boldsymbol{b}(w) := [b_1(w), b_2(w), \cdots, b_B(w)] \in \{0,1\}^B$ be the target bit array obtained for word w, where each $b_i(w) \in \{0,1\}$ is an independent binary function given w, and B is the number of bits in whole array. For convenience, we introduce some constraints on $\boldsymbol{b}$. First, a word w is mapped to only one bit array $\boldsymbol{b}(w)$. Second, all unique words can be discriminated by $\boldsymbol{b}$, i.e., all bit arrays satisfy that:[1]

$$\mathrm{id}(w) \neq \mathrm{id}(w') \Rightarrow \boldsymbol{b}(w) \neq \boldsymbol{b}(w'). \quad (5)$$

Third, multiple bit arrays can be mapped to the same word as described in Section 3.5. By considering second constraint, we can also constrain $B \geq \lceil \log_2 V \rceil$, because $\boldsymbol{b}$ should have at least V unique representations to distinguish each word. The output layer of the network independently predicts B probability values $\boldsymbol{q} := [q_1(\boldsymbol{h}), q_2(\boldsymbol{h}), \cdots, q_B(\boldsymbol{h})] \in [0,1]^B$ using the current hidden values $\boldsymbol{h}$ by logistic regressions:

$$\boldsymbol{q}(\boldsymbol{h}) = \sigma(W_{hq}\boldsymbol{h} + \boldsymbol{\beta}_q), \quad (6)$$
$$\sigma(\boldsymbol{x}) := 1/(1+\exp(-\boldsymbol{x})), \quad (7)$$

where $W_{hq} \in \mathbb{R}^{B\times H}$ and $\boldsymbol{\beta}_q \in \mathbb{R}^B$ are trainable parameters. When we assume that each q_i is the probability that "the i-th bit becomes 1," the joint probability of generating word w can be represented as:

$$\Pr(\boldsymbol{b}(w)|\boldsymbol{q}(\boldsymbol{h})) := \prod_{i=1}^{B} \left(b_i q_i + \bar{b}_i \bar{q}_i\right), \quad (8)$$

where $\bar{x} := 1 - x$. We can easily obtain the maximum-probability bit array from $\boldsymbol{q}$ by simply assuming the i-th bit is 1 if $q_i \geq 1/2$, or 0 otherwise. However, this calculation may generate invalid bit arrays which do not correspond to actual words according to the mapping between words and bit arrays. For now, we simply assume that $w = \texttt{UNK}$ (*unknown*) when such bit arrays are obtained, and discuss alternatives later in Section 3.5.

The constraints described here are very general requirements for bit arrays, which still allows us to choose between a wide variety of mapping functions. However, designing the most appropriate mapping method for NMT models is not a trivial problem. In this study, we use a simple mapping method described in Algorithm 1, which was empirically effective in preliminary experiments.[2] Here, $\mathcal{V}$ is the set of V target words including 3 extra markers: UNK, BOS (*begin-of-sentence*), and EOS (*end-of-sentence*), and $\mathrm{rank}(w) \in \mathbb{N}_{>0}$ is the rank of the word according to their frequencies in the training corpus. Algorithm 1 is one of the minimal mapping methods (i.e., satisfying $B = \lceil \log_2 V \rceil$), and generated bit arrays have the characteristics that their *higher* bits roughly represents the frequency of corresponding words (e.g., if w is frequently appeared in the training corpus, higher bits in $\boldsymbol{b}(w)$ tend to become 0).

3.2 Loss Functions

For learning correct binary representations, we can use any loss functions that is (sub-)differentiable and satisfies a constraint that:

$$L_{\mathcal{B}}(\boldsymbol{q}, \boldsymbol{b}) \begin{cases} = \epsilon_L, & \text{if } \boldsymbol{q} = \boldsymbol{b}, \\ \geq \epsilon_L, & \text{otherwise}, \end{cases} \quad (9)$$

[1] We designed this injective condition using the $\mathrm{id}(\cdot)$ function to ignore task-specific sensitivities between different word surfaces (e.g. cases, ligatures, etc.).

[2] Other methods examined included random codes, Huffman codes (Huffman, 1952) and Brown clustering (Brown et al., 1992) with zero-padding to adjust code lengths, and some original allocation methods based on the word2vec embeddings (Mikolov et al., 2013).

Algorithm 1 Mapping words to bit arrays.

Require: $w \in \mathcal{V}$
Ensure: $\boldsymbol{b} \in \{0,1\}^B$ = Bit array representing w

$$x := \begin{cases} 0, & \text{if } w = \texttt{UNK} \\ 1, & \text{if } w = \texttt{BOS} \\ 2, & \text{if } w = \texttt{EOS} \\ 2 + \mathrm{rank}(w), & \text{otherwise} \end{cases}$$

$b_i := \lfloor x / 2^{i-1} \rfloor \mod 2$
$\boldsymbol{b} \leftarrow [b_1, b_2, \cdots, b_B]$

where ϵ_L is the minimum value of the loss function which typically does not affect the gradient descent methods. For example, the *squared-distance*:

$$L_{\mathcal{B}}(\boldsymbol{q}, \boldsymbol{b}) := \sum_{i=1}^{B} (q_i - b_i)^2, \tag{10}$$

or the *cross-entropy*:

$$L_{\mathcal{B}}(\boldsymbol{q}, \boldsymbol{b}) := -\sum_{i=1}^{B} \left(b_i \log q_i + \bar{b}_i \log \bar{q}_i \right), \tag{11}$$

are candidates for the loss function. We also examined both loss functions in the preliminary experiments, and in this paper, we only used the squared-distance function (Equation (10)), because this function achieved higher translation accuracies than Equation (11).[3]

3.3 Efficiency of the Binary Code Prediction

The computational complexity for the parameters W_{hq} and $\boldsymbol{\beta}_q$ is $O(HB)$. This is equal to $O(H \log V)$ when using a minimal mapping method like that shown in Algorithm 1, and is significantly smaller than $O(HV)$ when using standard softmax prediction. For example, if we chose $V = 65536 = 2^{16}$ and use Algorithm 1's mapping method, then $B = 16$ and total amount of computation in the output layer could be suppressed to 1/4096 of its original size.

On a different note, the binary code prediction model proposed in this study shares some ideas with the hierarchical softmax (Morin and Bengio, 2005) approach. Actually, when we used a binary-tree based mapping function for $\boldsymbol{b}$, our model can be interpreted as the hierarchical softmax with two strong constraints for guaranteeing independence between all bits: all nodes in the same level of the hierarchy share their parameters, and all levels of the hierarchy are predicted independently of each other. By these constraints, all bits in $\boldsymbol{b}$ can be calculated in parallel. This is particularly important because it makes the model conducive to being calculated on parallel computation backends such as GPUs.

However, the binary code prediction model also introduces problems of robustness due to these strong constraints. As the experimental results show, the simplest prediction model which directly maps words into bit arrays seriously decreases translation quality. In Sections 3.4 and 3.5, we introduce two additional techniques to prevent reductions of translation quality and improve robustness of the binary code prediction model.

3.4 Hybrid Softmax/Binary Model

According to the Zipf's law (Zipf, 1949), the distribution of word appearances in an actual corpus is biased to a small subset of the vocabulary. As a result, the proposed model mostly learns characteristics for frequent words and cannot obtain enough opportunities to learn for rare words. To alleviate this problem, we introduce a hybrid model using both softmax prediction and binary code prediction as shown in Figure 2(c). In this model, the output layer calculates a standard softmax for the $N-1$ most frequent words and an `OTHER` marker which indicates all rare words. When the softmax layer predicts `OTHER`, then the binary code layer is used to predict the representation of rare words. In this case, the actual probability of generating a particular word can be separated into two equations according to the frequency of words:

$$\Pr(w|\boldsymbol{h}) \simeq \begin{cases} v'_{\mathrm{id}(w)}, & \text{if } \mathrm{id}(w) < N, \\ v'_N \cdot \pi(w, \boldsymbol{h}), & \text{otherwise}, \end{cases} \tag{12}$$

$$\boldsymbol{v}' := \exp \boldsymbol{u}' / \mathrm{sum} \exp \boldsymbol{u}', \tag{13}$$

$$\boldsymbol{u}' := W_{hu'} \boldsymbol{h} + \boldsymbol{\beta}_{u'}, \tag{14}$$

$$\pi(w, \boldsymbol{h}) := \Pr(\boldsymbol{b}(w) | \boldsymbol{q}(\boldsymbol{h})), \tag{15}$$

where $W_{hu'} \in \mathbb{R}^{N \times H}$ and $\boldsymbol{\beta}_{u'} \in \mathbb{R}^N$ are trainable parameters, and $\mathrm{id}(w)$ assumes that the value corresponds to the rank of frequency of each word. We also define the loss function for the hybrid

[3] In terms of learning probabilistic models, we should remind that using Eq. (10) is an approximation of Eq. (11). The output bit scores trained by Eq. (10) do not represent actual word perplexities, and this characteristics imposes some practical problems when comparing multiple hypotheses (e.g., reranking, beam search, etc.). We could ignore this problem in this paper because we only evaluated the one-best results in experiments.

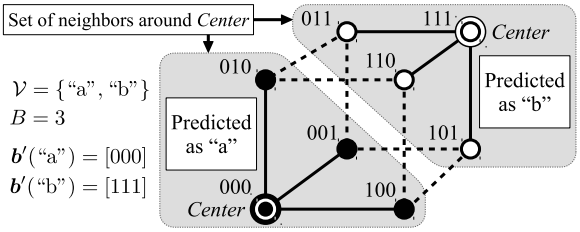


Figure 3: Example of the classification problem using redundant bit array mapping.

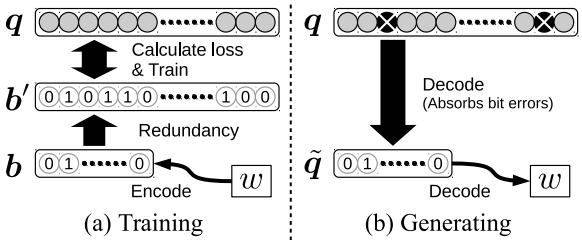

Figure 4: Training and generation processes with error-correcting code.

model using both softmax and binary code losses:

$$L := \begin{cases} l_{\mathcal{H}}(\mathrm{id}(w)), & \text{if } \mathrm{id}(w) < N, \\ l_{\mathcal{H}}(N) + l_{\mathcal{B}}, & \text{otherwise,} \end{cases} \quad (16)$$

$$l_{\mathcal{H}}(i) := \lambda_{\mathcal{H}} L_{\mathcal{H}}(\boldsymbol{v}', i), \quad (17)$$

$$l_{\mathcal{B}} := \lambda_{\mathcal{B}} L_{\mathcal{B}}(\boldsymbol{q}, \boldsymbol{b}), \quad (18)$$

where $\lambda_{\mathcal{H}}$ and $\lambda_{\mathcal{B}}$ are hyper-parameters to determine strength of both softmax/binary code losses. These also can be adjusted according to the training data, but in this study, we only used $\lambda_{\mathcal{H}} = \lambda_{\mathcal{B}} = 1$ for simplicity.

The computational complexity of the hybrid model is $O(H(N + \log V))$, which is larger than the original binary code model $O(H \log V)$. However, N can be chosen as $N \ll V$ because the softmax prediction is only required for a few frequent words. As a result, we can control the actual computation for the hybrid model to be much smaller than the standard softmax complexity $O(HV)$,

The idea of separated prediction of frequent words and rare words comes from the differentiated softmax (Chen et al., 2016) approach. However, our output layer can be configured as a fully-connected network, unlike the differentiated softmax, because the actual size of the output layer is still small after applying the hybrid model.

3.5 Applying Error-correcting Codes

The 2 methods proposed in previous sections impose constraints for all bits in $\boldsymbol{q}$, and the value of each bit must be estimated correctly for the correct word to be chosen. As a result, these models may generate incorrect words due to even a single bit error. This problem is the result of dense mapping between words and bit arrays, and can be avoided by creating *redundancy* in the bit array. Figure 3 shows a simple example of how this idea works when discriminating 2 words using 3 bits. In this case, the actual words are obtained by estimating the nearest *centroid* bit array according to the Hamming distance between each centroid and the predicted bit array. This approach can predict correct words as long as the predicted bit arrays are in the set of *neighbors* for the correct centroid (gray regions in the Figure 3), i.e., up to a 1-bit error in the predicted bits can be corrected. This ability to be robust to errors is a central idea behind *error-correcting codes* (Shannon, 1948). In general, an error-correcting code has the ability to correct up to $\lfloor (d-1)/2 \rfloor$ bit errors when all centroids differ d bits from each other (Golay, 1949). d is known as the *free distance* determined by the design of error-correcting codes. Error-correcting codes have been examined in some previous work on multi-class classification tasks, and have reported advantages from the raw classification (Dietterich and Bakiri, 1995; Klautau et al., 2003; Liu, 2006; Kouzani and Nasireding, 2009; Kouzani, 2010; Ferng and Lin, 2011, 2013). In this study, we applied an error-correcting algorithm to the bit array obtained from Algorithm 1 to improve robustness of the output layer in an NMT system. A challenge in this study is trying a large classification (#classes $>$ 10,000) with error-correction, unlike previous studies focused on solving comparatively small tasks (#classes $<$ 100). And this study also tries to solve a generation task unlike previous studies. As shown in the experiments, we found that this approach is highly effective in these tasks.

Figure 4 (a) and (b) illustrate the training and generation processes for the model with error-correcting codes. In the training, we first convert the original bit arrays $\boldsymbol{b}(w)$ to a *center* bit array $\boldsymbol{b}'$ in the space of error-correcting code: $\boldsymbol{b}'(\boldsymbol{b}) := [\boldsymbol{b}'_1(\boldsymbol{b}), \boldsymbol{b}'_2(\boldsymbol{b}), \cdots, \boldsymbol{b}'_{B'}(\boldsymbol{b})] \in \{0,1\}^{B'}$, where $B'(B) \geq B$ is the number of bits in the error-correcting code. The NMT model learns its

    $o_2(x) := ([x] \circ \boldsymbol{s}^{\text{cur}}) \cdot [1101101] \mod 2$
    $g'(x) := g(q_{2t-1}, o_1(x)) + g(q_{2t}, o_2(x))$
    $\phi'(x) := \phi_{t-1}[\boldsymbol{s}^{\text{prev}}(x)] + g'(x)$
    $\hat{x} \leftarrow \arg\max_{x \in \{0,1\}} \phi'(x)$
    $r_t[\boldsymbol{s}^{\text{cur}}] \leftarrow \boldsymbol{s}^{\text{prev}}(\hat{x})$
    $\phi_t[\boldsymbol{s}^{\text{cur}}] \leftarrow \phi'(\hat{x})$
  end for
end for
$\boldsymbol{s}' \leftarrow [000000]$
for $t = B \to 1$ **do**
  $\boldsymbol{s}' \leftarrow r_{t+6}[\boldsymbol{s}']$
  $\tilde{q}_t \leftarrow s'_1$
end for
$\tilde{\boldsymbol{q}} \leftarrow [\tilde{q}_1, \tilde{q}_2, \cdots, \tilde{q}_B]$

parameters based on the loss between predicted probabilities $\boldsymbol{q}$ and $\boldsymbol{b}'$. Note that typical error-correcting codes satisfy $O(B'/B) = O(1)$, and this characteristic efficiently suppresses the increase of actual computation cost in the output layer due to the application of the error-correcting code. In the generation of actual words, the decoding method of the error-correcting code converts the redundant predicted bits $\boldsymbol{q}$ into a dense representation $\tilde{\boldsymbol{q}} := [\tilde{\boldsymbol{q}}_1(\boldsymbol{q}), \tilde{\boldsymbol{q}}_2(\boldsymbol{q}), \cdots, \tilde{\boldsymbol{q}}_B(\boldsymbol{q})]$, and uses $\tilde{\boldsymbol{q}}$ as the bits to restore the word, as is done in the method described in the previous sections.

It should be noted that the method for performing error correction directly affects the quality of the whole NMT model. For example, the mapping shown in Figure 3 has only 3 bits and it is clear that these bits represent exactly the same information as each other. In this case, all bits can be estimated using exactly the same parameters, and we can not expect that we will benefit significantly from applying this redundant representation. Therefore, we need to choose an error correction method in which the characteristics of original bits should be distributed in various positions of the resulting bit arrays so that errors in bits are not highly correlated with each-other. In addition, it is desirable that the decoding method of the applied error-correcting code can directly utilize the probabilities of each bit, because $\boldsymbol{q}$ generated by the network will be a continuous probabilities between zero and one.

In this study, we applied convolutional codes (Viterbi, 1967) to convert between original and redundant bits. Convolutional codes perform a set of bit-wise convolutions between original bits and weight bits (which are hyper-parameters). They are well-suited to our setting here because they distribute the information of original bits in different places in the resulting bits, work robustly for random bit errors, and can be decoded using bit probabilities directly.

Algorithm 2 describes the particular convolutional code that we applied in this study, with two convolution weights [1001111] and [1101101] as fixed hyper-parameters.[4] Where $\boldsymbol{x}[i\,..\,j] := [x_i, \cdots, x_j]$ and $\boldsymbol{x} \cdot \boldsymbol{y} := \sum_i x_i y_i$. On the other hand, there are various algorithms to decode convolutional codes with the same format which are based on different criteria. In this study, we use the decoding method described in Algorithm 3, where $\boldsymbol{x} \circ \boldsymbol{y}$ represents the concatenation of vectors $\boldsymbol{x}$ and $\boldsymbol{y}$. This method is based on the Viterbi algorithm (Viterbi, 1967) and estimates original bits by directly using probability of redundant bits. Although Algorithm 3 looks complicated, this algorithm can be performed efficiently on CPUs at test time, and is not necessary at training time when we are simply performing calculation of Equation (6). Algorithm 2 increases the number of bits from B into $B' = 2(B+6)$, but does not restrict the actual value of B.

[4] We also examined many configurations of convolutional codes which have different robustness and computation costs, and finally chose this one.

4 Experiments

4.1 Experimental Settings

We examined the performance of the proposed methods on two English-Japanese bidirectional translation tasks which have different translation difficulties: ASPEC (Nakazawa et al., 2016) and BTEC (Takezawa, 1999). Table 1 describes details of two corpora. To prepare inputs for training, we used `tokenizer.perl` in Moses (Koehn et al., 2007) and KyTea (Neubig et al., 2011) for English/Japanese tokenizations respectively, applied `lowercase.perl` from Moses, and replaced out-of-vocabulary words such that $\mathrm{rank}(w) > V - 3$ into the `UNK` marker.

We implemented each NMT model using C++ in the DyNet framework (Neubig et al., 2017) and trained/tested on 1 GPU (GeForce GTX TITAN X). Each test is also performed on CPUs to compare its processing time. We used a bidirectional RNN-based encoder applied in Bahdanau et al. (2014), unidirectional decoder with the same style of (Luong et al., 2015), and the *concat* global attention model also proposed in Luong et al. (2015). Each recurrent unit is constructed using a 1-layer LSTM (input/forget/output gates and non-peepholes) (Gers et al., 2000) with 30% dropout (Srivastava et al., 2014) for the input/output vectors of the LSTMs. All word embeddings, recurrent states and model-specific hidden states are designed with 512-dimentional vectors. Only output layers and loss functions are replaced, and other network architectures are identical for the conventional/proposed models. We used the Adam optimizer (Kingma and Ba, 2014) with fixed hyper-parameters $\alpha = 0.001, \beta_1 = 0.9\, \beta_2 = 0.999, \varepsilon = 10^{-8}$, and mini-batches with 64 sentences sorted according to their sequence lengths. For evaluating the quality of each model, we calculated case-insensitive BLEU (Papineni et al., 2002) every 1000 mini-batches. Table 2 lists summaries of all methods we examined in experiments.

(b) BTEC (En → Ja)

Figure 5: Training curves over 180,000 epochs.

4.2 Results and Discussion

Table 3 shows the BLEU on the test set (**bold** and *italic* faces indicate the best and second places in each task), number of bits B (or B') for the binary code, actual size of the output layer $\#_{\mathrm{out}}$, number of parameters in the output layer $\#_{W,\boldsymbol{\beta}}$, as well as the ratio of $\#_{W,\boldsymbol{\beta}}$ or amount of whole parameters compared with *Softmax*, and averaged processing time at training (per mini-batch on GPUs) and test (per sentence on GPUs/CPUs), respectively. Figure 5(a) and 5(b) shows training curves up to 180,000 epochs about some English→Japanese settings. To relax instabilities of translation qualities while training (as shown in Figure 5(a) and 5(b)), each BLEU in Table 3 is calculated by averaging actual test BLEU of 5 consecutive results

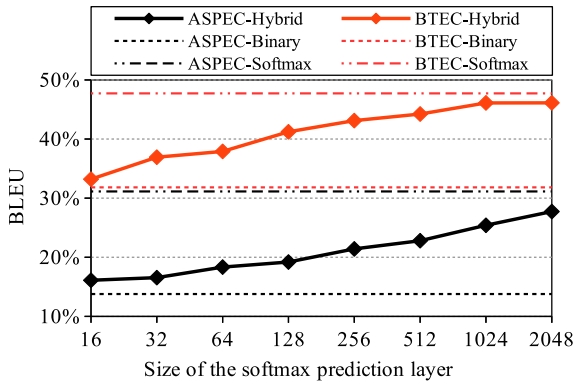

Figure 6: BLEU changes in the *Hybrid-N* methods according to the softmax size (En→Ja).

around the epoch that has the highest dev BLEU.

First, we can see that each proposed method largely suppresses the actual size of the output layer from ten to one thousand times compared with the standard softmax. By looking at the total number of parameters, we can see that the proposed models require only 70% of the actual memory, and the proposed model reduces the total number of parameters for the output layers to a practically negligible level. Note that most of remaining parameters are used for the embedding lookup at the input layer in both encoder/decoder. These still occupy $O(EV)$ memory, where E represents the size of each embedding layer and usually $O(E/H) = O(1)$. These are not targets to be reduced in this study because these values rarely are accessed at test time because we only need to access them for input words, and do not need them to always be in the physical memory. It might be possible to apply a similar binary representation as that of output layers to the input layers as well, then express the word embedding by multiplying this binary vector by a word embedding matrix. This is one potential avenue of future work.

Taking a look at the BLEU for the simple *Binary* method, we can see that it is far lower than other models for all tasks. This is expected, as described in Section 3, because using raw bit arrays causes many one-off estimation errors at the output layer due to the lack of robustness of the output representation. In contrast, *Hybrid-N* and *Binary-EC* models clearly improve BLEU from *Binary*, and they approach that of *Softmax*. This demonstrates that these two methods effectively improve the robustness of binary code prediction models. Especially, *Binary-EC* generally achieves higher quality than *Hybrid-512* despite the fact that it suppress the number of parameters by about 1/10. These results show that introducing redundancy to target bit arrays is more effective than incremental prediction. In addition, the *Hybrid-N-EC* model achieves the highest BLEU in all proposed methods, and in particular, comparative or higher BLEU than *Softmax* in BTEC. This behavior clearly demonstrates that these two methods are orthogonal, and combining them together can be effective. We hypothesize that the lower quality of *Softmax* in BTEC is caused by an over-fitting due to the large number of parameters required in the softmax prediction.

The proposed methods also improve actual computation time in both training and test. In particular on CPU, where the computation speed is directly affected by the size of the output layer, the proposed methods translate significantly faster

than *Softmax* by x5 to x20. In addition, we can also see that applying error-correcting code is also effictive with respect to the decoding speed.

Figure 6 shows the trade-off between the translation quality and the size of softmax layers in the hybrid prediction model (Figure 2(c)) without error-correction. According to the model definition in Section 3.4, the softmax prediction and raw binary code prediction can be assumed to be the upper/lower-bound of the hybrid prediction model. The curves in Figure 6 move between *Softmax* and *Binary* models, and this behavior intuitively explains the characteristics of the hybrid prediction. In addition, we can see that the BLEU score in BTEC quickly improves, and saturates at $N = 1024$ in contrast to the ASPEC model, which is still improving at $N = 2048$. We presume that the shape of curves in Figure 6 is also affected by the difficulty of the corpus, i.e., when we train the hybrid model for easy datasets (e.g., BTEC is easier than ASPEC), it is enough to use a small softmax layer (e.g. $N \leq 1024$).

5 Conclusion

In this study, we proposed neural machine translation models which indirectly predict output words via binary codes, and two model improvements: a hybrid prediction model using both softmax and binary codes, and introducing error-correcting codes to introduce robustness of binary code prediction. Experiments show that the proposed model can achieve comparative translation qualities to standard softmax prediction, while significantly suppressing the amount of parameters in the output layer, and improving calculation speeds while training and especially testing.

One interesting avenue of future work is to automatically learn encodings and error correcting codes that are well-suited for the type of binary code prediction we are performing here. In Algorithms 2 and 3 we use convolutions that were determined heuristically, and it is likely that learning these along with the model could result in improved accuracy or better compression capability.

Abstract

Neural machine translation (MT) models obtain state-of-the-art performance while maintaining a simple, end-to-end architecture. However, little is known about what these models learn about source and target languages during the training process. In this work, we analyze the representations learned by neural MT models at various levels of granularity and empirically evaluate the quality of the representations for learning morphology through extrinsic part-of-speech and morphological tagging tasks. We conduct a thorough investigation along several parameters: word-based vs. character-based representations, depth of the encoding layer, the identity of the target language, and encoder vs. decoder representations. Our data-driven, quantitative evaluation sheds light on important aspects in the neural MT system and its ability to capture word structure.[1]

1 Introduction

Neural network models are quickly becoming the predominant approach to machine translation (MT). Training neural MT (NMT) models can be done in an end-to-end fashion, which is simpler and more elegant than traditional MT systems. Moreover, NMT systems have become competitive with, or better than, the previous state-of-the-art, especially since the introduction of sequence-to-sequence models and the attention mechanism (Bahdanau et al., 2014; Sutskever et al., 2014). The improved translation quality is often attributed to better handling of non-local dependencies and morphology generation (Luong and Manning, 2015; Bentivogli et al., 2016; Toral and Sánchez-Cartagena, 2017).

However, little is known about what and how much these models learn about each language and its features. Recent work has started exploring the role of the NMT encoder in learning source syntax (Shi et al., 2016), but research studies are yet to answer important questions such as: *(i)* what do NMT models learn about word morphology? *(ii)* what is the effect on learning when translating into/from morphologically-rich languages? *(iii)* what impact do different representations (character vs. word) have on learning? and *(iv)* what do different modules learn about the syntactic and semantic structure of a language? Answering such questions is imperative for fully understanding the NMT architecture. In this paper, we strive towards exploring *(i)*, *(ii)*, and *(iii)* by providing quantitative, data-driven answers to the following specific questions:

- Which parts of the NMT architecture capture word structure?
- What is the division of labor between different components (e.g. different layers or encoder vs. decoder)?
- How do different word representations help learn better morphology and modeling of infrequent words?
- How does the target language affect the learning of word structure?

To achieve this, we follow a simple but effective procedure with three steps: *(i)* train a neural MT system on a parallel corpus; *(ii)* use the trained model to extract feature representations for words in a language of interest; and *(iii)* train a classifier using extracted features to make predictions

for another task. We then evaluate the quality of the trained classifier on the given task as a proxy to the quality of the extracted representations. In this way, we obtain a quantitative measure of how well the original MT system learns features that are relevant to the given task.

We focus on the tasks of part-of-speech (POS) and full morphological tagging. We investigate how different neural MT systems capture POS and morphology through a series of experiments along several parameters. For instance, we contrast word-based and character-based representations, use different encoding layers, vary source and target languages, and compare extracting features from the encoder vs. the decoder.

We experiment with several languages with varying degrees of morphological richness: French, German, Czech, Arabic, and Hebrew. Our analysis reveals interesting insights such as:

- Character-based representations are much better for learning morphology, especially for low-frequency words. This improvement is correlated with better BLEU scores. On the other hand, word-based models are sufficient for learning the structure of common words.

- Lower layers of the encoder are better at capturing word structure, while deeper networks improve translation quality, suggesting that higher layers focus more on word meaning.

- The target language impacts the kind of information learned by the MT system. Translating into morphologically-poorer languages leads to better source-side word representations. This is partly, but not completely, correlated with BLEU scores.

- The neural decoder learns very little about word structure. The attention mechanism removes much of the burden of learning word representations from the decoder.

2 Methodology

Given a source sentence $s = \{w_1, w_2, ..., w_N\}$ and a target sentence $t = \{u_1, u_2, ..., u_M\}$, we first generate a vector representation for the source sentence using an encoder (Eqn. 1) and then map this vector to the target sentence using a decoder (Eqn. 2) (Sutskever et al., 2014):

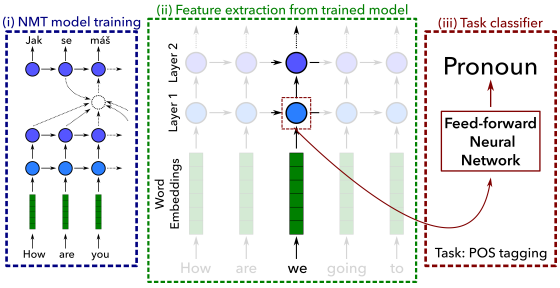

Figure 1: Illustration of our approach: (i) NMT system trained on parallel data; (ii) features extracted from pre-trained model; (iii) classifier trained using the extracted features. Here a POS tagging classifier is trained on features from the first hidden layer.

$$\texttt{ENC} : s = \{w_1, w_2, ..., w_N\} \mapsto \mathbf{s} \in \mathbb{R}^k \quad (1)$$

$$\texttt{DEC} : \mathbf{s} \in \mathbb{R}^k \mapsto t = \{u_1, u_2, ..., u_M\} \quad (2)$$

In this work, we use long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) encoder-decoders with attention (Bahdanau et al., 2014), which we train on parallel data.

After training the NMT system, we freeze the parameters of the encoder and use ENC as a feature extractor to generate vectors representing words in the sentence. Let $\texttt{ENC}_i(s)$ denote the encoded representation of word w_i. For example, this may be the output of the LSTM after word w_i. We feed $\texttt{ENC}_i(s)$ to a neural classifier that is trained to predict POS or morphological tags and evaluate the quality of the representation based on our ability to train a good classifier. By comparing the performance of classifiers trained with features from different instantiations of ENC, we can evaluate what MT encoders learn about word structure. Figure 1 illustrates this process. We follow a similar procedure for analyzing representation learning in DEC.

The classifier itself can be modeled in different ways. For example, it may be an LSTM over outputs of the encoder. However, as we are interested in assessing the quality of the representations learned by the MT system, we choose to model the classifier as a simple feed-forward neural network with one hidden layer and a ReLU non-linearity. Arguably, if the learned representations are good, then a non-linear classifier should be able to extract useful information from them.[2] We empha-

[2]We also experimented with a linear classifier and observed similar trends to the non-linear case, but overall lower results; Qian et al. (2016b) reported similar findings.

size that our goal is not to beat the state-of-the-art on a given task, but rather to analyze what NMT models learn about morphology. The classifier is trained with a cross-entropy loss; more details about its architecture are given in the supplementary material (appendix A.1).

3 Data

Language pairs We experiment with several language pairs, including morphologically-rich languages, that have received relatively significant attention in the MT community. These include Arabic-, German-, French-, and Czech-English pairs. To broaden our analysis and study the effect of having morphologically-rich languages on both source and target sides, we also include Arabic-Hebrew, two languages with rich and similar morphological systems, and Arabic-German, two languages with rich but different morphologies.

MT data Our translation models are trained on the WIT[3] corpus of TED talks (Cettolo et al., 2012; Cettolo, 2016) made available for IWSLT 2016. This allows for comparable and cross-linguistic analysis. Statistics about each language pair are given in Table 1 (under Pred). We use official dev and test sets for tuning and testing. Reported figures are the averages over test sets.

Annotated data We use two kinds of datasets to train POS and morphological classifiers: gold-standard and predicted tags. For predicted tags, we simply used freely available taggers to annotate the MT data. For gold tags, we use gold-annotated datasets. Table 1 provides statistics for datasets with gold and predicted tags; see the supplementary material (appendix A.2) for more details about taggers and gold data. We train and test our classifiers on predicted annotations, and similarly on gold annotations, when we have them. We report both results wherever available.

Table 2: POS accuracy on gold and predicted tags using word-based and character-based representations, as well as corresponding BLEU scores.

4 Encoder Analysis

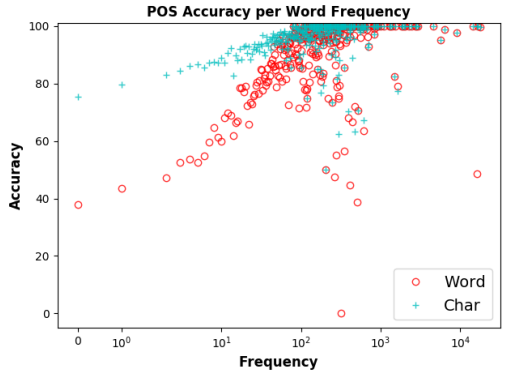
Recall that after training the NMT system we freeze its parameters and use it only to generate features for the POS/morphology classifier. Given a trained encoder $\texttt{ENC}$ and a sentence s with POS/morphology annotation, we generate word features $\texttt{ENC}_i(s)$ for every word in the sentence. We then train a classifier that uses the features $\texttt{ENC}_i(s)$ to predict POS or morphological tags.

4.1 Effect of word representation

In this section, we compare different word representations extracted with different encoders. Our word-based model uses a word embedding matrix which is initialized randomly and learned with other NMT parameters. For a character-based model we adopt a convolutional neural network (CNN) over character embeddings that is also learned during training (Kim et al., 2015); see appendix A.1 for specific settings. In both cases we run the encoder over these representations and use its output $\texttt{ENC}_i(s)$ as features for the classifier.

Table 2 shows POS tagging accuracy using features from different NMT encoders. Char-based models always generate better representations for POS tagging, especially in the case of morphologically-richer languages like Arabic and Czech. We observed a similar pattern in the full morphological tagging task. For example, we obtain morphological tagging accuracy of 65.2/79.66 and 67.66/81.66 using word/char-based representations from the Arabic-Hebrew and Arabic-English encoders, respectively.[3] The superior morphological power of the char-based model also manifests in better translation quality (measured by BLEU), as shown in Table 2.

[3]The results are not far below dedicated taggers (e.g. 95.1/84.1 on Arabic POS/morphology (Pasha et al., 2014)), indicating that NMT models learn quite good representations.



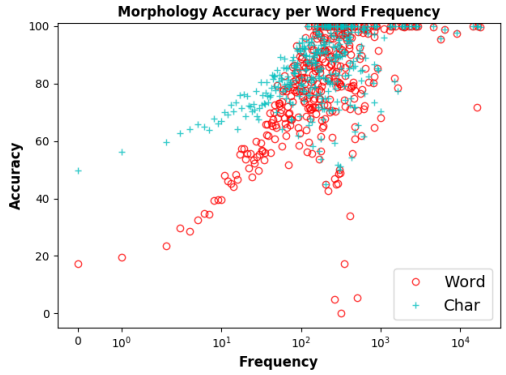


Figure 2: POS and morphological tagging accuracy of word-based and character-based models per word frequency in the training data. Best viewed in color.

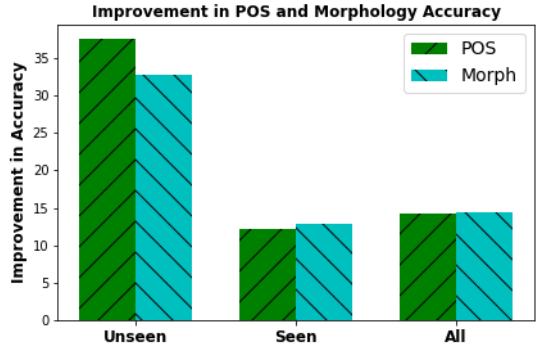

Figure 3: Improvement in POS/morphology accuracy of character-based vs. word-based models for words unseen/seen in training, and for all words.

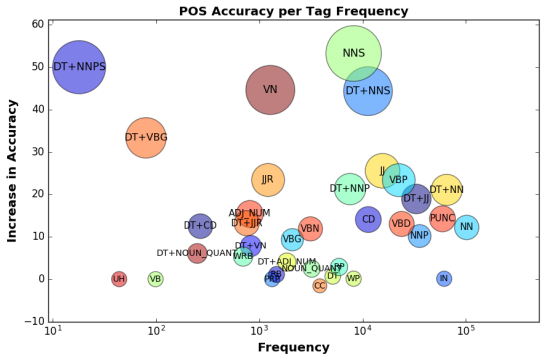

Figure 4: Increase in POS accuracy with char- vs. word-based representations per tag frequency in the training set; larger bubbles reflect greater gaps.

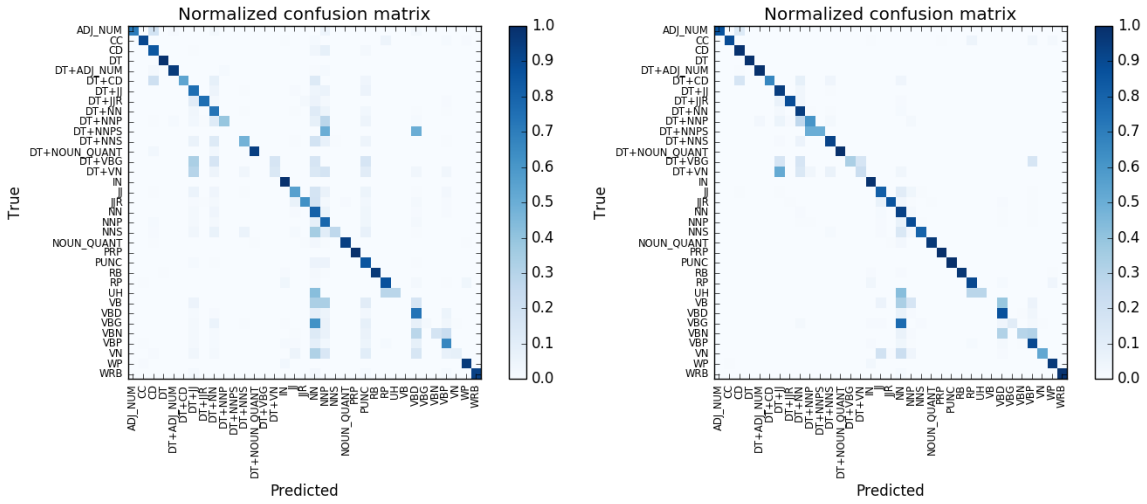
Impact of word frequency Let us look more closely at an example case: Arabic POS and morphological tagging. Figure 3 shows the effect of using word-based vs. char-based feature representations, obtained from the encoder of the Arabic-Hebrew system (other language pairs exhibit similar trends). Clearly, the char-based model is superior to the word-based one. This is true for the overall accuracy (+14.3% in POS, +14.5% in morphology), but more so in OOV words (+37.6% in POS, +32.7% in morphology). Figure 2 shows that the gap between word-based and char-based representations increases as the frequency of the word in the training data decreases. In other words, the more frequent the word, the less need there is for character information. These findings make intuitive sense: the char-based model is able to learn character n-gram patterns that are important for identifying word structure, but as the word becomes more frequent the word-based model has seen enough examples to make a decision.

Analyzing specific tags In Figure 5 we plot confusion matrices for POS tagging using word-based and char-based representations (from Arabic encoders). While the char-based representations are overall better, the two models still share similar misclassified tags. Much of the confusion comes from wrongly predicting nouns (NN, NNP). In the word-based case, relatively many tags with determiner (DT+NNP, DT+NNPS, DT+NNS, DT+VBG) are wrongly predicted as non-determined nouns (NN, NNP). In the char-based case, this hardly happens. This suggests that the char-based representations are predictive of the presence of a determiner, which in Arabic is expressed as the prefix "Al-" (the definite article), a pattern easily captured by a char-based model.

In Figure 4 we plot the difference in POS accuracy when moving from word-based to char-based representations, per POS tag frequency in the training data. Tags closer to the upper-right corner occur more frequently in the training set and are



(a) Word-based representations.

(b) Character-based representations.

Figure 5: Confusion matrices for POS tagging using word-based and character-based representations.

better predicted by char-based compared to word-based representations. There are a few fairly frequent tags (in the middle-bottom part of the figure) whose accuracy does not improve much when moving from word- to char-based representations: mostly conjunctions, determiners, and certain particles (CC, DT, WP). But there are several very frequent tags (NN, DT+NN, DT+JJ, VBP, and even PUNC) whose accuracy improves quite a lot. Then there are plural nouns (NNS, DT+NNS) where the char-based model really shines, which makes sense linguistically as plurality in Arabic is usually expressed by certain suffixes ("-wn/yn" for masc. plural, "-At" for fem. plural). The char-based model is thus especially good with frequent tags and infrequent words, which is understandable given that infrequent words typically belong to frequent open categories like nouns and verbs.

4.2 Effect of encoder depth

Modern NMT systems use very deep architectures with up to 8 or 16 layers (Wu et al., 2016; Zhou et al., 2016). We would like to understand what kind of information different layers capture. Given a trained NMT model with multiple layers, we extract feature representations from the different layers in the encoder. Let $\texttt{ENC}_i^l(s)$ denote the encoded representation of word w_i after the l-th layer. We can vary l and train different classifiers to predict POS or morphological tags. Here we focus on the case of a 2-layer encoder-decoder model for simplicity ($l \in \{1, 2\}$).

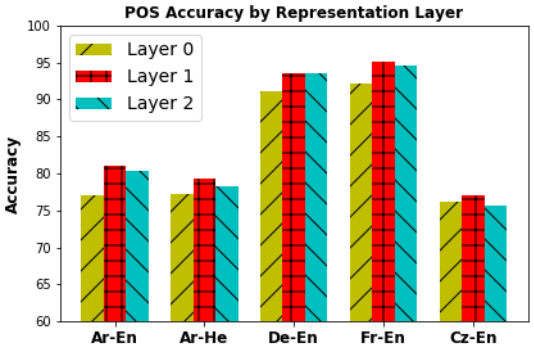


Figure 6: POS tagging accuracy using representations from layers 0 (word vectors), 1, and 2, taken from encoders of different language pairs.

Figure 6 shows POS tagging results using representations from different encoding layers across five language pairs. The general trend is that passing word vectors through the NMT encoder improves POS tagging, which can be explained by the contextual information contained in the representations after one layer. However, it turns out that representations from the 1st layer are better than those from the 2nd layer, at least for the purpose of capturing word structure. Figure 7 demonstrates that the same pattern holds for both word-based and char-based representations, on Arabic POS and morphological tagging. In all cases, layer 1 representations are better than layer 2 representations.[4] In contrast, BLEU scores ac-

[4] We found this result to be also true in French, German, and Czech experiments; see appendix A.3.

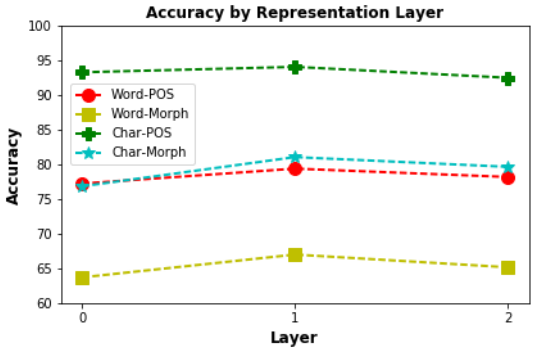

Figure 7: POS and morphological tagging accuracy across layers. Layer 0: word vectors or char-based representations before the encoder; layers 1 and 2: representations after the 1st and 2nd layers.

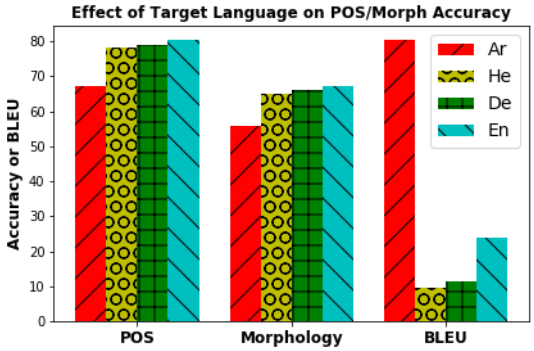

Figure 8: Effect of target language on representation quality of the Arabic source.

tually increase when training 2-layer vs. 1-layer models (+1.11/+0.56 BLEU for Arabic-Hebrew word/char-based models). Thus translation quality improves when adding layers but morphology quality degrades. Intuitively, it seems that lower layers of the network learn to represent word structure while higher layers are more focused on word meaning. A similar pattern was recently observed in a joint language-vision deep recurrent network (Gelderloos and Chrupała, 2016).

4.3 Effect of target language

While translating from morphologically-rich languages is challenging, translating into such languages is even harder. For instance, our basic system obtains BLEU scores of 24.69/23.2 on Arabic/Czech to English, but only 13.37/13.9 on English to Arabic/Czech. How does the target language affect the learned source language representations? Does translating into a morphologically-rich language require more knowledge about source language morphology? In order to investigate these questions, we fix the source language and train NMT models using different target languages. For example, given an Arabic source side, we train Arabic-to-English/Hebrew/German systems. These target languages represent a morphologically-poor language (English), a morphologically-rich language with similar morphology to the source language (Hebrew), and a morphologically-rich language with different morphology (German). To make a fair comparison, we train the models on the intersection of the training data based on the source language. In this way the experimental setup is completely identical: the models are trained on the same Arabic sentences with different translations.

Figure 8 shows POS and morphological tagging accuracy of word-based representations from the NMT encoders, as well as corresponding BLEU scores. As expected, translating into English is easier than translating into the morphologically-richer Hebrew and German, resulting in higher BLEU scores. Despite their similar morphological systems, translating Arabic to Hebrew is worse than Arabic to German, which can be attributed to the richer Hebrew morphology compared to German. POS and morphology accuracies share an intriguing pattern: the representations that are learned when translating into English are better for predicting POS or morphology than those learned when translating into German, which are in turn better than those learned when translating into Hebrew. This is remarkable given that English is a morphologically-poor language that does not display many of the morphological properties that are found in the Arabic source. In contrast, German and Hebrew have richer morphologies, so one could expect that translating into them would make the model learn more about morphology.

A possible explanation for this phenomenon is that the Arabic-English model is simply better than the Arabic-Hebrew and Arabic-German models, as hinted by the BLEU scores in Table 2. The inherent difficulty in translating Arabic to Hebrew/German may affect the ability to learn good representations of word structure. To probe this more, we trained an Arabic-Arabic autoencoder on the same training data. We found that it learns to recreate the test sentences extremely well, with very high BLEU scores (Figure 8). However, its

word representations are actually inferior for the purpose of POS/morphological tagging. This implies that higher BLEU does not necessarily entail better morphological representations. In other words, a better translation model learns more informative representations, but only when it is actually learning to translate rather than merely memorizing the data as in the autoencoder case. We found this to be consistently true also for char-based experiments, and in other language pairs.

5 Decoder Analysis

So far we only looked at the encoder. However, the decoder DEC is a crucial part in an MT system with access to both source and target sentences. In order to examine what the decoder learns about morphology, we first train an NMT system on the parallel corpus. Then, we use the trained model to encode a source sentence and extract features for words in the target sentence. These features are used to train a classifier on POS or morphological tagging on the target side.[5] Note that in this case the decoder is given the correct target words one-by-one, similar to the usual NMT training regime.

Table 3 (1st row) shows the results of using representations extracted with ENC and DEC from the Arabic-English and English-Arabic models, respectively. There is clearly a huge drop in representation quality with the decoder.[6] At first, this drop seems correlated with lower BLEU scores in English to Arabic vs. Arabic to English. However, we observed similar low POS tagging accuracy using decoder representations from high-quality NMT models. For instance, the French-to-English system obtains 37.8 BLEU, but its decoder representations give a mere 54.26% accuracy on English POS tagging.

As an alternative explanation for the poor quality of the decoder representations, consider the fundamental tasks of the two NMT modules: encoder and decoder. The encoder's task is to create a generic, close to language-independent representation of the source sentence, as shown by recent evidence from multilingual NMT (Johnson et al., 2016). The decoder's task is to use this representation to generate the target sentence in a specific language. Presumably, it is sufficient for the decoder to learn a strong language model in order to produce morphologically-correct output, without learning much about morphology, while the encoder needs to learn quite a lot about source language morphology in order to create a good generic representation. In the following section we show that the attention mechanism also plays an important role in the division of labor between encoder and decoder.

[5] In this section we only experiment with predicted tags as there are no parallel data with gold POS/morphological tags that we are aware of.

[6] Note that the decoder results are above a majority baseline of 20%, so the decoder is still learning something about the target language.

Attn	POS Accuracy ENC	POS Accuracy DEC	BLEU Ar-En	BLEU En-Ar
✓	89.62	43.93	24.69	13.37
✗	74.10	50.38	11.88	5.04

Table 3: POS tagging accuracy using encoder and decoder representations with/without attention.

5.1 Effect of attention

Consider the role of the attention mechanism in learning useful representations: during decoding, the attention weights are combined with the decoder's hidden states to generate the current translation. These two sources of information need to jointly point to the most relevant source word(s) and predict the next most likely word. Thus, the decoder puts significant emphasis on mapping back to the source sentence, which may come at the expense of obtaining a meaningful representation of the current word. We hypothesize that the attention mechanism hurts the quality of the target word representations learned by the decoder.

To test this hypothesis, we train NMT models with and without attention and compare the quality of their learned representations. As Table 3 shows (compare 1st and 2nd rows), removing the attention mechanism decreases the quality of the encoder representations, but improves the quality of the decoder representations. Without the attention mechanism, the decoder is forced to learn more informative representations of the target language.

5.2 Effect of word representation

We also conducted experiments to verify our findings regarding word-based versus character-based representations on the decoder side. By character representation we mean a character CNN on the input words. The decoder predictions are still done at the word-level, which enables us to use its hidden states as word representations.

Table 4 shows POS accuracy of word-based vs. char-based representations in the encoder and decoder. While char-based representations improve the encoder, they do not help the decoder. BLEU scores behave similarly: the char-based model leads to better translations in Arabic-to-English, but not in English-to-Arabic. A possible explanation for this phenomenon is that the decoder's predictions are still done at word level even with the char-based model (which encodes the target input but not the output). In practice, this can lead to generating unknown words. Indeed, in Arabic-to-English the char-based model reduces the number of generated unknown words in the MT test set by 25%, while in English-to-Arabic the number of unknown words remains roughly the same between word-based and char-based models.

	POS Accuracy		BLEU	
	ENC	DEC	Ar-En	En-Ar
Word	89.62	43.93	24.69	13.37
Char	95.35	44.54	28.42	13.00

Table 4: POS tagging accuracy using word-based and char-based encoder/decoder representations.

6 Related Work

Analysis of neural models The opacity of neural networks has motivated researchers to analyze such models in different ways. One line of work visualizes hidden unit activations in recurrent neural networks that are trained for a given task (Elman, 1991; Karpathy et al., 2015; Kádár et al., 2016; Qian et al., 2016a). While such visualizations illuminate the inner workings of the network, they are often qualitative in nature and somewhat anecdotal. A different approach tries to provide a quantitative analysis by correlating parts of the neural network with linguistic properties, for example by training a classifier to predict features of interest. Different units have been used, from word embeddings (Köhn, 2015; Qian et al., 2016b), through LSTM gates or states (Qian et al., 2016a), to sentence embeddings (Adi et al., 2016). Our work is most similar to Shi et al. (2016), who use hidden vectors from a neural MT encoder to predict syntactic properties on the English source side. In contrast, we focus on representations in morphologically-rich languages and evaluate both source and target sides across several criteria. Vylomova et al. (2016) also analyze different representations for morphologically-rich languages in MT, but do not directly measure the quality of the learned representations.

Word representations in MT Machine translation systems that deal with morphologically-rich languages resort to various techniques for representing morphological knowledge, such as word segmentation (Nieflen and Ney, 2000; Koehn and Knight, 2003; Badr et al., 2008) and factored translation and reordering models (Koehn and Hoang, 2007; Durrani et al., 2014). Characters and other sub-word units have become increasingly popular in neural MT, although they had also been used in phrase-based MT for handling morphologically-rich (Luong et al., 2010) or closely related language pairs (Durrani et al., 2010; Nakov and Tiedemann, 2012). In neural MT, such units are obtained in a pre-processing step—e.g. by byte-pair encoding (Sennrich et al., 2016) or the word-piece model (Wu et al., 2016)—or learned during training using a character-based convolutional/recurrent sub-network (Costa-jussà and Fonollosa, 2016; Luong and Manning, 2016; Vylomova et al., 2016). The latter approach has the advantage of keeping the original word boundaries without requiring pre- and post-processing. Here we focus on a character CNN which has been used in language modeling and machine translation (Kim et al., 2015; Belinkov and Glass, 2016; Costa-jussà and Fonollosa, 2016; Jozefowicz et al., 2016; Sajjad et al., 2017). We evaluate the quality of different representations learned by an MT system augmented with a character CNN in terms of POS and morphological tagging, and contrast them with a purely word-based system.

7 Conclusion

Neural networks have become ubiquitous in machine translation due to their elegant architecture and good performance. The representations they use for linguistic units are crucial for obtaining high-quality translation. In this work, we investigated how neural MT models learn word structure. We evaluated their representation quality on POS and morphological tagging in a number of languages. Our results lead to the following conclusions:

- Character-based representations are better than word-based ones for learning morphology, especially in rare and unseen words.

- Lower layers of the neural network are better at capturing morphology, while deeper networks improve translation performance. We hypothesize that lower layers are more focused on word structure, while higher ones are focused on word meaning.

- Translating into morphologically-poorer languages leads to better source-side representations. This is partly, but not completely, correlated with BLEU scores.

- The attentional decoder learns impoverished representations that do not carry much information about morphology.

These insights can guide further development of neural MT systems. For instance, jointly learning translation and morphology can possibly lead to better representations and improved translation. Our analysis indicates that this kind of approach should take into account factors such as the encoding layer and the type of word representation.

Another area for future work is to extend the analysis to other word representations (e.g. byte-pair encoding), deeper networks, and more semantically-oriented tasks such as semantic role-labeling or semantic parsing.

Acknowledgments

A Supplementary Material

A.1 Training Details

POS/Morphological classifier The classifier used for all prediction tasks is a feed-forward network with one hidden layer, dropout ($\rho = 0.5$), a ReLU non-linearity, and an output layer mapping to the tag set (followed by a Softmax). The size of the hidden layer is set to be identical to the size of the encoder's hidden state (typically 500 dimensions). We use Adam (Kingma and Ba, 2014) with default parameters to minimize the cross-entropy objective. Training is run with mini-batches of size 16 and stopped once the loss on the dev set stops improving; we allow a patience of 5 epochs.

Neural MT system We train a 2-layer LSTM encoder-decoder with attention. We use the `seq2seq-attn` implementation (Kim, 2016) with the following default settings: word vectors and LSTM states have 500 dimensions, SGD with initial learning rate of 1.0 and rate decay of 0.5, and dropout rate of 0.3. The character-based model is a CNN with a highway network over characters (Kim et al., 2015) with 1000 feature maps and a kernel width of 6 characters. This model was found to be useful for translating morphologically-rich languages (Costa-jussà and Fonollosa, 2016). The MT system is trained for 20 epochs, and the model with the best dev loss is used for extracting features for the classifier.

A.2 Data and Taggers

Datasets All of the translation models are trained on the Ted talks corpus included in WIT^3 (Cettolo et al., 2012; Cettolo, 2016). Statistics about each language pair are available on the WIT^3 website: `https://wit3.fbk.eu`. For experiments using gold tags, we used the Arabic Treebank for Arabic (with the versions and splits described in the MADAMIRA manual (Pasha et al., 2014)) and the Tiger corpus for German.[7]

POS and morphological taggers We used the following tools to annotate the MT corpora: MADAMIRA (Pasha et al., 2014) for Arabic POS and morphological tags, Tree-Tagger (Schmid, 1994) for Czech and French POS tags, LoPar (Schmid, 2000) for German POS and morphological tags, and MXPOST (Ratnaparkhi, 1998) for English POS tags. These tools are recommended on the Moses website.[8] As mentioned before, our goal is not to achieve state-of-the-art results, but rather to study what different components of the NMT architecture learn about word morphology. Please refer to Mueller et al. (2013) for representative POS and morphological tagging accuracies.

A.3 Supplementary Results

We report here results that were omitted from the paper due to the space limit. Table 5 shows encoder results using different layers, languages, and representations (word/char-based). As noted in the paper, all the results consistently show that i) layer 1 performs better than layers 0 and 2; and ii) char-based representations are better than word-based for learning morphology. Table 6 shows that translating into a morphologically-poor language (English) leads to better source representations, and Table 7 provides additional decoder results.

	Layer 0	Layer 1	Layer 2
	Word/Char (POS)		
De	91.1/92.0	93.6/95.2	93.5/94.6
Fr	92.1/92.9	95.1/95.9	94.6/95.6
Cz	76.3/78.3	77.0/79.1	75.7/80.6
	Word/Char (Morphology)		
De	87.6/88.8	89.5/91.2	88.7/90.5

Table 5: POS and morphology accuracy on predicted tags using word- and char-based representations from different layers of *-to-En systems.

Source \ Target	English	Arabic	Self
German	93.5	92.7	89.3
Czech	75.7	75.2	71.8

Table 6: Impact of changing the target language on POS tagging accuracy. Self = German/Czech in rows 1/2 respectively.

	En-De	En-Cz	De-En	Fr-En
POS	53.6	36.3	53.3	54.1
BLEU	23.4	13.9	29.6	37.8

Table 7: POS accuracy and BLEU using decoder representations from different language pairs.

Abstract

Multimodal sentiment analysis is a developing area of research, which involves the identification of sentiments in videos. Current research considers utterances as independent entities, i.e., ignores the interdependencies and relations among the utterances of a video. In this paper, we propose a LSTM-based model that enables utterances to capture contextual information from their surroundings in the same video, thus aiding the classification process. Our method shows 5-10% performance improvement over the state of the art and high robustness to generalizability.

1 Introduction

Sentiment analysis is a 'suitcase' research problem that requires tackling many NLP sub-tasks, e.g., aspect extraction (Poria et al., 2016a), named entity recognition (Ma et al., 2016), concept extraction (Rajagopal et al., 2013), sarcasm detection (Poria et al., 2016b), personality recognition (Majumder et al., 2017), and more.

Sentiment analysis can be performed at different granularity levels, e.g., subjectivity detection simply classifies data as either subjective (opinionated) or objective (neutral), while polarity detection focuses on determining whether subjective data indicate positive or negative sentiment. Emotion recognition further breaks down the inferred polarity into a set of emotions conveyed by the subjective data, e.g., positive sentiment can be caused by joy or anticipation, while negative sentiment can be caused by fear or disgust.

Even though the primary focus of this paper is to classify sentiment in videos, we also show the performance of the proposed method for the finer-grained task of emotion recognition.

Emotion recognition and sentiment analysis have become a new trend in social media, helping users and companies to automatically extract the opinions expressed in user-generated content, especially videos. Thanks to the high availability of computers and smartphones, and the rapid rise of social media, consumers tend to record their reviews and opinions about products or films and upload them on social media platforms, such as YouTube and Facebook. Such videos often contain comparisons, which can aid prospective buyers make an informed decision.

The primary advantage of analyzing videos over text is the surplus of behavioral cues present in vocal and visual modalities. The vocal modulations and facial expressions in the visual data, along with textual data, provide important cues to better identify affective states of the opinion holder. Thus, a combination of text and video data helps to create a more robust emotion and sentiment analysis model (Poria et al., 2017a).

An utterance (Olson, 1977) is a unit of speech bound by breathes or pauses. Utterance-level sentiment analysis focuses on tagging every utterance of a video with a sentiment label (instead of assigning a unique label to the whole video). In particular, utterance-level sentiment analysis is useful to understand the sentiment dynamics of different aspects of the topics covered by the speaker throughout his/her speech.

Recently, a number of approaches to multimodal sentiment analysis, producing interesting results, have been proposed (Pérez-Rosas et al., 2013; Wollmer et al., 2013; Poria et al., 2015). However, there are major issues that remain unaddressed. Not considering the relation and dependencies among the utterances is one of such issues. State-of-the-art approaches in this area treat utterances independently and ignore the order of utterances in a video (Cambria et al., 2017b).

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 873–883
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1081

Every utterance in a video is spoken at a distinct time and in a particular order. Thus, a video can be treated as a sequence of utterances. Like any other sequence classification problem (Collobert et al., 2011), sequential utterances of a video may largely be contextually correlated and, hence, influence each other's sentiment distribution. In our paper, we give importance to the order in which utterances appear in a video.

We treat surrounding utterances as the context of the utterance that is aimed to be classified. For example, the MOSI dataset (Zadeh et al., 2016) contains a video, in which a girl reviews the movie 'Green Hornet'. At one point, she says "The Green Hornet did something similar". Normally, doing something similar, i.e., monotonous or repetitive might be perceived as negative. However, the nearby utterances "It engages the audience more", "they took a new spin on it", "and I just loved it" indicate a positive context.

The hypothesis of the independence of tokens is quite popular in information retrieval and data mining, e.g., bag-of-words model, but it has a lot limitations (Cambria and White, 2014). In this paper, we discard such an oversimplifying hypothesis and develop a framework based on long short-term memory (LSTM) that takes a sequence of utterances as input and extracts contextual utterance-level features.

The other uncovered major issues in the literature are the role of speaker-dependent versus speaker-independent models, the impact of each modality across the dataset, and generalization ability of a multimodal sentiment classifier. Leaving these issues unaddressed has presented difficulties in effective comparison of different multimodal sentiment analysis methods. In this work, we address all of these issues.

Our model preserves the sequential order of utterances and enables consecutive utterances to share information, thus providing contextual information to the utterance-level sentiment classification process. Experimental results show that the proposed framework has outperformed the state of the art on three benchmark datasets by 5-10%.

The paper is organized as follows: Section 2 provides a brief literature review on multimodal sentiment analysis; Section 3 describes the proposed method in detail; experimental results and discussion are shown in Section 4; finally, Section 5 concludes the paper.

2 Related Work

The opportunity to capture people's opinions has raised growing interest both within the scientific community, for the new research challenges, and in the business world, due to the remarkable benefits to be had from financial market prediction.

Text-based sentiment analysis systems can be broadly categorized into knowledge-based and statistics-based approaches (Cambria et al., 2017a). While the use of knowledge bases was initially more popular for the identification of polarity in text (Cambria et al., 2016; Poria et al., 2016c), sentiment analysis researchers have recently been using statistics-based approaches, with a special focus on supervised statistical methods (Socher et al., 2013; Oneto et al., 2016).

In 1974, Ekman (Ekman, 1974) carried out extensive studies on facial expressions which showed that universal facial expressions are able to provide sufficient clues to detect emotions. Recent studies on speech-based emotion analysis (Datcu and Rothkrantz, 2008) have focused on identifying relevant acoustic features, such as fundamental frequency (pitch), intensity of utterance, bandwidth, and duration.

As for fusing audio and visual modalities for emotion recognition, two of the early works were (De Silva et al., 1997) and (Chen et al., 1998). Both works showed that a bimodal system yielded a higher accuracy than any unimodal system. More recent research on audio-visual fusion for emotion recognition has been conducted at either feature level (Kessous et al., 2010) or decision level (Schuller, 2011). While there are many research papers on audio-visual fusion for emotion recognition, only a few have been devoted to multimodal emotion or sentiment analysis using textual clues along with visual and audio modalities. (Wollmer et al., 2013) and (Rozgic et al., 2012) fused information from audio, visual, and textual modalities to extract emotion and sentiment.

Poria et al. (Poria et al., 2015, 2016d, 2017b) extracted audio, visual and textual features using convolutional neural network (CNN); concatenated those features and employed multiple kernel learning (MKL) for final sentiment classification. (Metallinou et al., 2008) and (Eyben et al., 2010a) fused audio and textual modalities for emotion recognition. Both approaches relied on a feature-level fusion. (Wu and Liang, 2011) fused audio and textual clues at decision level.

3 Method

In this work, we propose a LSTM network that takes as input the sequence of utterances in a video and extracts contextual unimodal and multimodal features by modeling the dependencies among the input utterances. M number of videos, comprising of its constituent utterances, serve as the input. We represent the dataset as $U = u_1, u_2, u_3..., u_M$ and each $u_i = u_{i,1}, u_{i,2}, ..., u_i, L_i$ where L_i is the number of utterances in video u_i. Below, we present an overview of the proposed method in two major steps.

A. Context-Independent Unimodal Utterance-Level Feature Extraction

Firstly, the unimodal features are extracted without considering the contextual information of the utterances (Section 3.1).

B. Contextual Unimodal and Multimodal Classification

Secondly, the context-independent unimodal features (from Step A) are fed into a LSTM network (termed contextual LSTM) that allows consecutive utterances in a video to share information in the feature extraction process (Section 3.2).

We experimentally show that this proposed framework improves the performance of utterance-level sentiment classification over traditional frameworks.

3.1 Extracting Context-Independent Unimodal Features

Initially, the unimodal features are extracted from each utterance separately, i.e., we do not consider the contextual relation and dependency among the utterances. Below, we explain the textual, audio, and visual feature extraction methods.

3.1.1 text-CNN: Textual Features Extraction

The source of textual modality is the transcription of the spoken words. For extracting features from the textual modality, we use a CNN (Karpathy et al., 2014). In particular, we first represent each utterance as the concatenation of vectors of the constituent words. These vectors are the publicly available 300-dimensional word2vec vectors trained on 100 billion words from Google News (Mikolov et al., 2013).

The convolution kernels are thus applied to these concatenated word vectors instead of individual words. Each utterance is wrapped to a window of 50 words which serves as the input to the CNN. The CNN has two convolutional layers; the first layer has two kernels of size 3 and 4, with 50 feature maps each and the second layer has a kernel of size 2 with 100 feature maps.

The convolution layers are interleaved with max-pooling layers of window 2×2. This is followed by a fully connected layer of size 500 and softmax output. We use a rectified linear unit (ReLU) (Teh and Hinton, 2001) as the activation function. The activation values of the fully-connected layer are taken as the features of utterances for text modality. The convolution of the CNN over the utterance learns abstract representations of the phrases equipped with implicit semantic information, which with each successive layer spans over increasing number of words and ultimately the entire utterance.

3.1.2 openSMILE: Audio Feature Extraction

Audio features are extracted at 30 Hz frame-rate and a sliding window of 100 ms. To compute the features, we use openSMILE (Eyben et al., 2010b), an open-source software that automatically extracts audio features such as pitch and voice intensity. Voice normalization is performed and voice intensity is thresholded to identify samples with and without voice. Z-standardization is used to perform voice normalization.

The features extracted by openSMILE consist of several low-level descriptors (LLD), e.g., MFCC, voice intensity, pitch, and their statistics, e.g., mean, root quadratic mean, etc. Specifically, we use IS13-ComParE configuration file in openSMILE. Taking into account all functionals of each LLD, we obtained 6373 features.

3.1.3 3D-CNN: Visual Feature Extraction

We use 3D-CNN (Ji et al., 2013) to obtain visual features from the video. We hypothesize that 3D-CNN will not only be able to learn relevant features from each frame, but will also learn the changes among given number of consecutive frames.

In the past, 3D-CNN has been successfully applied to object classification on tridimensional data (Ji et al., 2013). Its ability to achieve state-of-the-art results motivated us to adopt it in our framework.

Let $vid \in \mathbb{R}^{c \times f \times h \times w}$ be a video, where c = number of channels in an image (in our case $c = 3$, since we consider only RGB images), f = number of frames, h = height of the frames, and w = width of the frames. Again, we consider the 3D convolutional filter $filt \in \mathbb{R}^{f_m \times c \times f_d \times f_h \times f_w}$, where f_m = number of feature maps, c = number of channels, f_d = number of frames (in other words depth of the filter), f_h = height of the filter, and f_w = width of the filter. Similar to 2D-CNN, $filt$ slides across video vid and generates output $convout \in \mathbb{R}^{f_m \times c \times (f-f_d+1) \times (h-f_h+1) \times (w-f_w+1)}$. Next, we apply max pooling to $convout$ to select only relevant features. The pooling will be applied only to the last three dimensions of the array $convout$.

In our experiments, we obtained best results with 32 feature maps (f_m) with the filter-size of $5 \times 5 \times 5$ (or $f_d \times f_h \times f_w$). In other words, the dimension of the filter is $32 \times 3 \times 5 \times 5 \times 5$ (or $f_m \times c \times f_d \times f_h \times f_w$). Subsequently, we apply max pooling on the output of convolution operation, with window-size being $3 \times 3 \times 3$. This is followed by a dense layer of size 300 and softmax. The activation values of this dense layer are finally used as the video features for each utterance.

3.2 Context-Dependent Feature Extraction

In sequence classification, the classification of each member is dependent on the other members. Utterances in a video maintain a sequence. We hypothesize that, within a video, there is a high probability of inter-utterance dependency with respect to their sentimental clues.

In particular, we claim that, when classifying one utterance, other utterances can provide important contextual information. This calls for a model which takes into account such inter-dependencies and the effect these might have on the target utterance. To capture this flow of informational triggers across utterances, we use a LSTM-based recurrent neural network (RNN) scheme (Gers, 2001).

3.2.1 Long Short-Term Memory

LSTM (Hochreiter and Schmidhuber, 1997) is a kind of RNN, an extension of conventional feed-forward neural network. Specifically, LSTM cells are capable of modeling long-range dependencies, which other traditional RNNs fail to do given the vanishing gradient issue. Each LSTM cell consists of an input gate i, an output gate o, and a forget gate f, to control the flow of information.

Current research (Zhou et al., 2016) indicates the benefit of using such networks to incorporate contextual information in the classification process. In our case, the LSTM network serves the purpose of context-dependent feature extraction by modeling relations among utterances. We term our architecture 'contextual LSTM'. We propose several architectural variants of it later in the paper.

3.2.2 Contextual LSTM Architecture

Let unimodal features have dimension k, each utterance is thus represented by a feature vector $\boldsymbol{x}_{i,t} \in \mathbb{R}^k$, where t represents the t^{th} utterance of the video i. For a video, we collect the vectors for all the utterances in it, to get $\boldsymbol{X_i} = [\boldsymbol{x}_{i,1}, \boldsymbol{x}_{i,2}, ..., \boldsymbol{x}_{i,L_i}] \in \mathbb{R}^{L_i \times k}$, where L_i represents the number of utterances in the video. This matrix X_i serves as the input to the LSTM. Figure 1 demonstrates the functioning of this LSTM module.

In the procedure, *getLstmFeatures(X_i)* of Algorithm 1, each of these utterance $x_{i,t}$ is passed through a LSTM cell using the equations mentioned in line 32 to 37. The output of the LSTM cell $h_{i,t}$ is then fed into a dense layer and finally into a softmax layer (line 38 to 39). The activations of the dense layer $z_{i,t}$ are used as the context-dependent features of contextual LSTM.

3.2.3 Training

The training of the LSTM network is performed using categorical cross-entropy on each utterance's softmax output per video, i.e.,

$$loss = -\frac{1}{(\sum_{i=1}^{M} L_i)} \sum_{i=1}^{M} \sum_{j=1}^{L_i} \sum_{c=1}^{C} y_{i,c}^{j} \log_2(\hat{y}_{i,c}^{j}),$$

where M = total number of videos, L_i = number of utterances for i^{th} video, $y_{i,c}^{j}$ = original output of class c, and $\hat{y}_{i,c}^{j}$ = predicted output for j^{th} utterance of i^{th} video.

As a regularization method, dropout between the LSTM cell and dense layer is introduced to avoid overfitting. As the videos do not have the same number of utterances, padding is introduced to serve as neutral utterances. To avoid the proliferation of noise within the network, bit masking is done on these padded utterances to eliminate their effect in the network. Hyper-parameters tuning is done on the training set by splitting it into train and validation components with $80/20\%$ split.

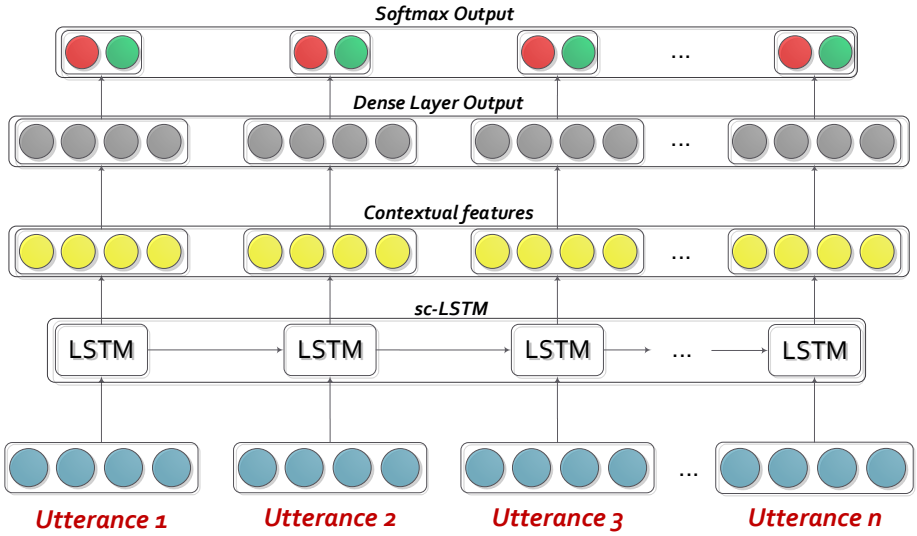

Figure 1: Contextual LSTM network: input features are passed through an unidirectional LSTM layer, followed by a dense and then a softmax layer. The dense layer activations serve as the output features.

RMSprop has been used as the optimizer which is known to resolve Adagrad's radically diminishing learning rates (Duchi et al., 2011). After feeding the training set to the network, the test set is passed through it to generate their context-dependent features. These features are finally passed through an SVM for the final classification.

Different Network Architectures We consider the following variants of the contextual LSTM architecture in our experiments.

sc-LSTM This variant of the contextual LSTM architecture consists of unidirectional LSTM cells. As this is the simple variant of the contextual LSTM, we termed it as simple contextual LSTM (sc-LSTM[1]).

h-LSTM We also investigate an architecture where the dense layer after the LSTM cell is omitted. Thus, the output of the LSTM cell $h_{i,t}$ provides our context-dependent features and the softmax layer provides the classification. We call this architecture hidden-LSTM (h-LSTM).

bc-LSTM Bi-directional LSTMs are two unidirectional LSTMs stacked together having opposite directions. Thus, an utterance can get information from utterances occurring before and after itself in the video. We replaced the regular LSTM with a bi-directional LSTM and named the resulting architecture as bi-directional contextual LSTM (bc-LSTM). The training process of this architecture is similar to sc-LSTM.

[1] http://github.com/senticnet/sc-lstm

uni-SVM In this setting, we first obtain the unimodal features as explained in Section 3.1, concatenate them and then send to an SVM for the final classification. It should be noted that using a gated recurrent unit (GRU) instead of LSTM did not improve the performance.

3.3 Fusion of Modalities

We accomplish multimodal fusion through two different frameworks, described below.

3.3.1 Non-hierarchical Framework

In this framework, we concatenate context-independent unimodal features (from Section 3.1) and feed that into the contextual LSTM networks, i.e., sc-LSTM, bc-LSTM, and h-LSTM.

3.3.2 Hierarchical Framework

Contextual unimodal features can further improve performance of the multimodal fusion framework explained in Section 3.3.1. To accomplish this, we propose a hierarchical deep network which consists of two levels.

Level-1 Context-independent unimodal features (from Section 3.1) are fed to the proposed LSTM network to get *context-sensitive* unimodal feature representations for each utterance. Individual LSTM networks are used for each modality.

Level-2 This level consists of a contextual LSTM network similar to Level-1 but independent in training and computation. Output from each LSTM network in Level-1 are concatenated and fed into this LSTM network, thus providing an inherent fusion scheme (see Figure 2).

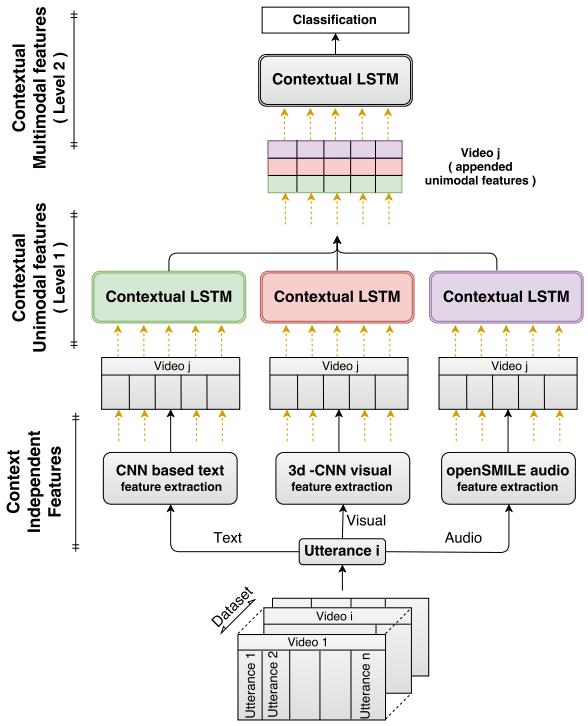

Figure 2: Hierarchical architecture for extracting context-dependent multimodal utterance features (see Figure 1 for the LSTM module).

The performance of the second level banks on the quality of the features from the previous level, with better features aiding the fusion process. Algorithm 1 describes the overall computation for utterance classification. For the hierarchical framework, we train Level-1 and Level-2 successively but separately, i.e., the training is not performed "end-to-end".

Weight		Bias	
W_i, W_f, W_c, W_o	$\in \mathbb{R}^{d \times k}$	b_i, b_f, b_c, b_o	$\in \mathbb{R}^{d}$
$P_i, P_f, P_c, P_o V_o$	$\in \mathbb{R}^{d \times d}$	b_z	$\in \mathbb{R}^{m}$
W_z	$\in \mathbb{R}^{m \times d}$	b_{sft}	$\in \mathbb{R}^{c}$
W_{sft}	$\in \mathbb{R}^{c \times m}$		

Table 1: Summary of notations used in Algorithm 1. Legenda: d = dimension of hidden unit; k = dimension of input vectors to LSTM layer; c = number of classes.

4 Experiments

4.1 Dataset details

Most of the research in multimodal sentiment analysis is performed on datasets with speaker overlap in train and test splits. Because each individual has a unique way of expressing emotions and sentiments, however, finding generic, person-independent features for sentiment analysis is very important.

Algorithm 1 Proposed Architecture

procedure TRAINARCHITECTURE(U, V)
  Train context-independent models with U
  for `i:[1,M]` **do** ▷ extract baseline features
    for `j:[1,`L_i`]` **do**
      $x_{i,j} \leftarrow TextFeatures(u_{i,j})$

    $Z^{*}_i \leftarrow getLSTMFeatures(X^{*}_i)$
  testArchitecture(V)
  return Z^*
procedure TESTARCHITECTURE(V)
  Similar to training phase. V is passed through the learnt models to get the features and classification outputs. Table 1 shows the trainable parameters.
procedure GETLSTMFEATURES(X_i) ▷ for i^{th} video
  $Z_i \leftarrow \phi$
  for `t:[1,`L_i`]` **do** ▷ Table 1 provides notation
    $i_t \leftarrow \sigma(W_i x_{i,t} + P_i . h_{t-1} + b_i)$
    $\widetilde{C_t} \leftarrow tanh(W_c x_{i,t} + P_c h_{t-1} + b_c)$
    $f_t \leftarrow \sigma(W_f x_t + P_f h_{t-1} + b_f)$
    $C_t \leftarrow i_t * \widetilde{C_t} + f_t * C_{t-1}$
    $o_t \leftarrow \sigma(W_o x_t + P_o h_{t-1} + V_o C_t + b_o)$
    $h_t \leftarrow o_t * tanh(C_t)$ ▷ output of lstm cell
    $z_t \leftarrow ReLU(W_z h_t + b_z)$ ▷ dense layer
    $prediction \leftarrow softmax(W_{sft} z_t + b_{sft})$
    $Z_i \leftarrow Z_i \cup z_t$
  return Z_i

In real-world applications, the model should be robust to person idiosyncrasy but it is very difficult to come up with a generalized model from the behavior of a limited number of individuals. To this end, we perform person-independent experiments to study generalization of our model, i.e., our train/test splits of the datasets are completely disjoint with respect to speakers.

Multimodal Sentiment Analysis Datasets

MOSI The MOSI dataset (Zadeh et al., 2016) is a dataset rich in sentimental expressions where 93 people review topics in English. The videos

are segmented with each segments sentiment label scored between +3 (strong positive) to -3 (strong negative) by 5 annotators. We took the average of these five annotations as the sentiment polarity and, hence, considered only two classes (positive and negative). The train/validation set consists of the first 62 individuals in the dataset. The test set contains opinionated videos by rest 31 speakers. In particular, 1447 and 752 utterances are used in training and test, respectively.

MOUD This dataset (Pérez-Rosas et al., 2013) contains product review videos provided by 55 persons. The reviews are in Spanish (we used Google Translate API[2] to get the English transcripts). The utterances are labeled to be either *positive, negative or neutral*. However, we drop the *neutral* label to maintain consistency with previous work. Out of 79 videos in the dataset, 59 videos are considered in the train/val set.

Multimodal Emotion Recognition Datasets

IEMOCAP The IEMOCAP (Busso et al., 2008) contains the acts of 10 speakers in a two-way conversation segmented into utterances. The medium of the conversations in all the videos is English. The database contains the following categorical labels: anger, happiness, sadness, neutral, excitement, frustration, fear, surprise, and other, but we take only the first four so as to compare with the state of the art (Rozgic et al., 2012). Videos by the first 8 speakers are considered in the training set. The train/test split details are provided in Table 2, which provides information regarding train/test split of all the datasets. Table 2 also provides cross-dataset split details where the datasets MOSI and MOUD are used for training and testing, respectively. The proposed model being used on reviews from different languages allows us to analyze its robustness and generalizability.

4.1.1 Characteristic of the Datasets

In order to evaluate the robustness of our proposed method, we employ it on multiple datasets of different kinds. Both MOSI and MOUD are used for the sentiment classification task but they consist of review videos spoken in different languages, i.e., English and Spanish, respectively.

[2] http://translate.google.com

IEMOCAP dataset is different from MOSI and MOUD since it is annotated with emotion labels. Apart from this, IEMOCAP dataset was created using a different method than MOSI and MOUD. These two datasets were developed by crawling consumers' spontaneous online product review videos from popular social websites and later labeled with sentiment labels. To curate the IEMOCAP dataset, instead, subjects were provided affect-related scripts and asked to act.

As pointed out by Poria et al. (Poria et al., 2017a), acted dataset like IEMOCAP can suffer from biased labeling and incorrect acting which can further cause the poor generalizability of the models trained on the acted datasets.

Dataset	Train		Test	
	uttrnce	*video*	*uttrnce*	*video*
IEMOCAP	4290	120	1208	31
MOSI	1447	62	752	31
MOUD	322	59	115	20
MOSI → MOUD	2199	93	437	79

Table 2: uttrnce: Utterance; Person-Independent Train/Test split details of each dataset (≈ 70/30 % split). Legenda: X→Y represents train: X and test: Y; Validation sets are extracted from the shuffled training sets using 80/20 % train/val ratio.

It should be noted that the datasets' individual configuration and splits are same throughout all the experiments (i.e., context-independent unimodal feature extraction, LSTM-based context-dependent unimodal and multimodal feature extraction and classification).

4.2 Performance of Different Models

In this section, we present unimodal and multimodal sentiment analysis performance of different LSTM network variants as explained in Section 3.2.3 and comparison with the state of the art.

Hierarchical vs Non-hierarchical Fusion Framework As expected, trained contextual unimodal features help the hierarchical fusion framework to outperform the non-hierarchical framework. Table 3 demonstrates this by comparing the hierarchical and the non-hierarchical frameworks using the bc-LSTM network.

For this reason, we the rest of the analysis only leverages on the hierarchical framework. The non-hierarchical model outperforms the baseline uni-SVM, which confirms that it is the context-sensitive learning paradigm that plays the key role in improving performance over the baseline.

Comparison of Different Network Variants It is to be noted that both sc-LSTM and bc-LSTM perform quite well on the multimodal emotion recognition and sentiment analysis datasets. Since bc-LSTM has access to both the preceding and following information of the utterance sequence, it performs consistently better on all the datasets over sc-LSTM. The usefulness of the dense layer in increasing the performance is evident from the experimental results shown in Table 3. The performance improvement is in the range of 0.3% to 1.5% on MOSI and MOUD datasets. On the IEMOCAP dataset, the performance improvement of bc-LSTM and sc-LSTM over h-LSTM is in the range of 1% to 5%.

Comparison with the Baselines Every LSTM network variant has outperformed the baseline uni-SVM on all the datasets by the margin of 2% to 5% (see Table 3). These results prove our initial hypothesis that modeling the contextual dependencies among utterances (which uni-SVM cannot do) improves the classification. The higher performance improvement on the IEMOCAP dataset indicates the necessity of modeling long-range dependencies among the utterances as continuous emotion recognition is a multiclass sequential problem where a person does not frequently change emotions (Wöllmer et al., 2008). We have implemented and compared with the current state-of-the-art approach proposed by (Poria et al., 2015). In their method, they extracted features from each modality and fed these to a MKL classifier. However, they did not conduct the experiment in a speaker-independent manner and also did not consider the contextual relation among the utterances. In Table 3, the results in bold are statistically significant ($p < 0.05$) in compare to uni-SVM. Experimental results in Table 4 show that the proposed method outperformes (Poria et al., 2015) by a significant margin. For the emotion recognition task, we have compared our method with the current state of the art (Rozgic et al., 2012), who extracted features in a similar fashion to (Poria et al., 2015) (although they used SVM trees (Yuan et al., 2006) for the fusion).

4.3 Importance of the Modalities

As expected, in all kinds of experiments, bimodal and trimodal models have outperformed unimodal models. Overall, audio modality has performed better than visual on all the datasets.

On MOSI and IEMOCAP datasets, the textual classifier achieves the best performance over other unimodal classifiers. On IEMOCAP dataset, the unimodal and multimodal classifiers obtained poor performance to classify *neutral* utterances. The textual modality, combined with non-textual modes, boosts the performance in IEMOCAP by a large margin. However, the margin is less in the other datasets.

On the MOUD dataset, the textual modality performs worse than audio modality due to the noise introduced in translating Spanish utterances to English. Using Spanish word vectors[3] in *text-CNN* results in an improvement of 10%. Nonetheless, we report results using these translated utterances as opposed to utterances trained on Spanish word vectors, in order to make fair comparison with (Poria et al., 2015).

4.4 Generalization of the Models

To test the generalizability of the models, we have trained our framework on complete MOSI dataset and tested on MOUD dataset (Table 5). The performance was poor for audio and textual modality as the MOUD dataset is in Spanish while the model is trained on MOSI dataset, which is in English language. However, notably the visual modality performs better than the other two modalities in this experiment, which means that in cross-lingual scenarios facial expressions carry more generalized, robust information than audio and textual modalities. We could not carry out a similar experiment for emotion recognition as no other utterance-level dataset apart from the IEMOCAP was available at the time of our experiments.

4.5 Qualitative Analysis

The need for considering context dependency (see Section 1) is of prime importance for utterance-level sentiment classification. For example, in the utterance *"What would have been a better name for the movie"*, the speaker is attempting to comment the quality of the movie by giving an appropriate name. However, the sentiment is expressed implicitly and requires the contextual knowledge about the mood of the speaker and his/her general opinion about the film. The baseline unimodal-SVM and state of the art fail to classify this utterance correctly[4].

[3] http://crscardellino.me/SBWCE

[4] RNTN classifies it as neutral. It can be seen here http://nlp.stanford.edu:8080/sentiment/rntnDemo.html

Table 5: Cross-dataset comparison in terms of classification accuracy.

However, information from neighboring utterances, e.g., *"And I really enjoyed it"* and *"The countryside which they showed while going through Ireland was astoundingly beautiful"* indicate its positive context and help our contextual model to classify the target utterance correctly. Such contextual relationships are prevalent throughout the dataset.

In order to have a better understanding of the roles of each modality for the overall classification, we have also done some qualitative analysis. For example, the utterance *"who doesn't have any presence or greatness at all"* was classified as positive by the audio classifier (as "presence and greatness at all" was spoken with enthusiasm). However, the textual modality caught the negation induced by "doesn't" and classified it correctly. The same happened to the utterance "amazing special effects", which presented no jest of enthusiasm in the speaker's voice nor face, but was correctly classified by the textual classifier.

On other hand, the textual classifier classified the utterance "that like to see comic book characters treated responsibly" as positive (for the presence of "like to see" and "responsibly") but the high pitch of anger in the person's voice and the frowning face helps to identify this as a negative utterance. In some cases, the predictions of the proposed method are wrong because of face occlusion or noisy audio. Also, in cases where sentiment is very weak and non contextual, the proposed approach shows some bias towards its surrounding utterances, which further leads to wrong predictions.

5 Conclusion

The contextual relationship among utterances in a video is mostly ignored in the literature. In this paper, we developed a LSTM-based network to extract contextual features from the utterances of a video for multimodal sentiment analysis. The proposed method has outperformed the state of the art and showed significant performance improvement over the baseline.

As future work, we plan to develop a LSTM-based attention model to determine the importance of each utterance and its specific contribution to each modality for sentiment classification.

Abstract

The sociolinguistic construct of stancetaking describes the activities through which discourse participants create and signal relationships to their interlocutors, to the topic of discussion, and to the talk itself. Stancetaking underlies a wide range of interactional phenomena, relating to formality, politeness, affect, and subjectivity. We present a computational approach to stancetaking, in which we build a theoretically-motivated lexicon of stance markers, and then use multidimensional analysis to identify a set of underlying stance dimensions. We validate these dimensions intrinsically and extrinsically, showing that they are internally coherent, match pre-registered hypotheses, and correlate with social phenomena.

1 Introduction

What does it mean to be welcoming or standoffish, light-hearted or cynical? Such interactional styles are performed primarily with language, yet little is known about how linguistic resources are arrayed to create these social impressions. The sociolinguistic concept of *interpersonal stancetaking* attempts to answer this question, by providing a conceptual framework that accounts for a range of interpersonal phenomena, subsuming formality, politeness, and subjectivity (Du Bois, 2007).[1] This framework has been applied almost exclusively through qualitative methods, using close readings of individual texts or dialogs to uncover how language is used to position individuals with respect to their interlocutors and readers.

We attempt the first large-scale operationalization of stancetaking through computational methods. Du Bois (2007) formalizes stancetaking as a multi-dimensional construct, reflecting the relationship of discourse participants to (a) the audience or interlocutor; (b) the topic of discourse; (c) the talk or text itself. However, the multidimensional nature of stancetaking poses problems for traditional computational approaches, in which labeled data is obtained by relying on annotator intuitions about scalar concepts such politeness (Danescu-Niculescu-Mizil et al., 2013) and formality (Pavlick and Tetreault, 2016).

Instead, our approach is based on a theoretically-guided application of unsupervised learning, in the form of factor analysis, applied to lexical features. Stancetaking is characterized in large part by an array of linguistic features ranging from discourse markers such as *actually* to backchannels such as *yep* (Kiesling, 2009). We therefore first compile a lexicon of stance markers, combining prior lexicons from Biber and Finegan (1989) and the Switchboard Dialogue Act Corpus (Jurafsky et al., 1998). We then extend this lexicon to the social media domain using word embeddings. Finally, we apply multi-dimensional analysis of co-occurrence patterns to identify a small set of *stance dimensions*.

To measure the internal coherence (construct validity) of the stance dimensions, we use a word

[1] Stancetaking is distinct from the notion of *stance* which corresponds to a position in a debate (Walker et al., 2012). Similarly, Freeman et al. (2014) correlate phonetic features with the *strength* of such argumentative stances.

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 884–895
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1082

intrusion task (Chang et al., 2009) and a set of preregistered hypotheses. To measure the utility of the stance dimensions, we perform a series of extrinsic evaluations. A predictive evaluation shows that the membership of online communities is determined in part by the interactional stances that predominate in those communities. Furthermore, the induced stance dimensions are shown to align with annotations of politeness and formality.

Contributions We operationalize the sociolinguistic concept of stancetaking as a multidimensional framework, making it possible to measure at scale. Specifically,

- we contribute a lexicon of stance markers based on prior work and adapted to the genre of online interpersonal discourse;
- we group stance markers into latent dimensions;
- we show that these stance dimensions are internally coherent;
- we demonstrate that the stance dimensions predict and correlate with social phenomena.[2]

2 Related Work

From a theoretical perspective, we build on prior work on interactional meaning in language. Methodologically, our paper relates to prior work on lexicon-based analysis and contrastive studies of social media communities.

2.1 Linguistic Variation and Social Meaning

In computational sociolinguistics (Nguyen et al., 2016), language variation has been studied primarily in connection with macro-scale social variables, such as age (Argamon et al., 2007; Nguyen et al., 2013), gender (Burger et al., 2011; Bamman et al., 2014), race (Eisenstein et al., 2011; Blodgett et al., 2016), and geography (Eisenstein et al., 2010). This parallels what Eckert (2012) has called the "first wave" of language variation studies in sociolinguistics, which also focused on macro-scale variables.

More recently, sociolinguists have dedicated increased attention to situational and stylistic variation, and the *interactional meaning* that such variation can convey (Eckert and Rickford, 2001). This linguistic research can be aligned with computational efforts to quantify phenomena such as subjectivity (Riloff and Wiebe, 2003), sentiment (Wiebe et al., 2005), politeness (Danescu-Niculescu-Mizil et al., 2013), formality (Pavlick and Tetreault, 2016), and power dynamics (Prabhakaran et al., 2012). While linguistic research on interactional meaning has focused largely on qualitative methodologies such as discourse analysis (e.g., Bucholtz and Hall, 2005), these computational efforts have made use of crowdsourced annotations to build large datasets of, for example, polite and impolite text. These annotation efforts draw on the annotators' intuitions about the meaning of these sociolinguistic constructs.

Interpersonal stancetaking represents an attempt to unify concepts such as sentiment, politeness, formality, and subjectivity under a single theoretical framework (Jaffe, 2009; Kiesling, 2009). The key idea, as articulated by Du Bois (2007), is that stancetaking captures the speaker's relationship to (a) the topic of discussion, (b) the interlocutor or audience, and (c) the talk (or writing) itself. Various configurations of these three legs of the "stance triangle" can account for a range of phenomena. For example, epistemic stance relates to the speaker's certainty about what is being expressed, while affective stance indicates the speaker's emotional position with respect to the content (Ochs, 1993).

The framework of stancetaking has been widely adopted in linguistics, particularly in the discourse analytic tradition, which involves close reading of individual texts or conversations (Kärkkäinen, 2006; Keisanen, 2007; Precht, 2003; White, 2003). But despite its strong theoretical foundation, we are aware of no prior efforts to operationalize stancetaking at scale. Since annotators may not have strong intuitions about stance — in the way that they do about formality and politeness — we cannot rely on the annotation methodologies employed in prior work. We take a different approach, performing a multidimensional analysis of the distribution of likely stance markers.

2.2 Lexicon-based Analysis

Our operationalization of stancetaking is based on the induction of lexicons of stance markers. The lexicon-based methodology is related to earlier work from social psychology, such as the General Inquirer (Stone, 1966) and LIWC (Tausczik and Pennebaker, 2010). In LIWC, the basic categories were identified first, based on psychological

[2]Lexicons and stance dimensions are available at https://github.com/umashanthi-research/multidimensional-stance-lexicon

constructs (e.g., positive emotion, cognitive processes, drive to power) and syntactic groupings of words and phrases (e.g., pronouns, prepositions, quantifiers). The lexicon designers then manually contructed lexicons for each category, augmenting their intuitions by using distributional statistics to suggest words that may have been missed (Pennebaker et al., 2015). In contrast, we follow the approach of Biber (1991), using multidimensional analysis to identify latent groupings of markers based on co-occurrence statistics. We then use crowdsourcing and extrinsic comparisons to validate the coherence of these dimensions.

2.3 Multicommunity Studies

Social media platforms such as Reddit, Stack Exchange, and Wikia can be considered *multicommunity environments*, in that they host multiple subcommunities with distinct social and linguistic properties. Such subcommunities can be contrasted in terms of topics (Adamic et al., 2008; Hessel et al., 2014) and social networks (Backstrom et al., 2006). Our work focuses on Reddit, emphasizing community-wide differences in norms for interpersonal interaction. In the same vein, Tan and Lee (2015) attempt to characterize stylistic differences across subreddits by focusing on very common words and parts-of-speech; Tran and Ostendorf (2016) use language models and topic models to measure similarity across threads within a subreddit. One distinction of our approach is that the use of multidimensional analysis gives us interpretable dimensions of variation. This makes it possible to identify the specific interpersonal features that vary across communities.

3 Data

Reddit, one of the internet's largest social media platforms, is a collection of subreddits organized around various topics of interest. As of January 2017, there were more than one million subreddits and nearly 250 million users, discussing topics ranging from politics (*r/politics*) to horror stories (*r/nosleep*).[3] Although Reddit was originally designed for sharing hyperlinks, it also provides the ability to post original textual content, submit comments, and vote on content quality (Gilbert, 2013). Reddit's conversation-like threads are therefore well suited for the study of interpersonal social and linguistic phenomena.

[3] http://redditmetrics.com/

Subreddits	126,789
Authors	6,401,699
Threads	52,888,024
Comments	531,804,658

Table 1: Dataset size

For example, the following are two comments from the subreddit *r/malefashionadvice*, posted in response to a picture posted by a user asking for fashion advise.

U_1: *"I think the beard* ***looks pretty good****.* ***Definitely*** *not the goatee. Clean shaven is always the safe option."*

U_2: *"****Definitely*** *the beard. But keep it trimmed."*

The phrases in **bold** face are markers of stance, indicating a *evaluative* stance. The following example is a part of a thread in the subreddit *r/photoshopbattles* where users discuss an edited image posted by the original poster *OP*. The phrases in **bold** face are markers of stance, indicating an *involved* and *interactional* stance.

U_3: *"****Ha ha*** *awesome!"*
U_4: "are those..... furries?"
OP: *"****yes****, sir. They are!"*
U_4: *"****Oh cool****. That makes sense!"*

We used an archive of 530 million comments posted on Reddit in 2014, retrieved from the public archive of Reddit comments.[4] This dataset consists of each post's textual content, along with metadata that identifies the subreddit, thread, author, and post creation time. More statistics about the full dataset are shown in Table 1.

4 Stance Lexicon

Interpersonal stancetaking can be characterized in part by an array of linguistic features such as hedges (e.g., *might*, *kind of*), discourse markers (e.g., *actually*, *I mean*), and backchannels (e.g., *yep*, *um*). Our analysis focuses on these markers, which we collect into a lexicon.

4.1 Seed lexicon

We began with a seed lexicon of stance markers from Biber and Finegan (1989), who compiled an

[4] https://archive.org/details/2015_reddit_comments_corpus

extensive list by surveying dictionaries, previous studies on stance, and texts in several genres of English. This list includes certainty adverbs (e.g., *actually*, *of course*, *in fact*), affect markers (e.g., *amazing*, *thankful*, *sadly*), and hedges (e.g., *kind of*, *maybe*, *something like*) among other adverbial, adjectival, verbal, and modal markers of stance. In total, this list consists of 448 stance markers.

The Biber and Finegan (1989) lexicon is primarily based on written genres from the pre-social media era. Our dataset — like much of the recent work in this domain — consists of online discussions, which differ significantly from printed texts (Eisenstein, 2013). One difference is that online discussions contain a number of dialog act markers that are characteristic of spoken language, such as *oh yeah*, *nah*, *wow*. We accounted for this by adding 74 dialog act markers from the Switchboard Dialog Act Corpus (Jurafsky et al., 1998). The final seed lexicon consists of 517 unique markers, from these two sources. Note that the seed lexicon also includes markers that contain multiple tokens (e.g. *kind of*, *I know*).

4.2 Lexicon expansion

Online discussions differ not only from written texts, but also from spoken discussions, due to their use of non-standard vocabulary and spellings. To measure stance accurately, these genre differences must be accounted for. We therefore expanded the seed lexicon using automated techniques based on distributional statistics. This is similar to prior work on the expansion of sentiment lexicons (Hatzivassiloglou and McKeown, 1997; Hamilton et al., 2016).

Our lexicon expansion approach used word embeddings to find words that are distributionally similar to those in the seed set. We trained word embeddings on a corpus of 25 million Reddit comments and a vocabulary of 100K most frequent words on Reddit using the structured skip-gram models of both WORD2VEC (Mikolov et al., 2013) and WANG2VEC (Ling et al., 2015) with default parameters. The WANG2VEC method augments WORD2VEC by accounting for word order information. We found the similarity judgments obtained from WANG2VEC to be qualitatively more meaningful, so we used these embeddings to construct the expanded lexicon.[5]

[5]We used the following default parameters: 100 dimensions, a window size of five, a negative sampling size of ten, five-epoch iterations, and a sub-sampling rate of 10^{-4}.

Seed term	Expanded terms
(*Example seeds from Biber and Finegan (1989)*)	
significantly	considerably, substantially, dramatically
certainly	surely, frankly, definitely
incredibly	extremely, unbelievably, exceptionally
(*Example seeds from Jurafsky et al. (1998)*)	
nope	nah, yup, nevermind
great	fantastic, terrific, excellent

Table 2: Stance lexicon: seed and expanded terms.

To perform lexicon expansion, we constructed a dictionary of candidate terms, consisting of all unigrams that occur with a frequency rate of at least 10^{-7} in the Reddit comment corpus. Then, for each single-token marker in the seed lexicon, we identified all terms from the candidate set whose embedding has cosine similarity of at least 0.75 with respect to the seed marker.[6] Table 2 shows examples of seed markers and related terms we extracted from word embeddings. Through this procedure, we identified 228 additional markers based on similarity to items in the seed list from Biber and Finegan (1989), and 112 additional markers based on the seed list of dialog acts. In total, our stance lexicon contains 812 unique markers.

5 Linguistic Dimensions of Stancetaking

To summarize the main axes of variation across the lexicon of stance markers, we apply a multidimensional analysis (Biber, 1992) to the distributional statistics of stance markers across subreddit communities. Each dimension of variation can then be viewed as a spectrum, characterized by the stance markers and subreddits that are associated with the positive and negative extremes. Multidimensional analysis is based on singular value decomposition, which has been applied successfully to a wide range of problems in natural language processing and information retrieval (e.g., Landauer et al., 1998). While Bayesian topic models are an appealing alternative, singular value decomposition is fast and deterministic, with a minimal number of tuning parameters.

[6]We tried different thresholds on the similarity value and the corpus frequency, and the reported values were chosen based on the quality of the resulting related terms. This was done prior to any of the validations or extrinsic analyses described later in the paper.

5.1 Extracting Stance Dimensions

Our analysis is based on the co-occurrence of stance markers and subreddits. This is motivated by our interest in comparisons of the interactional styles of online communities within Reddit, and by the premise that these distributional differences reflect socially meaningful communicative norms. A pilot study applied the same technique to the co-occurrence of stance markers and individual authors, and the resulting dimensions appeared to be less stylistically coherent.

Singular value decomposition is often used in combination with a transformation of the co-occurrence counts by pointwise mutual information (Bullinaria and Levy, 2007). This transformation ensures that each cell in the matrix indicates how much more likely a stance marker is to co-occur with a given subreddit than would happen by chance under an independence assumption. Because negative PMI values tend to be unreliable, we use positive PMI (PPMI), which involves replacing all negative PMI values with zeros (Niwa and Nitta, 1994). Therefore, we obtain stance dimensions by applying singular value decomposition to the matrix constructed as follows:

$$X_{m,s} = \left(\log \frac{\Pr(\text{marker} = m, \text{subreddit} = s)}{\Pr(\text{marker} = m) \Pr(\text{subreddit} = s)} \right)_+ .$$

Truncated singular value decomposition performs the approximate factorization $X \approx U \Sigma V^\top$, where each row of the matrix U is a k-dimensional description of each stance marker, and each row of V is a k-dimensional description of each subreddit. We included the 7,589 subreddits that received at least 1,000 comments in 2014.

5.2 Results: Stance Dimensions

From the SVD analysis, we extracted the six principal latent dimensions that explain the most variation in our dataset.[7] The decision to include only the first six dimensions was based on the strength of the singular values corresponding to the dimensions. Table 3 shows the top five stance markers for each extreme of the six dimensions. The stance dimensions convey a range of concepts, such as involved versus informational language, narrative versus dialogue-oriented writing, standard versus non-standard variation, and positive versus negative affect. Figure 1 shows the distribution of subreddits along two of these dimensions.

[7] Similar to factor analysis, the top few dimensions of SVD explain the most variation, and tend to be most interpretable. A scree plot (Cattell, 1966) showed that the amount of variation explained dropped after the top six dimensions, and qualitative interpretation showed that the remaining dimension were less interpretable.

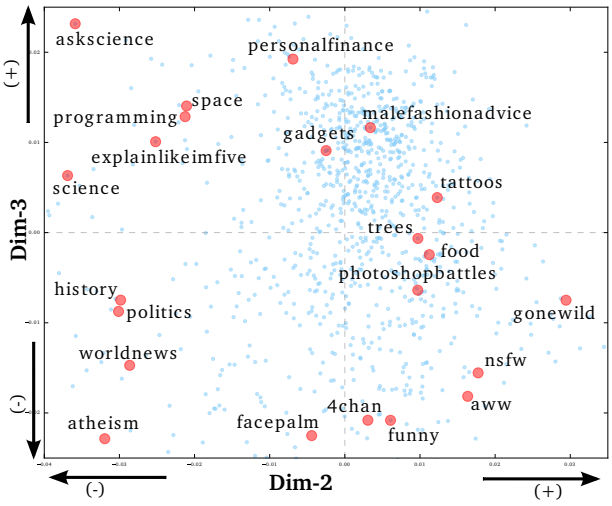

Figure 1: Mapping of subreddits in dimension two and dimension three, highlighting especially popular subreddits. Picture-oriented subreddits *r/gonewild* and *r/aww* map high on dimension two and low on dimension three, indicating involved and informal style of discourse. Subreddits dedicated for knowledge sharing discussions such as *r/askscience* and *r/space* map low on dimension two and high on dimension three indicating informational and formal style.

6 Construct Validity

Evaluating model output against gold-standard annotations is appropriate when there is some notion of a correct answer. As stancetaking is a multidimensional concept, we have taken an unsupervised approach. Therefore, we use evaluation techniques based on the notion of *validity*, which is the extent to which the operationalization of a construct truly captures the intended quantity or concept. Validation techniques for unsupervised content analysis are widely found in the social science literature (Weber, 1990; Quinn et al., 2010) and have also been recently used in the NLP and machine learning communities (e.g., Chang et al., 2009; Murphy et al., 2012; Sim et al., 2013).

We used several methods to validate the stance dimensions extracted from the corpus of Reddit comments. This section describes intrinsic evaluations, which test whether the extracted stance dimensions are linguistically coherent and mean-

		Stance markers	Subreddits

	+	anxious, stressed, exhausted, overwhelmed, relieved	relationships, sex, nosleep

Table 3: For each of the six dimensions extracted by our method, we show the five markers and three subreddits (among the 100 most popular subreddits) with the highest loadings.

ingful, thereby testing the *construct* or *content validity* of the proposed stance dimensions (Quinn et al., 2010). Extrinsic evaluations are presented in section 7.

6.1 Word Intrusion Task

A word intrusion task is used to measure the coherence and interpretability of a group of words. Human raters are presented with a list of terms, all but one of which are selected from a target concept; their task is to identify the intruder. If the target concept is internally coherent, human raters should be able to perform this task accurately; if not, their selections should be random. Word intrusion tasks have previously been used to validate the interpretability of topic models (Chang et al., 2009) and vector space models (Murphy et al., 2012).

We deployed a word intrusion task on Amazon Mechanical Turk (AMT), in which we presented the top four stance markers from one end of a dimension, along with an intruder marker selected from the top four markers of the opposite end of that dimension. In this way, we created four word intrusion tasks for each end of each dimension. The main reason for including only the top four words in each dimension is the expense of conducting crowd-sourced evaluations. In the most relevant prior work, Chang et al. (2009) used the top five words from each topic in their evaluation of topic models.

Worker selection We required that the AMT workers ("turkers") have completed a minimum of 1,000 HITs and have at least 95% approval rate Furthermore, because our task is based on analysis of English language texts, we required the turkers to be native speakers of English living in one of the majority English speaking countries. As a further requirement, we required the turkers to obtain a qualification which involves an English comprehension test similar to the questions in standardized English language tests. These requirements are based on best practices identified by Callison-Burch and Dredze (2010).

Task specification Each AMT human intelligence task (HIT) consists of twelve word intrusion tasks, one for each end of the six dimensions. We provided minimal instructions regarding the task, and did not provide any examples, to avoid introducing bias.[8] As a further quality control, each HIT included three questions which ask the turkers to pick the best synonym for a given word from a list of five answers, where one answer was clearly correct; Turkers who gave incorrect answers were to be excluded, but this situation did not arise in practice. Altogether each HIT consists of 15 questions, and was paid US$1.50. Five different turkers performed each HIT.

Results We measured the interrater reliability using Krippendorf's α (Krippendorff, 2007) and the *model precision* metric of Chang et al. (2009). Results on both metrics were encouraging. We obtained a value of $\alpha = 0.73$, on a scale where

[8]The prompt for the word intrusions task was: "Select the intruder word/phrase: you will be given a list of five English words/phrases and asked to pick the word/phrase that is least similar to the other four words/phrases when used in online discussion forums."

$\alpha = 0$ indicates chance agreement and $\alpha = 1$ indicates perfect agreement. The model precision was 0.82; chance precision is 0.20. To offer a sense of typical values for this metric, Chang et al. (2009) report model precisions in the range 0.7–0.83 in their analysis of topic models. Overall, these results indicate that the multi-dimensional analysis has succeeded at identifying dimensions that reflect natural groupings of stance markers.

6.2 Pre-registered Hypotheses

Content validity was also assessed using a set of pre-registered hypotheses. The practice of pre-registering hypotheses before an analysis and testing the correctness is widely used in the social sciences; it was adopted by Sim et al. (2013) to evaluate the induction of political ideological models from text. Before performing the muti-dimensional analysis, we identified two groups of hypotheses that are expected to hold with respect to the latent stancetaking dimensions using our prior linguistic knowledge:

- **Hypothesis I:** Stance markers that are synonyms should not appear on the opposite ends of a stance dimension.
- **Hypothesis II:** If at least one stance marker from a predefined *stance feature group* (defined below) appears on one end of a stance dimension, then other markers from the same feature group will tend not to appear at the opposite end of the same dimension.

6.2.1 Synonym Pairs

For each marker in our stance lexicon, we extracted synonyms from Wordnet, focusing on markers that appear in only one Wordnet synset, and not including pairs in which one term was an inflection of the other.[9] Our final list contains 73 synonym pairs (e.g., *eventually/finally*, *grateful/thankful*, *yea/yeah*). Of these pairs, there were 59 cases in which both terms appeared in either the top or bottom 200 positions of a stance dimension. In 51 of these cases (86%), the two terms appeared on the same side of the dimension. The chance rate would be 50%, so this supports Hypothesis I and further validates the stance dimensions. More details of the results are shown in Table 4. Note that synonym pairs may differ in aspects such as formality (e.g., *said/informed*, *want/desire*), which is one of the main dimensions of stancetaking. Therefore, perfect support for Hypothesis I is not expected.

[9]It is possible that inflections are semantically similar, because by definition they are changes in the form of a word to mark distinctions such as tense, person, or number. However, different inflections of a single word form might be used to mark different stances (e.g., some stances might be associated with the past while others might be associated with the present or future).

Stance Dimension	Number of synonym pairs On same end	On opposite ends
DIMENSION 1	6	3
DIMENSION 2	12	2
DIMENSION 3	2	1
DIMENSION 4	11	0
DIMENSION 5	10	2
DIMENSION 6	10	0
Total	51/59	8/59

Table 4: Results for pre-registered hypothesis that stance dimensions will not split synonym pairs.

6.2.2 Stance Feature Groups

Biber and Finegan (1989) group stance markers into twelve "feature groups", such as certainty adverbs, doubt adverbs, affect expressions, and hedges. Ideally, the stance dimensions should preserve these groupings. To test this, for each of the seven feature groups with at least ten stance markers in the lexicon, we counted the number of terms appearing among the top 200 positions in both ends (high/low) of each dimension. Under the null hypothesis, the stance dimensions are random with respect to the feature groups, so we would expect roughly an equal number of markers on both ends. As shown in Table 5, for five of the seven feature groups, it is possible to reject the null hypothesis at $p < .007$, which is the significance threshold at $\alpha = 0.05$, after correcting for multiple comparisons using the Bonferroni correction. This indicates that the stance dimensions are aligned with predefined stance feature groups.

7 Extrinsic Evaluations

The evaluations in the previous section test internal validity; we now describe evaluations testing whether the stance dimensions are relevant to external social and interactional phenomena.

7.1 Predicting Cross-posting

Online communities can be considered as *communities of practice* (Eckert and McConnell-Ginet, 1992), where members come together to engage in shared linguistic practices. These practices

Feature group	#Stance marker	χ^2	p-value	Reject null?
Certainty adv.	38	16.94	$4.6e^{-03}$	✓
Doubt adv.	23	13.21	$2.2e^{-02}$	×
Certainty verbs	36	48.99	$2.2e^{-09}$	✓
Doubt verbs	55	30.45	$1.2e^{-05}$	✓
Certainty adj.	28	29.73	$1.7e^{-05}$	✓
Doubt adj.	12	14.80	$1.1e^{-02}$	×
Affect exp.	227	97.17	$2.1e^{-19}$	✓

Table 5: Results for preregistered hypothesis that stance dimensions will align with stance feature groups of Biber and Finegan (1989).

evolve simultaneously with membership, coalescing into shared norms. The memberships of multiple subreddits on the same topic (e.g., *r/science* and *r/askscience*) often do not overlap considerably. Therefore we hypothesize that users of Reddit have preferred interactional styles, and that participation in subreddit communities is governed not only by topic interest, but also by these interactional preferences. The proposed stancetaking dimensions provide a simple measure of interactional style, allowing us to test whether it is predictive of community membership decisions.

Classification task We design a classification task, in which the goal is to determine whether a pair of subreddits is *high-crossover* or *low-crossover*. In high-crossover subreddit pairs, individuals are especially likely to participate in both. For the purpose of this evaluation, individuals are considered to participate in a subreddit if they contribute posts or comments. We compute the pointwise mutual information (PMI) with respect to cross-participation among the 100 most popular subreddits. For each subreddit s, we identify the five highest and lowest PMI pairs $\langle s, t \rangle$, and add these to the high-crossover and low-crossover sets, respectively. Example pairs are shown in Table 6. After eliminating redundant pairs, we identify 437 unique high-crossover pairs, and 465 unique low-crossover pairs. All evaluations are based on multiple random training/test splits over this dataset.

Classification approaches A simple classification approach is to predict that subreddits with similar text will have high crossover. We measure similarity using TF-IDF weighted cosine similarity, using two possible lexicons: the 8,000 most frequent words on reddit (BOW), and the stance lexicon (STANCE MARKERS). The similarity threshold between high-crossover and low-crossover pairs was estimated on the training data. We also tested the relevance of multi-dimensional analysis, by applying SVD to both lexicons. For each pair of subreddits, we computed a feature set of the absolute difference across the top six latent dimensions, and applied a logistic regression classifier. Regularization was tuned by internal cross-validation.

Cross-Community Participation	
High-Scoring Pairs	**Low-Scoring Pairs**
r/blog, r/announcements	r/gonewild, r/leagueoflegends
r/pokemon, r/wheredidthesodago	r/soccer, r/nosleep
r/politics, r/technology	r/programming, r/gonewild
r/LifeProTips, r/dataisbeautiful	r/nfl, r/leagueoflegends
r/Unexpected, r/JusticePorn	r/Minecraft, r/personalfinance

Table 6: Examples of subreddit pairs that have large and small amount of overlap of contributing members.

	Cosine	SVD
BOW	66.13%	77.48%
STANCE MARKERS	64.31%	84.93%

Table 7: Accuracy for prediction of subreddit cross-participation.

Results Table 7 shows average accuracies for these models. The stance-based SVD features are considerably more accurate than the BOW-based SVD features, indicating that interactional style does indeed predict cross-posting behavior.[10] Both are considerably more accurate than the bag-of-words models based on cosine similarity.

7.2 Politeness and Formality

The utility of the induced stance dimensions depends on their correlation with social phenomena of interest. Prior work has used crowdsourcing to annotate texts for politeness and formality. We now evaluate the stancetaking properties of these annotated texts.

Data We used the politeness corpus of Wikipedia edit requests from Danescu-Niculescu-Mizil et al. (2013), which includes the textual content of the edit requests, along with scalar annotations of politeness. Following the original

[10] We use BOW+SVD as the most comparable content-based alternative to our stancetaking dimensions. While there may be more accurate discriminative approaches, our goal is a direct comparison of stance and content-based features, not an exhaustive comparison of classification approaches.

authors, we compare the text for the messages ranked in the first and fourth quartiles of politeness scores. For formality, we used the corpus from Pavlick and Tetreault (2016), focusing on the blogs domain, which is most similar to our domain of Reddit. Each sentence in this corpus was annotated for formality levels from -3 to $+3$. We considered only the sentences with mean formality score greater than $+1$ (more formal) and less than -1 (less formal).

Stance dimensions For each document in the above datasets, we compute the stance properties, as follows: for each dimension, we compute the total frequency of the hundred most positive terms and the hundred most negative terms, and then take the difference. Instances containing no terms from either list are excluded. We focus on stance dimensions two and five (summarized in Table 3), because they appeared to be most relevant to politeness and formality. Dimension two contrasts informational and argumentative language against emotional and non-standard language. Dimension five contrasts positive and formal language against non-standard and somewhat negative language.

Results A kernel density plot of the resulting differences is shown in Figure 2. The effect sizes of the resulting differences are quantified using Cohen's d statistic (Cohen, 1988). Effect sizes for all differences are between 0.3 and 0.4, indicating small-to-medium effects — except for the evaluation of formality on dimension five, where the effect size is close to zero. The relatively modest effect sizes are unsurprising, given the short length of the texts. However, these differences lend insight to the relationship between formality and politeness, which may seem to be closely related concepts. On dimension two, it is possible to be polite while using non-standard language such as *hehe* and *awww*, so long as the sentiment expressed is positive; however, these markers are not consistent with formality. On dimension five, we see that positive sentiment terms such as *lovely* and *stunning* are consistent with politeness, but not with formality. Indeed, the distribution of dimension five indicates that both ends of dimension five are consistent only with informal texts.

Overall, these results indicate that interactional phenomena such as politeness and formality are reflected in our stance dimensions, which are induced in an unsupervised manner. Future work may consider the utility of these stance dimensions to predict these social phenomena, particularly in cross-domain settings where lexical classifiers may overfit.

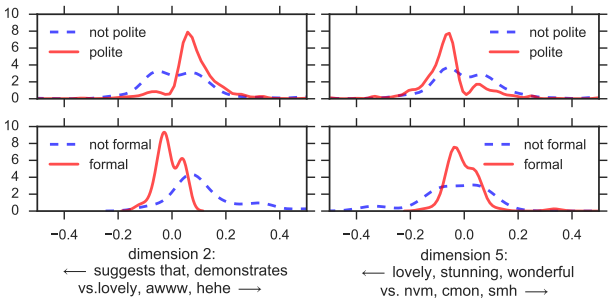

Figure 2: Kernel density distributions for stance dimensions 2 and 5, plotted with respect to annotations of politeness and formality.

8 Conclusion

Stancetaking provides a general perspective on the various linguistic phenomena that structure social interactions. We have identified a set of several hundred stance markers, building on previously-identified lexicons by using word embeddings to perform lexicon expansion. We then used multi-dimensional analysis to group these markers into stance dimensions, which we show to be internally coherent and extrinsically useful. Our hope is that these stance dimensions will be valuable as a convenient building block for future research on interactional meaning.

Acknowledgments Thanks to the anonymous reviewers for their useful and constructive feedback on our submission. This research was supported by Air Force Office of Scientific Research award FA9550-14-1-0379, by National Institutes of Health award R01-GM112697, and by the National Science Foundation awards 1452443 and 1111142. We thank Tyler Schnoebelen for helpful discussions; C.J. Hutto, Tanushree Mitra, and Sandeep Soni for assistance with Mechanical Turk experiments; and Ian Stewart for assistance with creating word embeddings. We also thank the Mechanical Turk workers for performing the word intrusion task, and for feedback on a pilot task.

Tandem Anchoring: a Multiword Anchor Approach for Interactive Topic Modeling

Abstract

Interactive topic models are powerful tools for understanding large collections of text. However, existing sampling-based interactive topic modeling approaches scale poorly to large data sets. Anchor methods, which use a single word to uniquely identify a topic, offer the speed needed for interactive work but lack both a mechanism to inject prior knowledge and lack the intuitive semantics needed for user-facing applications. We propose combinations of words as anchors, going beyond existing single word anchor algorithms—an approach we call "Tandem Anchors". We begin with a synthetic investigation of this approach then apply the approach to interactive topic modeling in a user study and compare it to interactive and non-interactive approaches. Tandem anchors are faster and more intuitive than existing interactive approaches.

Topic models distill large collections of text into topics, giving a high-level summary of the thematic structure of the data without manual annotation. In addition to facilitating discovery of topical trends (Gardner et al., 2010), topic modeling is used for a wide variety of problems including document classification (Rubin et al., 2012), information retrieval (Wei and Croft, 2006), author identification (Rosen-Zvi et al., 2004), and sentiment analysis (Titov and McDonald, 2008). However, the most compelling use of topic models is to help users understand large datasets (Chuang et al., 2012).

Interactive topic modeling (Hu et al., 2014) allows non-experts to refine automatically generated topics, making topic models less of a "take it or leave it" proposition. Including humans input during training improves the quality of the model and allows users to guide topics in a specific way, custom tailoring the model for a specific downstream task or analysis.

The downside is that interactive topic modeling is slow—algorithms typically scale with the size of the corpus—and requires non-intuitive information from the user in the form of must-link and cannot-link constraints (Andrzejewski et al., 2009). We address these shortcomings of interactive topic modeling by using an interactive version of the *anchor words* algorithm for topic models.

The anchor algorithm (Arora et al., 2013) is an alternative topic modeling algorithm which scales with the number of unique word types in the data rather than the number of documents or tokens (Section 1). This makes the anchor algorithm fast enough for interactive use, even in web-scale document collections.

A drawback of the anchor method is that anchor words—words that have high probability of being in a *single* topic—are not intuitive. We extend the anchor algorithm to use multiple anchor words in tandem (Section 2). Tandem anchors not only improve interactive refinement, but also make the underlying anchor-based method more intuitive.

For interactive topic modeling, tandem anchors produce higher quality topics than single word anchors (Section 3). Tandem anchors provide a framework for fast interactive topic modeling: users improve and refine an existing model through multiword anchors (Section 4). Compared to existing methods such as Interactive Topic Models (Hu et al., 2014), our method is much faster.

1 Vanilla Anchor Algorithm

The anchor algorithm computes the topic matrix $\boldsymbol{A}$, where $\boldsymbol{A}_{v,k}$ is the conditional probability of observing word v given topic k, e.g., the probability of seeing the word "lens" given the camera topic in a corpus of Amazon product reviews. Arora et al. (2012a) find these probabilities by assuming that every topic contains at least one 'anchor' word which has a non-zero probability only in that topic. Anchor words make computing the topic matrix $\boldsymbol{A}$ tractable because the occurrence pattern of the anchor word mirrors the occurrence pattern of the topic itself.

To recover the topic matrix $\boldsymbol{A}$ using anchor words, we first compute a $V \times V$ cooccurrence matrix $\boldsymbol{Q}$, where $\boldsymbol{Q}_{i,j}$ is the conditional probability $p(w_j \mid w_i)$ of seeing word type w_j after having seen w_i in the same document. A form of the Gram-Schmidt process on $\boldsymbol{Q}$ finds anchor words $\{g_1 \dots g_k\}$ (Arora et al., 2013).

Once we have the set of anchor words, we can compute the probability of a topic given a word (the inverse of the conditioning in $\boldsymbol{A}$). This coefficient matrix $\boldsymbol{C}$ is defined row-wise for each word i

$$\boldsymbol{C}^*_{i,\cdot} = \underset{C_{i,\cdot}}{\operatorname{argmin}} D_{KL}\left(\boldsymbol{Q}_{i,\cdot} \middle\| \sum_{k=1}^{K} \boldsymbol{C}_{i,k}\boldsymbol{Q}_{g_k,\cdot}\right), \tag{1}$$

which gives the best reconstruction (based on Kullback-Leibler divergence D_{KL}) of non-anchor words given anchor words' conditional probabilities. For example, in our product review data, a word such as "battery" is a convex combination of the anchor words' contexts ($\boldsymbol{Q}_{g_k,\cdot}$) such as "camera", "phone", and "car". Solving each row of C is fast and is embarrassingly parallel. Finally, we apply Bayes' rule to recover the topic matrix $\boldsymbol{A}$ from the coefficient matrix $\boldsymbol{C}$.

The anchor algorithm can be orders of magnitude faster than probabilistic inference (Arora et al., 2013). The construction of $\boldsymbol{Q}$ has a runtime of $O(DN^2)$ where D is the number of documents and N is the average number of tokens per document. This computation requires only a single pass over the data and can be pre-computed for interactive use-cases. Once $\boldsymbol{Q}$ is constructed, topic recovery requires $O(KV^2 + K^2VI)$, where K is the number of topics, V is the vocabulary size, and I is the average number of iterations (typically 100-1000). In contrast, traditional topic model inference typically requires multiple passes over the entire data. Techniques such as Online LDA (Hoffman et al., 2010) or Stochastic Variation Inference (Hoffman et al., 2013) improves this to a single pass over the entire data. However, from Heaps' law (Heaps, 1978) it follows that $V^2 \ll DN$ for large datasets, leading to much faster inference times for anchor methods compared to probabilistic topic modeling. Further, even if online were to be adapted to incorporate human guidance, a single pass is not tractable for interactive use.

Anchor	Top Words in Topics
backpack	backpack camera lens bag room carry fit cameras equipment comfortable
camera	camera lens pictures canon digital lenses batteries filter mm photos
bag	bag camera diaper lens bags genie smell room diapers odor

Table 1: Three separate attempts to construct a topic concerning camera bags in Amazon product reviews with single word anchors. This example is drawn from preliminary experiments with an author as the user. The term "backpack" is a good anchor because it uniquely identifies the topic. However, both "camera" and "bag" are poor anchors for this topic.

2 Tandem Anchor Extension

Single word anchors can be opaque to users. For an example of bewildering anchor words, consider a camera bag topic from a collection of Amazon product reviews (Table 1). The anchor word "backpack" may seem strange. However, this dataset contains nothing about regular backpacks; thus, "backpack" is unique to camera bags. Bizarre, low-to-mid frequency words are often anchors because anchor words must be *unique* to a topic; intuitive or high-frequency words cannot be anchors if they have probability in *any other topic*.

The anchor selection strategy can mitigate this problem to some degree. For example, rather than selecting anchors using an approximate convex hull in high-dimensional space, we can find an exact convex hull in a low-dimensional embedding (Lee and Mimno, 2014). This strategy will produce more salient topics but still makes it difficult for users to manually choose unique anchor words for interactive topic modeling.

If we instead ask users to give us representative

words for this topic, we would expect combinations of words like "camera" and "bag." However, with single word anchors we must choose a single word to anchor each topic. Unfortunately, because these words might appear in multiple topics, individually they are not suitable as anchor words. The anchor word "camera" generates a general camera topic instead of camera bags, and the topic anchored by "bag" includes bags for diaper pails (Table 1).

Instead, we need to use sets of representative terms as an interpretable, parsimonious description of a topic. This section discusses strategies to build anchors from multiple words and the implications of using multiword anchors to recover topics. This extension not only makes anchors more interpretable but also enables users to manually construct effective anchors in interactive topic modeling settings.

2.1 Anchor Facets

We first need to turn words into an anchor. If we interpret the anchor algorithm geometrically, each row of $\boldsymbol{Q}$ represents a word as a point in V-dimensional space. We then model each point as a convex combination of anchor words to reconstruct the topic matrix $\mathbf{A}$ (Equation 1). Instead of individual anchor words (one anchor word per topic), we use anchor **facets**, or sets of words that describe a topic. The facets for each anchor form a new **pseudoword**, or an invented point in V-dimensional space (described in more detail in Section 2.2).

While these new points do not correspond to words in the vocabulary, we can express non-anchor words as convex combinations of pseudowords. To construct these pseudowords from their facets, we combine the co-occurrence profiles of the facets. These pseudowords then augment the original cooccurrence matrix $\boldsymbol{Q}$ with K additional rows corresponding to synthetic pseudowords forming each of K multiword anchors. We refer to this augmented matrix as $\boldsymbol{S}$. The rest of the anchor algorithm proceeds unmodified.

Our augmented matrix $\boldsymbol{S}$ is therefore a $(V + K) \times V$ matrix. As before, V is the number of token types in the data and K is the number of topics. The first V rows of $\boldsymbol{S}$ correspond to the V token types observed in the data, while the additional K rows correspond to the pseudowords constructed from anchor facets. Each entry of $\boldsymbol{S}$ encodes conditional probabilities so that $S_{i,j}$ is equal to $p(w_i \mid w_j)$. For the additional K rows, we invent a cooccurrence pattern that can effectively explain the other words' conditional probabilities.

This modification is similar in spirit to supervised anchor words (Nguyen et al., 2015). This supervised extension of the anchor words algorithm adds columns corresponding to conditional probabilities of metadata values after having seen a particular word. By extending the vector-space representation of each word, anchor words corresponding to metadata values can be found. In contrast, our extension does not add dimensions to the representation, but simply places additional points corresponding to pseudoword words in the vector-space representation.

2.2 Combining Facets into Pseudowords

We now describe more concretely how to combine an anchor facets to describe the cooccurrence pattern of our new pseudoword anchor. In tandem anchors, we create vector representations that combine the information from anchor facets. Our anchor facets are $\mathcal{G}_1 \dots \mathcal{G}_K$, where $\mathcal{G}_k$ is a set of anchor facets which will form the kth pseudoword anchor. The pseudowords are $g_1 \dots g_K$, where g_k is the pseudoword from $\mathcal{G}_k$. These pseudowords form the new rows of $\boldsymbol{S}$. We give several candidates for combining anchors facets into a single multiword anchor; we compare their performance in Section 3.

Vector Average An obvious function for computing the central tendency is the vector average. For each anchor facet,

$$\boldsymbol{S}_{g_k,j} = \sum_{i \in \mathcal{G}_k} \frac{\boldsymbol{S}_{i,j}}{|\mathcal{G}_k|}, \tag{2}$$

where $|\mathcal{G}_k|$ is the cardinality of $\mathcal{G}_k$. Vector average makes the pseudoword $\boldsymbol{S}_{g_k,j}$ more central, which is intuitive but inconsistent with the interpretation from Arora et al. (2013) that anchors should be extreme points whose linear combinations explain more central words.

Or-operator An alternative approach is to consider a cooccurrence with *any* anchor facet in $\mathcal{G}_k$. For word j, we use De Morgan's laws to set

$$\boldsymbol{S}_{g_k,j} = 1 - \prod_{i \in \mathcal{G}_k} (1 - \boldsymbol{S}_{i,j}). \tag{3}$$

Unlike the average, which pulls the pseudoword inward, this or-operator pushes the word outward,

increasing each of the dimensions. Increasing the volume of the simplex spanned by the anchors explains more words.

Element-wise Min Vector average and or-operator are both sensitive to outliers and cannot account for polysemous anchor facets. Returning to our previous example, both "camera" and "bag" are bad anchors for camera bags because they appear in documents discussing other products. However, if both "camera" and "bag" are anchor facets, we can look at an *intersection* of their contexts: words that appear with both. Using the intersection, the cooccurrence pattern of our anchor facet will only include terms relevant to camera bags.

Mathematically, this is an element-wise min operator,

$$\boldsymbol{S}_{g_k,j} = \min_{i \in \mathcal{G}_k} \boldsymbol{S}_{i,j}. \tag{4}$$

This construction, while perhaps not as simple as the previous two, is robust to words which have cooccurrences which are not unique to a single topic.

Harmonic Mean Leveraging the intuition that we should use a combination function which is both centralizing (like vector average) and ignores large outliers (like element-wise min), the final combination function is the element-wise harmonic mean. Thus, for each anchor facet

$$\boldsymbol{S}_{g_k,j} = \sum_{i \in \mathcal{G}_k} \left(\frac{\boldsymbol{S}_{i,j}^{-1}}{|\mathcal{G}_k|} \right)^{-1}. \tag{5}$$

Since the harmonic mean tends towards the lowest values in the set, it is not sensitive to large outliers, giving us robustness to polysemous words.

2.3 Finding Topics

After constructing the pseudowords of $\boldsymbol{S}$ we then need to find the coefficients $\boldsymbol{C}_{i,k}$ which describe each word in our vocabulary as a convex combination of the multiword anchors. Like standard anchor methods, we solve the following for each token type:

$$\boldsymbol{C}^*_{i,\cdot} = \underset{\boldsymbol{C}_{i,\cdot}}{\operatorname{argmin}} D_{KL} \left(\boldsymbol{S}_{i,\cdot} \middle\| \sum_{k=1}^{K} \boldsymbol{C}_{i,k} \boldsymbol{S}_{g_k,\cdot} \right). \tag{6}$$

Finally, we appeal to Bayes' rule, we recover the topic-word matrix $\boldsymbol{A}$ from the coefficients of $\boldsymbol{C}$.

The correctness of the topic recovery algorithm hinges upon the assumption of separability. Separability means that the occurrence pattern across documents of the anchor words across the data mirrors that of the topics themselves. For single word anchors, this has been observed to hold for a wide variety of data (Arora et al., 2012b). With our tandem anchor extension, we make similar assumptions as the vanilla algorithm, except with pseudowords constructed from anchor facets. So long as the occurrence pattern of our tandem anchors mirrors that of the underlying topics, we can use the same reasoning as Arora et al. (2012a) to assert that we can provably recover the topic-word matrix $\boldsymbol{A}$ with all of the same theoretical guarantees of complexity and robustness. Furthermore, we runtime analysis given by Arora et al. (2013) applies to tandem anchors.

If desired, we can also add further robustness and extensibility to tandem anchors by adding regularization to Equation 6. Regularization allows us to add something which is mathematically similar to priors, and has been shown to improve the vanilla anchor word algorithm (Nguyen et al., 2014). We leave the question of the best regularization for tandem anchors as future work, and focus our efforts on solving the problem of interactive topic modeling.

3 High Water Mark for Tandem Anchors

Before addressing interactivity, we apply tandem anchors to real world data, but with anchors gleaned from metadata. Our purpose is twofold. First, we determine which combiner from Section 2.2 to use in our interactive experiments in Section 4 and second, we confirm that well-chosen tandem anchors can improve topics. In addition, we examine the runtime of tandem anchors and compare to traditional model-based interactive topic modeling techniques. We cannot assume that we will have metadata available to build tandem anchors, but we use them here because they provide a high water mark without the variance introduced by study participants.

3.1 Experimental Setup

We use the well-known 20 Newsgroups dataset (20NEWS) used in previous interactive topic modeling work: 18,846 Usenet postings from 20 different newgroups in the early 1990s.[1] We remove the newsgroup headers from each message, which contain the newsgroup names, but otherwise left messages intact with any footers or quotes. We

[1] http://qwone.com/~jason/20Newsgroups/

then remove stopwords and words which appear in fewer than 100 documents or more than 1,500 documents.

To seed the tandem anchors, we use the titles of newsgroups. To build each multiword anchor facet, we split the title on word boundaries and expand any abbreviations or acronyms. For example, the newsgroup title 'comp.os.ms-windows.misc' becomes {"computer", "operating", "system", "microsoft", "windows", "miscellaneous"}. We do not fully specify the topic; the title gives some intuition, but the topic modeling algorithm must still recover the complete topic-word distributions. This is akin to knowing the names of the categories used but nothing else. Critically, the topic modeling algorithm has no knowledge of document-label relationships.

3.2 Experimental Results

Our first evaluation is a classification task to predict documents' newsgroup membership. Thus, we do not aim for state-of-the-art accuracy,[2] but the experiment shows title-based tandem anchors yield topics closer to the underlying classes than Gram-Schmidt anchors. After randomly splitting the data into test and training sets we learn topics from the test data using both the title-based tandem anchors and the Gram-Schmidt single word anchors.[3] For multiword anchors, we use each of the combiner functions from Section 2.2. The anchor algorithm only gives the topic-word distributions and not word-level topic assignments, so we infer token-level topic assignments using LDA Latent Dirichlet Allocation (Blei et al., 2003) with *fixed* topics discovered by the anchor method. We use our own implementation of Gibbs sampling with fixed topics and a symmetric document-topic Dirichlet prior with concentration $\alpha = .01$. Since the topics are fixed, this inference is very fast and can be parallelized on a per-document basis. We then train a hinge-loss linear classifier on the newsgroup labels using Vowpal Wabbit[4] with topic-word pairs as features. Finally, we infer topic assignments in the test data and evaluate the classification using those topic-word features. For both training and test, we exclude words outside the LDA vocabulary.

The topics created from multiword anchor facets are more accurate than Gram-Schmidt topics (Figure 1). This is true regardless of the combiner function. However, harmonic mean is more accurate than the other functions.[5]

Since 20NEWS has twenty classes, accuracy alone does not capture confusion between closely related newsgroups. For example, accuracy penalizes a classifier just as much for labeling a document from 'rec.sport.baseball' with 'rec.sport.hockey' as with 'alt.atheism' despite the similarity between sports newsgroups. Consequently, after building a confusion matrix between the predicted and true classes, external clustering metrics reveal confusion between classes.

The first clustering metric is the adjusted Rand index (Yeung and Ruzzo, 2001), which is akin to accuracy for clustering, as it gives the percentage of correct pairing decisions from a reference clustering. Adjusted Rand index (ARI) also accounts for chance groupings of documents. Next we use F-measure, which also considers pairwise groups, balancing the contribution of false negatives, but without the true negatives. Finally, we use variation of information (VI). This metric measures the amount of information lost by switching from the gold standard labels to the predicted labels (Meilă, 2003). Since we are measuring the amount of information lost, lower variation of information is better.

Based on these clustering metrics, tandem anchors can yield superior topics to those created using single word anchors (Figure 1). As with accuracy, this is true regardless of which combination function we use. Furthermore, harmonic mean produces the least confusion between classes.[5]

The final evaluation is topic coherence by Newman et al. (2010), which measures whether the topics make sense, and correlates with human judgments of topic quality. Given V, the set of the n most probable words of a topic, coherence is

$$\sum_{v_1, v_2 \in V} log \frac{D(v_1, v_2) + \epsilon}{D(v_2)} \quad (7)$$

where $D(v_1, v_2)$ is the co-document frequency of

[2] The best system would incorporate topic features with other features, making it harder to study and understand the topical trends in isolation.

[3] With fixed anchors and data the anchor algorithm is deterministic, so we use random splits instead of the standard train/test splits so that we can compute variance.

[4] http://hunch.net/~vw/

[5] Significant at $p < 0.01/4$ when using two-tailed t-tests with a Bonferroni correction. For each of our evaluations, we verify the normality of our data (D'Agostino and Pearson, 1973) and use two-tailed t-tests with Bonferroni correction to determine whether the differences between the different methods are significant.

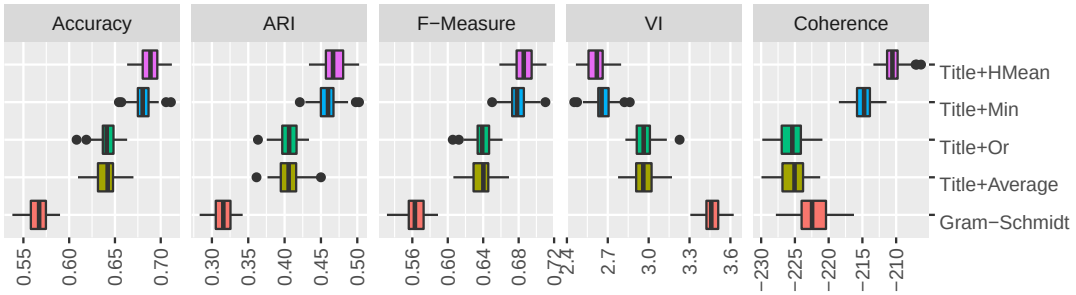

Figure 1: Using metadata can improve anchor-based topic models. For all metrics, the unsupervised Gram-Schmidt anchors do worse than creating anchors based on Newsgroup titles (for all metrics except VI, higher is better). For coherence, Gram-Schmidt does better than two functions for combining anchor words, but not the element-wise min or harmonic mean.

word types v_1 and v_2, and $D(v_2)$ is the document frequency of word type v_2. A smoothing parameter ϵ prevents zero logarithms.

Figure 1 also shows topic coherence. Although title-based anchor facets produce better classification features, topics from Gram-Schmidt anchors have better coherence than title-based anchors with the vector average or the or-operator. However, when using the harmonic mean combiner, title-based anchors produce the most human interpretable topics.[6]

Harmonic mean beats other combiner functions because it is robust to ambiguous or irrelevant term cooccurrences an anchor facet. Both the vector average and the or-operator are swayed by large outliers, making them sensitive to ambiguous terms in an anchor facet. Element-wise min also has this robustness, but harmonic mean is also able to better characterize anchor facets as it has more centralizing tendency than the min.

3.3 Runtime Considerations

Tandem anchors will enable users to direct topic inference to improve topic quality. However, for the algorithm to be interactive we must also consider runtime. Cook and Thomas (2005) argue that for interactive applications with user-initiated actions like ours the response time should be less than ten seconds. Longer waits can increase the cognitive load on the user and harm the user interaction.

[6]Significant at $p < 0.01/4$ when using two-tailed t-tests with a Bonferroni correction. For each of our evaluations, we verify the normality of our data (D'Agostino and Pearson, 1973) and use two-tailed t-tests with Bonferroni correction to determine whether the differences between the different methods are significant.

Fortunately, the runtime of tandem anchors is amenable to interactive topic modeling. On 20NEWS, interactive updates take a median time of 2.13 seconds. This result was obtained using a single core of an AMD Phemon II X6 1090T processor. Furthermore, larger datasets typically have a sublinear increase in distinct word types, so we can expect to see similar run times, even on much larger datasets.

Compared to other interactive topic modeling algorithms, tandem anchors has a very attractive run time. For example, using an optimized version of the sampler for the Interactive Topic Model described by Hu and Boyd-Graber (2012), and the recommended 30 iterations of sampling, the Interactive Topic Model updates with a median time of 24.8 seconds (Hu and Boyd-Graber, 2012), which is well beyond our desired update time for interactive use and an order of magnitude slower than tandem anchors.

Another promising interactive topic modeling approach is Utopian (Choo et al., 2013), which uses non-negative factorization, albeit without the benefit of anchor words. Utopian is much slower than tandem anchors. Even on the small InfoVis-VAST dataset which contains only 515 documents, Utopian takes 48 seconds to converge. While the times are not strictly comparable due to differing datasets, Utopian scales linearly with the size of the data, we can intuit that even for moderately sized datasets such as 20NEWS, Utopian is infeasible for interactive topic modeling due to run time.

While each of these interactive topic modeling algorithms do achieve reasonable topics, only our algorithm fits the run time requirements for inter-

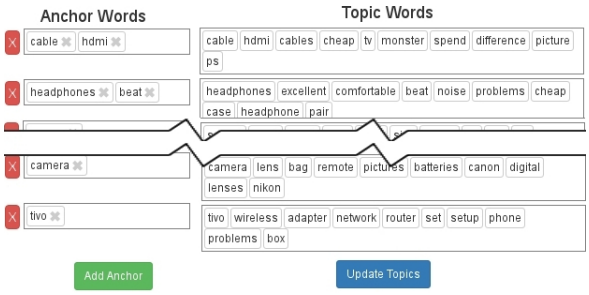

Figure 2: Interface for user study with multiword anchors applied to interactive topic modeling.

activity. Furthermore, since tandem anchors scales with the size of the vocabulary rather than the size of the data, this trend will only become more pronounced as we increase the amount of data.

4 Interactive Anchor Words

Given high quality anchor facets, the tandem anchor algorithm can produce high quality topic models (particularly when the harmonic mean combiner is used). Moreover, the tandem anchor algorithm is fast enough to be interactive (as opposed to model-based approaches such as the Interactive Topic Model). We now turn our attention to our main experiment: tandem anchors applied to the problem of interactive topic modeling. We compare both single word and tandem anchors in our study. We do not include the Interactive Topic Model or Utopian, as their run times are too slow for our users.

4.1 Interface and User Study

To show that interactive tandem anchor words are fast, effective, and intuitive, we ask users to understand a dataset using the anchor word algorithm. For this user study, we recruit twenty participants drawn from a university student body. The student median age is twenty-two. Seven are female, and thirteen are male. None of the students had any prior familiarity with topic modeling or the 20NEWS dataset.

Each participant sees a simple user interface (Figure 2) with topic given as a row with two columns. The left column allows users to view and edit topics' anchor words; the right column lists the most probable words in each topic.[7] The user can remove an anchor word or drag words from the topic word lists (right column) to become an anchor word. Users can also add additional topics by clicking the "Add Anchor" to create additional anchors. If the user wants to add a word to a tandem anchor set that does not appear in the interface, they manually type the word (restricted to the model's vocabulary). When the user wants to see the updated topics for their newly refined anchors, they click "Update Topics".

We give each a participant a high level overview of topic modeling. We also describe common problems with topic models including intruding topic words, duplicate topics, and ambiguous topics. Users are instructed to use their best judgement to determine if topics are useful. The task is to edit the anchor words to improve the topics. We asked that users spend at least twenty minutes, but no more than thirty minutes. We repeat the task twice: once with tandem anchors, and once with single word anchors.[8]

4.2 Quantitative Results

We now validate our main result that for interactive topic modeling, tandem anchors yields better topics than single word anchors. Like our title-based experiments in Section 3, topics generated from users become features to train and test a classifier for the 20NEWS dataset. We choose this dataset for easier comparison with the Interactive Topic Modeling result of Hu et al. (2014). Basedsie on our results with title-based anchors, we use the harmonic mean combiner in our analysis. As before, we report not only accuracy, but also multiple clustering metrics using the confusion matrix from the classification task. Finally, we report topic coherence.

Figure 3 summarizes the results of our quantitative evaluation. While we only compare user generated anchors in our analysis, we include the unsupervised Gram-Schmidt anchors as a baseline. Some of the data violate assumptions of normality. Therefore, we use Wilcoxon's signed-rank test (Wilcoxon, 1945) to determine if the differences between multiword anchors and single word anchors are significant.

Topics from user generated multiword anchors yield higher classification accuracy (Figure 3). Not only is our approach more scalable than the Interactive Topic Model, but we also achieve

[7] While we use topics generated using harmonic mean for our final analysis, users were shown topics generated using the min combiner. However, this does not change our result.

[8] The order in which users complete these tasks is counterbalanced.

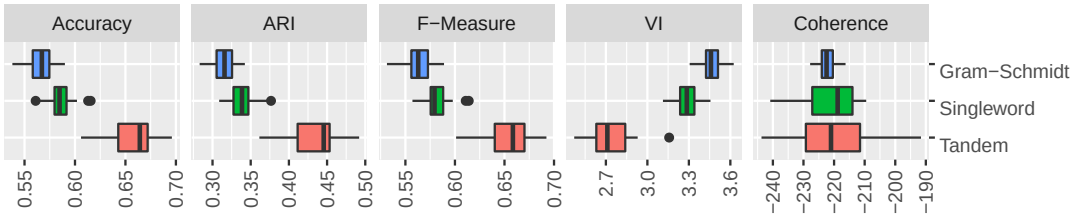

Figure 3: Classification accuracy and coherence using topic features gleaned from user provided multiword and single word anchors. Grahm-Schmidt anchors are provided as a baseline. For all metrics except VI, higher is better. Except for coherence, multiword anchors are best.

higher classification accuracy than Hu et al. (2014).[9] Tandem anchors also improve clustering metrics.[10]

While user selected tandem anchors produce better classification features than single word anchors, users selected single word anchors produce topics with similar topic coherence scores.[11]

To understand this phenomenon, we use quality metrics (AlSumait et al., 2009) for ranking topics by their correspondence to genuine themes in the data. Significant topics are likely skewed towards a few related words, so we measure the distance of each topic-word distribution from the **uniform** distribution over words. Topics which are close to the underlying word distribution of the entire data are likely to be **vacuous**, so we also measure the distance of each topic-word distribution from the underlying word distribution. Finally, **background** topics are likely to appear in a wide range of documents, while meaningful topics will appear in a smaller subset of the data.

Figure 4 reports our topic significance findings. For all three significance metrics, multiword anchors produce more significant topics than single word anchors.[10] Topic coherence is based solely on the top n words of a topic, while both accuracy and topic significance depend on the entire topic-word distributions. With single word anchors, topics with good coherence may still be too general. Tandem anchors enables users to produce topics with more specific word distributions which are better features for classification.

Anchor	Top Words in Topic
Automatic Gram Schmidt	
love	love god evolution romans heard car
game	game games team hockey baseball heard
Interactive Single-word	
evolution	evolution theory science faith quote facts
religion	religion god government state jesus israel
baseball	baseball games players word teams car

Interactive Tandem	
atheism god exists prove	god science evidence reason faith objective
christian jesus	jesus christian christ church bible christians
jew israel	israel jews jewish israeli state religion
baseball bat ball	hit baseball ball player games call
hockey nhl	team hockey player nhl win play

Table 2: Comparison of topics generated for 20NEWS using various types of anchor words. Users are able to combine words to create more specific topics with tandem anchors.

4.3 Qualitative Results

We examine the qualitative differences between how users select multiword anchor facets versus single word anchors. Table 2 gives examples of topics generated using different anchor strategies. In a follow-up survey with our users, 75% find it easier to affect individual changes in the topics using tandem anchors compared to single word anchors. Users who prefer editing multiword anchors over single word anchors often report that

[9] However, the values are not strictly comparable, as Hu et al. (2014) use the standard chronological test/train fold, and we use random splits.

[10] Significant at $p < 0.01$ when using Wilcoxon's signed-rank test.

[11] The difference between coherence scores was *not* statistically significant using Wilcoxon's signed-rank test.

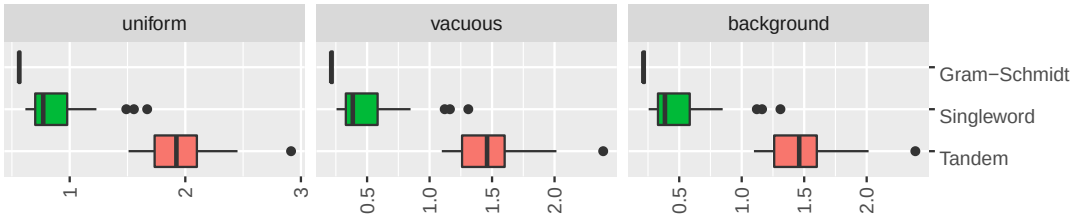

Figure 4: Topic significance for both single word and multiword anchors. In all cases higher is better. Multiword anchors produce topics which are more significant than single word anchors.

multiword anchors make it easier to merge similar topics into a single focused topic by combining anchors. For example, by combining multiple words related to Christianity, users were able to create a topic which is highly specific, and differentiated from general religion themes which included terms about Atheism and Judaism.

While users find that use tandem anchors is easier, only 55% of our users say that they prefer the final topics produced by tandem anchors compared to single word anchors. This is in harmony with our quantitative measurements of topic coherence, and may be the result of our stopping criteria: when users judged the topics to be useful.

However, 100% of our users feel that the topics created through interaction were better than those generated from Gram-Schmidt anchors. This was true regardless of whether we used tandem anchors or single word anchors.

Our participants also produce fewer topics when using multiword anchors. The mean difference between topics under single word anchors and multiple word anchors is 9.35. In follow up interviews, participants indicate that the easiest way to resolve an ambiguous topic with single word anchors was to create a new anchor for each of the ambiguous terms, thus explaining the proliferation of topics for single word anchors. In contrast, fixing an ambiguous tandem anchor is simple: users just add more terms to the anchor facet.

5 Conclusion

Tandem anchors extend the anchor words algorithm to allow multiple words to be combined into anchor facets. For interactive topic modeling, using anchor facets in place of single word anchors produces higher quality topic models and are more intuitive to use. Furthermore, our approach scales much better than existing interactive topic modeling techniques, allowing interactivity on large datasets for which interactivity was previous impossible.

Apples to Apples: Learning Semantics of Common Entities Through a Novel Comprehension Task

Abstract

Understanding common entities and their attributes is a primary requirement for any system that comprehends natural language. In order to enable learning about common entities, we introduce a novel machine comprehension task, GuessTwo: given a short paragraph comparing different aspects of two real-world semantically-similar entities, a system should guess what those entities are. Accomplishing this task requires deep language understanding which enables inference, connecting each comparison paragraph to different levels of knowledge about world entities and their attributes. So far we have crowdsourced a dataset of more than 14K comparison paragraphs comparing entities from a variety of categories such as fruits and animals. We have designed two schemes for evaluation: open-ended, and binary-choice prediction. For benchmarking further progress in the task, we have collected a set of paragraphs as the test set on which human can accomplish the task with an accuracy of 94.2% on open-ended prediction. We have implemented various models for tackling the task, ranging from semantic-driven to neural models. The semantic-driven approach outperforms the neural models, however, the results indicate that the task is very challenging across the models.

1 Introduction

In the past few years, there has been great progress on core NLP tasks (e.g., parsing and part of speech tagging) which has renewed interest in primary language learning tasks which require text understanding and reasoning, such as machine comprehension (Schoenick et al., 2016; Hermann et al., 2015; Rajpurkar et al., 2016; Mostafazadeh et al., 2016). Our question is *how far have we got in learning basic concepts of the world through language comprehension*. If we look at the large body of work on extracting knowledge from unstructured corpora, we will see that they often lack some very basic pieces of information. For example, let us focus on the basic concept of *apple*, the fruit. What do the state-of-the-art systems and resources know about an *apple*? None of the state-of-the-art knowledge bases (Speer and Havasi, 2012; Carlson et al., 2010; Fader et al., 2011) include much precise information about the fact that apples have an edible skin, vary from sweet to sour, are round, and relatively the same size of a fist. Moreover, there is no clear approach on how to extract such information, if any, from trained word embeddings. This paper focuses on how we can automatically learn about various attributes of such generic entities in the world.

A key observation motivating this work is that we can learn more detail about objects when they are compared to other similar objects. When we compare things we often contrast, that is, we count their similarities along with their dissimilarities. This results in covering the primary attributes and aspects of objects. As humans, we tend to recall and mention the difference between things (say *green skin* vs. *red skin* in apples) as opposed to absolute measures (say the existence of skin). Interestingly, there is evidence that human knowledge is structured by *semantic similarity* and the relations among objects are defined by their relative perceptual and conceptual properties, such as their form, function, behavior, and environment (Collins and Loftus, 1975; Tversky and Gati, 1978; Cree and Mcrae, 2003). Our idea is to leverage comparison as a way of naturally learning

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 906–916

https://doi.org/10.18653/v1/P17-1084

about common world concepts and their specific attributes.

Comparison, where we name the similarities and differences between things, is a unique cognitive ability in humans[1] which requires memorizing facts, experiencing things and integration of concepts of the world (Hazlitt, 1933). It is clear that developing AI systems that are capable of comprehending comparison is crucial. In this paper, in order to enable learning through comparison, we introduce a new language comprehension task which requires understanding different attributes of basic entities that are being compared.

The contributions of this paper are as follows: (1) To equip learning about common entities through comparison comprehension, we have crowdsourced a dataset of more than 14K comparison paragraphs comparing entities from nine broad categories (Section 2). This resource will be expanded over time and will be released to the public. (2) We introduce a novel task called GuessTwo, in which given a short paragraph comparing two entities, a system should guess what the two things are. (Section 3). To make systematic benchmarking on the task possible, we vet a collection of comparison paragraphs to obtain a test set on which human performs with an accuracy 94.2%. (3) We present a host of neural approaches and a novel semantic-driven model for tackling the GuessTwo task (Sections 4, 5). Our experiments show that the semantic approach outperforms the neural models. The results strongly suggest that closing the gap between system and human performances requires richer semantic processing (Section 6). We hope that this work will establish a new base for a machine comprehension test that requires systems to go beyond information extraction and towards levels of performing basic reasoning.

2 Data Collection

To enable learning about common entities, we aimed to create a dataset which meets the following goals:

1. The dataset should be a collection of high-quality documents which are rich in comparing and contrasting entities using their various attributes and aspects.

2. The comparisons in the dataset should involve everyday non-technical concepts, making their comprehension easy and commonsense for a human.

After many experiments with scraping existing Web resources, we decided to crowdsource the comparison paragraphs using Amazon Mechanical Turk[2] (Mturk). We prompt the crowd workers as follows: "Your task is to compare two given items in one simple language paragraph so that a knowledgeable person who reads it can guess what the two things are". The workers were instructed to compare only the major and well-known aspects of the two entities. We also asked them to use $\mathbb{X}$ and $\mathbb{Y}$ for anonymously referring to the two entities. Table 1 shows three examples of our crowdsourced comparison paragraphs. As these examples show, the paragraphs are very contentful and rich in comparison which meets our initial goals in the dataset creation.

Entity Pair Selection. The choice of the two entities which should be compared against each other plays a key role in the quality of the collected dataset. It is evident that naturally, we compare two things which are semantically similar, yet have some dissimilarities[3], such as *jam* and *jelly*. Given the goals of our task, we experimented with concrete nouns which share a common taxonomy class. We choose semantic classes which have at least five well-known entities. So far, we have covered nine broad categories as shown in Figure 2, with 21 subcategories shown in Figure 3. We use Wikipedia item categories and the WordNet (Miller, 1995) ontology for identifying entities from each subcategory. Then, we choose the most common entities by looking up their frequency on Google Web 1T N-grams[4]. We manually inspected the frequency-filtered list to make sure that the entities are rather easy to describe without getting technical. Given the list of entities, we paired each entity with at most five and at least three other entities from the same subcategory. We also include inter-subcategory compar-

[1] It has been suggested (Hazlitt, 1933) that children under seven years old cannot name differences between simple things such as *peach* and *apple*. This further shows that the ability for comparison develops at a later age and is cognitively complex.

[2] www.mturk.com

[3] Tversky's (1978) analysis of similarity suggests that similarity statements compare objects that belong to the same class of things.

Comparison Paragraph	Entity 𝕏	Entity 𝕐
Both 𝕏 and 𝕐 are fruits and a variety of apples. 𝕏 and 𝕐 are generally similar in size. 𝕏 are dark red in color when ripe, while 𝕐 are a bright green color. 𝕏 is sweeter and softer than 𝕐 in taste and texture, sometimes starchy. 𝕐 are tart and somewhat stringy. 𝕐 is often used in cooking, whereas 𝕏 is not.	*Red Delicious* Apple Fruit	*Granny Smith* Apple Fruit
The 𝕏 and 𝕐 are two types of vehicles. 𝕏 is a smaller vehicle than 𝕐. The 𝕏 has two wheels while 𝕐 has none. The 𝕏 travels on roadways and smooth surfaces, whereas 𝕐 is capable of flying. Only one or two people are able to ride on 𝕏 at once, while 𝕐 can carry more people.	*Motorcycle* Motor Vehicle Vehicle	*Helicopter* Aircraft Vehicle
𝕏 and 𝕐 are both types of world cuisines. 𝕏 incorporates a lot of pasta dishes and sauces, with basil, tomato, and cheese being major ingredients. 𝕐 consists of many curries and stir fried dishes, with coconut and lemongrass being used often. 𝕐 is generally spicier and more aromatic than 𝕏. 𝕏 is a European cuisine, while 𝕐 is an Asian cuisine.	*Italian Cuisine* Cuisine Cuisine	*Thai Cuisine* Cuisine Cuisine

Table 1: Examples from the GuessTwo comprehension dataset. Also provided with the dataset is the subcategory and the broad category of the entities which are listed below the entity names in this Table.

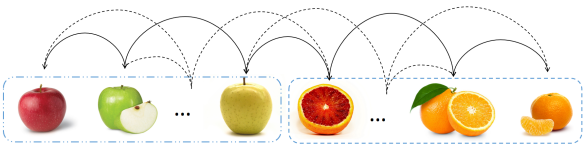

Figure 1: An example illustrating the entity pair matching process.

ison for a handful of entities at the boundaries. Figure 1 illustrates our entity pair matching process with an example on subcategories 'apple' and 'citrus'.

Data Quality Control. Our task of free-form writing is trickier than many other tasks such as tagging on Mturk. To instruct the non-expert workers, we designed a qualification test on Mturk in which the workers had to judge whether or not a given paragraph is acceptable according to our criteria. We used three carefully selected paragraphs to be a part of the qualification test. Moreover, to further ensure the quality of the submissions, one of our team members qualitatively browsed through the submissions and gave the workers detailed feedback before approving their paragraphs.

For each pair of entities, we collected eight comparison paragraphs from different workers. Given that different workers have different perspectives on what the major aspects to be compared are, collecting multiple paragraphs helps further enriching our dataset. We constrained the paragraphs to be at least 250 characters and at most 850 characters. Table 2 shows the basic statistics of our dataset. In this Table, we also included the median number of adjectives (including comparatives) per paragraph as a measure of descriptiveness of the comparison paragraphs. As a point of reference, the median number of adjectives in a random Wikipedia paragraph of the same length is 5.

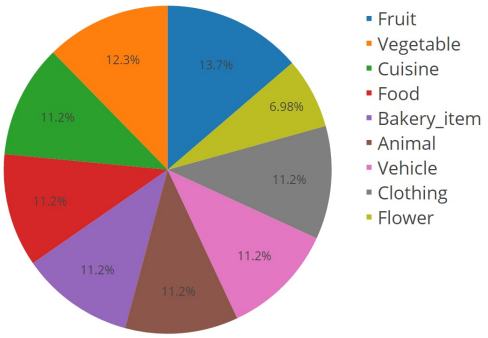

Figure 2: Distribution of broad category of the entities.

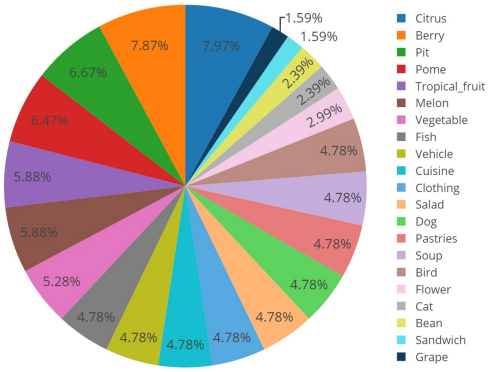

Figure 3: Distribution of subcategory of the entities.

Given the quality control we have in place, our data collection is going slowly. So far we have collected 14,142 paragraphs; however, we are aiming

Number of total approved paragraphs	**14,142**
Number of workers participated	649
Average number of paragraphs by one worker	21.7
Average work time among workers (minutes)	17.3
Median work time among workers (minutes)	6.4
Payment per paragraph (cents)	50
Number of broad entity categories	9
Number of entity sub-categories	24
Number of unique entities	920
Number of unique pairs compared	1974
Median number of sentences per paragraph	7
Median number of tokens per paragraph	70
Median number of adjectives per paragraph	7

Table 2: Statistics of the GuessTwo dataset as of April 2017.

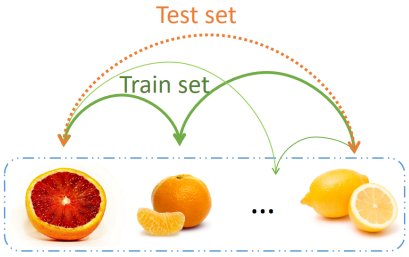

Figure 4: An example showing the entity pairs in the test and training sets.

to expand the resource over time.

Test Set Creation. In order to enable benchmarking on the task, we assessed the quality of a random sample of GuessTwo paragraphs as follows: we show the paragraph to three human workers on Mturk and ask them to guess what the two things are. Then, we choose 520 paragraphs for which all three workers have made exactly correct guesses for both entities. The test set will also be expanded along with the further data collection.

We divided the rest of the GuessTwo dataset into training and validation sets, with a 90%/10% split. To ensure that the test set requires some level of basic reasoning, our training set does not share any exact entity pairs with the validation or test set. This further enforces systems to learn about entities indirectly by processing across paragraphs. For instance, as shown in Figure 4, at test time, a system should be able to guess a comparison involving the entities *blood orange vs. lemon* by having seen comparisons of *blood orange vs. tangerine* and *tangerine vs. lemon*.

Our dataset will be released to the public through `https://omidb.github.io/guesstwo/`.

3 The GuessTwo Task Definition

We define the following two different schemes for the GuessTwo task:

• **Open-ended GuessTwo.** Given a short paragraph P which compares two entities $\mathbb{X}$ and $\mathbb{Y}$, guess what the two entities are. The scope of this prediction is the set of all entities appearing in the training dataset.

• **Binary Choice GuessTwo.** Given a short paragraph P which compares two entities $\mathbb{X}$ and $\mathbb{Y}$, and two nominals n_1 and n_2, choose 0 if $n_1 = \mathbb{X}$ and $n_2 = \mathbb{Y}$, choose 1 otherwise.

We speculate that system which can successfully tackle the GuessTwo task, has achieved two major objectives: (1) Has successfully learned the knowledge about entities stored in any form (e.g., continuous-space representation or symbolic) (2) Has a basic natural language understanding capability, using which, it can comprehend a paragraph and access its knowledge. We predict that our training dataset has enough detailed information about entities for learning the required knowledge for tackling the task. Given the design of our dataset, at test time, a system should perform some level of reasoning to go beyond understanding only one paragraph.

4 Neural Models

In this Section we present various end-to-end neural models for tackling the task of GuessTwo.

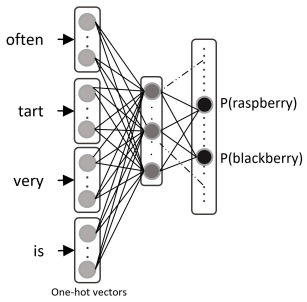
Continuous Bag-of-words Language Model. This model computes the probability of a sequence of consecutive words in context. The premise is that the probability of a paragraph with the correct realization of $\mathbb{X}$ and $\mathbb{Y}$ should be higher than the a paragraph with incorrect realizations. In order to compute the probability of a word given a context we use Continuous Bag-of-words (CBOW) (Mikolov et al., 2013a) which models the following conditional probability:

$$p(w|C(w), \theta) \quad (1)$$

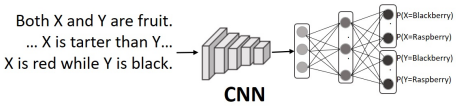
here, $C(w)$ is the context of the word w and θ is the model parameters. Then, the probability of a sequence of words (in a paragraph) is computed as follows:

$$\prod_{i=1}^{n} p(w_i|C(w_i), \theta) \quad (2)$$

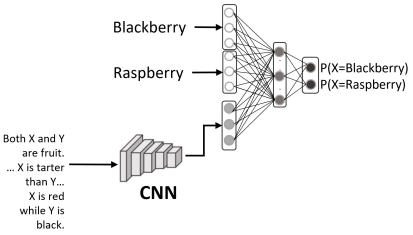
We define context to be a window of five words. Figure 5a summarizes this model. We train this



(a) The CBOW model.



(b) The CNN open-ended model.



(c) The CNN binary-choice model.

Figure 5: Various neural models for tackling the task of GuessTwo.

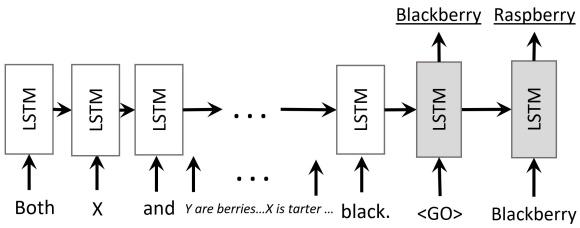


Figure 6: The Encoder-Decoder model.

model on two datasets: (1) A collection[5] of processed Wikipedia articles. Wikipedia articles often include definitions and descriptions of variety of items, which can provide a reasonable resource for our task. (2) the GuessTwo training dataset. We call these models *CBOW-Wikipedia* and *CBOW-GuessTwo* respectively.

At test time, for open-ended prediction we find the two nominals which maximize the following probability:

$$\underset{x,y}{\text{argmax}} \prod_{i=1}^{n} p(w_i | C(w_i)_{x,y}, \theta) \qquad (3)$$

where $C(w_i)_{x,y}$ indicates the context in which any occurrences of $\mathbb{X}$ have been replaced with x and $\mathbb{Y}$'s have been replaced with y. For binary choice classification, we use the same modeling except that we only consider $x = n_1, y = n_2$ and $x = n_2, y = n_1$.

Encoder-Decoder Recurrent Neural Net (RNN). This model is a sequence-to-sequence generation model (Cho et al., 2014; Sutskever et al., 2014) that maps an input sequence to an output sequence using an encoder-decoder RNN with attention (Bahdanau et al., 2014). The encoder RNN processes the comparison paragraph and the decoder generates the first item followed by the second item (Figure 6). The paragraph is encoded into a state vector of size 512. This vector is then set as the initial recurrent state of the decoder. We tune the model parameters on the validation set, where we set the number of layers to 2. The model is trained end-to-end, using Stochastic Gradient Descent with early stopping.

For open-ended prediction, we use beam search with beam-width = 25 and then output the two tokens with the highest probability. For binary choice classification, we use the same model where we set the encoder RNN inputs to the input paragraph tokens, then, we set the input of the decoder RNN once to $[n_1, n_2]$ and next to $[n_2, n_1]$. After running the network forward, we take the probability of the decoder logits and choose the ordering which has the highest probability.

Convolutional Neural Network (CNN) Encoder. As shown in the Figure 5b, this model first uses a Convolutional Neural Network (CNN) (LeCun and Bengio, 1998) for encoding the paragraph (Kim, 2014). We train a simple CNN with one layer of convolution on top of pre-trained word vectors. Here we use the word vectors trained by

[5] http://mattmahoney.net/dc/text8.zip

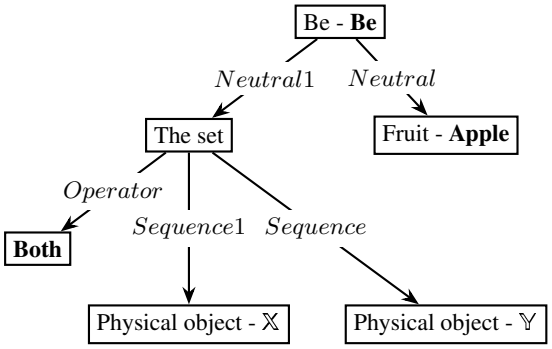

Figure 7: Semantic parsing for the sentence *Both* 𝕏 *and* 𝕐 *are apples.*

Skip-gram model (Mikolov et al., 2013b) on 100 billion words of Google News[6]. For open-ended prediction, the output of CNN is fed forward and transformed into a 300 dimension vector. Then, we use a softmax layer to get the probability of each of the possible nominals for 𝕏 and 𝕐. For binary choice classification, we use the same architecture and settings as above. Additionally, we encode each nominal into a 300-dimensional vector, which then gets concatenated with the paragraph vector. Figure 5c shows this model.

5 Semantic-driven Model

In this Section we present a semantic-driven approach which models the comparison paragraph using semantic features and is capable of performing basic reasoning across paragraphs.

5.1 Representing Paragraphs

The question is, given a comparison paragraph, what is the best representation which can enable further reasoning? The comparison paragraphs often have complex syntactic and semantic structures, which might be challenging for many off-the-shelf NLP tools to process. For instance, consider the sentence 𝕏 *is much sweeter in taste than* 𝕐. Although a dependency parser provides a lot of information regarding how the individual words relate grammatically, it does not give us any information regarding how 𝕐's sweetness (which is elided from the sentence and is implicit) relates to 𝕏's. As another processing technique, if we use the standard information extraction methods for extracting and representing syntactic triplets (*argument1, relation, argument2*) (Fader et al., 2014; Etzioni et al., 2011), we will extract a triplet such as 𝕏 *is sweeter* which shares the same shortcomings.

Our approach for better representation of comparison paragraphs starts with a broad-coverage semantic parser (Banarescu et al., 2013; Bos, 2008; Allen et al., 2008). A semantic parser maps an input sentence to its formal meaning representation, operating at the generic natural language level. Here we use the TRIPS[7] (Allen et al., 2008) broad-coverage semantic parser. TRIPS provides a very rich semantic structure; mainly it provides sense disambiguated deep structures augmented with semantic ontology types. Figure 7 shows an example TRIPS semantic parse. In this graph representation, each node specifies a word in bold along with its corresponding ontology type on its left. The edges in the graph are semantic roles[8]. As you can see, this semantic parse represents the sentence by decoupling the token 'both' and attributing the property of 'be apple' to both 𝕏 and 𝕐.

In our comparison paragraphs there are two major types of sentences:

• **Sentences with Absolute Information.** These sentences contain direct information about the entities, such as 𝕏 *is red* or *Both* 𝕏 *and* 𝕐 *are very sweet*. From each absolute sentence, we extract frames which describe the absolute attributes of the corresponding entity. We define a frame to be a subgraph of a semantic parse which involves exactly one entity and all of its semantic roles. Relying on the deep semantic features offered by the semantic parser, we perform negation propagation[9] and sequence decoupling, among others features. For example, given a sentence which has a sequence, as the one depicted in Figure 7, we perform sequence decoupling and extract the two frames *[*𝕏 *Be Apple]* and *[*𝕐 *Be Apple]*.

• **Sentences with Relative Information.** These sentences contain relative information about the two entities, for instance, 𝕏 *is somewhat sweeter than* 𝕐. As opposed to the sentences with absolute information, we cannot extract frames from sentences with comparisons directly. Various properties of entities can be associated with an abstract scale, such as 'size' or 'sweetness', on which dif-

[6] https://code.google.com/archive/p/word2vec/

[7] http://trips.ihmc.us/parser/cgi/parse

[8] Refer to http://trips.ihmc.us/parser/LFDocumentation.pdf for the full list of semantic roles in TRIPS parser.

[9] A common construction which needs negation propagation is *Neither* 𝕏 *nor* 𝕐 *are ...* .

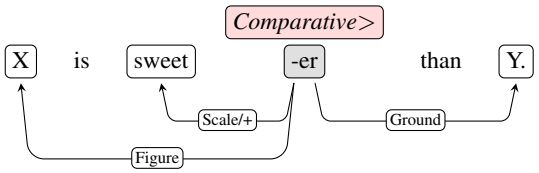

Figure 8: The comparison construction predicted for the sentence *X is sweeter than Y.*

ferent entities can be compared. In order to extract such scales and the relative standing of items on them we use the structured prediction model presented in Bakhshandeh et al. (2016), which given a sentence predicts its comparison structures. Figure 8 shows an example predicate-argument structure that is predicted by this model. We use pretrained model on the annotated corpus (Bakhshandeh et al., 2016) of comparison structures.

Given a comparison structure such as the one presented in Figure 8, we can extract the information that on the scale of 'sweetness' $\mathbb{X}$ is higher than $\mathbb{Y}$. It is clear that one can build a large knowledge base of such relations by reading large collections of comparison paragraphs. We populate our knowledge base of relative information about entities as follows: First, we predict the comparison structure of each sentence and then extract a binary relation $\prec_s$ which shows the relation on the scale of s. Second, for any scale s, we apply transitivity on its entities. As shown in equation 4, the binary relation $\prec_s$ is transitive over the set of all entities, A. This process, called closure, enables us do basic reasoning and derives implicit relations on scales from explicit relations.

$$\forall s \in S\ \forall x, y, z \in A : (x \prec_s y\ \wedge\ y \prec_s z) \\ \implies x \prec_s z \tag{4}$$

The product of this step is a structured knowledge base on entity ordering which we call the *ordering lattice*. Figure 9 shows an example partial ordering lattice inferred by our model, where the sweetness of *Golden Delicious* can be compared to *Granny Smith* through their direct link with *Red Delicious*.

5.2 Modeling

Given a paragraph P, we first extract the set of all the absolute information frames for $\mathbb{X}$ and $\mathbb{Y}$ (as described above), called $F_{\mathbb{X}}(P)$ and $F_{\mathbb{Y}}(P)$. Second, for the sentences with relative information,

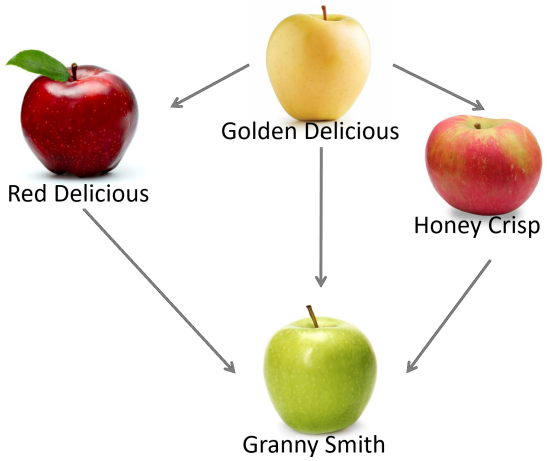

Figure 9: The inferred partial ordering lattice comparing the *sweetness* of different apples.

we extract all the binary relations $\prec_s \in R(P)$ that should hold between $\mathbb{X}$ and $\mathbb{Y}$. Then, our objective is to find two realizations for $\mathbb{X}$ and $\mathbb{Y}$ that maximize the following:

$$\underset{x,y}{\text{argmax}}\ p(x|F_{\mathbb{X}}(P)) + p(y|F_{\mathbb{Y}}(P)) \\ \text{s.t. } \forall \prec_s \in R(P) : x \prec_s y \tag{5}$$

In order to compute the $p(x|F_{\mathbb{X}}(P))$ and $p(y|F_{\mathbb{Y}}(P))$ scores we used Regularized Gradient Boosting (XGBoost) classifier (Friedman, 2000), which uses a regularized model formulation to limit overfitting. We directly use each frame in the $F_{\mathbb{X}}(P)$ and $F_{\mathbb{Y}}(P)$ sets as the classifier features. We use Integer Linear Programming (ILP) for formulating the constraints as follows: for each relation $r \in R$ on the scale s, we lookup the scale s in the ordering lattice and make the blacklist $B(P)$ containing each pair of entities which do not satisfy the relation r. Our ordering lattice does not have perfect complete information, hence, we have Open World Assumption and only prune our search space not to include the already observed pairs which violate the relation. our ILP objective function will be the following:

$$\underset{b,b'}{\text{argmax}} \sum_{x \in N} b_x\ p(x|F_{\mathbb{X}}(P)) + \\ \sum_{y \in N} b'_y\ p(y|F_{\mathbb{Y}}(P)) \\ \text{s.t. } \forall\ (j, j') \in B(P) : b_j + b'_{j'} \leq 1 \tag{6}$$

where N is the set of all possible realizations and b and b' are the binary indicator variables, so $b_x = 1$ indicates the realization of x for $\mathbb{X}$.

In the case of open-ended prediction, the maximization presented in Equation 6 is carried out on the set N. In the case of binary choice classification, however, only the two choices of n_1 and n_2 are considered in the maximization.

6 Results

We evaluate all the models presented in Sections 4 and 5 using the following accuracy measure:

$$\frac{\#\text{correct predictions of both entities}}{\#\text{test cases}} \quad (7)$$

As for the open-ended prediction we compute the nominator of the accuracy measure using three various matching methods on both entities: (1) exact-match, (2) subcategory match, (3) broad category match.

As Table 3 shows, the semantic model outperforms all the neural models. Moreover, the ILP constraints have been very effective in directing the system in the correct search space. Among the neural models, the Encoder-Decoder RNN model performs noticeably better than other models when matching the subcategory and broad category. According to the exact-matching, neither of the CBOW models could guess any of the two test entities correctly. Overall, it is evident that the end-to-end neural models have not been able to generalize well and learn about the attributes of entities across various training paragraphs. This can be partly due to not being trained on large enough comparison training dataset. The semantic model, however, could outperform the neural models using the same amount of data. To a degree, this is because the semantic model leverages the basic language understanding capabilities offered by the semantic parser.

It is also important to note that our semantic approach is not only capable of binary and open-ended prediction, but it also offers two by-products that can be used as knowledge in a variety of other tasks: (1) a set of the most important absolute information frames which can be chosen based on feature importance in the classification, (2) the partial ordering lattice of entities. Overall, the results strongly suggest that the GuessTwo task is challenging, with the open-ended scheme being the most challenging. There is a wide gap between human and system performance on this task, which makes it a very promising task for the community to pursue.

Model	**Binary**	**Open-ended**	
		Exact.	**Subcat.**
Human	100.0	94.2	100.0
CBOW-Wikipedia	51.9	0.0	1.5
CBOW-GuessTwo	51.7	0.0	1.1
Encoder-Decoder RNN	58.8	2.9	6.8
CNN	57.6	1.9	2.5
Semantic (no constraints)	61.5	10.5	38.5
Semantic (with ILP constraints)	**69.2**	**11.7**	**40.4**

Table 3: System accuracy results on the GuessTwo test set. A random baseline on binary choice task achieves 51%. The open-ended evaluation has two columns: exact-match (exact) and subcategory match (subcat), respectively.

7 Related Work

The task of Machine Comprehension (MC) has gained a significant attention over the past few years. The major driver for MC has been the publicly available benchmarking datasets. A variety of MC tasks have been introduced in the community (Richardson et al.; Hermann et al., 2015; Rajpurkar et al., 2016; Hill et al., 2015), in which the system reads a short text and answers a few multiple-choice questions. The reading comprehension involved in these tests ranges from reading a short fictional story (Richardson et al.) to reading a short news article (Hermann et al., 2015). In comparison, in the GuessTwo task the reading comprehension involves reading a short comparison paragraph and one can say the multiple-choice question is the constant *What are* $\mathbb{X}$ *and* $\mathbb{Y}$*?*

The CNN/DailyMail dataset consists of more than 100K short news articles with the questions automatically created from the bullet-point summaries of the original article. This dataset uses fill-in-the-blank-style questions such as 'Producer *X* will not press charges against Jeremy Clarkson' where the system should choose among all the anonymized entities in the corresponding paragraph to fill in *X*. The Stanford Question Answering (SQuAD) dataset is another recent machine comprehension test with over 500 Wikipedia articles and +100,000 crowdsourced questions. The answer to every question in this dataset is a span of text from the corresponding reading passage.

Human accuracy on CNN/DailyMail is estimated to be around 75% (Chen et al., 2016) with the current state-of-the-art at 76.1 on CNN (Sordoni et al., 2016), and 75.8 on DailyMail (Chen et al., 2016). The human F1 score on SQuAD

dataset is reported to be at 86.8%, with the current state-of-the-art achieving 82.9%. Given these statistics, neither of these datasets leave enough room for further research. Given that in both these tasks the answer to the question is directly found in the provided passage, we argue that the community requires a more challenging MC task which goes beyond matching and needs some level of inference across passages. The GuessTwo task requires basic reasoning and inference across paragraphs for comprehending various aspects of entities relative to one another.

Another interesting task is MCTest (Richardson et al.), which is a reading comprehension test with 660 fictional stories as the passage and four questions per story. The human-level performance on MCTest is estimated to be around 90%, with the state-of-the-art achieving an accuracy of 70% (Wang et al., 2015). MCTest is also proven to be challenging, however, given its very limited training data, further progress on the task has been hindered. Yet another relevant QA task is the Allen AI Science Challenge (Clarke et al., 2010; Schoenick et al., 2016), which is a dataset of multiple-choice questions and answers from a standardized 8th grade science exam. The questions can range from simple fact lookup to complex ones which require extensive world knowledge and commonsense reasoning. This task requires machine reading of a variety of resources such as textbooks and goes beyond reading a couple of passages.

8 Conclusion

We introduced the novel task of GuessTwo, in which given a short paragraph comparing two common entities, a system should guess what the two entities are. The comparison paragraphs often have complex semantic structures which make this comprehension task demanding. Furthermore, guessing the two entities requires a system to go beyond only understanding one given passage and requires reasoning across paragraphs, which is one of the most under-explored, yet crucial, capabilities of an intelligent agent.

So far, we have crowdsourced a dataset of more than 14K comparison paragraphs comparing entities from nine major categories. For benchmarking the progress, we filter a collection of these paragraphs to create a test set, on which humans perform with an accuracy of 94.2%. For continuing our data collection, we would like to have a targeted entity pair selection where we particularly collect the missing relations in our partial ordering lattice. We believe that this process can help developing more effective systems. For the most recent statistics of the dataset and the best performing systems please check this website.

We presented a host of neural models and a novel semantic-driven approach for tackling the task of GuessTwo. Our experiments show that the semantic approach outperforms the neural models by a large margin. The poor performance of the neural models we experimented with can motivate designing new architectures which are capable of performing basic reasoning across paragraphs. The results strongly suggest that bridging the gap between system and human performance on this task requires models with richer language representation and reasoning capabilities. As a future work, we would like to explore the feasibility of marrying our semantic and neural models to exploit the benefits that each of them has to offer.

Abstract

We present a novel attention-based recurrent neural network for joint extraction of entity mentions and relations. We show that attention along with long short term memory (LSTM) network can extract semantic relations between entity mentions without having access to dependency trees. Experiments on Automatic Content Extraction (ACE) corpora show that our model significantly outperforms feature-based joint model by Li and Ji (2014). We also compare our model with an end-to-end tree-based LSTM model (SPTree) by Miwa and Bansal (2016) and show that our model performs within 1% on entity mentions and 2% on relations. Our fine-grained analysis also shows that our model performs significantly better on AGENT-ARTIFACT relations, while SPTree performs better on PHYSICAL and PART-WHOLE relations.

1 Introduction

Extraction of entities and their relations from text belongs to a very well-studied family of structured prediction tasks in NLP. There are several NLP tasks such as fine-grained opinion mining (Choi et al., 2006), semantic role labeling (Gildea and Jurafsky, 2002), etc., which have a similar structure; thus making it an important and a challenging task.

Several methods have been proposed for entity mention and relation extraction at the sentence-level. These can be broadly categorized into – 1) pipeline models that treat the identification of entity mentions (Nadeau and Sekine, 2007) and relation classification (Zhou et al., 2005) as two separate tasks; and 2) joint models, also the more recent, which simultaneously identify the entity mention and relations (Li and Ji, 2014; Miwa and Sasaki, 2014). Joint models have been argued to perform better than the pipeline models as knowledge of the typed relation can increase the confidence of the model on entity extraction and vice versa.

Recurrent networks (RNNs) (Elman, 1990) have recently become very popular for sequence tagging tasks such as entity extraction that involves a set of contiguous tokens. However, their ability to identify relations between *non-adjacent* tokens in a sequence, e.g., the head nouns of two entities, is less explored. For these tasks, RNNs that make use of tree structures have been deemed more suitable. Miwa and Bansal (2016), for example, propose an RNN comprised of a sequence-based long short term memory (LSTM) for entity identification and a separate tree-based dependency LSTM layer for relation classification using shared parameters between the two components. As a result, their model depends critically on access to dependency trees, restricting it to sentence-level extraction and to languages for which (good) dependency parsers exist. Also, their model does not jointly extract entities and relations; they first extract all entities and then perform relation classification on all pairs of entities in a sentence.

In our previous work (Katiyar and Cardie, 2016), we address the same task in an opinion extraction context. Our LSTM-based formulation explicitly encodes distance between the head of entities into opinion relation labels. The output space of our model is quadratic in size of the entity and relation label set and we do not specifically identify the relation type. Unfortunately, adding relation type makes the output label space very sparse, making it difficult for the model to learn.

In this paper, we propose a novel RNN-based model for the joint extraction of entity mentions

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 917–928
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1085

and relations. Unlike other models, our model does not depend on any dependency tree information. Our RNN-based model is a multi-layer bi-directional LSTM over a sequence. We encode the output sequence from left-to-right. At each time step, we use an attention-like model on the previously decoded time steps, to identify the tokens in a specified relation with the current token. We also add an additional layer to our network to encode the output sequence from right-to-left and find significant improvement on the performance of relation identification using bi-directional encoding.

Our model significantly outperforms the feature-based structured perceptron model of Li and Ji (2014), showing improvements on both entity and relation extraction on the ACE05 dataset. In comparison to the dependency tree-based LSTM model of Miwa and Bansal (2016), our model performs within 1% on entities and 2% on relations on ACE05 dataset. We also find that our model performs significantly better than their tree-based model on the AGENT-ARTIFACT relation, while their tree-based model performs better on PHYSICAL and PART-WHOLE relations; the two models perform comparably on all other relation types. The very competitive performance of our non-tree-based model bodes well for relation extraction of non-adjacent entities in low-resource languages that lack good parsers.

In the sections that follow, we describe related work (Section 2); our bi-directional LSTM model with attention (Section 3); the training (Section 4); the experiments on ACE dataset (Section 5); results (Section 6); error analysis (Section 7) and conclusion (Section 8).

2 Related Work

RNNs (Hochreiter and Schmidhuber, 1997) have been recently applied to many sequential modeling and prediction tasks, such as machine translation (Bahdanau et al., 2015; Sutskever et al., 2014), named entity recognition (NER) (Hammerton, 2003), opinion mining (Irsoy and Cardie, 2014). Variants such as adding CRF-like objective on top of LSTMs have been found to produce state-of-the-art results on several sequence prediction NLP tasks (Collobert et al., 2011; Huang et al., 2015; Katiyar and Cardie, 2016). These models assume conditional independence at the output layer whereas the model we propose in this paper does not assume any conditional independence at the output layer, allowing it to model an arbitrary distribution over output sequences.

Relation classification has been widely studied as a stand-alone task, assuming that the arguments of the relations are known in advance. There have been several models proposed including feature-based models (Bunescu and Mooney, 2005; Zelenko et al., 2003) and neural network based models (Socher et al., 2012; dos Santos et al., 2015; Hashimoto et al., 2015; Xu et al., 2015a,b).

For joint-extraction of entities and relations, feature-based structured prediction models (Li and Ji, 2014; Miwa and Sasaki, 2014), joint inference integer linear programming models(Yih and Roth, 2007; Yang and Cardie, 2013), card-pyramid parsing (Kate and Mooney, 2010) and probabilistic graphical models (Yu and Lam, 2010; Singh et al., 2013) have been proposed. In contrast, we propose a neural network model which does not depend on the availability of any features such as part of speech (POS) tags, dependency trees, etc.

Recently, Miwa and Bansal (2016) proposed an end-to-end LSTM based sequence and tree-structured model. They extract entities via a sequence layer and relations between the entities via the shortest path dependency tree network. In this paper, we try to investigate recurrent neural networks with attention for extracting semantic relations between entity mentions without using any dependency parse tree features. We also present the *first* neural network based joint model that can extract entity mentions and relations along with the relation type. In our previous work (Katiyar and Cardie, 2016), as explained earlier, we proposed a LSTM-based model for joint extraction of opinion entities and relations, but no relation types. This model cannot be directly extended to include relation types as the output space becomes sparse making it difficult for the model to learn.

Recent advances in recurrent neural network has seen the application of attention on recurrent neural networks to obtain a representation weighted by the importance of tokens in the sequence model. Such models have been very frequently used in question-answering tasks (for recent examples, see Chen et al. (2016) and Lee et al. (2016)), machine translation (Luong et al., 2015; Bahdanau et al., 2015), and many other NLP applications. Pointer networks (Vinyals et al., 2015), an adaptation of attention models, use these token-level weights as pointers to the input elements.

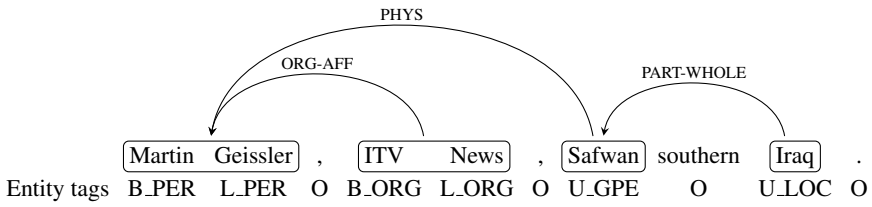

Figure 1: Gold standard annotation for an example sentence from ACE05 dataset.

Zhai et al. (2017), for example, have used these for neural chunking, and Nallapati et al. (2016) and Cheng and Lapata (2016), for summarization. However, to the best of our knowledge, these networks have not been used for joint extraction of entity mentions and relations. We present first such attempt to use these attention models with recurrent neural networks for joint extraction of entity mentions and relations.

3 Model

Our model comprises of a multi-layer bi-directional recurrent network which learns a representation for each token in the sequence. We use the hidden representation from the top layer for joint entity and relation extraction. For each token in the sequence, we output an entity tag and a relation tag. The entity tag corresponds to the entity type, whereas the relation tag is a tuple of pointers to related entities and their respective relation types. Figure 1 shows the annotation for an example sentence from the dataset. We transform the relation tags from entity level to token level. For example, we separately model the relation "ORG-AFF" for each token in the entity "ITV News". Thus, we model the relations between "ITV" and "Martin Geissler", and "News" and "Martin Geissler" separately. We employ a pointer-like network on top of the sequence layer in order to find the relation tag for each token as shown in Figure 2. At each time step, the network utilizes the information available about all output tags from the previous time steps in order to output the entity tag and relation tag *jointly* for the current token.

3.1 Multi-layer Bi-directional Recurrent Network

We use multi-layer bi-directional LSTMs for sequence tagging because LSTMs are more capable of capturing long-term dependencies between tokens, making it ideal for both entity mention and relation extraction.

Using LSTMs, we can compute the hidden state $\overrightarrow{h_t}$ in the forward direction and $\overleftarrow{h_t}$ in the backward direction for every token as below:

$$\overrightarrow{h}_t = LSTM(x_t, \overrightarrow{h}_{t-1})$$
$$\overleftarrow{h}_t = LSTM(x_t, \overleftarrow{h}_{t+1})$$

For every token t in the subsequent layer l, we combine the representations $\overrightarrow{h}_t^{l-1}$ and $\overleftarrow{h}_t^{l-1}$ from previous layer l-1 and feed it as an input. In this paper, we only use the hidden state from the last layer L for output layer and compute the top hidden layer representation as below:

$$z_t^{'} = \overrightarrow{V}\overrightarrow{h}_t^{(L)} + \overleftarrow{V}\overleftarrow{h}_t^{(L)} + c$$

$\overrightarrow{V}$ and $\overleftarrow{V}$ are weight matrices for combining hidden representations from the two directions.

3.2 Entity detection

We formulate entity detection as a sequence labeling task using BILOU scheme similar to Li and Ji (2014) and Miwa and Bansal (2016). We assign each token in the entity with the tag B appended with the entity type if it is the beginning of the entity, I for inside of an entity, L for the end of the entity or U if there is only one token in the entity. Figure 1 shows an example of the entity tag sequence assigned to the sentence. For each token in the sequence, we perform a softmax over all candidate tags to output the most likely tag:

$$y_t = \text{softmax}(Uz_t^{'} + b)$$

Our network structure as shown in Figure 2 also contains connections from the output y_{t-1} of the previous time step to the current top hidden layer. Thus our outputs are not conditionally independent from each other. In order to add connections from y_{t-1}, we transform this output k into a label embedding b_{t-1}^k [1]. We represent each label type

[1] We can also add relation label embeddings using the relation tag output from the previous time step.

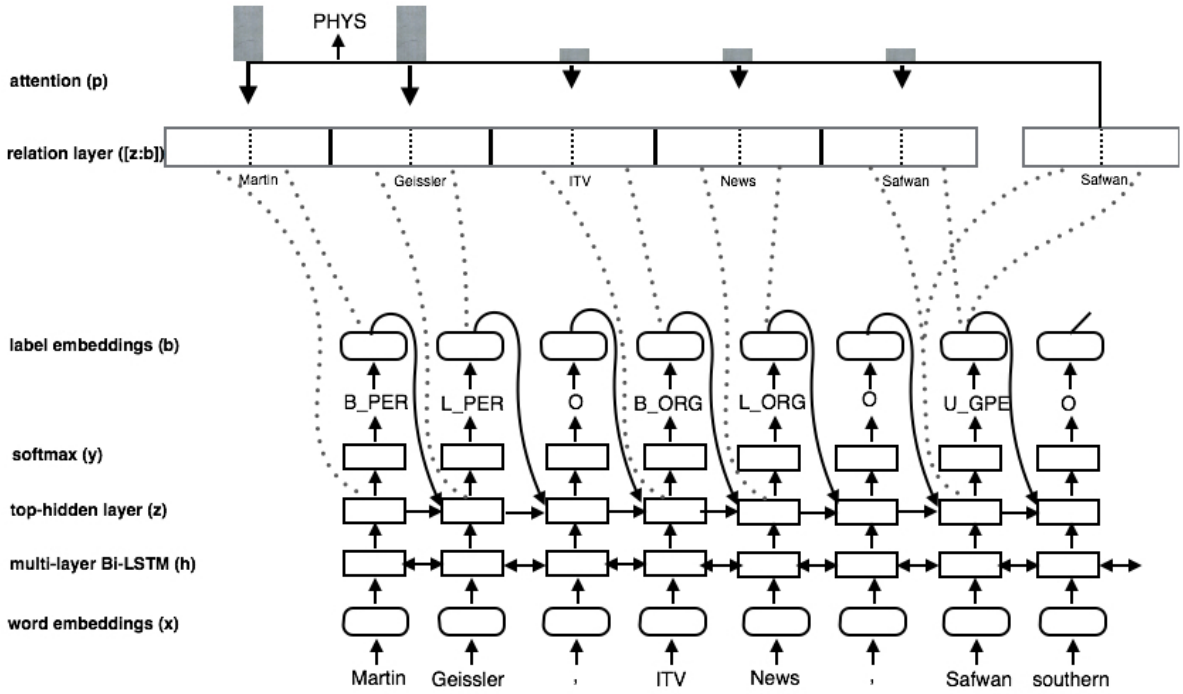

Figure 2: Our network structure based on bi-directional LSTMs for joint entity and relation extraction. This snapshot shows the network when encoding the relation tag for the word "Safwan" in the sentence. The dotted lines in the figure show that top hidden layer and label embeddings for tokens is copied into relation layer. The pointers at attention layer indicate the probability distribution over tokens, the length of the pointers is used to denote the probability value.

k with a dense representation b^k. We compute the output layer representations as:

$$z_t = LSTM([z_t^{'}; b_{t-1}^k], h_{t-1})$$
$$y_t = \text{softmax}(Uz_t + b^{'})$$

We decode the output sequence from left to right in a greedy manner.

3.3 Attention Model

We use attention model for relation extraction. Attention models, over an encoder sequence of representations z, can compute a soft probability distribution p over these learned representations, where d_i is the i^{th} token in decoder sequence. These probabilities are an indication of the importance of different tokens in the encoder sequence:

$$u_t^i = v^T \tanh(W_1 z + W_2 d_i)$$
$$p_t^i = \text{softmax}(u_t^i)$$

v is a weight matrix for attention which transforms the hidden representations into attention scores.

We use pointer networks (Vinyals et al., 2015) in our approach, which are a variation of these attention models. Pointer networks interpret these p_t^i as the probability distribution over the input encoding sequence and use u_t^i as pointers to the input elements. We can use these pointers to encode relation between the current token and the previous predicted tokens, making it fit for relation extraction as explained in Section 3.4.

3.4 Relation detection

We formulate relation extraction also as a sequence labeling task. For each token, we want to find the tokens in the past that the current token is related to along with its relation type. In Figure 1, "Safwan" is related to the tokens "Martin" as well as "Geissler" by the relation type "PHYS". For simplicity, let us assume that there is only one previous token the current token is related to when training, i.e., "Safwan" is related to "Geissler" via PHYS relation. We can extend our approach to output multiple relations as explained in Section 4.

We use pointer networks as described in Sec-

tion 3.3. At each time step, we stack the top hidden layer representations from the previous time steps $z_{\leq t}$[2] and its corresponding label embeddings $b_{\leq t}$. We only stack the top hidden layer representations for the tokens which were predicted as non-O's for previous time steps as shown in Figure 2. Our decoding representation at time t is the concatenation of z_t and b_t. The attention probabilities can now be computed as below:

$$u^t_{\leq t} = v^T \tanh(W_1[z_{\leq t}; b_{\leq t}] + W_2[z_t; b_t])$$
$$p^t_{\leq t} = \text{softmax}(u^t_{\leq t})$$

Thus, $p^t_{\leq t}$ corresponds to the probability of each token, in the sequence so far, being related to the current token at time step t. For the case of NONE relations, the token at t is related to itself.

We also want to find the type of the relations. In order to achieve this, we add an extra dimension to v corresponding to the size of relation types R space. Thus, u^i_t is no longer a score but a R dimensional vector. We then take softmax over this vector of size $O(|z_{\leq t}| \times R)$ to find the most likely tuple of pointer to the related entity and its relation type.

3.5 Bi-directional Encoding

Bi-directional LSTMs have been found to be able to capture context better than plain left-to-right LSTMs, based on their performance on various NLP tasks (Irsoy and Cardie, 2014). Also, Sutskever et al. (2014) found that their performance on machine translation task improved on reversing the input sentences during training. Inspired by these developments, we experiment with bi-directional encoding at the output layer. We add another top hidden layer on Bi-LSTM in Figure 2 which encodes the output sequence from right-to-left. The two encoding share the same multi-layer bi-directional LSTM except for the top hidden layer. Thus, we have two output layers in our network which output the entity tags and relation tags separately. At inference time, we employ heuristics to combine the output from the two directions.

[2]The notation $\leq$ is used to denote the stacking of the representations from the previous time steps. Thus, if z_t is a 2-dimensional matrix then $z_{\leq t}$ will be a 3-dimensional tensor. The size along the first dimension will now correspond to the number of 2-dimensional matrices stacked.

4 Training

We train our network by maximizing the log-probability of the correct entity E and relation R tag sequences *jointly* given the sentence S as below:

$$\begin{aligned}
&\log p(E, R|S, \theta) \\
=&\frac{1}{|S|}\sum_{i \in |S|} \log p(e_i, r_i|e_{<i}, r_{<i}, S, \theta) \\
=&\frac{1}{|S|}\sum_{i \in |S|} \log p(e_i|e_{<i}, r_{<i}) + \log p(r_i|e_{\leq i}, r_{<i})
\end{aligned}$$

Thus, we can decompose our objective into the sum of log-probabilities over entity sequence and relation sequence. We use the gold entity tags while training. As shown in Figure 2, we input the label embedding from the previous time step to the top hidden layer at the current time step along with the other recurrent inputs. During training, we pass the gold label embedding to the next time step which enables better training of our model. However, at test time when the gold label is not available we use the predicted label at previous time step as input to the current step.

At inference time, we can greedily decode the sequence to find the most likely entity $\widehat{E}$ and relation $\widehat{R}$ tag sequences:

$$(\widehat{E}, \widehat{R}) = \underset{E,R}{\text{argmax}}\, p(E, R)$$

Since, we add another top layer to encode tag sequences in the reverse order as explained in Section 3.5, there may be conflicts in the output. We select the positive and more confident label similar to Miwa and Bansal (2016).

Multiple Relations Our approach to relation extraction is different from Miwa and Bansal (2016). Miwa and Bansal (2016) present each pair of entities to their model for relation classification. In our approach, we use pointer networks to identify the related entities. Thus, for our approach described so far if we only compute the argmax on our objective then we limit our model to output only one relation label per token. However, from our analysis of the dataset, an entity may be related to more than one entity in the sentence. Hence, we modify our objective to include multiple relations. In Figure 2, token "Safwan" is related to both tokens "Martin" and "Geissler" of the entity "Martin Geissler", hence we assign probability of 0.5

to both these tokens. This can be easily expanded to include tokens from other related entities, such that we assign equal probability $\frac{1}{N}$ to all tokens[3] depending on the number N of these related tokens.

The log-probability for the entity part remain the same as in our objective discussed in Section 4, however we modify the relation log-probability as below:

$$\sum_{|j:\mathbf{r}'_{\mathbf{i,j}}>0|} \mathbf{r}'_{\mathbf{i,j}} \log p(\mathbf{r_{i,j}}|e_{\leq i}, \mathbf{r_{<i}}, S, \theta)$$

where, $\mathbf{r}'_{\mathbf{i}}$ is the true distribution over relation label space and $\mathbf{r_i}$ is the softmax output from our model. From empirical analysis, we find that $\mathbf{r}'_{\mathbf{i}}$ is generally sparse and hence using a cross entropy objective like this can be useful to find multiple relations. We can also use Sparsemax (Martins and Astudillo, 2016) instead of softmax which is more suitable for sparse distributions. However, we leave it for future work.

At inference time, we output all the labels with probability value above a certain threshold. We adapt this threshold based on the validation set.

5 Experiments

5.1 Data

We evaluate our proposed model on the two datasets from the Automatic Content Extraction (ACE) program – ACE05 and ACE04. There are 7 main entity types namely Person (PER), Organization (ORG), Geographical Entities (GPE), Location (LOC), Facility (FAC), Weapon (WEA) and Vehicle (VEH). For each entity, both entity mentions and its head phrase are annotated. For the scope of this paper, we only use the entity head phrase similar to Li and Ji (2014) and Miwa and Bansal (2016). Also, there are relation types namely Physical (PHYS), Person-Social (PER-SOC), Organization-Affiliation (ORG-AFF), Agent-Artifact (ART), GPE-Affiliation (GPE-AFF).

ACE05 has a total of 6 relation types including PART-WHOLE. We use the same data splits as Li and Ji (2014) and Miwa and Bansal (2016) such that there are 351 documents for training, 80 for development and the remaining 80 documents for the test set.

ACE04 has 7 relation types with an additional Discourse (DISC) type and split ORG-AFF relation type into ORG-AFF and OTHER-AFF. We perform 5-fold cross validation similar to Chan and Roth (2011) for fair comparison with the state-of-the-art.

5.2 Evaluation Metrics

In order to compare our system with the previous systems, we report micro F1-scores, Precision and Recall on both entities and relations similar to Li and Ji (2014) and Miwa and Bansal (2016). An entity is considered correct if we can identify its head and the entity type correctly. A relation is considered correct if we can identify the head of the argument entities and also the relation type. We also report a combined score when both argument entities and relations are correct.

5.3 Baselines and Previous Models

We compare our approach with two previous approaches. The model proposed by Li and Ji (2014) is a feature-based structured perceptron model with efficient beam-search. They employ a segment-based decoder instead of token-based decoding. Their model outperformed previous state-of-the-art pipelined models. Miwa and Sasaki (2014) (SPTree) recently proposed a LSTM-based model with a sequence layer for entity identification, and a tree-based dependency layer which identifies relations between pairs of candidate entities using the shortest dependency path between them. We also employed our previous approach (Katiyar and Cardie, 2016) for extraction of opinion entities and relations to this task. We found that the performance was not competitive with the two approaches mentioned above, performing upto 10 points lower on relations. Hence, we do not include the results in Table 1. Also, Li and Ji (2014) showed that the joint model performs better than the pipelined approaches. Thus, we do not include any pipeline baselines.

5.4 Hyperparameters and Training Details

We train our model using Adadelta (Zeiler, 2012) with gradient clipping. We regularize our network using dropout (Srivastava et al., 2014) with the drop-out rate tuned using development set. We initialized our word embeddings

[3] In this paper, we only identify mention heads and hence the span is limited to a few tokens. We can also include only the last token of the gold entity span in the gold probability distribution.

	Entity			Relation			Entity+Relation		
Method	P	R	F1	P	R	F1	P	R	F1
Li and Ji (2014)	.852	.769	.808	.689	.419	.521	.654	.398	.495
SPTree	.829	.839	.834	–	–	–	.572	.540	.556
SPTree[1]	.823	.839	.831	.605	.553	.578	.578	.529	.553
Our Model	.840	.813	.826	.579	.540	.559	.555	.518	.536

Table 1: Performance on ACE05 test dataset. The dashed ("–") performance numbers were missing in the original paper (Miwa and Bansal, 2016).

[1] We ran the system made publicly available by Miwa and Bansal (2016), on ACE05 dataset for filling in the missing values and comparing our system with theirs at fine-grained level.

	Entity			Relation			Entity+Relation		
Encoding	P	R	F1	P	R	F1	P	R	F1

+Bi-directional (Our Model)	.840	.813	.826	.579	.540	.559	.555	.518	.536

Table 2: Performance of different encoding methods on ACE05 dataset.

with 300-dimensional word2vec (Mikolov et al., 2013) word embeddings trained on Google News dataset. We have 3 hidden layers in our network and the dimensionality of the hidden units is 100. All the weights in the network are initialized from small random uniform noise. We tune our hyperparameters based on ACE05 development set and use them for training on ACE04 dataset.

6 Results

Table 1 compares the performance of our system with respect to the baselines on ACE05 dataset. We find that our joint model significantly outperforms the joint structured perceptron model (Li and Ji, 2014) on both entities and relations, despite the unavailability of features such as dependency trees, POS tags, etc. However, if we compare our model to the SPTree models, then we find that their model has better recall on both entities and relations. In Section 7, we perform error analysis to understand the difference in the performance of the two models in detail.

We also compare the performance of various encoding schemes in Table 2. We compare the benefits of introducing multiple relations in our objective and bi-directional encoding compared to left-to-right encoding.

Multiple Relations We find that modifying our objective to include multiple relations improves the recall of our system on relations, leading to slight improvement on the overall performance on relations. However, careful tuning of the threshold may further improve precision.

Bi-directional Encoding By adding bi-directional encoding to our system, we find that we can significantly improve the performance of our system compared to left-to-right encoding. It also improves precision compared to left-to-right decoding combined with multiple relations objective.

We find that for some relations it is easier to detect them with respect to one of the entities in the entity pair. PHYS relation is easier identified with respect to GPE entity than PER entity. Thus, our bi-directional encoding of relations allows us to encode these relations with respect to both entities in the relation.

Table 3 shows the performance of our model on ACE04 dataset. We believe that tuning the hyperparameters of our model can further improve the results on this dataset. As also pointed out by Li and Ji (2014) that ACE05 has better annotation quality, we focused on ACE05 dataset for this work.

7 Error Analysis

In this section, we perform a fine-grained comparison of our model with respect to the SPTree (Miwa and Bansal, 2016) model. We compare the performance of the two models with respect to entities, relation types and the distance between the relation arguments and provide examples from the test set in Table 6.

	Entity			Relation			Entity+Relation		
Method	P	R	F1	P	R	F1	P	R	F1
Li and Ji (2014)	.835	.762	.797	.647	.385	.483	.608	.361	.453
SPTree	.808	.829	.818	–	–	–	.487	.481	.484
Our Model	.812	.781	.796	.502	.488	.493	.464	.453	.457

Table 3: Performance on ACE04 test dataset. The dashed ("–") performance numbers were missing in the original paper (Miwa and Bansal, 2016).

7.1 Entities

We find that our model has lower recall on entity extraction than SPTree as shown in Table 1. Miwa and Bansal (2016), in one of the ablation tests on ACE05 development set, show that their model can gain upto 2% improvement in recall by entity pretraining. Since we propose a joint-model, we cannot directly apply their pretraining trick on entities separately. We leave it for future work. Li and Ji (2014) mentioned in their analysis of the dataset that there were many "UNK" tokens in the test set which were never seen during training. We verified the same and we hypothesize that for this reason the performance on the entities depends largely on the pretrained word embeddings being used. We found considerable improvements on entity recall when using pretrained word embeddings, if available, for these "UNK" tokens. Miwa and Bansal (2016) also use additional features such as POS tags in addition to pretrained word embeddings at the input layer.

Relation Type	Method	R	P	F1
ART	SPTree	.363	.552	.438
	Our model	.431	.611	**.505**
PART-WHOLE	SPTree	.560	.538	**.548**
	Our model	.520	.538	.528
PER-SOC	SPTree	.671	.671	.671
	Our model	.657	.648	.652
PHYS	SPTree	.489	.513	**.500**
	Our model	.388	.426	.406
GEN-AFF	SPTree	.414	.640	.502
	Our model	.484	.516	.500
ORG-AFF	SPTree	.692	.704	.697
	Our model	.706	.700	.703

Table 4: Performance on different relation types in ACE05 test dataset. Numbers in the bracket denote the number of relations of each relation type in the test set.

7.2 Relation Types

We evaluate our model on different relation types and compare the performance with SPTree model in Table 4. Interestingly, we find that the performance of the two models is varied over different relation types. The dependency tree-based model significantly outperforms our joint-model on PHYS and PART-WHOLE relations, whereas our model is significantly better than tree-based model on ART relation. We show an example sentence (S1) in Table 6, where SPTree model identifies the entities in ART relation correctly but fails to identify ART relation. We compare the performance with respect to PHYS relation in Section 7.3.

		Relation		
Distance	Method	R	P	F1
≤ 7	SPTree	.589	.628	.608
	Our model	.591	.605	.598
> 7	SPTree	.275	.375	**.267**
	Our model	.153	.259	.192

Table 5: Performance based on the distance between entity arguments in relations for ACE05 test dataset.

7.3 Distance-based Analysis

We also compare the performance of the two models on relations based on the distance between the entities in a relation in Table 5. We find that the performance of both the models is very low for distance greater than 7. SPTree model can identify 36 relations out of 131 such relations correctly, while our model can only identify 20 relations in this category. We manually compare the output of the two systems on these cases on several examples to understand the gain of using dependency tree on longer distances. Interestingly, the majority of these relations belong to PHYS type, thus resulting in lower performance on PHYS as discussed in Section 7.2. We found that there were a few instances of co-reference errors as shown in S2 in Table 6. Our model identifies a PHYS relation between "here" and "baghdad", whereas the gold annotation has PHYS relation between "location" and "baghdad". We think that

S1 :	the [men]$_{\text{PER:ART-1}}$ held on the sinking [vessel]$_{\text{VEH:ART-1}}$ until the [passenger]$_{\text{PER:ART-2}}$ [ship]$_{\text{VEH:ART-2}}$ was able...
SPTree :	the [men]$_{\text{PER}}$ held on the sinking [vessel]$_{\text{VEH}}$ until the [passenger]$_{\text{PER}}$ [ship]$_{\text{VEH}}$ was able to reach them.
Our Model :	the [men]$_{\text{PER:ART-1}}$ held on the sinking [vessel]$_{\text{VEH:ART-1}}$ until the [passenger]$_{\text{PER:ART-2}}$ [ship]$_{\text{VEH:ART-2}}$ was able...
S2 :	[her]$_{\text{PER}}$ research was conducted [here]$_{\text{FAC}}$ at a [location]$_{\text{FAC:PHYS1}}$ well-known to [u.n.]$_{\text{ORG:ORG-AFF1}}$ [arms]$_{\text{WEA}}$ [inspectors]$_{\text{PER:ORG-AFF1}}$. 300 miles west of [baghdad]$_{\text{GPE:PHYS1}}$.
SPTree :	[her]$_{\text{PER}}$ research was conducted [here]$_{\text{GPE}}$ at a [location]$_{\text{LOC:PHYS1}}$ well-known to u.n. [arms]$_{\text{WEA}}$ [[inspectors]$_{\text{PER:PHYS1,PHY2}}$. 300 miles west of [baghdad]$_{\text{GPE:PHYS2}}$.
Our Model :	[her]$_{\text{PER}}$ research was conducted [here]$_{\text{FAC:PHYS1}}$ at a [location]$_{\text{GPE}}$ well-known to [u.n.]$_{\text{ORG:ORG-AFF1}}$ [arms]$_{\text{WEA}}$ [inspectors]$_{\text{PER:ORG-AFF1}}$. 300 miles west of [baghdad]$_{\text{GPE:PHYS1}}$.
S3 :	... [Abigail Fletcher]$_{\text{PER:PHYS1}}$, a [marcher]$_{\text{FAC:GEN-AFF2}}$ from [Florida]$_{\text{FAC:GEN-AFF2}}$, said outside the [president]$_{\text{PER:ART3}}$'s [[residence]$_{\text{FAC:ART3, PHYS1}}$.
SPTree :	... [Abigail Fletcher]$_{\text{PER:PHYS1}}$, a [marcher]$_{\text{FAC:GEN-AFF2}}$ from [Florida]$_{\text{FAC:GEN-AFF2}}$, said outside the [president]$_{\text{PER:ART3}}$'s [[residence]]$_{\text{FAC:ART3, PHYS1}}$.
Our Model :	... [Abigail Fletcher]$_{\text{PER}}$, a [marcher]$_{\text{FAC:GEN-AFF2}}$ from [Florida]$_{\text{FAC:GEN-AFF2}}$, said outside the [president]$_{\text{PER}}$'s residence.

Table 6: Examples from the dataset with label annotations from SPTree and our model for comparison. The first row for each example is the gold standard.

incorporating these co-reference information during both training and evaluation will further improve the performance of both systems. Another source of error that we found was the inability of our system to extract entities (lower recall) as in S3. Our model could not identify the FAC entity "residence". Hence, we think an improvement on entity performance via methods like pretraining might be helpful in identifying more relations. For distance less than 7, we find that our model has better recall but lower precision, as expected.

8 Conclusion

In this paper, we propose a novel attention-based LSTM model for joint extraction of entity mentions and relations. Experimentally, we found that our model significantly outperforms feature-rich structured perceptron joint model by Li and Ji (2014). We also compare our model to an end-to-end LSTM model by Miwa and Bansal (2016) which comprises of a sequence layer for entity extraction and a tree-based dependency layer for relation classification. We find that our model, without access to dependency trees, POS tags, etc performs within 1% on entities and 2% on relations on ACE05 dataset. We also find that our model performs significantly better than their tree-based model on the ART relation, while their tree-based model performs better on PHYS and PART-WHOLE relations; the two models perform comparably on all other relation types.

In future, we plan to explore pretraining methods for our model which were shown to improve recall on entity and relation performance by Miwa and Bansal (2016). We introduce bi-directional output encoding as well as an objective to learn multiple relations in this paper. However, this presents the challenge of combining predictions from the two directions. We use heuristics in this paper to combine the predictions. We think that using probabilistic methods to combine model predictions from both directions may further improve the performance. We also plan to use Sparsemax (Martins and Astudillo, 2016) instead of Softmax for multiple relations, as the former is more suitable for multi-label classification for sparse labels.

It would also be interesting to see the effect of reranking (Collins and Koo, 2005) on our joint model. We also plan to extend the identification of entities to full entity mention span instead of only the head phrase as in Lu and Roth (2015).

Acknowledgments

We thank Qi Li and Makoto Miwa for their help with the dataset and sharing their code for analysis. We also thank Xilun Chen, Xanda Schofield, Yiqing Hua, Vlad Niculae, Tianze Shi and the three anonymous reviewers for their helpful feedback and discussion.

Naturalizing a Programming Language via Interactive Learning

Sida I. Wang, Samuel Ginn, Percy Liang, Christopher D. Manning

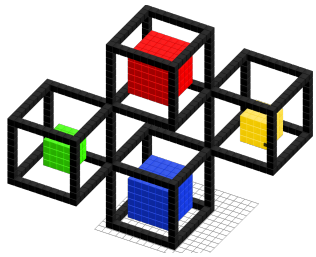
Abstract

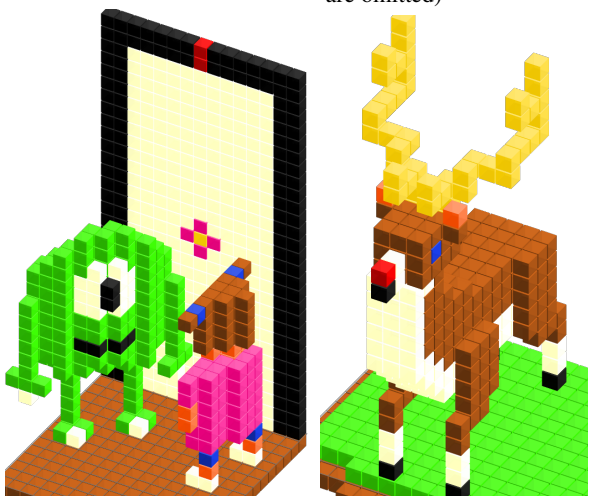
Our goal is to create a convenient natural language interface for performing well-specified but complex actions such as analyzing data, manipulating text, and querying databases. However, existing natural language interfaces for such tasks are quite primitive compared to the power one wields with a programming language. To bridge this gap, we start with a core programming language and allow users to "naturalize" the core language incrementally by defining alternative, more natural syntax and increasingly complex concepts in terms of compositions of simpler ones. In a voxel world, we show that a community of users can simultaneously teach a common system a diverse language and use it to build hundreds of complex voxel structures. Over the course of three days, these users went from using only the core language to using the naturalized language in 85.9% of the last 10K utterances.

1 Introduction

In tasks such as analyzing and plotting data (Gulwani and Marron, 2014), querying databases (Zelle and Mooney, 1996; Berant et al., 2013), manipulating text (Kushman and Barzilay, 2013), or controlling the Internet of Things (Campagna et al., 2017) and robots (Tellex et al., 2011), people need computers to perform well-specified but complex actions. To accomplish this, one route is to use a programming language, but this is inaccessible to most and can be tedious even for experts because the syntax is uncompromising and all statements have to be precise. Another route is to convert natural language into a formal language, which has been the subject of work in semantic parsing (Zettlemoyer and Collins, 2005; Artzi and Zettlemoyer, 2011, 2013; Pasupat and Liang, 2015). However, the capability of semantic parsers is still quite primitive compared to the power one wields with a programming language. This gap is increasingly limiting the potential of



Cubes: initial – select left 6 – select front 8 – black 10x10x10 frame – black 10x10x10 frame – move front 10 – red cube size 6 – move bot 2 – blue cube size 6 – green cube size 4 – (some steps are omitted)



Monsters, Inc: initial – move forward – add green monster – go down 8 – go right and front – add brown floor – add girl – go back and down – add door – add black column 30 – go up 9 – finish door – (some steps for moving are omitted)

Deer: initial – bird's eye view – deer head; up; left 2; back 2; { left antler }; right 2; {right antler} – down 4; front 2; left 3; deer body; down 6; {deer leg front}; back 7; {deer leg back}; left 4; {deer leg back}; front 7; {deer leg front} – (some steps omitted)

both text and voice interfaces as they become more ubiquitous and desirable.

In this paper, we propose bridging this gap with an interactive language learning process which we call *naturalization*. Before any learning, we seed a system with a core programming language that is always available to the user. As users instruct the system to perform actions, they augment the language by *defining* new utterances — e.g., the user can explicitly tell the computer that 'X' means 'Y'. Through this process, users gradually and interactively teach the system to understand the language that they *want to use*, rather than the core language that they are forced to use initially. While the first users have to learn the core language, later users can make use of everything that is already taught. This process accommodates both users' preferences and the computer action space, where the final language is both interpretable by the computer and easier to produce by human users.

Compared to interactive language learning with weak denotational supervision (Wang et al., 2016), definitions are critical for learning complex actions (Figure 1). Definitions equate a novel utterance to a sequence of utterances that the system already understands. For example, 'go left 6 and go front' might be defined as 'repeat 6 [go left]; go front', which eventually can be traced back to the expression 'repeat 6 [select left of this]; select front of this' in the core language. Unlike function definitions in programming languages, the user writes concrete values rather than explicitly declaring arguments. The system automatically extracts arguments and learns to produce the correct generalizations. For this, we propose a grammar induction algorithm tailored to the learning from definitions setting. Compared to standard machine learning, say from demonstrations, definitions provide a much more powerful learning signal: the system is told directly that 'a 3 by 4 red square' is '3 red columns of height 4', and does not have to infer how to generalize from observing many structures of different sizes.

We implemented a system called Voxelurn, which is a command language interface for a voxel world initially equipped with a programming language supporting conditionals, loops, and variable scoping etc. We recruited 70 users from Amazon Mechanical Turk to build 230 voxel structures using our system. All users teach the system at once, and what is learned from one user can be used by another user. Thus a *community* of users evolves the language to becomes more efficient over time, in a distributed way, through interaction. We show that the user community defined many new utterances—short forms, alternative syntax, and also complex concepts such as 'add green monster, add yellow plate 3 x 3'. As the system learns, users increasingly prefer to use the naturalized language over the core language: 85.9% of the last 10K accepted utterances are in the naturalized language.

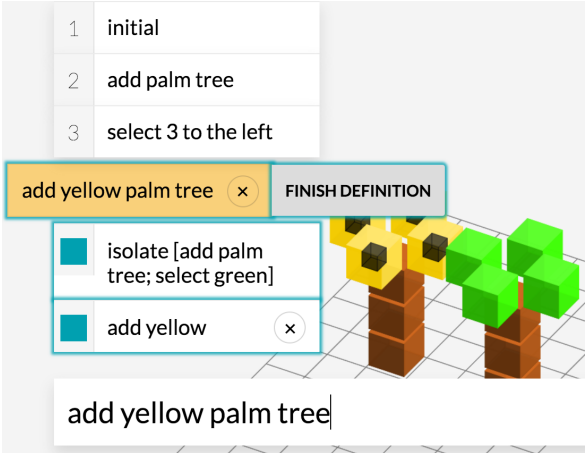

Figure 2: Interface used by users to enter utterances and create definitions.

2 Voxelurn

World. A world state in Voxelurn contains a set of voxels, where each voxel has relations 'row', 'col', 'height', and 'color'. There are two domain-specific actions, 'add' and 'move', one domain-specific relation 'direction'. In addition, the state contains a selection, which is a set of positions. While our focus is Voxelurn, we can think more generally about the world as a set of objects equiped with relations — events on a calendar, cells of a spreadsheet, or lines of text.

Core language. The system is born understanding a core language called Dependency-based Action Language (DAL), which we created (see Table 1 for an overview).

The language composes actions using the usual but expressive control primitives such as 'if', 'foreach', 'repeat', etc. Actions usually take sets as arguments, which are represented using lambda dependency-based compositional semantics (lambda DCS) expressions (Liang, 2013). Besides standard set operations like union, intersec-

Rule(s)	Example(s)	Description
$A \rightarrow A$; A	select left; add red	perform actions sequentially
$A \rightarrow$ repeat N A	repeat 3-1 add red top	repeat action N times
$A \rightarrow$ if S A	if has color red [select origin]	action if S is non-empty
$A \rightarrow$ while S A	while not has color red [select left of this]	action while S is non-empty
$A \rightarrow$ foreach S A	foreach this [remove has row row of this]	action for each item in S
$A \rightarrow [A]$	[select left or right; add red; add red top]	group actions for precedence
$A \rightarrow \{A\}$	{select left; add red}	scope only selection
$A \rightarrow$ isolate A	isolate [add red top; select has color red]	scope voxels and selection
$A \rightarrow$ select S	select all and not origin	set the selection
$A \rightarrow$ remove S	remove has color red	remove voxels
$A \rightarrow$ update R S	update color [color of left of this]	change property of selection
S	this	current selection
S	all | none | origin	all voxels, empty set, $(0, 0)$
R of S | has R S	has color red or yellow | has row [col of this]	lambda DCS joins
not S | S and S | S or S	this or left and not has color red	set operations
N | N+N | N-N	1,...,10 | 1+2 | row of this + 1	numbers and arithmetic
argmax R S | argmin R S	argmax col has color red	superlatives
R	color | row | col | height | top | left | $\cdots$	voxel relations
C	red | orange | green | blue | black | $\cdots$	color values
D	top | bot | front | back | left | right	direction values
$S \rightarrow$ very D of S	very top of very bot of has color green	syntax sugar for argmax
$A \rightarrow$ add C [D] | move D	add red | add yellow bot | move left	add voxel, move selection

Table 1: Grammar of the core language (DAL), which includes actions (A), relations (R), and sets of values (S). The grammar rules are grouped into four categories. From top to bottom: domain-general action compositions, actions using sets, lambda DCS expressions for sets, and domain-specific relations and actions.

tion and complement, lambda DCS leverages the tree dependency structure common in natural language: for the relation 'color', 'has color red' refers to the set of voxels that have color red, and its reverse 'color of has row 1' refers to the set of colors of voxels having row number 1. Tree-structured joins can be chained without using any variables, e.g., 'has color [yellow or color of has row 1]'.

We protect the core language from being redefined so it is always precise and usable.[1] In addition to expressivity, the core language *interpolates* well with natural language. We avoid explicit variables by using a *selection*, which serves as the default argument for most actions.[2] For example, 'select has color red; add yellow top; remove' adds yellow on top of red voxels and then removes the red voxels.

To enable the building of more complex structures in a more modular way, we introduce a notion of *scoping*. Suppose one is operating on one of the palm trees in Figure 2. The user might want to use 'select all' to select only the voxels in that tree rather than all of the voxels in the scene. In general, an action A can be viewed as taking a set of voxels v and a selection s, and producing an updated set of voxels v' and a modified selection s'. The default scoping is '[A]', which is the same as 'A' and returns (v', s'). There are two constructs that alter the flow: First, '{A}' takes (v, s) and returns (v', s), thus restoring the selection. This allows A to use the selection as a temporary variable without affecting the rest of the program. Second, 'isolate [A]' takes (v, s), calls A with (s, s) (restricting the set of voxels to just the selection) and returns (v'', s), where v'' consists of voxels in v' and voxels in v that occupy empty locations in v'. This allows A to focus only on the selection (e.g., one of the palm trees). Although scoping can be explicitly controlled via

[1] Not doing so resulted in ambiguities that propagated uncontrollably, e.g., once 'red' can mean many different colors.

[2] The selection is like the turtle in LOGO, but can be a set.

'[]', 'isolate', and '{}', it is an unnatural concept for non-programmers. Therefore when the choice is not explicit, the parser generates all three possible scoping interpretations, and the model learns which is intended based on the user, the rule, and potentially the context.

3 Learning interactively from definitions

The goal of the user is to build a structure in Voxelurn. In Wang et al. (2016), the user provided interactive supervision to the system by selecting from a list of candidates. This is practical when there are less than tens of candidates, but is completely infeasible for a complex action space such as Voxelurn. Roughly, 10 possible colors over the $3 \times 3 \times 4$ box containing the palm tree in Figure 2 yields 10^{36} distinct denotations, and many more programs. Obtaining the structures in Figure 1 by selecting candidates alone would be infeasible.

This work thus uses *definitions* in addition to selecting candidates as the supervision signal. Each definition consists of a *head* utterance and a *body*, which is a sequence of utterances that the system understands. One use of definitions is paraphrasing and defining alternative syntax, which helps naturalize the core language (e.g., defining 'add brown top 3 times' as 'repeat 3 add brown top'). The second use is building up complex concepts hierarchically. In Figure 2, 'add yellow palm tree' is defined as a sequence of steps for building the palm tree. Once the system understands an utterance, it can be used in the body of other definitions. For example, Figure 3 shows the full definition tree of 'add palm tree'. Unlike function definitions in a programming language, our definitions do not specify the exact arguments; the system has to learn to extract arguments to achieve the correct generalization.

The interactive definition process is described in Figure 4. When the user types an utterance x, the system parses x into a list of candidate programs. If the user selects one of them (based on its denotation), then the system executes the resulting program. If the utterance is unparsable or the user rejects all candidate programs, the user is asked to provide the definition body for x. Any utterances in the body not yet understood can be defined recursively. Alternatively, the user can first execute a sequence of commands X, and then provide a head utterance for body X.

When constructing the definition body, users can type utterances with multiple parses; e.g., 'move forward' could either modify the selection ('select front') or move the voxel ('move front'). Rather than propagating this ambiguity to the head, we force the user to commit to one interpretation by selecting a particular candidate. Note that we are using interactivity to control the exploding ambiguity.

```
def: add palm tree
    def: brown trunk height 3
        def: add brown top 3 times
            repeat 3 [add brown top]
    def: go to top of tree
        select very top of has color brown
    def: add leaves here
        def: select all sides
            select left or right or front or back
        add green
```

Figure 3: Defining 'add palm tree', tracing back to the core language (utterances without **def:**).

begin execute x:
  if x *does not parse* **then** define x;
  if *user rejects all parses* **then** define x;
  execute user choice

begin define x:
  repeat starting with $X \leftarrow [\,]$
    user enters x';
    if x' *does not parse* **then** define x';
    if *user rejects all* x' **then** define x';
    $X \leftarrow [X; x']$;
  until *user accepts* X *as the def'n of* x;

Figure 4: When the user enters an utterance, the system tries to parse and execute it, or requests that the user define it.

4 Model and learning

Let us turn to how the system learns and predicts. This section contains prerequisites before we describe definitions and grammar induction in Section 5.

Semantic parsing. Our system is based on a semantic parser that maps utterances x to programs z, which can be executed on the current state s (set of voxels and selection) to produce the next state $s' = [\![z]\!]_s$. Our system is implemented as the interactive package in SEMPRE (Berant et al., 2013);

Feature	Description
Rule.ID	ID of the rule
Rule.Type	core?, used?, used by others?
Social.Author	ID of author
Social.Friends	(ID of author, ID of user)
Social.Self	rule is authored by user?
Span	(left/right token(s), category)
Scope	type of scoping for each user

Table 2: Summary of features.

see Liang (2016) for a gentle exposition.

A *derivation* d represents the process by which an utterance x turns into a program $z = \text{prog}(d)$. More precisely, d is a tree where each node contains the corresponding span of the utterance $(\text{start}(d), \text{end}(d))$, the grammar rule $\text{rule}(d)$, the grammar category $\text{cat}(d)$, and a list of child derivations $[d_1, \ldots, d_n]$.

Following Zettlemoyer and Collins (2005), we define a log-linear model over derivations d given an utterance x produced by the user u:

$$p_\theta(d \mid x, u) \propto \exp(\theta^\mathsf{T} \phi(d, x, u)), \qquad (1)$$

where $\phi(d, x, u) \in \mathbb{R}^p$ is a feature vector and $\theta \in \mathbb{R}^p$ is a parameter vector. The user u does not appear in previous work on semantic parsing, but we use it to personalize the semantic parser trained on the community.

We use a standard chart parser to construct a chart. For each chart cell, indexed by the start and end indices of a span, we construct a list of partial derivations recursively by selecting child derivations from subspans and applying a grammar rule. The resulting derivations are sorted by model score and only the top K are kept. We use $\text{chart}(x)$ to denote the set of all partial derivations across all chart cells. The set of grammar rules starts with the set of rules for the core language (Table 1), but grows via grammar induction when users add definitions (Section 5). Rules in the grammar are stored in a trie based on the right-hand side to enable better scalability to a large number of rules.

Features. Derivations are scored using a weighted combination of features. There are three types of features, summarized in Table 2.

Rule features fire on each rule used to construct a derivation. ID features fire on specific rules (by ID). Type features track whether a rule is part of the core language or induced, whether it has been used again after it was defined, if it was used by someone other than its author, and if the user and the author are the same ($5 +$ #rules features).

Social features fire on properties of rules that capture the unique linguistic styles of different users and their interaction with each other. Author features capture the fact that some users provide better, and more generalizable definitions that tend to be accepted. Friends features are cross products of author ID and user ID, which captures whether rules from a particular author are systematically preferred or not by the current user, due to stylistic similarities or differences (#users+#users×#users features).

Span features include conjunctions of the category of the derivation and the leftmost/rightmost token on the border of the span. In addition, span features include conjunctions of the category of the derivation and the 1 or 2 adjacent tokens just outside of the left/right border of the span. These capture a weak form of context-dependence that is generally helpful ($<\approx V^4 \times$ #cats features for a vocabulary of size V).

Scoping features track how the community, as well as individual users, prefer each of the 3 scoping choices (none, selection only '{A}', and voxels+selection 'isolate {A}'), as described in Section 2. 3 global indicators, and 3 indicators for each user fire every time a particular scoping choice is made ($3 + 3 \times$ #users features).

Parameter estimation. When the user types an utterance, the system generates a list of candidate next states. When the user chooses a particular next state s' from this list, the system performs an online AdaGrad update (Duchi et al., 2010) on the parameters θ according to the gradient of the following loss function:

$$-\log \sum_{d:[\![\text{prog}(d)]\!]_s = s'} p_\theta(d \mid x, u) + \lambda ||\theta||_1,$$

which attempts to increase the model probability on derivations whose programs produce the next state s'.

5 Grammar induction

Recall that the main form of supervision is via user definitions, which allows creation of user-defined concepts. In this section, we show how to turn

these definitions into new grammar rules that can be used by the system to parse new utterances.

Previous systems of grammar induction for semantic parsing were given utterance-program pairs (x, z). Both the GENLEX (Zettlemoyer and Collins, 2005) and higher-order unification (Kwiatkowski et al., 2010) algorithms overgenerate rules that liberally associate parts of x with parts of z. Though some rules are immediately pruned, many spurious rules are undoubtedly still kept. In the interactive setting, we must keep the number of candidates small to avoid a bad user experience, which means a higher precision bar for new rules.

Fortunately, the structure of definitions makes the grammar induction task easier. Rather than being given an utterance-program (x, z) pair, we are given a definition, which consists of an utterance x (head) along with the body $X = [x_1, \ldots, x_n]$, which is a sequence of utterances. The body X is fully parsed into a derivation d, while the head x is likely only partially parsed. These partial derivations are denoted by $\text{chart}(x)$.

At a high-level, we find *matches*—partial derivations $\text{chart}(x)$ of the head x that also occur in the full derivation d of the body X. A grammar rule is produced by substituting any set of non-overlapping matches by their categories. As an example, suppose the user defines

'add red top times 3' as 'repeat 3 [add red top]'.

Then we would be able to induce the following two grammar rules:

$$A \rightarrow \text{add } C\ D \text{ times } N\ :$$
$$\lambda CDN.\text{repeat } N\ [\text{add } C\ D]$$
$$A \rightarrow A \text{ times } N\ :$$
$$\lambda AN.\text{repeat } N\ [A]$$

The first rule substitutes primitive values ('red', 'top', and '3') with their respective pre-terminal categories (C, D, N). The second rule contains compositional categories like actions (A), which require some care. One might expect that greedily substituting the largest matches or the match that covers the largest portion of the body would work, but the following example shows that this is not the case:

$$\overbrace{\underbrace{\text{add red left}}_{A_2}}^{A_1} \text{ and here} = \overbrace{\underbrace{\text{add red left;}}_{A_2}}^{A_1}\ \overbrace{\text{add red}}^{A_1}$$

Here, both the highest coverage substitution (A_1: 'add red', which covers 4 tokens of the body), and the largest substitution available (A_2: 'add red left') would generalize incorrectly. The correct grammar rule only substitutes the primitive values ('red', 'left').

5.1 Highest scoring abstractions

We now propose a grammar induction procedure that optimizes a more global objective and uses the learned semantic parsing model to choose substitutions. More formally, let M be the set of partial derivations in the head whose programs appear in the derivation d_X of the body X:

$$M \stackrel{\text{def}}{=} \{d \in \text{chart}(x) :$$
$$\exists d' \in \text{desc}(d_X) \wedge \text{prog}(d) = \text{prog}(d')\},$$

where $\text{desc}(d_X)$ are the descendant derivations of d_X. Our goal is to find a *packing* $P \subseteq M$, which is a set of derivations corresponding to non-overlapping spans of the head. We say that a packing P is maximal if no other derivations may be added to it without creating an overlap.

Let $\text{packings}(M)$ denote the set of maximal packings, we can frame our problem as finding the maximal packing that has the highest score under our current semantic parsing model:

$$P_L^* = \underset{P \in \text{packings}(M);}{\text{argmax}} \sum_{d \in P} \text{score}(d). \quad (2)$$

Finding the highest scoring packing can be done using dynamic programming on P_i^* for $i = 0, 1, \ldots, L$, where L is the length of x and $P_0^* = \emptyset$. Since $d \in M$, $\text{start}(d)$ and $\text{end}(d)$ (exclusive) refer to span in the head x. To obtain this dynamic program, let D_i be the highest scoring maximal packing containing a derivation ending *exactly* at position i (if it exists):

$$D_i = \{d_i\} \cup P^*_{\text{start}(d_i)}, \quad (3)$$
$$d_i = \underset{d \in M; \text{end}(d) = i}{\text{argmax}} \text{score}(d \cup P^*_{\text{start}(d)}). \quad (4)$$

Then the maximal packing of up to i can be defined recursively as

$$P_i^* = \underset{D \in \{D_{s(i)+1}, D_{s(i)+2}, \ldots, D_i\}}{\text{argmax}} \text{score}(D) \quad (5)$$
$$s(i) = \max_{d: \text{end}(d) \leq i} \text{start}(d), \quad (6)$$

Input : x, d_X, P^*
Output: rule
$r \leftarrow x$;
$f \leftarrow d_X$;
for $d \in P^*$ **do**
  $r \leftarrow r[\text{cat}(d)/\text{span}(d)]$
  $f \leftarrow \lambda\, \text{cat}(d).f[\text{cat}(d)/d]$
return *rule* $(\text{cat}(d_X) \rightarrow r : f)$

Algorithm 1: Extract a rule r from a derivation d_X of body X and a packing P^*. Here, $f[t/s]$ means substituting s by t in f, with the usual care about names of bound variables.

where $s(i)$ is the largest index such that $D_{s(i)}$ is no longer maximal for the span $(0, i)$ (i.e. there is a $d \in M$ on the span $\text{start}(d) \geq s(i) \wedge \text{end}(d) \leq i$.

Once we have a packing $P^* = P^*_L$, we can go through $d \in P^*$ in order of $\text{start}(d)$, as in Algorithm 1. This generates one high precision rule per packing per definition. In addition to the highest scoring packing, we also use a "simple packing", which includes only primitive values (in Voxelurn, these are colors, numbers, and directions). Unlike the simple packing, the rule induced from the highest scoring packing does not always generalize correctly. However, a rule that often generalizes incorrectly should be down-weighted, along with the score of its packings. As a result, a different rule might be induced next time, even with the same definition.

5.2 Extending the chart via alignment

Algorithm 1 yields high precision rules, but fails to generalize in some cases. Suppose that 'move up' is defined as 'move top', where 'up' does not parse, and does not match anything. We would like to infer that 'up' means 'top'. To handle this, we leverage a property of definitions that we have not used thus far: the utterances themselves. If we align the head and body, then we would intuitively expect aligned phrases to correspond to the same derivations. Under this assumption, we can then transplant these derivations from d_X to $\text{chart}(x)$ to create new matches. This is more constrained than the usual alignment problem (e.g., in machine translation) since we only need to consider spans of X which corresponds to derivations in $\text{desc}(d_X)$.

Algorithm 2 provides the algorithm for extending the chart via alignments. The aligned function is implemented using the following two heuristics:

Input : x, X, d_X
for $d \in \text{desc}(d_X)$, $x' \in \text{spans}(x)$ **do**
  if $\text{aligned}(x', d, (x, X))$ **then**
    $d' \leftarrow d$;
    $\text{start}(d') \leftarrow \text{start}(x')$;
    $\text{end}(d') \leftarrow \text{end}(x')$;
    $\text{chart}(x) \leftarrow \text{chart}(x) \cup d'$
  end
end

Algorithm 2: Extending the chart by alignment: If d is aligned with x' based on the utterance, then we pretend that x' should also parse to d, and d is transplanted to $\text{chart}(x)$ as if it parsed from x'.

- **exclusion**: if all but 1 pair of short spans (1 or 2 tokens) are matched, the unmatched pair is considered aligned.
- **projectivity**: if $d_1, d_2 \in \text{desc}(d_X) \cap \text{chart}(x)$, then $\text{ances}(d_1, d_2)$ is aligned to the corresponding span in x.

With the extended chart, we can run the algorithm from Section 5.1 to induce rules. The transplanted derivations (e.g., 'up') might now form new matches which allows the grammar induction to induce more generalizable rules. We only perform this extension when the body consists of one utterance, which tend to be a paraphrase. Bodies with multiple utterances tend to be new concepts (e.g., 'add green monster'), for which alignment is impossible. Because users have to select from candidates parses in the interactive setting, inducing low precision rules that generate many parses degrade the user experience. Therefore, we induce alignment-based rules conservatively—only when all but 1 or 2 tokens of the head aligns to the body and vice versa.

6 Experiments

Setup. Our ultimate goal is to create a community of users who can build interesting structures in Voxelurn while naturalizing the core language. We created this community using Amazon Mechanical Turk (AMT) in two stages. First, we had *qualifier* tasks, in which an AMT worker was instructed to replicate a fixed target exactly (Figure 5), ensuring that the initial users are familiar with at least some of the core language, which is the starting point of the naturalization process.

Figure 5: The target used for the qualifier.

Next, we allowed the workers who qualified to enter the second *freebuilding* task, in which they were asked to build any structure they wanted in 30 minutes. This process was designed to give users freedom while ensuring quality. The analogy of this scheme in a real system is that early users (or a small portion of expert users) have to make some learning investment, so the system can learn and become easier for other users.

Statistics. 70 workers passed the qualifier task, and 42 workers participated in the final freebuilding experiment. They built 230 structures. There were over 103,000 queries consisting of 5,388 distinct token types. Of these, 64,075 utterances were tried and 36,589 were accepted (so an action was performed). There were 2,495 definitions combining over 15,000 body utterances with 6.5 body utterances per head on average (96 max). From these definitions, 2,817 grammar rules were induced, compared to less than 100 core rules. Over all queries, there were 8.73 parses per utterance on average (starting from 1 for core).

Is naturalization happening? The answer is yes according to Figure 6, which plots the cummulative percentage of utterances that are core, induced, or unparsable. To rule out that more induced utterances are getting rejected, we consider only accepted utterances in the middle of Figure 6, which plots the percentage of induced rules among accepted utterances for the entire community, as well as for the 5 heaviest users. Since unparsable utterances cannot be accepted, accepted core (which is not shown) is the complement of accepted induced. At the conclusion of the experiment, 72.9% of all accepted utterances are induced—this becomes 85.9% if we only consider the final 10,000 accepted utterances.

Three modes of naturalization are outlined in Table 3. For very common operations, like moving the selection, people found ‘select left’ too verbose and shorterned this to `|, left, >, sel |`. One user preferred ‘go down and right’ instead of ‘select bot; select right’ in core and defined it as ‘go down; go right’. Definitions for high-level

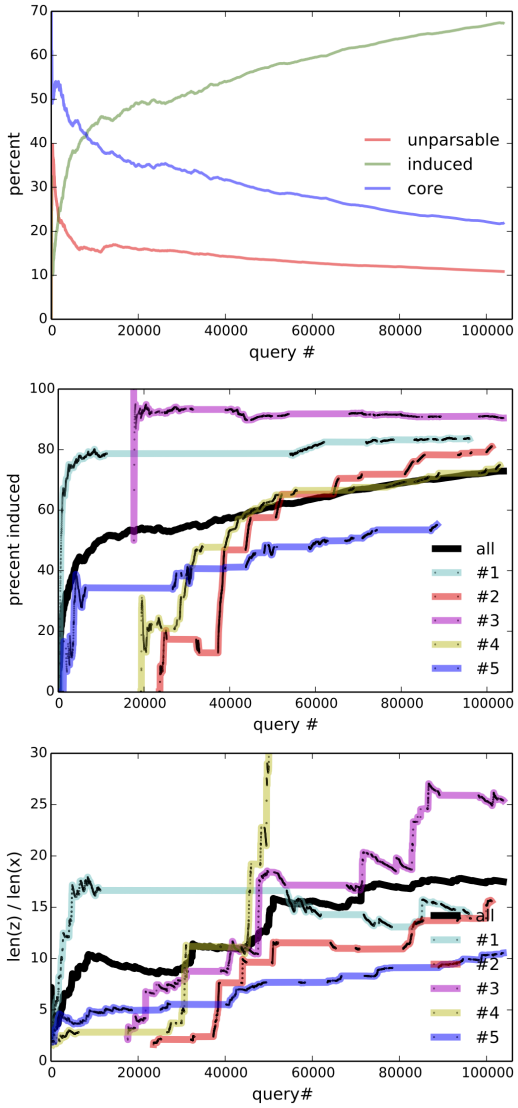

Figure 6: Learning curves. **Top:** percentage of all utterances that are part of the *core* language, the *induced* language, or *unparsable* by the system. **Middle:** percentage of accepted utterances belonging to the induced language, overall and for the 5 heaviest users. **Bottom:** expressiveness measured by the ratio of the length of the program to the length of the corresponding utterance.

concepts tend to be whole objects that are not parameterized (e.g., ‘dancer’). The bottom plot of Figure 6 suggests that users are defining and using higher level concepts, since programs become longer relative to utterances over time.

As a result of the automatic but implicit grammar induction, some concepts do not generalize correctly. In definition head ‘3 tall 9 wide white tower centered here’, arguments do not match the body; for ‘black 10x10x10 frame’, we failed to tokenize.

Short forms
left, l, mov left, go left, <, sel left
br, black, blu, brn, orangeright, left3
add row brn left 5 := add row brown left 5
Alternative syntax
go down and right := go down; go right
select orange := select has color orange
add red top 4 times := repeat 4 [add red top]
l white := go left and add white
mov up 2 := repeat 2 [select up]
go up 3 := go up 2; go up
Higher level
add red plate 6 x 7, green cube size 4,
add green monster, black 10x10x10 frame,
flower petals, deer leg back, music box, dancer

Table 3: Example definitions. See CodaLab worksheet for the full leaderboard.

Learned parameters. Training using L1 regularization, we obtained 1713 features with nonzero parameters. One user defined many concepts consisting of a single short token, and the Social.Author feature for that user has the most negative weight overall. With user compatibility (Social.Friends), some pairs have large positive weights and others large negative weights. The 'isolate' scoping choice (which allows easier hierarchical building) received the most positive weights, both overall and for many users. The 2 highest scoring induced rules correspond to 'add row red right 5' and 'select left 2'.

Incentives. Having complex structures show that the actions in Voxelurn are expressive and that hierarchical definitions are useful. To incentivize this behavior, we created a leaderboard which ranked structures based on recency and upvotes (like Hacker News). Over the course of 3 days, we picked three prize categories to be released daily. The prize categories for each day were bridge, house, animal; tower, monster, flower; ship, dancer, and castle.

To incentivize more definitions, we also track *citations*. When a rule is used in an accepted utterance by another user, the rule (and its author) receives a citation. We pay bonuses to top users according to their h-index. Most cited definitions are also displayed on the leaderboard. Our qualitative results should be robust to the incentives scheme, because the users do not overfit to the incentives—e.g., around 20% of the structures are not in the prize categories and users define complex concepts that are rarely cited.

7 Related work and discussion

This work is an evolution of Wang et al. (2016), but differs crucially in several ways: While Wang et al. (2016) starts from scratch and relies on selecting candidates, this work starts with a programming language (PL) and additionally relies on definitions, allowing us to scale. Instead of having a private language for each user, the user community in this work shares one language.

Azaria et al. (2016) presents Learning by Instruction Agent (LIA), which also advocates learning from users. They argue that developers cannot anticipate all the actions that users want, and that the system cannot understand the corresponding natural language even if the desired action is built-in. Like Jia et al. (2017), Azaria et al. (2016) starts with an ad-hoc set of initial slot-filling commands in natural language as the basis of further instructions—our approach starts with a more expressive core PL designed to interpolate with natural language. Compared to previous work, this work studied interactive learning in a shared community setting and hierarchical definitions resulting in more complex concepts.

Allowing ambiguity and a flexible syntax is a key reason why natural language is easier to produce—this cannot be achieved by PLs such as Inform and COBOL which look like natural language. In this work, we use semantic parsing techniques that can handle ambiguity (Zettlemoyer and Collins, 2005, 2007; Kwiatkowski et al., 2010; Liang et al., 2011; Pasupat and Liang, 2015). In semantic parsing, the semantic representation and action space is usually designed to accommodate the natural language that is considered constant. In contrast, the action space is considered constant in the naturalizing PL approach, and the language adapts to be more natural while accommodating the action space.

Our work demonstrates that interactive definitions is a strong and usable form of supervision. In the future, we wish to test these ideas in more domains, naturalize a real PL, and handle paraphrasing and implicit arguments. In the process of naturalization, both data and the semantic grammar have important roles in the evolution of a language that is easier for humans to produce while still parsable by computers.

Semantic Word Clusters Using Signed Spectral Clustering

Abstract

Vector space representations of words capture many aspects of word similarity, but such methods tend to produce vector spaces in which antonyms (as well as synonyms) are close to each other. For spectral clustering using such word embeddings, words are points in a vector space where synonyms are linked with positive weights, while antonyms are linked with negative weights. We present a new signed spectral normalized graph cut algorithm, *signed clustering*, that overlays existing thesauri upon distributionally derived vector representations of words, so that antonym relationships between word pairs are represented by negative weights. Our signed clustering algorithm produces clusters of words that simultaneously capture distributional and synonym relations. By using randomized spectral decomposition (Halko et al., 2011) and sparse matrices, our method is both fast and scalable. We validate our clusters using datasets containing human judgments of word pair similarities and show the benefit of using our word clusters for sentiment prediction.

1 Introduction

In distributional vector representations, opposite relations are not fully captured. Take, for example, words such as "great" and "awful" that can appear with similar frequency in the same sentence structure: "John had a great meeting" and "John had an awful day." Word embeddings, which are successful in a wide array of NLP tasks (Turney et al., 2010; Dhillon et al., 2015), fail to capture this antonymy because they follow the *distributional hypothesis* that similar words are used in similar contexts (Harris, 1954), thus assigning small cosine or euclidean distances between the vector representations of "great" and "awful".

While vector space models (Turney et al., 2010) such as word2vec (Mikolov et al., 2013), Global vectors (GloVe) (Pennington et al., 2014), or Eigenwords (Dhillon et al., 2015) capture relatedness, they do not adequately encode synonymy and semantic similarity (Mohammad et al., 2013; Scheible et al., 2013). Our goal is to create clusters of synonyms or semantically equivalent words and linguistically motivated unified constructs. Signed graphs, which are graphs with negative edge weights, were first introduced by Cartwright and Harary (1956). However, signed graph clustering for multiclass normalized cuts (K-clusters) has been largely unexplored until recently. We present a novel theory and method that extends multiclass normalized cuts (K-cluster) of Yu and Shi (2003) to signed graphs (Gallier, 2016)[1] and the work of Kunegis et al. (2010) to K-clustering. This extension allows the incorporation of knowledge base information, positive and negatively weighted links (see figure 2.1). Negative edges serve as repellent or opposite relationships between nodes.

Our signed spectral normalized graph cut algorithm (henceforth, signed clustering) builds negative edge relations into graph embeddings using similarity structure in vector spaces. It takes as input an initial set of vectors and edge relations, and hence is easy to combine with any word embedding method. This paper formally improves on the discrete optimization problem of Yu and Shi (2003).

Signed clustering gives better clusters than spectral clustering (Shi and Malik, 2000) of word embeddings, and it has better coverage and is more robust than thesaurus look-up. This is because the-

[1] Gallier (2016) is a full theoretical exposition of our methods with proofs on arXiv.

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 939–949
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1087

sauri erroneously give equal weight to rare senses of a word – for example, "rich" as a rarely used synonym of "absurd". Also, the overlap between thesauri is small, due to their manual creation. Lin (1998) found 17.8397% overlap between synonym sets from Roget's Thesaurus and WordNet 1.5. We find similarly small overlap between all three thesauri tested.

We evaluate our clusters using SimLex-999 (Hill et al., 2014) and SimVerb-3500 (Gerz et al., 2016) as a ground truth for our cluster evaluation. Finally, we test our method on the sentiment analysis task. Overall, signed spectral clustering can augment methods using signed information and has broad application for many fields.

Our main contributions are: the novel extension of signed clustering to the multiclass (K-cluster), and the application of this method to create semantic word clusters that are agnostic to vector space representations and thesauri.

1.1 Related Work

Semantic word cluster and distributional thesauri have been well studied in the NLP literature (Lin, 1998; Curran, 2004). Recently there has been a line of research on incorporating synonyms and antonyms into word embeddings. Our approach is very much in the line of Vlachos et al. (2009). However, they explicitly made verb clusters using Dirichlet Process Mixture Models and must-link / cannot-link clustering. Furthermore, they note that cannot-link clustering does not improve performance whereas our signed clustering antonyms are key.

Most recent models either attempt to make richer contexts, in order to find semantic similarity, or overlay thesaurus information in a supervised or semi-supervised manner. One line of active research is post processing the word vector embedding by transforming the space using a single or multi-relational objective (Yih et al., 2012; Tang et al., 2014; Chang et al., 2013; Tang et al., 2014; Zhang et al., 2014; Faruqui et al., 2015; Mrkšić et al., 2016).

Alternatively, there are methods to modify the objective function for generating the word embeddings (Ono et al., 2015; Pham et al., 2015; Schwartz et al., 2015).

Our approach differs from the aforementioned methods in that we created word clusters using the antonym relationships as negative links. Unlike the previous approaches using semi-supervised methods, we incorporated the thesauri as a knowledge base. Similar to word vector retrofitting and counter-fitting methods described in Faruqui et al. (2015) and Mrkšić et al. (2016), our signed clustering method uses existing vector representations to create word clusters.

To our knowledge, this work is the first theoretical foundation of multiclass signed normalized cuts.[2] Zass and Shashua (2005) solved multiclass cluster from another approach, by relaxing the orthogonality assumption and focusing instead on the non-negativity constraint. This led to a doubly stochastic optimization problem. Negative edges are handled by a constrained hyperparameter. Hou (2005) used positive degrees of nodes in the degree matrix of a signed graph with weights (-1, 0, 1), which was advanced by Kolluri et al. (2004) and Kunegis et al. (2010) using absolute values of weights in the degree matrix. Interestingly, Chiang et al. (2014) presented a theoretical foundation for edge sign prediction and a recursive clustering approach. Mercado et al. (2016) found that using the geometric mean of the graph Laplacian improves performance.

Wang et al. (2016) used semi-supervised polarity induction (Rao and Ravichandran, 2009) to create clusters of words with similar valence and arousal. Must-link and cannot-link soft spectral clustering (Rangapuram and Hein, 2012) share similarities with our method, particularly in the limit where there are no must-link edges present. Both must-link and cannot-link clustering as well as polarity induction differ in optimization method. Our method is significantly faster due to the use of randomized SVD (Halko et al., 2011) and can thus be applied to large scale NLP problems.

We developed a novel theory and algorithm that extends the clustering of Shi and Malik (2000) and Yu and Shi (2003) to the multiclass signed graph case.

2 Signed Graph Cluster Estimation

2.1 Signed Normalized Cut

Weighted graphs for which the weight matrix is a symmetric matrix in which negative and positive entries are allowed are called *signed graphs*.

[2]The full exposition by Gallier (2016) is available on arXiv.

Such graphs (with weights $(-1, 0, +1)$) were introduced as early as 1953 by (Harary, 1953), to model social relations involving disliking, indifference, and liking. The problem of clustering the nodes of a signed graph arises naturally as a generalization of the clustering problem for weighted graphs. Figure 1 shows a signed graph of word similarities with a thesaurus overlay. Gallier

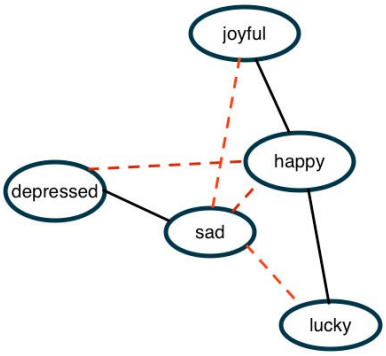

Figure 1: Signed graph of words using a distance metric from the word embedding. The red dashed edges represent the antonym relation while solid edges represent synonymy relations.

(2016) extends normalized cuts to signed graphs in order to incorporate antonym information into word clusters.

Definition 2.1. A *weighted graph* is a pair $G = (V, W)$, where $V = \{v_1, \ldots, v_m\}$ is a set of *nodes* or *vertices*, and W is a symmetric matrix called the *weight matrix*, such that $w_{ij} \geq 0$ for all $i, j \in \{1, \ldots, m\}$, and $w_{ii} = 0$ for $i = 1, \ldots, m$. We say that a set $\{v_i, v_j\}$ is an edge iff $w_{ij} > 0$. The corresponding (undirected) graph (V, E) with $E = \{\{v_i, v_j\} \mid w_{ij} > 0\}$, is called the *underlying graph* of G.

Given a signed graph $G = (V, W)$ (where W is a symmetric matrix with zero diagonal entries), the *underlying graph* of G is the graph with node set V and set of (undirected) edges $E = \{\{v_i, v_j\} \mid w_{ij} \neq 0\}$.

If (V, W) is a signed graph, where W is an $m \times m$ symmetric matrix with zero diagonal entries and with the other entries $w_{ij} \in \mathbb{R}$ arbitrary, for any node $v_i \in V$, the *signed degree* of v_i is defined as

$$\overline{d}_i = \overline{d}(v_i) = \sum_{j=1}^{m} |w_{ij}|,$$

and the *signed degree matrix* $\overline{D}$ as

$$\overline{D} = \mathrm{diag}(\overline{d}(v_1), \ldots, \overline{d}(v_m)).$$

For any subset A of the set of nodes V, let

$$\mathrm{vol}(A) = \sum_{v_i \in A} \overline{d}_i = \sum_{v_i \in A} \sum_{j=1}^{m} |w_{ij}|.$$

For any two subsets A and B of V and A^C which is the complement of A, define $\mathrm{links}^+(A, B)$, $\mathrm{links}^-(A, B)$, and $\mathrm{cut}(A, A^C)$ by

$$\mathrm{links}^+(A, B) = \sum_{\substack{v_i \in A, v_j \in B \\ w_{ij} > 0}} w_{ij}$$

$$\mathrm{links}^-(A, B) = \sum_{\substack{v_i \in A, v_j \in B \\ w_{ij} < 0}} -w_{ij}$$

$$\mathrm{cut}(A, A^C) = \sum_{\substack{v_i \in A, v_j \in A^C \\ w_{ij} \neq 0}} |w_{ij}|.$$

Then, the *signed Laplacian* $\overline{L}$ is defined by

$$\overline{L} = \overline{D} - W,$$

and its normalized version $\overline{L}_{\mathrm{sym}}$ by

$$\overline{L}_{\mathrm{sym}} = \overline{D}^{-1/2} \overline{L} \overline{D}^{-1/2} = I - \overline{D}^{-1/2} W \overline{D}^{-1/2}.$$

Kunegis et al. (2010) showed that $\overline{L}$ is positive semidefinite. For a graph without isolated vertices, we have $\overline{d}(v_i) > 0$ for $i = 1, \ldots, m$, so $\overline{D}^{-1/2}$ is well defined.

Given a partition of V into K clusters $(A_1, \ldots, A_K)$, if we represent the jth block of this partition by a vector X^j such that

$$X_i^j = \begin{cases} a_j & \text{if } v_i \in A_j \\ 0 & \text{if } v_i \notin A_j, \end{cases}$$

for some $a_j \neq 0$. For illustration, suppose $m = 5$ and $A_1 = \{v_1, v_3\}$ then $(X^1)^\top = [a_1, 0, a_1, 0, 0]$.

Definition 2.2. The *signed normalized cut* $\mathrm{sNcut}(A_1, \ldots, A_K)$ of the partition $(A_1, ..., A_K)$ is defined as

$$\mathrm{sNcut}(A_1, \ldots, A_K) = \sum_{j=1}^{K} \frac{\mathrm{cut}(A_j, A_j^C) + 2\mathrm{links}^-(A_j, A_j)}{\mathrm{vol}(A_j)}.$$

It should be noted that this formulation differs significantly from Kunegis et al. (2010) and even more so from must-link / cannot-link clustering.

Observe that minimizing $\mathrm{sNcut}(A_1, \ldots, A_K)$ minimizes the number of positive and negative edges between clusters and also the number of negative edges within clusters. Removing the term $\mathrm{links}^-(A_j, A_j)$ reduces sNcut to normalized cuts.

A linear algebraic formulation is

$$\mathrm{sNcut}(A_1, \ldots, A_K) = \sum_{j=1}^{K} \frac{(X^j)^\top \overline{L} X^j}{(X^j)^\top \overline{D} X^j}.$$

where X is the $N \times K$ matrix whose jth column is X^j.

2.2 Optimization Problem

We now formulate K-way clustering of a graph using normalized cuts.

If we let

$$\mathcal{X} = \Big\{ [X^1 \ \ldots \ X^K] \mid X^j = a_j(x_1^j, \ldots, x_N^j), \\ x_i^j \in \{1, 0\}, a_j \in \mathbb{R},\ X^j \neq 0 \Big\}$$

our solution set is

$$\mathcal{K} = \Big\{ X \in \mathcal{X} \mid (X^i)^\top \overline{D} X^j = 0, \\ 1 \leq i, j \leq K, \quad i \neq j \Big\}.$$

The resulting optimization problem is

$$\begin{aligned} \text{minimize} \quad & \sum_{j=1}^{K} \frac{(X^j)^\top \overline{L} X^j}{(X^j)^\top \overline{D} X^j} \\ \text{subject to} \quad & (X^i)^\top \overline{D} X^j = 0, \\ & 1 \leq i, j \leq K,\ i \neq j, \quad X \in \mathcal{X}. \end{aligned}$$

The problem can be reformulated to an equivalent optimization problem:

$$\begin{aligned} \text{minimize} \quad & \mathrm{tr}(X^\top \overline{L} X) \\ \text{subject to} \quad & X^\top \overline{D} X = I, \quad X \in \mathcal{X}. \end{aligned}$$

We then form a relaxation of the above problem, dropping the condition that $X \in \mathcal{X}$, giving

Relaxed Problem

$$\begin{aligned} \text{minimize} \quad & \mathrm{tr}(Y^\top \overline{D}^{-1/2} \overline{L} \overline{D}^{-1/2} Y) \\ \text{subject to} \quad & Y^\top Y = I. \end{aligned}$$

The minimum of the relaxed problem is achieved by the K unit eigenvectors associated with the smallest eigenvalues of L_{sym}.

2.3 Finding an Approximate Discrete Solution

Given a solution Z of the relaxed problem, we look for pairs (X, Q) with $X \in \mathcal{X}$ and where Q is a $K \times K$ matrix with nonzero and pairwise orthogonal columns, with $\|X\|_F = \|Z\|_F$, that minimize

$$\varphi(X, Q) = \|X - ZQ\|_F .$$

Here, $\|A\|_F$ is the Frobenius norm of A.

This nonlinear optimization problem involves two unknown matrices X and Q. To solve the relaxed problem, we proceed by alternating between minimizing $\varphi(X, Q) = \|X - ZQ\|_F$ with respect to X holding Q fixed (step 5 in algorithm 1), and minimizing $\varphi(X, Q)$ with respect to Q holding X fixed (steps 6 and 7 in algorithm 1).

This second stage in which X is held fixed has been studied, but it is still a hard problem for which no closed-form solution is known. Hence we divide the problem into steps 6 and 7 for which the solution is known. Since Q is of the form $Q = R\Lambda$ where $R \in \mathbf{O}(K)$ and Λ is a diagonal invertible matrix, we minimize $\|X - ZR\Lambda\|_F$. The matrix $R\Lambda$ is not a minimizer of $\|X - ZR\Lambda\|_F$ in general, but it is an improvement on R alone, and both stages can be solved quite easily. In step 6 the problem reduces to minimizing $-2\mathrm{tr}(Q^\top Z^\top X)$; that is, maximizing $\mathrm{tr}(Q^\top Z^\top X)$.

Algorithm 1 Signed Clustering

1: **Input:** W the weight matrix (without isolated nodes), K the number of clusters, and termination threshold ϵ.
2: Using the $\overline{D}$ the degree matrix, and the signed Laplacian $\overline{L}$, compute $\overline{L}_{sym}$ the signed normalized Laplacian.
3: Initialize $\Lambda = I$, $X = \overline{D}^{-\frac{1}{2}} U$ where U is the matrix of the eigenvectors corresponding to the K smallest eigenvalues of $\overline{L}_{sym}$. [3]
4: **while** $\|X - ZR\Lambda\|_F > \epsilon$ **do**
5: Minimize $\|X - ZR\Lambda\|_F$ with respect to X holding Q fixed.
6: Fix X, Z, and Λ, find $R \in \mathbf{O}(K)$ that minimizes $\|X - ZR\Lambda\|_F$.
7: Fix X, Z, and R, find a diagonal invertible matrix Λ that minimizes $\|X - ZR\Lambda\|_F$.
8: **end while**
9: Find the discrete solution X^* by choosing the largest entry x_{ij} on row i set $x_{ij} = 1$ and all other $x_{ij} = 0$ for row i.
10: **Output:** X^*.

Steps 3 through 10 may be replaced by standard K-means clustering. It should also be noted that by

removing the solution requirement that $X^j \neq 0$, the algorithm can find $k \leq K$ clusters.

3 Similarity Calculation

The main input to the spectral signed clustering algorithm is the similarity matrix W, which overlays both the distributional properties and thesaurus information. Following Belkin and Niyogi (2003), we chose the heat kernel based on the Euclidean distance between word vector representations as our similarity metric, such that

$$W_{ij} = \begin{cases} 0 & \text{if } e^{-\frac{\|w_i - w_j\|^2}{\sigma}} < \epsilon \\ e^{-\frac{\|w_i - w_j\|^2}{\sigma}} & \text{otherwise} \end{cases}.$$

where σ and ϵ are hyperparameters found using grid search (see Supplemental material for more detail).

We represented the thesaurus as two matrices where

$$T^{syn}_{ij} = \begin{cases} 1 & \text{if words } i \text{ and } j \text{ are synonyms} \\ 0 & \text{otherwise} \end{cases}.$$

and

$$T^{ant}_{ij} = \begin{cases} -1 & \text{if words } i \text{ and } j \text{ are antonyms} \\ 0 & \text{otherwise} \end{cases}.$$

T^{syn} is the synonym graph and T^{ant} is the antonym graph. The signed graph can then be written in matrix form as $\hat{W} = \gamma W + \beta^{ant} T^{ant} \odot W + \beta^{syn} T^{syn} \odot W$, where $\odot$ computes Hadamard product (element-wise multiplication).

The parameters γ, β^{syn}, and β^{ant} are tuned to the data target dataset using cross validation. The reader should note that σ and ϵ are not found using a target dataset, but instead using cross validation and grid search to minimize the number of negative edges within clusters and the number of disconnected components in the cluster.

4 Evaluation Metrics

We evaluated the clusters using both intrinsic and extrinsic methods. For intrinsic evaluation, we used thesaurus information for two novel metrics: 1) the number of negative edges (NNE) within the clusters, which in our semantic clusters is the number of antonyms in the same cluster, and 2) the number of disconnected components (NDC) in the synonym graph, so the number of groups of words that are not connected by a synonym relation in the thesaurus. The NDC thus has the disadvantage that it is a function of the thesaurus coverage. Our third intrinsic measure uses a gold standard designed to measure how well we capture word similarity: Semantically similar words should be in the same cluster and semantically dissimilar words should not. For extrinsic evaluation, as descibed below, we measure how much our clusters help to identify text polarity. We also compare multiple word embeddings and thesauri to demonstrate the stability of our method.

5 Experiments with Synthetic Data

In order to evaluate our signed graph clustering method, we first focused on intrinsic measures of cluster quality in synthetic data. To do so, we created random signed graphs with the same proportion of positive and negative edges as in our real dataset. Figure 2 demonstrates that the number of negative edges within a cluster is minimized using our clustering algorithm on simulated data. As the number of clusters becomes large, the number of disconnected components, which includes clusters of size one, consistently increases. Determining the optimal cluster size and similarity parameters requires making a trade off between NDC and NNE. For example, in figure 2 the optimal cluster size is 20. One can see that as the number of clusters increases NNE goes to zero, but the number of disconnected components becomes the number of vertices. In the extreme case all clusters contain one vertex. K-means, also shown in figure 2, does not optimize NNE.

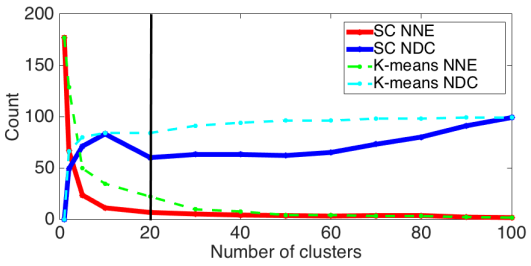

Figure 2: The relation between disconnected component (NDC) and negative edge (NNE) using simulated signed graphs with 100 vertices.

6 Experimental Setup

6.1 Word Embeddings

We used four different word embedding methods for evaluation: Skip-gram vectors (word2vec) (Mikolov et al., 2013), Global vectors (GloVe) (Pennington et al., 2014), Eigenwords (Dhillon et al., 2015), and Global Context (GloCon) (Huang et al., 2012); however, we only report the results for word2vec, which is the most popular word embedding (see the supplemental material for other embeddings). We used word2vec 300 dimensional embeddings which were trained on several billion words of English: the Gigaword and the English discussion forum data gathered as part of BOLT. Tokenization was performed using CMU's Twokenize.[4]

6.2 Thesauri

Several thesauri were used in order to test the robustness including Roget's Thesaurus (Roget, 1852), the Microsoft Word English (MS Word) thesaurus from Samsonovic et al. (2010) and WordNet 3.0 (Miller, 1995).

We chose a subset of 5108 words for the training dataset, which had high overlap between various sources. Changes to the training dataset had minimal effects on the optimal parameters. Within the training dataset, each of the thesauri had roughly 3700 antonym pairs; combined they had 6680. However, the number of distinct connected components varied, with Roget's Thesaurus having the fewest (629), and MS Word Thesaurus (1162) and WordNet (2449) having the most. These ratios were consistent across the full dataset.

6.3 Gold Standard SimLex-999 And SimVerb-3500

Following the analysis of Vlachos et al. (2009), we threshold the semantically similar datasets to find word pairs which should or should not belong to the same cluster. As ground truth, we extracted 120 semantically similar words from SimLex-999 with a similarity score greater than 8 out of 10. SimLex-999 is a gold standard resource for semantic similarity, not relatedness, based on ratings by human annotators.

Our 120 pair subset of SimLex-999 has multiple parts-of-speech including Noun-Noun pairs, Verb-Verb pairs and Adjective-Adjective pairs. Within SimVerb-3500, we used a subset of 318 semantically similar verb pairs.

The community is attempting to define better gold standards; however, currently these are the best datasets that we are aware of. We tried to use WordNet, Roget, and the Paraphrase Database (PPDB) (Ganitkevitch et al., 2013) as a gold standard, but manual inspection as well as empirical results showed that none of the automatically generated datasets were a sufficient gold standard. Possibly the symmetric pattern of (Schwartz et al., 2015) would have been sufficient; we did not have time to validate this.

6.4 Stanford Sentiment Treebank

We also evaluated our clusters by using them as features for predicting sentiment, using sentiment treebank [5] (Socher et al., 2013) with coarse-grained labels on phrases and sentences from movie review excerpts. This dataset is widely used for the evaluation of sentiment analysis. We used the standard partition of the treebank into training (6920), development (872), and test (1821) sets.

7 Cluster Evaluation

Table 1 shows the four most-associated words with "accept" using different methods.

We now turn to quantitative measures of word similarity and synonym cluster quality.

7.1 Comparison with K-means and Normalized Cuts

In order to assess the model we tested (1) K-means, (2) normalized cuts without thesaurus, and (3) signed normalized cuts. As a baseline, we created clusters using K-means on the original word2vec vector representations where the number of K clusters was set to 750.

Table 2 shows the relative ratios of the different clustering methods of with respect to antonym pair inclusion and the number of disconnected components within the clusters. For both methods, over twenty percent of the clusters contain antonym pairs even though the median cluster size is six. Signed clustering radically reduced the number of antonyms within clusters compared to the other methods.

Ref word	Roget	WordNet	MS Word	W2V	SC W2V
accept	adopt	agree	take	accepts	grant
	accept your fate	get	swallow	reject	permit
	be fooled by	fancy	consent	agree	let
	acquiesce	hold	assume	accepting	okay

Table 1: Qualitative comparison of clusters.

Method	Antonym Ratio	DC Ratio
K-Means	0.24	0.95
NC	0.21	0.97
SC	0.06	0.49

Table 2: Clustering evaluation of K-means, normalized cuts, and signed normalized cuts with 750 clusters. Ratio of clusters with containing one or more antonym pair and ratio of clusters with disconnected components.

Method	Acc SimLex	Err
MSW Lookup	0.70	0
Roget Lookup	0.63	0
WordNet Lookup	0.43	0
Combined Lookup	0.90	0
NC(W2V)	0.36	0.05
SC (W2V)	**0.67**	0
Lookup + NC(W2V)	0.91	0.05
Lookup + **SC**(W2V)	**0.96**	0
MSW + **SC**(W2V)	0.95	0

Table 3: Clustering evaluation using SimLex-999 with 120 word pairs having similarity score over 8. SC stands for our signed clustering and NC is standard normalized cuts. **SC**(W2V) are the word clusters from signed clustering using word2vec and the combined thesauri. **Err** is the proportion of dissimilar words (with score < 2) present in the same cluster.

8 Empirical Results

Tables 3 and 5 present our main result. When using our signed clustering method with similar words, as labeled by SimLex-999 and SimVerb-3500, our clustering accuracy increased by 5% on both SimLex-999 and SimVerb-3000. Furthermore, by combining the thesauri lookup with our clustering, we achieved almost perfect accuracy (96%). Table 5 shows the sentiment analysis task performance. Our method outperforms all methods with similar complexity; however, we did not reach state-of-the-art results when compared to much more complex models which also use a richer dataset.

8.1 Evaluation Using Word Similarity Datasets

In a perfect setting, all word pairs rated highly similar by human annotators would be in the same cluster, and all words which were rated dissimilar would be in different clusters. Since our clustering algorithm produced sets of words, we used this evaluation instead of the more commonly reported correlations.

In table 3 we show the results of the evaluation with SimLex-999. Combining thesaurus lookup and word2vec+CombThes clusters, labeled as Lookup + **SC**(W2V), yielded an accuracy of 0.96 (5 errors). Note that clusters using word2vec with normalized cuts does not improve accuracy. The MSW thesaurus has much lower coverage, but 100 % accuracy, which is why when combined with the signed clustering the performance is 0.95. In table 3 we state the proportion of clusters containing dissimilar words as a sanity check for cluster size. (See supplemental material for full cluster size optimization information.) Another important result is that the verb accuracy yielded the largest accuracy gains, consistent with the results of Schwartz et al. (2015).

Table 4 clearly shows that the overall performance of all methods is lower for verb similarity. However, the improvement using both signed clustering as well as thesaurus look is also larger.

8.2 Sentiment Analysis

We trained an l_2-norm regularized logistic regression (Friedman et al., 2001) and simultaneously γ, β^{syn}, and β^{ant} using our word clusters in order to predict the coarse-grained sentiment at the sentence level. The γ and β parameters were found using a portion of the data where we iteratively switch between the logistic regression and the parameters, holding each fixed. However, hyperparameters σ and ϵ, and the number of clusters

Method	Acc SimVerb
MSW Lookup	0.45
Roget Lookup	0.59
WordNet Lookup	0.43
Combined Lookup	0.83
NC(W2V)	0.24
SC (W2V)	**0.56**
Lookup + NC(W2V)	0.83
Lookup + **SC**(W2V)	**0.88**

Table 4: Clustering evaluation using SimVerb-3500 with 317 word pairs having similarity score over 8. SC stands for our signed clustering and NC is standard normalized cuts. **SC**(W2V) are the word clusters from signed clustering using word2vec and the combined thesauri.

Model	Accuracy
NB (Socher et al., 2013)	0.818
VecAvg (W2V) (Faruqui et al., 2015)	0.812
RVecAvg (W2V) (Faruqui et al., 2015)	0.821
RNN(Socher et al., 2013)	0.824
NC(W2V)	0.79
SC(Thes)	0.752
SC(W2V)	**0.836**

Table 5: Sentiment analysis accuracy for binary predictions of signed clustering algorithm (SC) versus other models. **SC**(W2V) are the signed clusters using word2vec word representations.

K were optimized minimizing error using grid search. We compared our model against existing models: Naive Bayes with bag of words (NB) (Socher et al., 2013), sentence word embedding averages (VecAvg), retrofitted sentence word embeddings (RVecAvg) (Faruqui et al., 2015) that incorporate thesaurus information, simple recurrent neural networks (RNN), and two baselines of normalized cuts and signed normalized cuts using only thesaurus information.

While the state-of-the art Convolutional Neural Network (CNN) (Kim, 2014) is at 0.881, our model performs quite well with much less information and complexity. Table 5 shows that signed clustering outperforms the baselines of Naive Bayes, normalized cuts, and signed cuts using just thesaurus information. Furthermore, we outperform comparable models, including retrofitting, which has thesaurus information, and the recurrent neural network, which has access to domain specific context information.

Signed clustering using only thesaurus information (**SC(Thes)**) performed significantly worse than all other methods. This was largely due to low coverage; rare words such as "WOW" and "???" are not covered. As expected, because normalized cut clusters include antonyms, the method performs worse than others. Nonetheless the improvement from 0.79 to 0.836 is quite drastic.

9 Conclusion

We developed a novel theory for signed normalized cuts and an algorithm for finding their discrete solution. We showed that we can find superior semantically similar clusters which do not require new word embeddings but simply overlay thesaurus information on preexisting ones. The clusters are general and can be used with many out-of-the-box word embeddings. By accounting for antonym relationships, our algorithm greatly outperforms simple normalized cuts. Finally, we examined our clustering method on the sentiment analysis task from Socher et al. (2013) sentiment treebank dataset and showed that it improved performance versus comparable models.

Our automatically generated clusters give better coverage than manually constructed thesauri. Our signed spectral clustering method allows us to incorporate the knowledge contained in these thesauri without modifying the word embeddings themselves. We further showed that use of the thesauri can be tuned to the task at hand.

Our signed spectral clustering method could be applied to a broad range of NLP tasks, such as prediction of social group clustering, identification of personal versus non-personal verbs, and analyses of clusters which capture positive, negative, and objective emotional content. It could also be used to explore multi-view relationships, such as aligning synonym clusters across multiple languages. Another possibility is to use thesauri and word vector representations together with word sense disambiguation to generate semantically similar clusters for multiple senses of words. Furthermore, signed spectral clustering has broader applications such as cellular biology, social networking, and electricity networks. Finally, we plan to extend the hard signed clustering presented here to probabilistic soft clustering.

An Interpretable Knowledge Transfer Model for Knowledge Base Completion

Qizhe Xie, Xuezhe Ma, Zihang Dai, Eduard Hovy

Pittsburgh, PA 15213, USA
{qzxie, xuezhem, dzihang, hovy}@cs.cmu.edu

Abstract

Knowledge bases are important resources for a variety of natural language processing tasks but suffer from incompleteness. We propose a novel embedding model, *ITransF*, to perform knowledge base completion. Equipped with a sparse attention mechanism, ITransF discovers hidden concepts of relations and transfer statistical strength through the sharing of concepts. Moreover, the learned associations between relations and concepts, which are represented by sparse attention vectors, can be interpreted easily. We evaluate ITransF on two benchmark datasets—WN18 and FB15k for knowledge base completion and obtains improvements on both the mean rank and Hits@10 metrics, over all baselines that do not use additional information.

1 Introduction
